The olfactory bulb (OB), the first relay for odor processing in the brain, receives dense GABAergic and cholinergic long-range projections from basal forebrain (BF) nuclei that provide information about the internal state and behavioral context of the animal. However, the targets, impact and dynamic of these afferents are still unclear. I studied how BF synaptic inputs modulate activity in diverse subtypes of periglomerular (PG) interneurons using optogenetic stimulation and loose cell-attached or whole-cell patch-clamp recording in OB slices from adult mice. GABAergic BF inputs potently blocked PG cells firing except in a minority of calretinin-expressing cells in which GABA release elicited spiking. Parallel cholinergic projections excited a previously overlooked PG cell subtype via synaptic activation of M1 muscarinic receptors. Low frequency stimulation of the cholinergic axons drove persistent firing in these PG cells thereby increasing tonic inhibition in principal neurons. Taken together, these findings suggest that modality-specific BF inputs can orchestrate synaptic inhibition in OB glomeruli using multiple, potentially independent, inhibitory or excitatory target-specific pathways.

POPULATION CODING OF ODOR CONCENTRATION IN THE GLOMERULAR LAYER OF THE MOUSE OLFACTORY BULB

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Mathieu Loizeau[1], Alexandra Angelova[1], Harold Cremer[1], Hervé Rouault[2], Jean Claude Platel[2]
[1]Institut de Biologie du Développement de Marseille (IBDM), Cnrs, Marseille, France, [2]INSERM, Inmed, Umr1249, Marseille, France

The first step of olfactory processing takes place in the glomeruli of the olfactory bulb (OB) where a variety of interneurons integrate the sensory information, before it is transmitted to OB output neurons. Yet, due to the high density and diversity of interneurons, their role in odor processing and in odor concentration coding remains unknown. We chose to focus on a specific population of excitatory interneurons of the glomerular layer, the external tufted cells (ETCs). We use the ND6-Cre transgenic mouse line crossed with a fluorescent reporter line and a calcium genetic sensor line to study this population. We combine high resolution two-photon structural imaging to reconstruct the dendritic morphology of ETCs and assign them to a specific glomerulus, with *in vivo* calcium imaging. By using this approach, we show that ETCs can be activated by olfactory stimulation and surprisingly, they can also be inhibited or generate complex responses. Interestingly, responding ETCs connected to the same glomerulus have significantly correlated responses. Then, we stimulate with different odor concentrations and we observe an increase of the percentage of responding ETCs within the same glomerulus meaning that ETCs are progressively recruited. This process creates a specific ETCs recruitment map in each glomerulus to discriminate odor concentration. We demonstrate that these cellular recruitment maps for a specific odor are stable over a month. Our work describes for the first time the *in vivo* properties of ETCs and a new network mechanism to decode odor concentration in the glomerular layer.

Cilia are hair-like structures enriched in receptors and signaling molecules, which play key roles in signal transduction. Notably, olfactory sensory neurons (OSN) cilia harbor all the machinery necessary for odor detection, and thus are indispensable for olfaction. To date, the regulatory pathways involved in controlling cilia formation in OSN remain elusive. Particularly, OSN cilia have properties of motile cilia, akin to those on respiratory and ependymal cells, yet in most vertebrates, OSN cilia lack motility. In our study, we reveal that mammalian and zebrafish OSN express the master regulator of motile ciliogenesis, *foxj1*. Interestingly, the expression of *foxj1* target genes involved in cilia motility are actively repressed in OSN as compared to motile ciliated respiratory cells, explaining their immotility. Next, we investigated the function of *foxj1* in cilia formation in zebrafish OSNs. We observed that OSN cilia are lacking in *foxj1* mutants. In line with ciliogenesis defects, we identified that *foxj1* mutant display aberrant responses to olfactory cues. Altogether, we identified a novel and critical role of *foxj1* in OSN cilia formation but not motility. We argue that understanding the regulatory pathways underlying diversity in cilia formation and function is necessary to better understand sensory deficits in patients with ciliary disorders.

PERIPHERAL OLFACTORY CODING IN DROSOPHILA MELANOGASTER

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Lydia Ellison[1], George Kemenes[1], Thomas Nowotny[2]
[1]University of Sussex, Sussex Neuroscience, School Of Life Sciences, Brighton, United Kingdom, [2]University of Sussex, Sussex Neuroscience, School Of Engineering And Informatics, Brighton, United Kingdom

Insects, like many animals, rely strongly on their sense of smell for locating potential food sources, mates and predators. Flying insects such as *Drosophila melanogaster* possess an exceptional ability to interpret complex odour plumes. In addition to identifying odorants and their intensities, plume navigation also requires differentiating relevant odorant mixtures originating from one source from irrelevant odorants emitted from separate sources. This capacity is typically attributed to lateral inhibition in the antennae lobe. However, we propose that non-synaptic “ephaptic” interactions (NSIs) between olfactory receptor neurons (ORNs) co-located in sensilla on the antenna could also play an important role by pre-processing olfactory information. In this work, we are investigating the feasibility of this hypothesis using single sensillum recordings and a two-channel high-precision olfactory stimulator for delivering precisely timed pulses of odours selective for each of two co-localised ORNs in *Drosophila* sensilla. We demonstrate that NSIs can occur on short timescales as seen in natural odour plumes. When a brief pulse of one odorant is delivered at increasing delays from the start of a second odorant, this inhibition increases as the delay increases, and eventually saturates. These results provide not only insights into the processing speed of the insect olfactory system, but also elucidate the significance of potential interactions in other examples of compartmentalised sensory neurons, including mammalian taste buds and a wide range of invertebrate sensilla. This work was funded by a Leverhulme Trust Research Project Grant.

ANATOMICAL AND FUNCTIONAL CONNECTIVITY AT THE DENDRODENDRITIC RECIPROCAL MITRAL CELL-GRANULE CELL SYNAPSE: IMPACT ON RECURRENT AND LATERAL INHIBITION

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Veronica Egger[1], S. Aghvami[2], Yoshiyuki Kubota[3]
[1]University of Regensburg, Neurobiology And Animal Physiology, Regensburg, Germany, [2]IPM, School Of Cognitive Sciences, Tehran, Iran, [3]NIPS, Neuroscience, Okazaki, Japan

In the olfactory bulb, reciprocal dendrodendritic interactions between its principal neurons, the mitral and tufted cells (MTCs), and inhibitory interneurons in the external plexiform layer mediate both recurrent and lateral inhibition, with the most numerous of these interneurons being granule cells (GCs). Here, we use recently established anatomical data (most importantly the density of reciprocal synapses on MC lateral dendrites, ~ 1 per µm) and functional data (most importantly the properties of recurrent unitary GABAergic inputs from GC spines onto MCs, ~ 200 pS) to simulate the strength of recurrent MC inhibition specifically from the reciprocal spines of rat olfactory bulb GCs in a compartmental NEURON model. We predict a total recurrent inhibition in the wake of a MC action potential $\Delta V_m \approx 2$ mV. Based on these recent data sets we also update and refine a preexisting model of lateral connectivity between any two MCs (Egger & Urban 2006), including functional ensembles of MCs belonging to a glomerular column. We compute the average dendrodendritic connectivity via interconnecting GCs as a function of the distance between MCs and/or entire glomerular MC ensembles. Our results predict the extents of three regimes of anatomical connectivity between ensembles: high connectivity within a glomerulus and the first three rings of adjacent glomeruli, considerable connectivity to up to seven glomeruli away and negligible connectivity beyond. We plan to combine this anatomical connectivity with the above simulations of inhibitory output from GC spines to estimate the functional impact of lateral active columns.

Carney Institute For Brain Science, Providence, United States of America, [2]Brown University, Neuroscience, Providence, United States of America, [3]Brown University, Department Of Computer Science, Providence, United States of America, [4]Inria, Inria Centre De Lyon, Lyon, France

Mammals co-evolved ancient conserved cortical circuits such as the *paleocortex* together with novel ones, the *neocortex*. A *paleo* principal cell stands apart from a *neocortex* principal cell for its developmental origin, morphology, and co-expression of genetic determinants for neuronal identity. However, the mechanisms driving cell type diversification across distinct cortical traits remain unknown. Here, we characterize the gene regulatory network (GRN) that defines principal cell type identity in the mouse olfactory cortex, and we compare GRN activity across *paleo*-, *peri-paleo*- and *neo*cortical traits. Using single-nucleus dual omics (ATAC and RNA) sequencing, we reveal *cis* enhancer-gene pair interactions and identify transcription factors cross-repression as a key mechanism for cell type diversification. Finally, we propose semilunar cells of the olfactory cortex as the ancestral principal cell in the mammalian cortex. Our data provide the first comprehensive molecular description of cell types in the mouse olfactory cortex and identify epigenetic mechanisms underlying cell type diversification during evolution.

ODOR HEDONIC RATINGS ARE RELATED TO INDIVIDUAL ODOR DETECTION THRESHOLDS

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Charlotte Bontempi, Laurence Jacquot, Gérard Brand
Université de Franche Comté, UFR Sciences et Techniques, Laboratoire De Recherches Intégratives En Neurosciences Et Psychologie Cognitive, Besançon, France

Aims Odor hedonic perception is considered as one of the most prominent dimensions in olfaction and is known to depend on several parameters (odorant properties, contexts, subject characteristics…). Among them, the relation between the stimulus concentration and the hedonic estimation has been widely studied. However, few studies have considered odor hedonic ratings in relation to individual detection thresholds. Thus, the aim of this study was to determine olfactory detection thresholds and to describe the evolution of hedonic ratings from the individual threshold to higher concentrations. Methods Odor detection thresholds were assessed for four odorants (two pleasant and two unpleasant) using a classical psychophysical method. Then, different odorant concentrations, above individual odor detection thresholds, were presented to the participants in a randomized order. Participants had to rate odor pleasantness of these stimuli on a visual analog scale. Results Individual detections thresholds presented a large dispersion in relation to the dilutions as function of the odorant stimulus and subjects. When individual thresholds were considered, hedonic scores evolved in the same way for all subjects. For a specific odorant, results showed a similar evolution of hedonic ratings in relation to stimulus concentration whatever the olfactory thresholds. Conclusion These findings suggest a relation between odor hedonic ratings and individual detection thresholds. Given the strong interindividual differences in olfactory sensitivity, these data contribute to explain the large variability of the hedonic tone at specific concentration in the general population, and could serve future research in this field.

IMPACT OF OXYTOCIN IN THE PIRIFORM CORTEX AND EFFECT ON SOCIAL BEHAVIORS

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Camille Miermon, Geoffrey Terral, Giulio Casali, Alena Spitsyn, Tiphaine Dolique, Lisa Roux
Institut Interdisciplinaire de Neuroscience - UMR 5297, Cnrs - Université De Bordeaux, Bordeaux, France

Social interactions are crucial for the survival of most species. In rodents, these interactions are strongly influenced by olfactory cues emitted by individuals, collected during social investigation and processed by the olfactory system. Previous works indicated that the neuropeptide oxytocin (OXT) promotes social interactions and social memory in rodents and that it is released during interactions with conspecifics. Interestingly, OXT receptor expression is enriched in the piriform cortex (PIR), suggesting a role for OXT in the processing of social olfactory cues in this major part of the olfactory cortex. Yet, such role and the neurophysiological impact of OXT in PIR remains obscure. Using a local pharmacological approach and a three-chamber behavioral test, we showed that blocking OXT receptors in the PIR does not impair sociability nor social memory. However, using the Live Mouse Tracker which allows for more naturalistic social behaviors and automatic profiling of interactions motives, we showed that OXT receptor blockade in PIR induces an increase in nose-to-nose contacts between mice. To decipher how OXT modulates PIR circuits, we implanted mice with multisite electrodes in the PIR as well as nasal cannulas to monitor respiration and sniffing. Our preliminary data indicated that intraperitoneal injections of a selective OXT receptor agonist increased the firing rate of putative excitatory cells, and decreased their entrainment by the respiration signal. Overall, our work suggests that endogenous OXT modulates specific aspects of social interactions involving olfactory investigation and that neuronal activity in the PIR is sensitive to OXT manipulations.

PHYSIOLOGICAL CHARACTERIZATION OF PIRIFORM CORTEX MODULATION BY RESPIRATORY SIGNAL ACROSS BRAIN STATES

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Giulio Casali[1], Geoffrey Terral[1], Camille Miermon[1], Pascal Ravassard[2], Lisa Roux[2]
[1]Institut Interdisciplinaire de Neuroscience - UMR 5297, Cnrs - Université De Bordeaux, Bordeaux, France, [2]IINS, UMR 5297 CNRS, Centre Broca Nouvelle-aquitaine, Bordeaux, France

A number of studies using time-controlled odorant presentation have demonstrated that the piriform cortex plays a key role in olfaction. However, the baseline physiological description of piriform cortex activity during odor-free baseline states remains largely unexplored. To answer this, we examined the activity of large ensembles of extracellularly recorded piriform cortex cells from freely moving mice implanted with intra-nasal pressure sensors to monitor instantaneous respiration patterns. Mice were engaged in various tasks mimicking naturalistic conditions and rest/sleep states. Close examination of respiratory traces revealed that they encompass intermingled oscillatory (inhalation/exhalation) and linear (pauses) components which piriform cortex populations are differently responsive to. Moreover, we found that when nasal pressure fluctuations are treated as an oscillatory signal, a large fraction of piriform cortex neurons are entrained by the oscillation. Interestingly, their phase locking is either altered or preserved depending on the respiration frequency and internal brain state. Next, we explored whether gamma rhythm, the most prominent oscillation typical of the piriform cortex, could be similarly modulated by the respiration phase and frequency during different brain states. Consistent with previous results, we observed two independent non-harmonical gamma bands resonating around 40 Hz and 60 Hz. During wake state, their prominence was differentially modulated by the phase and frequency of the respiratory oscillation pattern. Together, these results highlight several physiological features of the piriform cortex during different brain states and behavioral tasks, enriching our global understanding of its complexity and computation supporting olfactory representation.

ADAPTIVE TRAITS IN THE DROSOPHILA MUSHROOM BODY

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Sophie Caron, Kaitlyn Ellis
University of Utah, School Of Biological Sciences, Salt Lake City, United States of America

How the brain adapts as species evolve remains largely unknown. Thus far, adaptive traits have been primarily identified in sensory systems, suggesting that sensory neurons might be more malleable to evolutionary pressures than the neurons embedded in higher brain centers. In *Drosophila*, comparative studies of closely related species that live in drastically different ecology revealed that olfactory sensory neurons adapt by developing new detection capabilities. For instance, the obligate noni specialist *Drosophila sechellia* is equipped with olfactory sensory neurons finely tuned to noni volatiles whereas its close generalist relatives — *Drosophila melanogaster* and *Drosophila simulans* — is equipped with olfactory sensory neurons tuned to more general fruit volatiles . Here, we use different neuronal tracing techniques to determine how the olfactory circuit connects to higher brain centers in these three species. Statistical analyses of these connections enable us to test which, if any, global architectural features of higher brain centers vary across these species. We found that — although most features do not vary — the projection neurons downstream of the olfactory sensory neurons detecting noni and fruit volatiles have adapted in *D. sechellia*through different cellular mechanisms: these projection neurons either change in number, vary in their connectivity rates or target different neuropiles. Altogether, this study shows that higher brain centers are just as malleable to evolutionary pressures as sensory systems, suggesting that the brain might adapt to novel sensory environments through concomitant cellular changes distributed along neuronal circuits.

THE ENDOCANNABINOID SYSTEM REGULATES OLFACTORY PERCEPTION IN THE ANTERIOR PIRIFORM CORTEX

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Geoffrey Terral[1], Gabriel Lepousez[2], Yohan Wards[3], Dinghuang Huang[3], Giulio Casali[1], Antoine Nissant[2], Pierre-Marie Lledo[2], Guillaume Ferreira[4], Giovanni Marsicano[3], Lisa Roux[1]
[1]Institut Interdisciplinaire de Neuroscience - UMR 5297, Cnrs - Université De Bordeaux, Bordeaux, France, [2]Perception and Memory Unit, Institut Pasteur, Neuroscience, Paris, France, [3]Neurocentre Magendie, Inserm U1215, Bordeaux, France, [4]INRAE, Nutrineuro Laboratory, Bordeaux CEDEX, France

The endocannabinoid system (ECS) is a potent modulator of cognitive processes, but it is still unclear how it controls sensory perception. In the olfactory system, a major structure involved in sensory processing is the anterior piriform cortex (aPC). Although recent evidence suggests that the ECS regulates aPC functions through its main cannabinoid type 1 receptor (CB1R), little is known about how ECS impacts aPC circuits *in vivo* and whether it influences olfactory perception. Using a combination of pharmacology and aPC multi-electrode recordings in freely moving mice, we showed that an antagonist/inverse agonist of the CB1R increases local field potential power selectively in the gamma frequency band as well as the phase-locking of aPC units to gamma oscillations. Moreover, we found that CB1R antagonist reduces unit synchrony, mainly during active sniffing. The latter observation was in line with a reduced occurrence of spontaneous and odor-evoked calcium transients recorded with fiber photometry following local CB1R blockade in aPC, consistent with a lower neuronal synchronization. This increased gamma power combined with reduced unit synchrony suggested that the ECS could tune olfactory perception in the aPC. Indeed, as compared to vehicle injected animals, mice injected with CB1R antagonist in aPC had a lower threshold for odor detection. We propose that the endocannabinoids in aPC tend to dampen olfactory perception by limiting gamma oscillations and odor-induced neuronal desynchronization.

DRAMATIC CHANGES IN THE RABBIT VOMERONASAL ORGAN TRANSCRIPTOME BEFORE BIRTH AND ITS CRITICAL ROLE IN FIRST MILK INTAKE

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Paula Rodríguez Villamayor[1,2,3], Pablo Sánchez-Quinteiro[1], Julián Gullón[4], Paulino Martínez[2], Diego Robledo[3]
[1]Veterinary Faculty, Universidade de Santiago de Compostela (USC), Department Of Anatomy, Animal Production And Veterinary Science, Lugo, Spain, [2]Universidade de Santiago de Compostela, Department Of Genetics, Lugo, Spain, [3]Roslin Institute, University Of Edinburgh, Edinburgh, Spain, [4]COGAL SL, Cuniculture Company, Rodeiro, Spain

Mother-offspring chemical communication is essential to ensure pup survival. The maternal mammary pheromone (2MB2), which has only been identified in rabbits, triggers nipple-search and suckling behavior. While some studies suggest that this pheromone is solely detected by the main olfactory epithelium, the importance of the vomeronasal system in innate pheromone-mediated behaviours makes the study of the pup vomeronasal organ (VNO) at perinatal stages very promising to look for cues involved in mother-pup interaction. A total of 48 VNO samples from individuals at embryonic day 28 (E28), postnatal day 0 (P0) before and 2.5 h after fist milk intake, and postnatal day 4 (P4) were dissected out and processed for RNA extraction, library construction and sequencing using Illumina Nova-Seq 75 bp PE run. Gene expression was analyzed using Kallisto and DESeq2. The VNO gene expression showed significant differences between the four groups. Importantly, P0 pre and P0 post suckling showed 399 differentially expressed genes, supporting that cues delivered in milk might be detected through the VNO. Vomeronasal receptors were barely expressed at E28, their expression increased after birth and reached a maximum at P4, suggesting that exposure to the outside world activates the VNO not only innately but also after prior experience. These results suggest that the VNO has an essential role in dam-kits communication after birth. This vital interaction guarantees kits survival since birth. Further studies are required to assess the nature of the pheromone-receptor interaction and how to apply this information to improve mother-offspring bond.

Assessment of Biostimulation Methods Based on Chemical Communication in Female Doe Reproduction.
Biostimulation is an animal management practice that helps improve reproductive parameters by modulating animal sensory systems. Chemical signals, mostly known as pheromones, have a great potential in this regard. This study was conducted to determine the influence of short-term female rabbit exposure to different conditions, mainly pheromone-mediated, on reproductive parameters of inseminated does. Groups of 60 females/each were exposed to (1) female urine, (2) male urine, (3) seminal plasma and (4) female-female (F-F) separated, just before artificial insemination, and compared to a 'golden method' female-female interaction. The following reproductive parameters were analyzed for each group: receptivity (vulvar color), fertility (kindling rate), prolificacy and number of born alive and dead kits/litter. Our results showed that the biostimulation methods employed in this experiment did not significantly improve any of the analyzed parameters. However, female doe exposure to urine, especially to male urine, showed no significant higher fertility values (95.4%) when compared to the rest of the experimental conditions (on average 92.4%). Female-female interaction before artificial insemination, which is a common practice in rabbit farms, showed similar results as not establishing social interaction (F-F separated), which suggests that F-F interaction could be replaced by F-F separated, therefore avoiding unnecessary animal management and time cost. On the other hand, fertility ranges were lower for animals with a pale vulvar color whereas no differences were noticed among the other three colors which measure receptivity (pink, red, purple), thus suggesting that these three colors could be grouped together. Future studies should aim at determining potential chemical cues/pheromones released through bodily secretions that influence reproduction in rabbits, therefore contributing to animal welfare and to a natural image of animal production.

Can domestication shape Canidae brain morphology? The accessory olfactory bulb of the red fox as a case in point.
The accessory olfactory bulb (AOB) is the first integrative center of the vomeronasal system (VNS), and the general macroscopic, microscopic, and neurochemical organizational patterns of the AOB differ fundamentally among species.

Therefore, the low degree of differentiation observed for the dog AOB is surprising. As the artificial selection pressure exerted on domestic dogs has been suggested to play a key role in the involution of the dog VNS, a wild canid, such as the fox, represents a useful model for studying the hypothetical effects of domestication on the AOB morphology.
Ann Anat, 2022; 240

Does a third intermediate model for the vomeronasal processing of information exist? Insights from the macropodid neuroanatomy.
The study of the α-subunit of Gi2 and Go proteins in the accessory olfactory bulb (AOB) was crucial for the identification of the two main families of vomeronasal receptors, V1R and V2R. Both families are expressed in the rodent and lagomorph AOBs, according to a segregated model characterized by topographical anteroposterior zonation. Many mammal species have suffered from the deterioration of the Gαo pathway and are categorized as belonging to the uniform model. This scenario has been complicated by characterization of the AOB in the tammar wallaby, Notamacropus eugenii, which appears to follow a third model of vomeronasal organization featuring exclusive Gαo protein expression, referred to as the intermediate model, which has not yet been replicated in any other species. Our morphofunctional study of the vomeronasal system (VNS) in Bennett's wallaby, Notamacropus rufogriseus, provides further information regarding this third model of vomeronasal transduction. A comprehensive histological, lectin, and immunohistochemical study of the Bennett's wallaby VNS was performed. Anti-Gαo and anti-Gαi2 antibodies were particularly useful because they labeled the transduction cascade of V2R and V1R receptors, respectively. Both G proteins showed canonical immunohistochemical labeling in the vomeronasal organ and the AOB, consistent with the anterior-posterior zonation of the segregated model. The lectin Ulex europaeus agglutinin selectively labeled the anterior AOB, providing additional evidence for the segregation of vomeronasal information in the wallaby. Overall, the VNS of the Bennett's wallaby shows a degree of differentiation and histochemical and neurochemical diversity comparable to species with greater VNS development. The existence of the third intermediate type in vomeronasal information processing reported in Notamacropus eugenii is not supported by our lectin-histochemical and immunohistochemical findings in Notamacropus rufogriseus.

Analysis of the vomeronasal organ transcriptome reveals variable gene expression depending on age and function in rabbits.
The vomeronasal organ (VNO) is a chemosensory organ specialized in pheromone detection that shows a broad morphofunctional and genomic diversity among mammals. However, its expression patterns have only been well-characterized in mice. Here, we provide the first comprehensive RNA sequencing study of the rabbit VNO across gender and sexual maturation stages. We characterized the VNO transcriptome, updating the number and expression of the two main vomeronasal receptor families, including 128 V1Rs and 67 V2Rs. Further, we defined the expression of formyl-peptide receptor and transient receptor potential channel families, both known to have specific roles in the VNO. Several sex hormone-related pathways were consistently enriched in the VNO, highlighting the relevance of this organ in reproduction. Moreover, whereas juvenile and adult VNOs showed significant transcriptome differences, male and female did not. Overall, these results contribute to understand the genomic basis of behavioural responses mediated by the VNO in a non-rodent model.
Genomics, 2021; 113

A comprehensive structural, lectin and immunohistochemical characterization of the zebrafish olfactory system.
Fish chemosensory olfactory receptors allow them to detect a wide range of water-soluble chemicals, that mediate fundamental behaviours. Zebrafish possess a well-developed sense of smell which governs reproduction, appetite, and fear responses. The spatial organization of functional properties within the olfactory epithelium and bulb are comparable to those of mammals, making this species suitable for studies of olfactory differentiation and regeneration and neuronal representation of olfactory information. The advent of genomic techniques has been decisive for the discovery of specific olfactory cell types and the identification of cell populations expressing vomeronasal receptors. These advances have marched ahead of morphological and neurochemical studies. This study aims to fill the existing gap in specific histological, lectin-histochemical and immunohistochemical studies on the olfactory rosette and the olfactory bulb of the zebrafish. Tissue dissection and microdissection techniques were employed, followed by histological staining techniques, lectin-histochemical labelling (UEA, LEA, BSI-B) and immunohistochemistry using antibodies against G proteins subunits αo and αi2, growth-associated protein-43, calbindin, calretinin, glial-fibrillary-acidic-protein and luteinizing-hormone-releasing-hormone. The results obtained enrich the available information on the neurochemical patterns of the zebrafish olfactory system, pointing to a greater complexity than the one currently considered, especially when taking into account the peculiarities of the nonsensory epithelium.

The vomeronasal system of the newborn capybara: a morphological and immunohistochemical study.
The vomeronasal system (VNS) is responsible for the perception mainly of pheromones and kairomones. Primarily studied in laboratory rodents, it plays a crucial role in their socio-sexual behaviour. As a wild rodent, the capybara offers a more objective and representative perspective to understand the significance of the system in the Rodentia, avoiding the risk of extrapolating from laboratory rodent strains, exposed to high levels of artificial selection pressure. We have studied the main morphological and immunohistochemical features of the capybara vomeronasal organ (VNO) and accessory olfactory bulb (AOB). The study was done in newborn individuals to investigate the maturity of the system at this early stage. We used techniques such as histological stains, lectins-labelling and immunohistochemical characterization of a range of proteins, including G proteins (Gαi2, Gαo) and olfactory marking protein. As a result, we conclude that the VNS of the capybara at birth is capable of establishing the same function as that of the adult, and that it presents unique features as the high degree of differentiation of the AOB and the active cellular migration in the vomeronasal epithelium. All together makes the capybara a promising model for the study of chemical communication in the first days of life.
Sci Rep, 2020; 10
32584430: Ortiz-Leal I, Torres MV, Villamayor PR, López-Beceiro A, Sanchez-Quinteiro P
The vomeronasal organ of wild canids: the fox (Vulpes vulpes) as a model.
The vomeronasal system (VNS) has been extensively studied within specific animal families, such as Rodentia. However, the study of the VNS in other families, such as Canidae, has long been neglected. Among canids, the vomeronasal organ (VNO) has only been studied in detail in the dog, and no studies have examined the morphofunctional or immunohistochemical characteristics of the VNS in wild canids, which is surprising, given the well-known importance of chemical senses for the dog and fox and the likelihood that the VNS plays roles in the socio-reproductive physiology and behaviours of these species. In addition, characterising the fox VNS could contribute to a better understanding of the domestication process that occurred in the dog, as the fox would represent the first wild canid to be studied in depth. Therefore, the aim of this study was to analyze the morphological and immunohistochemical characteristics of the fox VNO. Tissue dissection and microdissection techniques were employed, followed by general and specific histological staining techniques, including with immunohistochemical and lectin-histochemical labelling strategies, using antibodies against olfactory marker protein (OMP), growth-associated protein 43 (GAP-43), calbindin (CB), calretinin (CR), α-tubulin, Gαo, and Gαi2 proteins, to highlight the specific features of the VNO in the fox. This study found significant differences in the VNS between the fox and the dog, particularly concerning the expression of Gαi2 and Gαo proteins, which were associated with the expression of the type 1 vomeronasal receptors (V1R) and type 2 vomeronasal receptors (V2R), respectively, in the vomeronasal epithelium. Both are immunopositive in foxes, as opposed to the dog, which only expresses Gαi2. This finding suggests that the fox possesses a well-developed VNO and supports the hypothesis that a profound transformation in the VNS is associated with domestication in the canid family. Furthermore, the unique features identified in the fox VNO confirm the necessity of studying the VNS system in different species to better comprehend specific phylogenetic aspects of the VNS.

Structural, morphometric and immunohistochemical study of the rabbit accessory olfactory bulb.
The accessory olfactory bulb (AOB) is the first neural integrative centre of the vomeronasal system (VNS), which is associated primarily with the detection of semiochemicals. Although the rabbit is used as a model for the study of chemocommunication, these studies are hampered by the lack of knowledge regarding the topography, lamination, and neurochemical properties of the rabbit AOB. To fill this gap, we have employed histological stainings: lectin labelling with Ulex europaeus (UEA-I), Bandeiraea simplicifolia (BSI-B4), and Lycopersicon esculentum (LEA) agglutinins, and a range of immunohistochemical markers. Anti-G proteins Gαi2/Gαo, not previously studied in the rabbit AOB, are expressed following an antero-posterior zonal pattern. This places Lagomorpha among the small groups of mammals that conserve a double-path vomeronasal reception. Antibodies against olfactory marker protein (OMP), growth-associated protein-43 (GAP-43), glutaminase (GLS), microtubule-associated protein-2 (MAP-2), glial fibrillary-acidic protein (GFAP), calbindin (CB), and calretinin (CR) characterise the strata and the principal components of the BOA, demonstrating several singular features of the rabbit AOB. This diversity is accentuated by the presence of a unique organisation: four neuronal clusters in the accessory bulbar white matter, two of them not previously characterised in any species (the γ and δ groups). Our morphometric study of the AOB has found significant differences between sexes in the numerical density of principal cells, with larger values in females, a pattern completely opposite to that found in rats. In summary, the rabbit possesses a highly developed AOB, with many specific features that highlight the significant role played by chemocommunication among this species.

Morphological and immunohistochemical study of the rabbit vomeronasal organ.

The characterization of the rabbit mammary pheromone, which is sensed by the main olfactory system, has made this species a unique model for the study of pheromonal communication in mammals. This discovery has brought attention to the global understanding of chemosensory communication in this species. Chemocommunication is mediated by two distinct organs located in the nasal cavity, the main olfactory epithelium and the vomeronasal organ (VNO). However, there is a lack of knowledge about the vomeronasal system in rabbits. To understand the role of this system, an exhaustive anatomical and histological study of the rabbit VNO was performed. The rabbit VNO was studied macroscopically by light microscopy, and by histochemical and immunohistochemical techniques. We employed specific histological staining techniques (periodic acid-Schiff, Alcian blue, Gallego's trichrome), confocal autofluorescence, histochemical labelling with the lectin Ulex europaeus agglutinin (UEA-I), and immunohistochemical studies of the expression of the Gαi2 and Gαo proteins and olfactory marker protein. The opening of the vomeronasal duct into the nasal cavity and its indirect communication with the oral cavity through a functional nasopalatine duct was demonstrated by classical dissection and microdissection. In a series of transverse histological sections, special attention was paid to the general distribution of the various soft-tissue components of this organ (duct, glands, connective tissue, blood vessels and nerves) and to the nature of the capsule of the organ. Among the main morphological features that distinguish the rabbit VNO, the presence of a double envelope, which is bony externally and cartilaginous internally, and highly developed venous sinuses stand out. This observation indicates the crucial role played in this species by the pumping mechanism that introduces chemical signals into the vomeronasal duct. The functional properties of the organ are also confirmed by the presence of a well-developed neuroepithelium and profuse glandular tissue that is positive for neutral mucopolysaccharides. The role of glycoconjugates was assessed by the identification of the α1-2 fucose glycan system in the neuroepithelium of the VNO employing UEA-I lectin. The pattern of labelling, which was concentrated around the commissures of the sensory epithelium and more diffuse in the central segments, is different from that found in most mammals studied. According to the expression of G-proteins, two pathways have been described in the VNOs of mammals: neuroreceptor cells expressing the Gαi2 protein (associated with vomeronasal receptor type 1); and cells expressing Gαo (associated with vomeronasal receptor type 2). The latter pathway is absent in most mammals studied. The expression of both G-protein families in the rabbit VNO places Lagomorpha together with rodents and insectivores in a small group of mammals belonging to the two-path model. These findings support the notion that the rabbit possesses a highly developed VNO, with many specific morphological features, which highlights the significance of chemocommunication in this species.

Brief Sensory Deprivation Triggers Cell Type-Specific Structural and Functional Plasticity in Olfactory Bulb Neurons.
Can alterations in experience trigger different plastic modifications in neuronal structure and function, and if so, how do they integrate at the cellular level? To address this question, we interrogated circuitry in the mouse olfactory bulb responsible for the earliest steps in odor processing. We induced experience-dependent plasticity in mice of either sex by blocking one nostril for one day, a minimally invasive manipulation that leaves the sensory organ undamaged and is akin to the natural transient blockage suffered during common mild rhinal infections. We found that such brief sensory deprivation produced structural and functional plasticity in one highly specialized bulbar cell type: axon-bearing dopaminergic neurons in the glomerular layer. After 24 h naris occlusion, the axon initial segment (AIS) in bulbar dopaminergic neurons became significantly shorter, a structural modification that was also associated with a decrease in intrinsic excitability. These effects were specific to the AIS-positive dopaminergic subpopulation because no experience-dependent alterations in intrinsic excitability were observed in AIS-negative dopaminergic cells. Moreover, 24 h naris occlusion produced no structural changes at the AIS of bulbar excitatory neurons, mitral/tufted and external tufted cells, nor did it alter their intrinsic excitability. By targeting excitability in one specialized dopaminergic subpopulation, experience-dependent plasticity in early olfactory networks might act to fine-tune sensory processing in the face of continually fluctuating inputs. Sensory networks need to be plastic so they can adapt to changes in incoming stimuli. To see how cells in mouse olfactory circuits can change in response to sensory challenges, we blocked a nostril for just one day, a naturally relevant manipulation akin to the deprivation that occurs with a mild cold. We found that this brief deprivation induces forms of axonal and intrinsic functional plasticity in one specific olfactory bulb cell subtype: axon-bearing dopaminergic interneurons. In contrast, intrinsic properties of axon-lacking bulbar dopaminergic neurons and neighboring excitatory neurons remained unchanged. Within the same sensory circuits, specific cell types can therefore make distinct plastic changes in response to an ever-changing external landscape.

MEASURING PERK (PHOSPHORYLATED EXTRACELLULAR-SIGNAL REGULATED KINASE) ACTIVITY IN ACUTE IN-VITRO SLICES OF THE RAT OLFACTORY BULB

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Lisa Kindler, Hajime Suyama, Veronica Egger, Michael Lukas
University of Regensburg, Neurobiology And Animal Physiology, Regensburg, Germany

Vasopressin (VP), when released in the olfactory bulb, enables the discrimination of conspecifics in rats. Intriguingly, tufted cells in the olfactory bulb that express VP (VPCs) show IPSPs following olfactory nerve (ON) stimulation in-vitro, whereas other tufted cell types are excited. However, following social interaction in-vivo, we measured increased pERK (*phosphorylated extracellular-signal regulated kinase*) immunohistochemistry in VPCs, indicating that excitation of VPCs is possible. Interestingly, cholinergic modulation also enables a switch from inhibition to excitation following in-vitro ON stimulation. The aim of this study was to establish pERK activity as a reliable population marker to study excitation patterns in acute in-vitro OB slices following pharmacological and/or electrical stimulation, using VPCs and their known acetylcholine-modulated switch from inhibition to excitation as an indicator. Thus, we examined the effect of general depolarization, ON stimulation and cholinergic modulation on pERK activity in OB VPCs. Incubation of acute OB slices in KCl-ACSF (*artificial cerebrospinal fluid, 90mM*) only led to a pERK activation in the mitral cell and the granule cell layer but not in VPCs. Further, we could show that electrical ON stimulation results in pERK activation within columnar units, including mitral and granule cells. Finally, ON stimulation coupled with acetylcholine application resulted in a significant increase in pERK+/VPCs, thereby confirming that the combination of ACh presence and ON stimulation is necessary to obtain excitation of VPCs, as previously shown in our electrophysiological experiments on the single-cell level.

VASOPRESSIN INHIBITS PROJECTION NEURONS IN THE OLFACTORY BULB VIA INCREASED EXCITATION OF INHIBITORY INTERNEURONS

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Hajime Suyama, Veronica Egger, Michael Lukas
University of Regensburg, Neurobiology And Animal Physiology, Regensburg, Germany

Vasopressin (VP) is essential for social memory already at the level of the olfactory bulb (OB). Further, we previously showed that OB VP cells are activated by social interaction. However, it remains unclear how VP modulates odor processing to enable enhanced discrimination of very similar odors, e.g., rat body odors. So far, it was shown that VP reduces firing rates in mitral cells (MCs) during odor presentation *in-vivo* and decreases the amplitudes of olfactory nerve-evoked excitatory postsynaptic potentials (ON-evoked EPSPs) in external tufted cells *in-vitro*.
We performed whole-cell patch-clamp recordings and Ca^{2+} imaging in acute rat OB slices. We recorded ON-evoked EPSPs as well as spontaneous inhibitory postsynaptic currents (IPSCs) from both projection neurons, middle tufted cells (mTCs) and MCs. VP bath-application reduced the amplitudes of ON-evoked EPSPs and the frequencies of spontaneous IPSCs in mTCs but did not change those in MCs. To search for the origin of increased inhibition in mTCs, we analyzed ON evoked-EPSPs in inhibitory interneurons, i.e., periglomerular cells (PGCs) and granule cells (GCs). However, VP did not increase EPSPs in either type of interneuron. We next performed two-photon Ca^{2+} imaging in PGCs and GCs to record postsynaptic activity during stronger ON stimulation, evoking action potentials in the interneurons. We observed that ON-evoked Ca^{2+} influx at the proximal apical dendrite of PGCs and the soma of GCs was increased during VP application. Thus, our findings imply that VP could mediate inhibition of projection neurons via enhanced inhibitory interneuron activity upon strong olfactory inputs.

Vasopressin Cells in the Rodent Olfactory Bulb Resemble Non-Bursting Superficial Tufted Cells and Are Primarily Inhibited upon Olfactory Nerve Stimulation.
The intrinsic vasopressin system of the olfactory bulb is involved in social odor processing and consists of glutamatergic vasopressin cells (VPCs) located at the medial border of the glomerular layer. To characterize VPCs in detail, we combined various electrophysiological, neuroanatomical, and two-photon Ca imaging techniques in acute bulb slices from juvenile transgenic rats with eGFP-labeled VPCs. VPCs showed regular non-bursting firing patterns, and displayed slower membrane time constants and higher input resistances versus other glutamatergic tufted cell types. VPC axons spread deeply into the external plexiform and superficial granule cell layer (GCL). Axonal projections fell into two subclasses, with either denser local columnar collaterals or longer-ranging single projections running laterally within the internal plexiform layer and deeper within the granule cell layer. VPCs always featured lateral dendrites and a tortuous apical dendrite that innervated a single glomerulus with a homogenously branching tuft. These tufts lacked Ca transients in response to single somatically-evoked action potentials and showed a moderate Ca increase upon prolonged action potential trains.Notably, electrical olfactory nerve stimulation did not result in synaptic excitation of VPCs, but triggered substantial GABA receptor-mediated IPSPs that masked excitatory barrages with yet longer latency. Exogenous vasopressin application reduced those IPSPs, as well as olfactory nerve-evoked EPSPs recorded from external tufted cells. In summary, VPCs can be classified as non-bursting, vertical superficial tufted cells. Moreover, our findings imply that sensory input alone cannot trigger excitation of VPCs, arguing for specific additional pathways for excitation or disinhibition in social contexts.

Top-down acetylcholine signaling via olfactory bulb vasopressin cells contributes to social discrimination in rats.
Social discrimination in rats requires activation of the intrinsic bulbar vasopressin system, but it is unclear how this system comes into operation, as olfactory nerve stimulation primarily inhibits bulbar vasopressin cells (VPCs). Here we show that stimulation with a conspecific can activate bulbar VPCs, indicating that VPC activation depends on more than olfactory cues during social interaction. A series of in vitro electrophysiology, pharmacology and immunohistochemistry experiments implies that acetylcholine, probably originating from centrifugal projections, can enable olfactory nerve-evoked action potentials in

VPCs. Finally, cholinergic activation of the vasopressin system contributes to vasopressin-dependent social discrimination, since recognition of a known rat was blocked by bulbar infusion of the muscarinic acetylcholine receptor antagonist atropine and rescued by additional bulbar application of vasopressin. Thus, our results implicate that top-down cholinergic modulation of bulbar VPC activity is involved in social discrimination in rats.

DEVELOPMENT OF SPARSE, COMBINATORIAL CONNECTIVITY IN THE DROSOPHILA MUSHROOM BODY CALYX

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Vanessa Puñal[1], M. Jamal Jenkins[1], Najia Elkahlah[1], Mark Lewis[1], Mona Saeed[1], Jackson Rogow[2], E. Josie Clowney[1]
[1]University of Michigan, Molecular, Cellular And Developmental Biology, Ann Arbor, United States of America, [2]Rockefeller University, Laboratory Of Neurophysiology And Behavior, New York, United States of America

Detection of environmental stimuli is essential for survival. The total number of sensory stimuli encountered by an organism is unpredictable and nearly limitless, making genetic coding of detectors for all possible stimuli impossible. Instead, evolution has selected for amplifying the number of discriminable stimuli from a limited number of genetically encoded sensors to the number of combinations among them by expanding sensory neuron inputs via sparse, combinatorial wiring to higher order neurons involved in perceptual processing. It is not understood in any species what developmental mechanisms give rise to the input sparseness necessary for sensory amplification. To address this, we use the fly olfactory system where 50 odor channels are dispersed, via Projection Neurons (PNs), among ~2,500 higher order neurons called Kenyon Cells (KCs) in the mushroom body calyx. Previous work in the lab demonstrated that in the absence of KCs during development, adult PN axons no longer provide input to the calyx. We subsequently found this is because developing PNs never initiate collateral formation when KCs are not present. These results have led to the hypothesis that KCs dictate their input density via retrograde feedback to PNs. To test this hypothesis, we generated a bulk RNA sequencing dataset for developing KCs and used this as the basis for a candidate screen to search for KC-derived retrograde signals required for the production of odor channel inputs. Furthermore, we utilized fixed brain samples along with *ex vivo* live imaging to ask whether cell biological events of calyx development support the hypothesis that KCs direct PN input production.

NMDA RECEPTORS SHAPE SENSORY PROCESSING IN THE PIRIFORM CORTEX

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Mary Ardren, John Bekkers
The Australian National University, Eccles Institute Of Neuroscience, Canberra, Australia

The piriform cortex (PCx) is the first cortical destination of olfactory information and is essential for discriminating and learning odours. As in other cortical regions, synapses in the PCx can express activity-dependent plasticity that requires NMDA receptors. However, the extent to which NMDA receptors contribute to other operations of the PCx remains unknown. Here, we used *in vivo* patch clamping to examine the role of NMDA receptors in the encoding of odour stimuli in the PCx. Blind whole-cell recordings were made in the PCx of anaesthetised mice (P30-P50) while applying odorants to the nares using an olfactometer. Neurons were identified using soma depth, intrinsic electrical properties and recovered morphology. In a subset of experiments, a non-competitive NMDA receptor blocker, MK-801 (1 mM), was applied to the PCx. We found that MK-801 had no effect on intrinsic electrical properties of excitatory neurons. In contrast, MK-801 significantly suppressed spontaneous EPSPs and action potentials in these neurons. Furthermore, in the presence of MK-801, odour responses were more stereotyped and coupled to respiration, while the fraction of odours to which neurons responded was not significantly different from control. Our results show that NDMA receptors play a key role in a variety of functions of the PCx beyond synaptic plasticity. NMDA receptors are fundamentally involved in olfaction by altering network activity under quiescent conditions and by shaping the responses of neurons to odour stimulation. Further work on NMDA receptors will provide insight into the intricate link between odour processing and sensory learning in the PCx.

BREATHING- AND OLFACTORY-DRIVEN ACTIVITY IN THE OLFACTORY CORTEX

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Filippo Michelon[1,2], Alireza Abolghasemi Dehaqani[1], Giuliano Iurilli[1]
[1]Center for Neuroscience and Cognitive Systems, Italian Institute Of Technology, Rovereto, Italy, [2]University of Trento, Cimec, Rovereto, Italy

Modulation of breathing rate is crucial to flexibly explore the olfactory environment. Inhalation gates the perception of scents, and the act of sniffing is necessary for the olfactory percept.
However, different airflows due to distinct types of inhalations, such as during regular breathing and sniffing, alter the concentration of an odorant inside the nose regardless of its concentration at the source. Yet, animals can discriminate the concentration of an odor regardless of the speed of their inhalations. This ability is fundamental in instances such as foraging as the navigating system must be able to assess the concentration gradient towards an odor source regardless of how fast the animal is breathing. The olfactory cortex is arguably important for olfactory perception, therefore we asked how distinct types of inhalation affect the activity of the cortex.
We recorded the activity of hundreds of neurons along with the respiratory activity using high-density electrodes implanted in the primary olfactory cortex of awake head-fixed mice. Our results push further our understanding of how the brain can reliably discriminate olfactory features regardless of breathing fluctuations.

THE ROLE OF THE OLFACTORY GNRH SYSTEM IN THE CONTROL OF CHEMOSENSORY PROCESSING AND NEUROENDOCRINE CHANGES

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Laurine Decoster[1], Sara Trova[1], Stefano Zucca[2], Gaëtan Ternier[1], Tori Lhomme[1], Paolo Peretto[2], Serena Bovetti[2], Mauro Batista Da Silva[1], Paolo Giacobini[1]
[1]Univ Lille, INSERM, CHU Lille, U - LilNCog - Lille Neuroscience and Cognition, Laboratory Of The Development And Plasticity Of Neuroendocrine Brain, Lille Cedex, France, [2]University of Turin, Neuroscience Institute Cavalieri Ottolenghi, Torino, Italy

The role of the olfactory GnRH system in the control of chemosensory processing and neuroendocrine changes in the mouse The role of gonadotropin releasing hormone (GnRH) neurons as the final neural output controlling reproduction fitness and fertility is well established among the different vertebrates. An extra-hypothalamic GnRH neuron population is present in areas dedicated to olfactory processing and more precisely within the olfactory bulbs. We named this population OB-GnRH neurons. We hypothesized that this newly identified GnRH neuronal population may convey olfactory and/or pheromonal information to participate to the neuroendocrine responses controlling reproduction. Accordingly, we evaluated whether OB-GnRH neurons can be activated by opposite-sex smell exposure. The use of *in vivo* calcium imaging coupled with two-photons microscopy confirmed that olfactory and pheromonal stimulations can activate the OB-GnRH neurons. We next showed using a combination of viral tracing experiments and electrophysiological recordings that the OB-GnRH neurons are connected with the neuroendocrine GnRH population located in the rostral preoptic area. The function of OB-GnRH neurons on sex-related sensory processing was investigated using bidirectional chemogenetic neuromodulation combined with behavioral testing. Remarkably, our data demonstrate that OB-GnRH neurons are essential to drive the opposite-sex preference as well as a robust Luteinizing Hormone (LH) and testosterone secretion in males. Together, our study highlights a novel role for olfactory GnRH neurons as a central regulatory hub linking pheromonal stimulations with sexual behavior and reproductive functions.

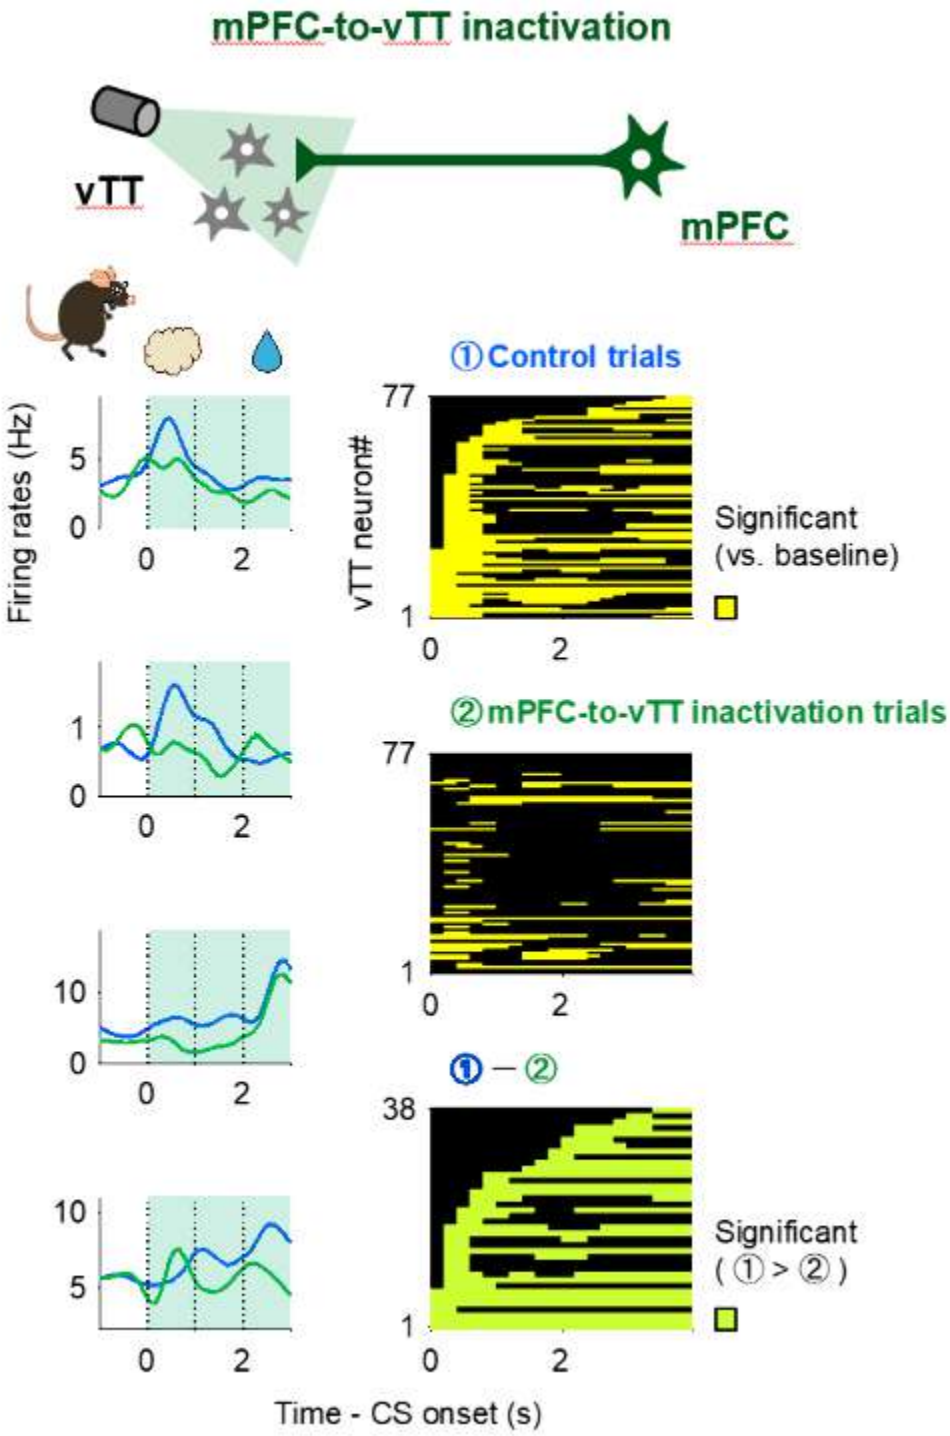
PREFRONTAL TO OLFACTORY CORTEX VENTRAL TENIA TECTA INPUTS SHARE ODOR-EVOKED BEHAVIORAL-STATE SIGNALS TO AFFECT CONTEXT-DEPENDENT LEARNING

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Yuta Tanisumi[1], Kazuki Shiotani[2], Yuma Osako[1], Tomoya Ohnuki[1], Shogo Takamiya[1], Junya Hirokawa[1], Yoshio Sakurai[1], Hiroyuki Manabe[1]
[1]Graduate School of Brain Science, Doshisha University, Laboratory Of Neural Information, Kyotanabe, Kyoto, Japan, [2]College of Life Sciences, Ritsumeikan University, Laboratory Of Brain Network Information, Kusatsu, Shiga, Japan



How sensory cortex shares top-down signals from higher-order regions is a significant question. We previously provided the first recordings of neuronal activity in the ventral tenia tecta (vTT) in the olfactory cortex, which receives top-down projections from the medial prefrontal cortex (mPFC) and projects to the broad olfactory areas. Here, we developed and combined electrophysiological recordings in the vTT with optogenetic mPFC-silencing while mice associated different four different odor cues with appetitive and aversive outcomes. First, we found individual vTT neurons encoded not only encoded odor-presentation associated with

positive and negative value, but also the odor-evoked outcome waiting and positive/negative outcome phases. Second, we investigated whether the neural activity undergoes temporal scaling from the short to long intervals using the different-interval timing task. The neural tunings to the extension of short-delay to long-delay were expanded, suggesting the scalable vTT state encoding. Third, to reveal the source of the top-down signals, we expressed inhibitory opsin Arch3.0 in the mPFC and recorded from vTT neurons with and without the optogenetic silencing of mPFC axons while mice conducted the task. Without mPFC-to-vTT inputs, the vTT-state representations were degraded and less integrated. Finally, we performed optogenetic silencing during the odor-outcome association task and the reversal learning to ask whether the mPFC-to-vTT inputs contribute to the learning of appetitive associations. Mice that experienced mPFC-to-vTT axons inhibition exhibited learning deficits. Taken together, our data suggest that the vTT acts as a hub that sends various context-dependent signals for learning from the mPFC to broad olfactory areas.

BENEFICIAL EFFECTS OF PROLONGED 2-PHENYLETHYL ALCOHOL INHALATION ON ALTERED FEEDING BEHAVIOR AND NEURAL ACTIVITY IN CHRONICALLY DISTRESSED FEMALE MICE

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Bahrie Ramadan[1], Lidia Cabeza[1], Stéphanie Cramoisy[1], Christophe Houdayer[1], Patrice Andrieu[1], Jean-Louis Millot[1], Emmanuel Haffen[1,2,3], Pierre-Yves Risold[1], Yvan Peterschmitt[1]
[1]Laboratoire de recherches Integratives en Neurosciences & psychologie Cognitive, Ur 481 - Ufr Santé - Université De Franche-comté, Besançon Cedex, France, [2]Centre Hospitalier Universitaire de Besançon CHU, Service De Psychiatrie De L'adulte, Besançon, France, [3]Centre Hospitalier Universitaire de Besançon CHU, Centre D'investigation Clinique, Cic-inserm-1431, Besançon, France

Chronic distress is core to the pathophysiology of neuropsychiatric disorders, such as anxiety and depression. Due to the diverse side effects of available classical medications, there has been a growing interest in developing safer therapeutic strategies based on substances derived from aromatic plants. Among them, rose essential oil is commonly used in aromatherapy which is considered as an adjuvant treatment for the improvement of patients' quality of life. The purpose of this study was to investigate the potential beneficial effects of 2-phenylethyl alcohol (PEA), one of the pharmacologically active constituents of rose oil, on behavioral and neurobiological changes that occur in a neuroendocrine mouse model of anxiety-depression. Female C57BL/6JRJ mice were orally treated with corticosterone (CORT) for 8 weeks. After a prolonged PEA inhalation (30 min per day, for 15 consecutive days), animals were submitted to the Novelty-Suppressed Feeding task (NSF). Immunohistochemistry was performed to provide a global map of functional neural network activity based on cerebral cFos expression analysis. Our results show that chronic CORT administration induces an anxio-depressive-like phenotype, evidenced by an increased latency to feed in the NSF. The altered feeding behavior negatively correlates with the olfactory bulb cFos-positive cells density. Moreover, cross-correlation-based network analysis reveals CORT-induced altered brain connectivity. These behavioral and neurobiological changes are reversed by prolonged PEA inhalation in chronically distressed female mice. The presented data suggest that the olfactory system contributes to the beneficial behavioral effects of prolonged PEA inhalation. Additional investigations are needed to further characterize the exact underlying neurobiological mechanisms.

STIMULUS NOVELTY DIFFERENTIALLY MODULATES ODOR RESPONSES IN THE ANTERIOR OLFACTORY NUCLEUS AND PIRIFORM CORTEX

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Martijn Broux[1,2], Cagatay Aydin[1,2], José Esquivelzeta Rabell[1,2], Eleonore Schiltz[1,2], Sebastian Haesler[1,2,3,4]
[1]KU Leuven, Department Of Neurosciences, Leuven, Belgium, [2]KU Leuven, Neuro-electronics Research Flanders, Heverlee, Belgium, [3]IMEC, Interuniversitary Micro Electronics Center, Heverlee, Belgium, [4]VIB, Flemish Institute For Biotechnology, Zwijnaarde, Belgium

When animals detect novel stimuli in their environment, they react with distinct orienting and exploratory behaviors. Detection of stimulus novelty is fast – behavioral novelty responses are observed already less than 100ms after stimulus presentation. In order to accomplish such rapid detection, the brain needs to perform a remarkably efficient computation involving a memory-based classification of incoming sensory stimuli. To begin to unravel the mechanism by which the brain discriminates novel from familiar olfactory stimuli, we performed multielectrode recordings in the anterior olfactory nucleus (AON) and piriform cortex (PCx) of awake, behaving mice, while presenting novel and familiar odorants. As described previously, novel stimuli evoked rapid increases in respiration frequency, also referred to as exploratory sniffing, which diminished with subsequent stimulus presentations. Neurons in the AON and PCx showed robust responses to novel and familiar odorants. However, odor responses in the AON responded much stronger to the initial presentations of novel stimuli than neurons in the PCx. To quantify this effect, we calculated the mean Euclidean distance from each trial population response to the last odor presentations as described previously (Bolding et al. 2020). The distance-to-stable was much larger in the neuronal population of the AON than the PCx. Consistent with this, a linear support vector machine showed superior performance in classifying novel from familiar trials when trained with AON compared to PCx neurons. Collectively, these results suggest the sensory representation in the AON is modulated by stimulus experience, while it appears relatively invariant to experience in the PCx.

LONG TERM STABILITY AND VOLATILITY OF ODOR-EVOKED RESPONSES IN THE MOUSE OLFACTORY BULB

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Haran Shani-Narkiss, David Beniaguev, Idan Segev, Adi Mizrahi
The Hebrew university of Jerusalem, Edmond And Lily Safra Center For Neuroscience, Jerusalem, Israel

Recent developments in methods to measure neuronal activity led to a general shift from recordings in anesthetized to awake animals. In sensory systems, and particularly olfaction, the differences between sensory coding in anesthetized versus awake states received only limited attention. Here, we used in vivo two-photon calcium imaging of odor responses in mitral cells from the olfactory bulb of mice in wakefulness and under anesthesia. Using a diverse panel of stimuli, including simple and complex odorants, we show an extensive change in mitral cells responses between states, supporting previous findings. Unlike previous finding we find heterogeneous, bidirectional changes by state rather than uniform modulation. Further, odor coding under anesthesia carries more sensory-relevant information, supporting the role of strong modulatory contextual information in awake mice. Using time-lapse imaging experiments, weeks apart, we found that despite the large differences between states, coding in each one of the states alone is highly stable over time. These findings show that different brain states dictate distinct, yet stable, coding schemes in the olfactory bulb.

DOUBLE-CODING: A MECHANISTIC EVALUATION OF NEURONAL MULTI-CISTRONIC GENES PERFORMED ON THE EXAMPLE OF THE P/Q-TYPE CALCIUM CHANNEL CAV2.1

POSTER SESSION 02 - SECTION: GENE EXPRESSION & REGULATION IN NEURAL FUNCTION

Jennifer Heck, Sinem Saka, Kyung-Min Noh
European Molecular Biology Laboratory (EMBL), Genome Biology Unit, Heidelberg, Germany

Besides their classical role as calcium-conducting elements controlling neuronal communication, voltage-gated calcium channels (VGCCs) have been shown to act on different regulatory levels of neuronal physiology by initiating signaling pathways that coordinate downstream gene expression. Observations have been made underpinning the idea that fragments of VGCCs might also directly act as gene regulators. In particular, the neuronal P/Q-type channel ($Ca_v2.1$) has been reported to express a C-terminal fragment (α1ACT) which translocates to nuclei of neurons *in vitro* and *in vivo*, where it binds to promotor regions of the DNA and orchestrates genes associated with neurogenesis, synaptic transmission, and cell adhesion. Although previous reports describe a cap-independent translation mechanism, an internal ribosomal entry site (IRES), to initiate the expression of these VGCC fragments, other studies rather suggest a transcriptional regulation of two independent mRNA transcripts via an exonic (cryptic) promoter in the *CACNA1A* gene, coding for $Ca_v2.1$. Thus, we aim to elucidate the nature of the underlying expression mechanism and how the expression of α1ACT is regulated during neuronal differentiation and upon pathological stimuli (e.g., elevated intracellular calcium levels or oxidative stress). After confirming the expression of α1ACT in various cellular model systems, we are now applying enhanced fluorescence in situ hybridization together with proximity labelling to dissect transcriptional and translational regulation mechanisms. Resolving the mechanistic underpinnings of multi-cistronic genes, by the example of α1ACT, will provide new insights into how functional neuronal complexity is achieved with a limited number of genes.

More than a pore: How voltage-gated calcium channels act on different levels of neuronal communication regulation.
Voltage-gated calcium channels (VGCCs) represent key regulators of the calcium influx through the plasma membrane of excitable cells, like neurons. Activated by the depolarization of the membrane, the opening of VGCCs induces very transient and local changes in the intracellular calcium concentration, known as calcium nanodomains, that in turn trigger calcium-dependent signaling cascades and the release of chemical neurotransmitters. Based on their central importance as concierges of excitation-secretion coupling and therefore neuronal communication, VGCCs have been studied in multiple aspects of neuronal function and malfunction. However, studies on molecular interaction partners and recent progress in omics technologies have extended the actual concept of these molecules. With this review, we want to illustrate some new perspectives of VGCCs reaching beyond their function as calcium-permeable pores in the plasma membrane. Therefore, we will discuss the relevance of VGCCs as voltage sensors in functional complexes with ryanodine receptors, channel-independent actions of auxiliary VGCC subunits, and provide an insight into how VGCCs even directly participate in gene regulation. Furthermore, we will illustrate how structural changes in the intracellular C-terminus of VGCCs generated by alternative splicing events might not only affect the biophysical channel characteristics but rather determine their molecular environment and downstream signaling pathways.

Auxiliary α2δ1 and α2δ3 Subunits of Calcium Channels Drive Excitatory and Inhibitory Neuronal Network Development.
VGCCs are multisubunit complexes that play a crucial role in neuronal signaling. Auxiliary α2δ subunits of VGCCs modulate trafficking and biophysical properties of the pore-forming α1 subunit and trigger excitatory synaptogenesis. Alterations in the expression level of α2δ subunits were implicated in several syndromes and diseases, including chronic neuropathic pain, autism, and epilepsy. However, the contribution of distinct α2δ subunits to excitatory/inhibitory imbalance and aberrant network connectivity characteristic for these pathologic conditions remains unclear. Here, we show that α2δ1 overexpression enhances spontaneous neuronal network activity in developing and mature cultures of hippocampal neurons. In contrast,

overexpression, but not downregulation, of α2δ3 enhances neuronal firing in immature cultures, whereas later in development it suppresses neuronal activity. We found that α2δ1 overexpression increases excitatory synaptic density and selectively enhances presynaptic glutamate release, which is impaired on α2δ1 knockdown. Overexpression of α2δ3 increases the excitatory synaptic density as well but also facilitates spontaneous GABA release and triggers an increase in the density of inhibitory synapses, which is accompanied by enhanced axonaloutgrowth in immature interneurons. Together, our findings demonstrate that α2δ1 and α2δ3 subunits play distinct but complementary roles in driving formation of structural and functional network connectivity during early development. An alteration in α2δ surface expression during critical developmental windows can therefore play a causal role and have a profound impact on the excitatory-to-inhibitory balance and network connectivity. The computational capacity of neuronal networks is determined by their connectivity. Chemical synapses are the main interface for transfer of information between individual neurons. The initial formation of network connectivity requires spontaneous electrical activity and the calcium channel-mediated signaling. We found that, in early development, auxiliary α2δ3 subunits of calcium channels foster presynaptic release of GABA, trigger formation of inhibitory synapses, and promote axonal outgrowth in inhibitory interneurons. In contrast, later in development, α2δ1 subunits promote the glutamatergic neurotransmission and synaptogenesis, as well as strongly enhance neuronal network activity. We propose that formation of connectivity in neuronal networks is associated with a concerted interplay of α2δ1 and α2δ3 subunits of calcium channels.

Dynamic compartmentalization of calcium channel signalling in neurons.
Calcium fluxes through the neuronal membrane are strictly limited in time due to biophysical properties of voltage-gated and ligand-activated ion channels and receptors. Being embedded into the crowded dynamic environment of biological membranes, Ca-permeable receptors and channels undergo perpetual spatial rearrangement, which enables their temporary association and formation of transient signalling complexes. Thus, efficient calcium-mediated signal transduction requires mechanisms to support very precise spatiotemporal alignment of the calcium source and Ca-binding lipids and proteins in a highly dynamic environment. The mobility of calcium channels and calcium-sensing proteins themselves can be considered as a physiologically meaningful variable that affects calcium-mediated signalling in neurons. In this review, we will focus on voltage-gated calcium channels (VGCCs) and activity-induced relocation of stromal interaction molecules (STIMs) in the endoplasmic reticulum (ER) to show that particularly in time ranges between milliseconds to minutes, dynamic rearrangement of calcium conducting channels and sensor molecules is of physiological relevance. This article is part of the special issue entitled 'Mobility and trafficking of neuronal membrane proteins'.

Transient Confinement of Ca2.1 Ca-Channel Splice Variants Shapes Synaptic Short-Term Plasticity.
The precision and reliability of synaptic information transfer depend on the molecular organization of voltage-gated calcium channels (VGCCs) within the presynaptic membrane. Alternative splicing of exon 47 affects the C-terminal structure of VGCCs and their affinity to intracellular partners and synaptic vesicles (SVs). We show that hippocampal synapses expressing VGCCs either with exon 47 (Ca2.1) or without (Ca2.1) differ in release probability and short-term plasticity. Tracking single channels revealed transient visits (~100 ms) of presynaptic VGCCs in nanodomains (~80 nm) that were controlled by neuronal network activity. Surprisingly, despite harboring prominent binding sites to scaffold proteins, Ca2.1 persistently displayed higher mobility within nanodomains. Synaptic accumulation of Ca2.1 was accomplished by optogenetic clustering, but only Ca2.1 increased transmitter release and enhanced synaptic short-term depression. We propose that exon 47-related alternative splicing of Ca2.1 channels controls synapse-specific release properties at the level of channel mobility-dependent coupling between VGCCs and SVs.

Biophysics of high density nanometer regions extracted from super-resolution single particle trajectories: application to voltage-gated calcium channels and phospholipids.
The cellular membrane is very heterogenous and enriched with high-density regions forming microdomains, as revealed by single particle tracking experiments. However the organization of these regions remain unexplained. We determine here the biophysical properties of these regions, when described as a basin of attraction. We develop two methods to recover the dynamics and local potential wells (field of force and boundary). The first method is based on the local density of points distribution of trajectories, which differs inside and outside the wells. The second method focuses on recovering the drift field that is convergent inside wells and uses the transient field to determine the boundary. Finally, we apply these two methods to the distribution of trajectories recorded from voltage gated calcium channels and phospholipid anchored GFP in the cell

membrane of hippocampal neurons and obtain the size and energy of high-density regions with a nanometer precision.

Dynamic association of calcium channel subunits at the cellular membrane.
High voltage gated calcium channels (VGCCs) are composed of at least three subunits, one pore forming [Formula: see text]-subunit, an intracellular [Formula: see text]-variant, and a mostly extracellular [Formula: see text]-variant. Interactions between these subunits determine the kinetic properties of VGCCs. It is unclear whether these interactions are stable over time or rather transient. Here, we used single-molecule tracking to investigate the surface diffusion of [Formula: see text]- and [Formula: see text]-subunits at the cell surface. We found that [Formula: see text]-subunits show higher surface mobility than [Formula: see text]-subunits, and that they are only transiently confined together, suggesting a weak association between [Formula: see text]- and [Formula: see text]-subunits. Moreover, we observed that different [Formula: see text]-subunits engage in different degrees of association with the [Formula: see text]-subunit, revealing the tighter interaction of [Formula: see text] with [Formula: see text]. These data indicate a distinct regulation of the [Formula: see text] interaction in VGCC subtypes. We modeled their membrane dynamics in a Monte Carlo simulation using experimentally determined diffusion constants. Our modeling predicts that the ratio of associated [Formula: see text]- and [Formula: see text]-subunits mainly depends on their expression density and confinement in the membrane. Based on the different motilities of particular [Formula: see text]-subunit combinations, we propose that their dynamic assembly and disassembly represent an important mechanism to regulate the signaling properties of VGCC.

Surface dynamics of voltage-gated ion channels.
Neurons encode information in fast changes of the membrane potential, and thus electrical membrane properties are critically important for the integration and processing of synaptic inputs by a neuron. These electrical properties are largely determined by ion channels embedded in the membrane. The distribution of most ion channels in the membrane is not spatially uniform: they undergo activity-driven changes in the range of minutes to days. Even in the range of milliseconds, the composition and topology of ion channels are not static but engage in highly dynamic processes including stochastic or activity-dependent transient association of the pore-forming and auxiliary subunits, lateral diffusion, as well as clustering of different channels. In this review we briefly discuss the potential impact of mobile sodium, calcium and potassium ion channels and the functional significance of this for individual neurons and neuronal networks.

THE LONG NON-CODING RNA MIMI SCAFFOLDS NEURONAL GRANULES TO MAINTAIN NERVOUS SYSTEM MATURITY

POSTER SESSION 02 - SECTION: GENE EXPRESSION & REGULATION IN NEURAL FUNCTION

Dominika Grzejda, Valérie Hilgers
Max Planck Institute of Immunobiology and Epigenetics, Valérie Hilgers Lab, Freiburg, Germany

RNA-binding proteins and messenger RNAs assemble into ribonucleoprotein granules that regulate mRNA trafficking, local translation, and turnover. RNP granule-mediated regulation of gene expression is abundantly utilized by neurons— cells that particularly rely on precise spatiotemporal compartmentalization of cellular events. Dysregulation of RNA-protein condensation can disturb neuronal survival and function: granule hypo- and hyper-assembly are associated with human neurological diseases, including Alzheimer's disease, ALS/FTD (amyotrophic lateral sclerosis/ frontotemporal dementia), SMA (spinal muscular atrophy) or Huntington's disease. Neuronal granules are thought to condense around particular proteins. Contrasting with this prevailing model, here, we show in Drosophila that a previously uncharacterized long non-coding RNA, *mimi*, is required to scaffold large neuronal granules in the adult nervous system. Neuronal ELAV-like proteins directly bind *mimi* and mediate granule assembly, while Staufen maintains *mimi* expression and condensate integrity. *mimi* is undetectable outside of condensates, suggesting that its main cellular function is to support RNP granules. *mimi* mutant flies constitute a unique animal model for granule hypo-assembly that provides a handle to interrogate functions of a condensate independently from those of its constituents. *mimi* granules contain mRNAs and proteins involved in synaptic processes; granule loss in *mimi* mutant flies impairs nervous system maturity, neuropeptide-mediated signaling, causes memory defects and phenotypes of neurodegeneration. Our work reports the first architectural RNA for a neuronal granule and showcases how the molecular functions of highly conserved RNA-binding proteins converge in phase-separated condensates to regulate neuronal function and behavior.

ELAV and FNE Determine Neuronal Transcript Signatures through EXon-Activated Rescue.
The production of alternative RNA variants contributes to the tissue-specific regulation of gene expression. In the animal nervous system, a systematic shift toward distal sites of transcription termination produces transcript signatures that are crucial for neuron development and function. Here, we report that, in Drosophila, the highly conserved protein ELAV globally regulates all sites of neuronal 3' end processing and directly binds to proximal polyadenylation sites of target mRNAs in vivo. We uncover an endogenous strategy of functional gene rescue that safeguards neuronal RNA signatures in an ELAV loss-of-function context. When not directly repressed by ELAV, the transcript encoding the ELAV paralog FNE acquires a mini-exon, generating a new protein able to translocate to the nucleus and rescue ELAV-mediated alternative polyadenylation and alternative splicing. We propose that exon-activated functional rescue is a more widespread mechanism that ensures robustness of processes regulated by a hierarchy, rather than redundancy, of effectors.

Biosurfactant production and hydrocarbon degradation activity of endophytic bacteria isolated from Chelidonium majus L.
The process of plant growth in the contaminated environment is often inhibited and entails the neutralization of harmful compounds. To reduce the negative impact of harmful compounds microorganisms produce unique compounds called biosurfactants. This paper describes the potential of culturable endophytic microorganisms from synanthropic plant-Chelidonium majus L. for the production of biosurfactants, as indirect plant promoting factors as well as their degradation activity. Emulsifying activity and degradation potential of tested strains were assessed by cultivation of isolates in the presence of diesel oil and waste engine oil.

ROLE OF DEVELOPMENTAL REGULATORS OF AXONAL LOCAL TRANSLATION IN ADULT AXONS

POSTER SESSION 02 - SECTION: GENE EXPRESSION & REGULATION IN NEURAL FUNCTION

Marina Vidaki, Nikoletta Triantopoulou, Sofia Pasadaki
University of Crete, School Of Medicine, Heraklion, Greece

Local mRNA translation (LT) is vital for axon development. Disruption of LT has been linked to the emergence of neurodevelopmental disorders, while several studies suggest that LT is related to the intrinsic regenerative capacity of mature neurons. Axonal regeneration displays similarities with axon growth during development, exhibiting a number of cellular processes that require LT. Although mature PNS axons maintain the ability for LT, maturing CNS axons exhibit a gradually decreasing LT potential, highly correlated with their limited regenerative capacity. Despite the evident role of LT in axon stability and regeneration, the regulatory mechanisms behind the process and their role in post-injury regeneration remain elusive. We have previously identified a ribonucleoprotein complex (Mena-RNP) that regulates axonal LT in the developing brain. It consists of the cytoskeleton-associated protein Mena that interacts with known regulators of translation (i.e. HnrnpK, PCBP1), thus controlling the translation of the RNP-bound mRNAs. Here, we investigate the conservation of Mena-RNP in the adult nervous system, in an attempt to elucidate the role of Mena and Mena-dependent translation in adult axon regeneration. Employing both *in vivo* and *ex vivo* injury assays we observe that the Mena-RNP components differ between the developing and adult nervous system and in CNS vs PNS axons. In an additional, unbiased line of work we are currently exploring other molecular components that function locally in axons and could potentially explain the differential capacity of adult CNS and PNS axons for regeneration.

TALKING TO THE NUCLEUS: TUNING OF CORTICAL INHIBITION BY BMP-SMAD1 SIGNALING

POSTER SESSION 02 - SECTION: GENE EXPRESSION & REGULATION IN NEURAL FUNCTION

Zeynep Okur, Nadia Schlauri, Vassilis Bitsikas, Peter Scheiffele
Biozentrum, University Of Basel, Basel, Switzerland

Neocortical networks are responsive to environmental changes during development and at adult stages. Parvalbumin expressing fast spiking interneurons (PV-INs) are the most abundant population of inhibitory neurons in the neocortex. PV-INs and their plasticity are critically involved in the generation of network oscillations, learning, and maintaining the excitation - inhibition in balance. During late postnatal development, PV-INs mature significantly as evidenced by functional properties, increases in parvalbumin expression, and the elaboration of perineuronal nets. Moreover, mature PV-INs undergo reversible state changes during learning. However, the molecular mechanisms underlying such transitions are largely unknown. Growth factors are candidate regulators as they can be mobilized upon neuronal activation and through effects on transcription factors direct neuronal transcriptome changes. We demonstrate that Bone Morphogenic Proteins (BMPs), a class of morphogens acting in early development, remain expressed in adult neocortex and are significantly elevated in response to neuronal stimulation. Neuron specific BMP signaling loss of function from cultured neocortical cells results in elevated network activity and pervasive disruption of the neuronal transcriptome. Postnatal conditional knock-out of Smad1, selectively in PV-INs ($Smad1^{cKO}$), results in reduced parvalbumin levels, perineuronal nets and parvalbumin driven inhibitory synapses in adult mice. Electrophysiological recordings show delayed action potential firing of PV-INs in adult $Smad1^{cKO}$ mice. Consistent with a hypofunction of PV-INs, $Smad1^{cKO}$ mice exhibit spontaneous seizures. In ongoing work, we are investigating the activity-dependent mobilization of BMPs in the adult cortex. We propose that BMP-SMAD1 signaling balances PV-IN connectivity by driving functional PV-IN state shifts in mature neocortical networks.

LTP of inhibition at PV interneuron output synapses requires developmental BMP signaling.
Parvalbumin (PV)-expressing interneurons (PV-INs) mediate well-timed inhibition of cortical principal neurons, and plasticity of these interneurons is involved in map remodeling of primary sensory cortices during critical periods of development. To assess whether bone morphogenetic protein (BMP) signaling contributes to the developmental acquisition of the synapse- and plasticity properties of PV-INs, we investigated conditional/conventional double KO mice of BMP-receptor 1a (BMPR1a; targeted to PV-INs) and 1b (BMPR1a/1b (c)DKO mice). We report that spike-timing dependent LTP at the synapse between PV-INs and principal neurons of layer 4 in the auditory cortex was absent, concomitant with a decreased paired-pulse ratio (PPR). On the other hand, baseline synaptic transmission at this connection, and action potential (AP) firing rates of PV-INs were unchanged. To explore possible gene expression targets of BMP signaling, we measured the mRNA levels of the BDNF receptor TrkB and of P/Q-type Ca channel α-subunits, but did not detect expression changes of the corresponding genes in PV-INs of BMPR1a/1b (c)DKO mice. Our study suggests that BMP-signaling in PV-INs during and shortly after the critical period is necessary for the expression of LTP at PV-IN output synapses, involving gene expression programs that need to be addressed in future work.

Promotion of neurite outgrowth by rationally designed NGF-β binding peptide nanofibers.
Promotion of neurite outgrowth is an important limiting step for regeneration in nerve injury and depends strongly on the local expression of nerve growth factor (NGF). The rational design of bioactive materials is a promising approach for the

development of novel therapeutic methods for nerve regeneration, and biomaterials capable of presenting NGF to nerve cells are especially suitable for this purpose. In this study, we show bioactive peptide amphiphile (PA) nanofibers capable of promoting neurite outgrowth by displaying high density binding epitopes for NGF. A high-affinity NGF-binding sequence was identified by phage display and combined with a beta-sheet forming motif to produce a self-assembling PA molecule. The bioactive nanofiber had higher affinity for NGF compared to control nanofibers and in vitro studies revealed that the NGF binding peptide amphiphile nanofibers (NGFB-PA nanofiber) significantly promote the neurite outgrowth of PC-12 cells. In addition, the nanofibers induced differentiation of PC-12 cells into neuron-like cells by enhancing NGF/high-activity NGF receptor (TrkA) interactions and activating MAPK pathway elements. The NGFB-PA nanofiber was further shown as a promising material to support axonal outgrowth from primary sensory neurons. These materials will pave the way for the development of new therapeutic agents for peripheral nervous system injuries.

The human body is composed of many different cell types which communicate with each other. In particular, the brain consists of billions of neurons and non-neuronal cells which are interconnected and require tight and precise regulation of cellular processes. RNA editing is a cellular process that diversifies gene function by enzymatic deamination of cytidine or adenine. This can result in changes of protein structure and function. Altered RNA editing is becoming increasingly associated with all kind of disease, but most approaches use advanced sequencing technologies to analyze bulk material. However, it is also becoming progressively evident that changes in RNA editing have to be analyzed and considered in a cell type specific way. We present here a triple fluorescence reporter system that discriminates between Apobec1- and Apobec3-dependent C-to-U RNA editing at the single cell level. In particular, the Apobec3 reporter enables C-to-U RNA editing inducible protein expression through generation of a RNA splice donor site. We used the new system here to analyze Apobec1- and Apobec3-dependent RNA editing in primary neuron culture. The results reveal a large heterogeneity of C-to-U RNA editing in neurons and glia cells. The new system can be the foundation of therapeutic application systems that counteract changes in Apobec3-dependent RNA editing in disease while simultaneously monitoring Apobec1-dependent RNA editing at the single cell level.

The orbitofrontal cortex (OFC) plays a fundamental role in post-decision confidence and value-based decision-making. The integrative function of this ventral subregion of the prefrontal cortex makes it heavily circuit dependent; OFC projection efferents include superior colliculus and ventral striatum. The network underlying economic value has been dissected by neuroimaging, anatomic tracing and single-unit recordings, but the transcriptomic profile remains unclear. Within neurons, translation occurs in different subcellular locations allowing dynamic adaptation to the anatomic location and cellular environment. Research shows transcriptional differences between neuronal types are more prominent in somata than dendritic arbours, therefore gene expression patterns and subcellular localization of mRNA transcripts can help narrow projecting neuronal types in the OFC. Here, we aimed to identify expression markers of OFC efferent projection neurons from a set of pre-selected putative biomarkers, by combining retrograde viral vector tracing with RNA Scope. RNA Scope is an in-situ hybridization method; It consists of sequence-specific probes and a two-step amplification allowing specific detection of single mRNA molecules. Co-localization of the mRNA with retrograde tracer labelled neurons enabled accurate spatial context detection, cellular localization and quantification of candidate gene expression in OFC efferent projecting neurons. We identified specific transcriptomic markers of OFC efferent projections, which can prove useful as predictive markers for projection target identification of neurons. Overall, our approach allowed transcriptomic profiling of OFC circuitry enabling the genetic and anatomic bottom-up understanding of the connectivity underlying value-based decision making and post-decision confidence. Research supported by the Austrian Science Fund (I 5458).

Transcription factor 4 (TCF4) belongs to a family of basic helix-loop-helix transcription factors, also known as E-proteins, and is vital for the development of a normally functioning nervous system. TCF4 has been associated with several mental disorders such as schizophrenia, intellectual disability, and a very rare but severe disease known as Pitt-Hopkins syndrome (PTHS). We have previously demonstrated that human TCF4 gene is transcribed using numerous alternative 5'-exons, potentially yielding in many TCF4 protein isoforms with different N-termini that vary in their subcellular distribution and transcription activation capability. We have found that PTHS-associated mutations impair the functions of TCF4 by diverse mechanisms ranging from hypomorphic to dominant-negative effects. Our results have also demonstrated that TCF4 transcriptional activity is induced by neuronal activity via direct phosphorylation of TCF4 by protein kinase A. Additionally, our recently published data showed that different TCF4 isoforms have differential synergism with class II basic helix-loop-helix transcription factors. TCF4 expression studies have been mainly focused on TCF4 mRNA levels whereas expression of protein isoforms has been less characterized. Here we present our recent results of the expression pattern of different TCF4 mRNA and protein isoforms in the brain and peripheral organs during rodent and human development.

ROLE OF NETRIN-1 IN EXPERIMENTAL MODEL OF MULTIPLE SCLEROSIS

POSTER SESSION 02 - SECTION: GENE EXPRESSION & REGULATION IN NEURAL FUNCTION

Fritz Kagerer[1], Almir Aljovic[1], Clara De La Rosa Del Val[1], Arek Kendirli[1], Florence Bareyre[2], Martin Kerschensteiner[3]
[1]Ludwig-Maximilians University Munich, Neuroimmunology, Planegg-Martinsried, Germany, [2]University Hospital LMU Munich, Institute For Clinical Neuroimmunology, Munich, Germany, [3]Biomedical Center of LMU, Institute Of Clinical Neuroimmunology, Martinsried, Germany

Multiple sclerosis (MS) is a disease affecting 2,8 million people worldwide, however, there are still many open questions about this disease and targeted treatments are lacking. MS is mostly caused by an autoimmune reaction against myelination of neurons. Therefore, first order treatments are mostly restricted to immunomodulators that downregulate the immune system. This immunomodulation is rather unspecific and we are interested in finding regulators that could modulate inflammatory environment specifically in CNS. Recent studies suggest that the axon guidance protein Netrin-1 was shown to also play a significant role in inflammation. We hypothesized that Netrin-1 could be a potent candidate for immune modulation specific to CNS environment. In line with our hypothesis, we found that Netrin-1 expression not only significantly increases in tissue of experimental autoimmune encephalomyelitis (EAE) mice, but also that the protein expression correlates almost perfectly with the stage of the disease. Additionally, we found a significant increase of Netrin-1-positive cells at EAE-induced lesion sites in the spinal cord. These cells were mostly CD11b positive, suggesting that Netrin-1 gets upregulated in macrophages and microglia in EAE lesion site. We therefore want to further study this up-regulation of Netrin-1 in tissue of EAE mice and the role of Netrin-1 in EAE inflammation.

Brain-derived neurotrophic factor (BDNF) is a widely expressed neurotrophin that supports the survival, differentiation and signaling of various neuronal populations. To utilize the great potential of neurotrophic factors in treating nervous system disorders, it is crucial to understand their regulation. Here, we aimed to elucidate the BDNF gene regulation after different stimuli to better understand how cells express BDNF gene to regulate the development and maintenance of the nervous system. To this end, we have used an unbiased approach using *in vitro* DNA pulldown coupled with mass-spectrometry to discover the transcription factors binding to BDNF promoters I and IV in cultured cortical neurons after different stimuli. Our results confirm many previously described regulators of BDNF and suggest novel regulators of BDNF gene. We next studied a selection of the novel candidate regulators using coexpression with promoter constructs in cultured neurons, then deciphered the role of selected factors in the regulation of BDNF gene in the endogenous context, and finally confirmed their binding to BDNF promoters in the endogenous context using chromatin immunoprecipitation. Our data reveals complicated fine-tuning of BDNF expression at the promoter regions and provides insight to how neurons respond to different stimuli and control BDNF transcription.

Intronic enhancer region governs transcript-specific expression in rodent neurons.
Brain-derived neurotrophic factor (BDNF) controls the survival, growth, and function of neurons both during the development and in the adult nervous system. is transcribed from several distinct promoters generating transcripts with alternative 5' exons. transcripts initiated at the first cluster of exons have been associated with the regulation of body weight and various aspects of social behavior, but the mechanisms driving the expression of these transcripts have remained poorly understood. Here, we identify an evolutionarily conserved intronic enhancer region inside the gene that regulates both basal and stimulus-dependent expression of the transcripts starting from the first cluster of 5' exons in mouse and rat neurons. We further uncover a functional E-box element in the enhancer region, linking the expression of and various pro-neural basic helix-loop-helix transcription factors. Collectively, our results shed new light on the cell-type- and stimulus-specific regulation of the important neurotrophic factor BDNF.

CREB Family Transcription Factors Are Major Mediators of BDNF Transcriptional Autoregulation in Cortical Neurons.
BDNF signaling via its transmembrane receptor TrkB has an important role in neuronal survival, differentiation, and synaptic plasticity. Remarkably, BDNF is capable of modulating its own expression levels in neurons, forming a transcriptional positive feedback loop. In the current study, we have investigated this phenomenon in primary cultures of rat cortical neurons using overexpression of dominant-negative forms of several transcription factors, including CREB, ATF2, C/EBP, USF, and NFAT. We show that CREB family transcription factors, together with the coactivator CBP/p300, but not the CRTC family, are the main regulators of rat gene expression after TrkB signaling. CREB family transcription factors are required for the early induction of all the major transcripts, whereas CREB itself directly binds only to promoter IV, is phosphorylated in response to BDNF-TrkB signaling, and activates transcription from promoter IV by recruiting CBP. Our complementary reporter assays with promoter constructs indicate that the regulation of by CREB family after BDNF-TrkB signaling is generally conserved between rat and human. However, we demonstrate that a nonconserved functional cAMP-responsive element in promoter IXa in humans renders the human promoter responsive to BDNF-TrkB-CREB signaling, whereas the rat ortholog is unresponsive. Finally, we show that extensive BDNF transcriptional autoregulation, encompassing all major transcripts, occurs also in the adult rat hippocampus during BDNF-induced LTP. Collectively, these results improve the understanding of the intricate mechanism of BDNF transcriptional autoregulation. Deeper understanding of stimulus-specific regulation of gene expression is essential to precisely adjust BDNF levels that are dysregulated in various neurological disorders. Here, we have

elucidated the molecular mechanisms behind TrkB signaling-dependent mRNA induction and show that CREB family transcription factors are the main regulators of gene expression after TrkB signaling. Our results suggest that BDNF-TrkB signaling may induce gene expression in a distinct manner compared with neuronal activity. Moreover, our data suggest the existence of a stimulus-specific distal enhancer modulating gene expression.

AP-1 Transcription Factors Mediate BDNF-Positive Feedback Loop in Cortical Neurons.
Brain-derived neurotrophic factor (BDNF), a member of the neurotrophin family, regulates both survival and differentiation of several neuronal populations in the nervous system during development, as well as synaptic plasticity in the adult brain. BDNF exerts its biological functions through its receptor TrkB. Although the regulation of BDNF transcription by neuronal activity has been widely studied, little is known about TrkB signaling-dependent expression of BDNF. Using rat primary cortical neuron cultures, we show that the BDNF gene is a subject to an extensive autoregulatory loop, where TrkB signaling upregulates the expression of all major BDNF transcripts, mainly through activating MAPK pathways. Investigating the mechanisms behind this autoregulation, we found that AP-1 transcription factors, comprising Jun and Fos family members, participate in the induction of BDNF exon I, III, and VI transcripts. AP-1 transcription factors directly upregulate the expression of exon I transcripts by binding two novel AP-1 cis-elements in promoter I. Moreover, our results show that the effect of AP-1 proteins on the activity of rat BDNF promoters III and VI is indirect, because AP-1 proteins were not detected to bind the respective promoter regions by chromatin immunoprecipitation (ChIP). Collectively, we describe an extensive positive feedback system in BDNF regulation, adding a new layer to the elaborate control of BDNF gene expression.

STUDY OF THE DYNAMIC EFFECTS OF GLUCOCORTICOID PULSATILITY ON BRAIN-DERIVED NEUROTROPHIC FACTOR EXPRESSION IN ASTROCYTES

POSTER SESSION 02 - SECTION: GENE EXPRESSION & REGULATION IN NEURAL FUNCTION

Alexandros Tsimpolis[1,2], Aris Logothetis[1,2], Konstantinos Kalafatakis[1,2], Ioannis Charalampopoulos[1,2]

Both glucocorticoids (GCs) and neurotrophins, like brain-derived neurotrophic factor (BDNF), are strongly implicated in the pathophysiology of stress-related diseases through their defined effects on adult hippocampal neurogenesis and synaptic plasticity. Functional interactions between BDNF and GCs have been recently demonstrated indicating a potential synergy or antagonism on neuroplasticity under physiological or neuropathological conditions. In order to further investigate this neuro-immunological crosstalk, we examined the baseline effects of a physiologically-relevant GC concentration on BDNF expression in primary cultures of hippocampal neurons, astrocytes and co-cultures of the two cell populations, in consecutive timepoints during a 24-hour exposure. Our results, demonstrate a different reaction of each cell type to administrated GCs and characterize the existence, in astrocytes, of two temporally distinct functions with opposing outcomes on BDNF expression: an early, very fast effect that occurs well within the first hour of GC administration and leads to BDNF overexpression and a late inhibitory effect, that can last for up to 24 hours. Using selective pharmacological inhibitors, we were able to match the involvement of Glucocorticoid receptor to the late effect and interestingly, the necessity of both Mineralocorticoid receptor and TrkB (BDNF receptor) for the regulation of the early effect. Finally, by simulating *in vitro* the physiological pulsatile secretion of GCs, we demonstrated astrocyte's ability to restore BDNF expression, back to its baseline untreated level, thus highlighting the well-established homeostatic capabilities of GCs and the important role of astrocyte susceptibility to GC pulsatility.

Using the Allen gene expression atlas of the adult mouse brain to gain further insight into the physiological significance of TAG-1/Contactin-2.
The anatomic gene expression atlas (AGEA) of the adult mouse brain of the Allen Institute for Brain Science is a transcriptome-based atlas of the adult C57Bl/6 J mouse brain, based on the extensive in situ hybridization dataset of the Institute. This spatial mapping of the gene expression levels of mice under baseline conditions could assist in the formation of new, reasonable transcriptome-derived hypotheses on brain structure and underlying biochemistry, which could also have functional implications. The aim of this work is to use the data of the AGEA (in combination with Tabula Muris, a compendium of single cell transcriptome data collected from mice, enabling direct and controlled comparison of gene expression among cell types) to provide further insights into the physiology of TAG-1/Contactin-2 and its interactions, by presenting the expression of the corresponding gene across the adult mouse brain under baseline conditions and to investigate any spatial genomic correlations between TAG-1/Contactin-2 and its interacting proteins and markers of mature and immature oligodendrocytes, based on the pre-existing experimental or bibliographical evidence. The across-brain correlation analysis on the gene expression intensities showed a positive spatial correlation of TAG-1/Contactin-2 with the gene expression of Plp1, Myrf, Mbp, Mog, Cldn11, Bace1, Kcna1, Kcna2, App and Nfasc and a negative spatial correlation with the gene expression of Cspg4, Pdgfra, L1cam, Ncam1, Ncam2 and Ptprz1. Spatially correlated genes are mainly expressed by mature oligodendrocytes (like Cntn2), while spatially anticorrelated genes are mainly expressed by oligodendrocyte precursor cells. According to the data presented in this work, we propose that even though Contactin-2 expression during development correlates with high plasticity events, such as neuritogenesis, in adulthood it correlates with pathways characterized by low plasticity.

Gene expression and genetic variation studies suggest an important contribution of microglia cells to the onset and progression of most prevalent neurodegenerative conditions, such as Alzheimer's disease (AD), where a putative diversity of microglia states with divergent homeostatic or pathophysiological roles has been proposed. However, very little is known on the mechanisms regulating the ability of these highly plastic cells of the brain to adopt specialized roles when exposed to different conditions. Here, we combine high-throughput genomics and in situ RNA expression analysis at the single-cell level with functional assays to reveal the molecular underpinnings of the transitions and maintenance of the distinct phenotypic and functional states of brain's innate immune cells through the initiation, activation and resolution of the neuroinflammatory response. These data deepen our understanding of microglia heterogeneity which is critical to devise new therapeutics for most prevalent neurodegenerative diseases.

Epilepsy is a complex disease with a high contribution of genetic factors, including several hundreds of Mendelian disorders. In those case, pathogenic variants disrupt the expression or function of proteins essential for neuronal development, synaptic transmission, or ion currents. Yet the identification of variants of unknown clinical relevance in patients raises the need to validate that the mutations affect some of the functions of the gene. We focused on *RORB*, which encodes the retinoid-related orphan receptor beta (RORß), and was recently associated to moderate intellectual disability and epilepsy. We characterized that knockdown of RORß expression altered axon morphogenesis in mouse cortical neurons. Conversely, overexpression of RORß led to a tractable axonal phenotype (ie. increased axonal complexity). Taking advantage of this phenotype, we generated plasmids expressing mutant RORß proteins mimicking variants identified in epileptic patients, and validated that these mutations impair the functions of the RORß protein. Overall, our study demonstrates the pathogenic nature of the variants tested in our cell model.

Brain derived neurotrophic factor (BDNF) has a fundamental role in the developing and adult nervous system, where BDNF assists the development of neuronal circuits, promotes neuronal survival, differentiation and synaptic plasticity. Therefore, dysregulation of BDNF expression has been implicated in many neurological disorders, for example Rett syndrome, schizophrenia and Alzheimer's disease. The stimulus- and tissue-specific expression of BDNF is ensured with a complex transcriptional regulation. BDNF gene contains several promoters that are activated in response to various stimuli, including neuronal activity and TrkB-signalling in neurons, and catecholamine-dependent signalling in astrocytes. Although the promoter regions of the BDNF gene have been extensively studied, very little is known about the enhancer regions regulating the transcription of BDNF. In this study, we investigated five potential enhancer regions and report that an enhancer far upstream of BDNF gene regulates the BDNF gene expression in rodent neurons and astrocytes. Specifically, the far upstream enhancer participates in basal and stimulus-dependent expression of BDNF in rodent neurons and is responsible for catecholamine-induced CREB and AP1 family-dependent expression of BDNF in cortical astrocytes. Altogether, these findings reveal a new enhancer region crucial for BDNF gene expression in the nervous system.

Transcription factor 4 (TCF4), belonging to the basic helix-loop-helix transcription factor superfamily, plays an important role in the development of the nervous system. Dysregulation of TCF4 is associated with various neurological diseases, including autism spectrum disorder Pitt-Hopkins syndrome, intellectual disability, and schizophrenia. We have previously reported that TCF4 is a neuronal activity-dependent transcriptional activator in neurons. Although numerous studies have described the TCF4 target genes and processes in various cellular and animal model systems, little is known about the gene expression programs regulated by TCF4 upon neuronal activity. Here, we combined TCF4 knock-down in rat cultured cortical neurons and depolarization with KCl to mimic neuronal activity, and measured the gene expression changes with RNA-seq. We also carried out TCF4 ChIP-seq analysis to determine the binding of endogenous TCF4 in neurons and identified direct transcriptional targets of TCF4 upon neuronal activity. We further used *in vitro* DNA pulldown coupled with mass-spectrometry to elucidate the transcription factors binding to different E-box *cis*-elements, and identified TCF4 interaction partners in neurons using TCF4 co-IP and mass-spectrometry. Collectively, our results reveal novel neuronal activity-dependent transcriptional programs regulated by TCF4.

Functional consequences of TCF4 missense substitutions associated with Pitt-Hopkins syndrome, mild intellectual disability, and schizophrenia.
Transcription factor 4 (TCF4) is a basic helix-loop-helix transcription factor essential for neurocognitive development. The aberrations in TCF4 are associated with neurodevelopmental disorders including schizophrenia, intellectual disability, and Pitt-Hopkins syndrome, an autism-spectrum disorder characterized by developmental delay. Several disease-associated missense mutations in TCF4 have been shown to interfere with TCF4 function, but for many mutations, the impact remains undefined. Here, we tested the effects of 12 functionally uncharacterized disease-associated missense mutations and variations in TCF4 using transient expression in mammalian cells, confocal imaging, in vitro DNA-binding assays, and reporter assays. We show that Pitt-Hopkins syndrome-associated missense mutations within the basic helix-loop-helix domain of TCF4 and a Rett-like syndrome-associated mutation in a transcription activation domain result in altered DNA-binding and transcriptional activity of the protein. Some of the missense variations found in schizophrenia patients slightly increase TCF4 transcriptional activity, whereas no effects were detected for missense mutations linked to mild intellectual disability. We in addition find that the outcomes of several disease-related mutations are affected by cell type, TCF4 isoform, and dimerization partner, suggesting that the effects of TCF4 mutations are context-dependent. Together with previous work, this study provides a basis for the interpretation of the functional consequences of TCF4 missense variants.

Isoform-Specific Reduction of the Basic Helix-Loop-Helix Transcription Factor TCF4 Levels in Huntington's Disease.
Huntington's disease (HD) is an inherited neurodegenerative disorder with onset of characteristic motor symptoms at midlife, preceded by subtle cognitive and behavioral disturbances. Transcriptional dysregulation emerges early in the disease course and is considered central to HD pathogenesis. Using wild-type (wt) and HD knock-in mouse striatal cell lines we observed a HD genotype-dependent reduction in the protein levels of transcription factor 4 (TCF4), a member of the basic helix-loop-helix (bHLH) family with critical roles in brain development and function. We characterized mouse gene structure and expression of alternative mRNAs and protein isoforms in cell-based models of HD, and in four different brain regions of male transgenic HD mice (R6/1) from young to mature adulthood. The largest decrease in the levels of TCF4 at mRNA and specific protein isoforms were detected in the R6/1 mouse hippocampus. Translating this finding to human disease, we found reduced expression of long TCF4 isoforms in the postmortem hippocampal CA1 area and in the cerebral cortex of HD patients. Additionally, TCF4 protein isoforms showed differential synergism with the proneural transcription factor ASCL1 in activating reporter gene transcription in hippocampal and cortical cultured neurons. Induction of neuronal activity increased these synergistic effects in hippocampal but not in cortical neurons, suggesting brain region-dependent differences in TCF4 functions. Collectively, this study demonstrates isoform-specific changes in TCF4 expression in HD that could contribute to the progressive impairment of transcriptional regulation and neuronal function in this disease.

Intronic enhancer region governs transcript-specific expression in rodent neurons.
Brain-derived neurotrophic factor (BDNF) controls the survival, growth, and function of neurons both during the development and in the adult nervous system. is transcribed from several distinct promoters generating transcripts with alternative 5' exons. transcripts initiated at the first cluster of exons have been associated with the regulation of body weight and various aspects of social behavior, but the mechanisms driving the expression of these transcripts have remained poorly understood. Here, we identify an evolutionarily conserved intronic enhancer region inside the gene that regulates both basal and stimulus-dependent expression of the transcripts starting from the first cluster of 5' exons in mouse and rat neurons. We further uncover a functional E-box element in the enhancer region, linking the expression of and various pro-neural basic helix-loop-helix transcription factors. Collectively, our results shed new light on the cell-type- and stimulus-specific regulation of the important neurotrophic factor BDNF.

The Fuchs corneal dystrophy-associated CTG repeat expansion in the TCF4 gene affects transcription from its alternative promoters.
The CTG trinucleotide repeat (TNR) expansion in Transcription factor 4 (TCF4) intron 3 is the main cause of Fuchs' endothelial corneal dystrophy (FECD) and may confer an increased risk of developing bipolar disorder (BD). Usage of alternative 5' exons for transcribing the human TCF4 gene results in numerous TCF4 transcripts which encode for at least 18 N-terminally different protein isoforms that vary in their function and transactivation capability. Here we studied the TCF4 region containing the CTG TNR and characterized the transcription initiation sites of the nearby downstream 5' exons 4a, 4b and 4c. We demonstrate that these exons are linked to alternative promoters and show that the CTG TNR expansion decreases the activity of the nearby downstream TCF4 promoters in primary cultured neurons. We confirm this finding using two RNA sequencing (RNA-seq) datasets of corneal endothelium from FECD patients with expanded CTG TNR in the TCF4 gene. Furthermore, we report an increase in the expression of various other TCF4 transcripts in FECD, possibly indicating a compensatory mechanism. We conclude that the CTG TNR affects TCF4 expression in a transcript-specific manner both in neurons and in the cornea.

Daughterless, the orthologue of TCF4, is required for associative learning and maintenance of the synaptic proteome.
Mammalian transcription factor 4 (TCF4) has been linked to schizophrenia and intellectual disabilities, such as Pitt-Hopkins syndrome (PTHS). Here, we show that similarly to mammalian TCF4, fruit fly orthologue Daughterless (Da) is expressed widely in the brain. Furthermore, silencing of , using several central nervous system-specific Gal4 driver lines, impairs appetitive associative learning of the larvae and leads to decreased levels of the synaptic proteins Synapsin (Syn) and Discs large 1 (Dlg1), suggesting the involvement of Da in memory formation. Here, we demonstrate that and are direct target genes of Da in adult heads, as Da binds to the regulatory regions of these genes and the modulation of Da levels alter the levels of and mRNA. Silencing of also affects negative geotaxis of the adult flies, suggesting the impairment of locomotor function. Overall, our findings suggest that Da regulates larval memory and adult negative geotaxis, possibly via its synaptic target genes and These behavioural phenotypes can be further used as a PTHS model to screen for therapeutics.This article has an associated First Person interview with the first author of the paper.

CREB Family Transcription Factors Are Major Mediators of BDNF Transcriptional Autoregulation in Cortical Neurons.
BDNF signaling via its transmembrane receptor TrkB has an important role in neuronal survival, differentiation, and synaptic plasticity. Remarkably, BDNF is capable of modulating its own expression levels in neurons, forming a transcriptional positive feedback loop. In the current study, we have investigated this phenomenon in primary cultures of rat cortical neurons using overexpression of dominant-negative forms of several transcription factors, including CREB, ATF2, C/EBP, USF, and NFAT. We show that CREB family transcription factors, together with the coactivator CBP/p300, but not the CRTC family, are the main regulators of rat gene expression after TrkB signaling. CREB family transcription factors are required for the early induction of all the major transcripts, whereas CREB itself directly binds only to promoter IV, is phosphorylated in response to BDNF-TrkB signaling, and activates transcription from promoter IV by recruiting CBP. Our complementary reporter assays with promoter constructs indicate that the regulation of by CREB family after BDNF-TrkB signaling is generally conserved between rat and human. However, we demonstrate that a nonconserved functional cAMP-responsive element in promoter IXa in humans renders the human promoter responsive to BDNF-TrkB-CREB signaling, whereas the rat ortholog is unresponsive. Finally, we show that extensive BDNF transcriptional autoregulation, encompassing all major transcripts, occurs also in the adult rat hippocampus during BDNF-induced LTP. Collectively, these results improve the understanding of the intricate mechanism of BDNF transcriptional autoregulation. Deeper understanding of stimulus-specific regulation of gene expression is essential to precisely adjust BDNF levels that are dysregulated in various neurological disorders. Here, we have elucidated the molecular mechanisms behind TrkB signaling-dependent mRNA induction and show that CREB family transcription factors are the main regulators of gene expression after TrkB signaling. Our results suggest that BDNF-TrkB signaling may induce gene expression in a distinct manner compared with neuronal activity. Moreover, our data suggest the existence of a stimulus-specific distal enhancer modulating gene expression.

Dopamine cross-reacts with adrenoreceptors in cortical astrocytes to induce BDNF expression, CREB signaling and morphological transformation.
Expression of brain-derived neurotrophic factor (BDNF) is induced in cultured rat cortical astrocytes by catecholamines norepinephrine and dopamine as well as selective α1 and β adrenergic agonists. However, it has remained unknown which receptors mediate dopamine-induced BDNF upregulation in astrocytes. Here, we demonstrate that β adrenoreceptors are the main mediators of this effect in cultured cortical astrocytes, while α1 adrenoreceptors and D1 dopamine receptors contribute to a lesser extent. We show that in cortical astrocytes BDNF exon IV and exon VI containing mRNAs are induced by dopamine and norepinephrine via CREB-dependent signaling and that this regulation is mediated by a mechanism that is distinct from activity-dependent CREB-mediated activation of BDNF transcription in neurons. We also show that regulation of BDNF promoters IV and VI by catecholamines requires a distal regulatory element in the BDNF locus. Finally, we demonstrate that dopamine-induced astrocyte stellation and induction of CREB signaling are mediated by cross-reaction of dopamine with β adrenoreceptors.

Efficient use of a translation start codon in BDNF exon I.
The brain-derived neurotrophic factor (BDNF) gene contains a number of 5' exons alternatively spliced with a common 3'

exon. BDNF protein is synthesized from alternative transcripts as a prepro-precursor encoded by the common 3' exon IX, which has a translation start site 21 bp downstream of the splicing site. BDNF mRNAs containing exon I are an exception to this arrangement as the last three nucleotides of this exon constitute an in-frame AUG. Here, we show that this AUG is efficiently used for translation initiation in PC12 cells and cultured cortical neurons. Use of exon I-specific AUG produces higher levels of BDNF protein than use of the common translation start site, resulting from a higher translation rate. No differences in protein degradation, constitutive or regulated secretion were detected between BDNF isoforms with alternative 5' termini. As the BDNF promoter preceding exon I is known to be highly regulated by neuronal activity, our results suggest that the function of this translation start site may be efficient stimulus-dependent synthesis of BDNF protein. The brain-derived neurotrophic factor (BDNF) gene contains multiple untranslated 5' exons alternatively spliced to one common protein-coding 3' exon. However, exon I contains an in-frame ATG in a favorable translation context. Here, we show that use of this ATG is associated with more efficient protein synthesis than the commonly used ATG in exon IX.

ROLE OF DEVELOPMENTAL REGULATORS OF AXONAL LOCAL TRANSLATION IN ADULT AXONS

POSTER SESSION 02 - SECTION: GENE EXPRESSION & REGULATION IN NEURAL FUNCTION

Nikoletta Triantopoulou[1,2], Sofia Pasadaki[1,2], Marina Vidaki[2]
[1]Foundation for Research and Technology - Hellas (FORTH), Imbb, Heraklion, Greece, [2]University of Crete, School Of Medicine, Heraklion, Greece

Local mRNA translation (LT) is vital for axon development. Disruption of LT has been linked to the emergence of neurodevelopmental disorders, while several studies suggest that LT is related to the intrinsic regenerative capacity of mature neurons. Axonal regeneration displays similarities with axon growth during development, exhibiting a number of cellular processes that require LT. Although mature PNS axons maintain the ability for LT, maturing CNS axons exhibit a gradually decreasing LT potential, highly correlated with their limited regenerative capacity. Despite the evident role of LT in axon stability and regeneration, the regulatory mechanisms behind the process and their role in post-injury regeneration remain elusive. We have previously identified a ribonucleoprotein complex (Mena-RNP) that regulates axonal LT in the developing brain. It consists of the cytoskeleton-associated protein Mena that interacts with known regulators of translation (i.e. HnrnpK, PCBP1), thus controlling the translation of the RNP-bound mRNAs. Here, we investigate the conservation of Mena-RNP in the adult nervous system, in an attempt to elucidate the role of Mena and Mena-dependent translation in adult axon regeneration. Employing both *in vivo* and *ex vivo* injury assays we observe that the Mena-RNP components differ between the developing and adult nervous system and in CNS vs PNS axons. In an additional, unbiased line of work we are currently exploring other molecular components that function locally in axons and could potentially explain the differential capacity of adult CNS and PNS axons for regeneration.

CNS CAPILLARY PERICYTES EXPRESS MRNA OF CARDINAL CONTRACTILE PROTEINS, α-SMA AND MYH11: AN IN-SITU HYBRIDIZATION STUDY

POSTER SESSION 02 - SECTION: GENE EXPRESSION & REGULATION IN NEURAL FUNCTION

Meftun Doğa Başaran[1], Nevin Belder[2,3], Gülce Küreli[1], Şefik Evren Erdener[1], Turgay Dalkara[1]
[1]Hacettepe University Institute of Neurological Sciences and Psychiatry, Neurological Sciences And Psychiatry, Ankara, Turkey, [2]Hacettepe University, The Institute Of Neurlogical Sciences And Psychiatry, Ankara, Turkey, [3]Hacettepe University, The Institute Of Neurological Sciences And Psychiatry, Ankara, Turkey

Aims: Pericytes are contractile cells located on the walls of microvessels. Although physiological and pathological impacts of pericyte contractility on microcirculation have recently been disclosed, the molecular machinery that imparts contractility to pericytes needs further elucidation because of the inconsistencies between protein and single cell transcriptomic data regarding the presence of the contractile protein alpha-smooth muscle actin (α-SMA) in pericytes. **Methods:** In this study, expression of the Acta2 and Myh11 genes encoding α-SMA and myosin heavy chain-11, was investigated in pericytes along the microvascular tree in intact retinal tissue by RNAscope in situ hybridization. **Results:** We found that both genes were intensely expressed in peri-nuclear cytoplasm and processes of pericytes on upstream capillaries (<4th order). Although both transcripts considerably decreased in downstream branches (≥4th order), they were unambiguously detectable and overlapping in about 2/3 of pericytes and mostly localized in the peri-nuclear cytoplasm, in parallel with our immunohistochemical findings. **Discussion:** These data support the view that contraction and relaxation of the upstream pericytes is mediated by actomyosin bridging as in vascular smooth muscle cells (vSMCs) for distributing blood flow between sister branches, whereas pericytes located on the downstream branches express low amounts of contractile proteins sufficient for regulating flow by changing capillary resistance with subtle contractions and relaxations. Thus, our study provides an *in situ* answer to the decades-long debate about α-SMA expression in pericytes, providing supporting evidence for the view that microvascular pericytes express contractile protein sets and employ the same contractile mechanisms as in vSMCs.

CONTRIBUTION OF CELL TYPE-SPECIFIC ALTERNATIVE SPLICING PROGRAMS IN SPECIFICATION OF NEURONAL PROPERTIES

POSTER SESSION 02 - SECTION: GENE EXPRESSION & REGULATION IN NEURAL FUNCTION

Giulia Di Bartolomei[1], Dietmar Schreiner[1], Susanne Falkner[1], Raul Ortiz[1], Esther Creemers[2], Peter Scheiffele[1]

Brain function relies on complex assemblies of multiple neuron types, each characterized by distinctive anatomical, physiological and molecular features. To a large extent, these features are instructed by genetic programs, including alternative splicing. Recent evidence suggests that the selective expression of splicing regulators in certain neuron classes may contribute to their differentiation. However, whether and how these cell type-specific splicing factors specify molecular programs is largely unknown. In a survey of ribosome-associated mRNAs from genetically-defined neuron populations of the mouse brain we identified the RNA-binding protein Rbm20 to be selectively expressed in glutamatergic mitral and tufted cells of the olfactory bulb. Thus far, Rbm20 expression had been thought to be heart and skeletal muscle specific, where RBM20 drives the alternative splicing of Titin and calcium signaling components (CACNA1C, CAMK2D).
We hypothesized that RBM20 contributes to the regulation of intrinsic properties and plasticity of neurons, driving alternative splicing programs encoding calcium signaling proteins. To uncover Rbm20 dependent splicing regulation we performed affinity isolation of ribosome-associated mRNAs from conditional Rbm20 knock-out neurons of the olfactory bulb. Moreover, using Crosslinking-Immuno-Precipitation and sequencing experiments (CLIP-seq) we identified endogenous mRNAs bound by neuronal RBM20. Our analysis identifies brain-specific targets and highlights the unexpected function of RBM20 in neuronal cell type-specific transcript isoform regulation in vivo.

Microglia remodel synapses by presynaptic trogocytosis and spine head filopodia induction.
Microglia are highly motile glial cells that are proposed to mediate synaptic pruning during neuronal circuit formation. Disruption of signaling between microglia and neurons leads to an excess of immature synaptic connections, thought to be the result of impaired phagocytosis of synapses by microglia. However, until now the direct phagocytosis of synapses by microglia has not been reported and fundamental questions remain about the precise synaptic structures and phagocytic mechanisms involved. Here we used light sheet fluorescence microscopy to follow microglia-synapse interactions in developing organotypic hippocampal cultures, complemented by a 3D ultrastructural characterization using correlative light and electron microscopy (CLEM). Our findings define a set of dynamic microglia-synapse interactions, including the selective partial phagocytosis, or trogocytosis (trogo-: nibble), of presynaptic structures and the induction of postsynaptic spine head filopodia by microglia. These findings allow us to propose a mechanism for the facilitatory role of microglia in synaptic circuit remodeling and maturation.

Sexual dimorphism of microglia and synapses during mouse postnatal development.
Microglia participate in synapse remodeling in the cortex and hippocampus during mouse postnatal development. Although sex differences in microglia activity during embryonic development have been reported in these regions, it remains unexplored whether microglia show sexually dimorphic features during the early postnatal period, a critical window for synapse formation and maturation. Here, we investigated morphological and functional features of microglia across early postnatal development as well as morphological features of both pre- and postsynaptic neuronal compartments in the mouse hippocampus. We found a sex-dependent shift in microglia volume and phagocytic capacity across the first four postnatal weeks. Measurements of synaptic features revealed sex differences in the density of synaptic spines and boutons during the second postnatal week. These data are consistent with a precocious development of both microglia and synapses in the female brain. We further hypothesize that this bias may contribute to sex-specific brain wiring. © 2017 The Authors.

JAK2-STAT3-DEPENDENT MOLECULAR SIGNATURE IN REACTIVE ASTROCYTES OF THE MOUSE STRIATUM

POSTER SESSION 02 - SECTION: GENE EXPRESSION & REGULATION IN NEURAL FUNCTION

Miriam Riquelme-Pérez[1,2], Laurene Abjean[1], Lucile Ben Haim[1], María-Ángeles Carrillo-De Sauvage[1], Celine Derbois[2], Philippe Hantraye[1], Emmanuel Brouillet[1], Robert Olaso[2], Jean-François Deleuze[2], Eric Bonnet[2], Virginie Redeker[3], Solene Brohard[2], Carole Escartin[1]

Astrocytes undergo morphological and functional changes in disease that remain to be fully characterized. JAK2-STAT3 signalling pathway is a central regulator of astrocyte reactive response in neurodegenerative disorders. These include Huntington's disease (HD), which mainly affects the striatum. Therefore, the objective is to establish the molecular changes induced by the JAK2-STAT3 pathway in mouse striatal astrocytes. To activate the STAT3-JAK2 pathway, astrocyte-targeting adeno-associated vectors encoding a constitutively active form of JAK2 (AAV-JAK2ca) were generated. The striatum of WT mice was injected with AAV-JAK2ca and AAV-GFP to label infected GFP+ astrocytes. Control mice were injected with AAV-GFP only. Histological analysis demonstrated increased soma surface and branching index in striatal astrocytes together with GFAP and Vimentin overexpression, following the activation of the JAK2-STAT3 cascade. Microarray analysis of sorted infected astrocytes revealed extensive transcriptional expression changes with 689 genes differentially expressed by JAK2ca, including genes linked to inflammation, cytokine signalling, proteostasis and energy metabolism. Interestingly, many of these functions were also confirmed by RNA sequencing analysis of astrocytes isolated from the striatum of a HD murine model when activating JAK2-STAT3 pathway (Abjean, in press, Brain). Last, by label-free mass spectrometry, 87 proteins were found differentially expressed between JAK2ca- and GFP-astrocytes. They were involved in cell adhesion, cytoskeleton and oxidative phosphorylation, revealing only limited overlap between mRNA and protein changes. Our multi-omics analysis of the JAK2-STAT3 signature identifies coordinated morphological and molecular changes in striatal reactive astrocytes, which helps defining a specific reactive state that could be observed in different brain diseases.

EXPLORATION OF A NOVEL MECHANISM FOR RAPID GENE REGULATION IN NEURONAL PLASTICITY AND LEARNING

POSTER SESSION 02 - SECTION: GENE EXPRESSION & REGULATION IN NEURAL FUNCTION

Oriane Mauger[1], Maxime Mazille[1], Julien Courtin[2], Peter Scheiffele[1]
[1]University of Basel, Biozentrum, Basel, Switzerland, [2]FMI, Neurosciences, Basel, Switzerland

Neuronal development and plasticity rely on the dynamic modification of molecular repertoires through a variety of mechanisms. Activity-dependent transcription has emerged as a major source of gene products that regulate neuronal excitability, connectivity and synaptic properties. However, the elongation rate of RNA polymerases imposes a significant temporal constraint for transcript synthesis, in particular for long genes where new synthesis requires tens of hours. In our work, we uncovered a novel, transcription-independent mechanism that releases transcripts within minutes of neuronal stimulation. It relies on nuclear storage of highly stable transcripts retaining select introns. Within few minutes after neuronal stimulation, these transcripts undergo splicing completion, they are then exported to the cytosol and loaded onto the ribosome - thereby representing a pool of mRNAs readily available for synthesis of plasticity regulators. Remarkably, we found that distinct groups of intron-retaining transcripts are regulated in response to different forms of stimulation and this selectivity arises from the activation of specific intracellular signaling pathways. Finally, we demonstrate that sensory stimulation in the mouse visual system triggers regulated intron excision in vivo.

Stroke recovery is a dynamic process that evolves over time. Here, we investigated the processes that mediate recovery from cortical stroke at different time points post-injury in a mouse model of endothelin-1 stroke model. We utilized three sequencing strategies: Visium Spatial Transcriptomics, 10X Chromium and a new platform DISCO (Digital microfluidic Single Cell -Omic) to gain temporally and spatially defined RNA sequencing datasets. Visium was performed on acute (d2), subacute (d10), and chronic (d21) post-stroke brains. With this data we saw an astrocyte-dominant signature at day 10 post-stroke. To investigate potential roles of astrocytes during the subacute phase we performed single cell RNA-sequencing using 10X Chromium on GLAST+ cells isolated from the d14 stroke-injured cortex. Finally, with DISCO, we were able to selectively isolate individual astrocytes within and outside the penumbra to identify, validate and discover cell markers and roles of astrocytes governing repair at the injury site. Our datasets compare and highlight the strength of each sequencing platform and the compatibility of each approach. Altogether, a unique combination of sequencing approaches led to a novel, highly resolved, chronicle of the molecular signatures underlying cortical ischemic stroke.

FEATURES OF LNCRNA EXPRESSIONS AND ITS REGULATION IN ACROSS BRAIN REGIONS OF PRIMATES

POSTER SESSION 02 - SECTION: GENE EXPRESSION & REGULATION IN NEURAL FUNCTION

Mohit Navandar[1], Susanne Gerber[2]
[1]Institute of Human Genetics, University Medical Center Mainz, Mainz, Germany, [2]University Medical Centre of the Johannes Gutenberg University, Institute Of Human Genetics, Mainz, Germany

Human and non-human primates like chimpanzee have strikingly similar genomes, but differs phenotypically, behaviourally and cognitive wise. It is fascinating to understand how brain was evolved. With the advancement of next generation sequencing techniques, function of protein coding genes underlying evolution is widely studied. Looking at the complexity of the eukaryotic genome, little is known about the non-coding parts such as long non-coding RNAs (lncRNAs). In this study, we analysed transcriptional expression pattern of lncRNAs across different brain regions from human and non-human primates (chimpanzee, gorilla and gibbon). Our analysis identified shared/orthologous and species specific lncRNAs based on orthology studies. Orthologous lncRNAs differentially expressed in human and non-human primate showed alike expression pattern (clusters) across brain regions with potential regulation involved in cognition, neurogenesis and central nervous system development. Our downstream analysis also predicted the potential transcription factors driven regulation of lncRNAs. We further characterized the number of co-expression pairs (lncRNAs and protein coding genes), which are different in human and non-human primates. Network analysis of each cluster pair shades light on the potential gene regulation by novel predicted orthologous lncRNAs. Overall, our study provides the insight of gene regulatory landscape, evolutionary conservation, and a resource for candidate lncRNAs in human and non-human primate's brain.

A specific prelimbic-nucleus accumbens pathway controls resilience versus vulnerability to food addiction.
Food addiction is linked to obesity and eating disorders and is characterized by a loss of behavioral control and compulsive food intake. Here, using a food addiction mouse model, we report that the lack of cannabinoid type-1 receptor in dorsal telencephalic glutamatergic neurons prevents the development of food addiction-like behavior, which is associated with enhanced synaptic excitatory transmission in the medial prefrontal cortex (mPFC) and in the nucleus accumbens (NAc). In contrast, chemogenetic inhibition of neuronal activity in the mPFC-NAc pathway induces compulsive food seeking. Transcriptomic analysis and genetic manipulation identified that increased dopamine D2 receptor expression in the mPFC-NAc pathway promotes the addiction-like phenotype. Our study unravels a new neurobiological mechanism underlying resilience and vulnerability to the development of food addiction, which could pave the way towards novel and efficient interventions for this disorder.

Transcriptional signatures in prefrontal cortex confer vulnerability versus resilience to food and cocaine addiction-like behavior.
Addiction is a chronic relapsing brain disease characterized by compulsive reward-seeking despite harmful consequences. The mechanisms underlying addiction are orchestrated by transcriptional reprogramming in the reward system of vulnerable subjects. This study aims at revealing gene expression alterations across different types of addiction. We analyzed publicly available transcriptome datasets of the prefrontal cortex (PFC) from a palatable food and a cocaine addiction study. We found 56 common genes upregulated in the PFC of addicted mice in these two studies, whereas most of the differentially expressed genes were exclusively linked to either palatable food or cocaine addiction. Gene ontology analysis of shared genes revealed that these genes contribute to learning and memory, dopaminergic synaptic transmission, and histone phosphorylation. Network analysis of shared genes revealed a protein-protein interaction node among the G protein-coupled receptors (Drd2, Drd1, Adora2a, Gpr6, Gpr88) and downstream targets of the cAMP signaling pathway (Ppp1rb1, Rgs9, Pde10a) as a core network in addiction. Upon extending the analysis to a cell-type specific level, some of these common molecular players were selectively expressed in excitatory neurons, oligodendrocytes, and endothelial cells. Overall,

computational analysis of publicly available whole transcriptome datasets provides new insights into the molecular basis of addiction-like behaviors in PFC.

Low-cost scalable discretization, prediction, and feature selection for complex systems.
Finding reliable discrete approximations of complex systems is a key prerequisite when applying many of the most popular modeling tools. Common discretization approaches (e.g., the very popular -means clustering) are crucially limited in terms of quality, parallelizability, and cost. We introduce a low-cost improved quality scalable probabilistic approximation (SPA) algorithm, allowing for simultaneous data-driven optimal discretization, feature selection, and prediction. We prove its optimality, parallel efficiency, and a linear scalability of iteration cost. Cross-validated applications of SPA to a range of large realistic data classification and prediction problems reveal marked cost and performance improvements. For example, SPA allows the data-driven next-day predictions of resimulated surface temperatures for Europe with the mean prediction error of 0.75°C on a common PC (being around 40% better in terms of errors and five to six orders of magnitude cheaper than with common computational instruments used by the weather services).

ERK signalling modulates epigenome to drive epithelial to mesenchymal transition.
The series of events that allow the conversion from adherent epithelial cells into migratory cells is collectively known as epithelial-mesenchymal transition (EMT). EMT is employed during embryonic development such as for gastrulation and neural crest migration and is misused in diseases, such as cancer metastasis. ERK signalling is known to be essential for EMT, however its influence on the epigenetic and transcriptional programme underlying EMT is poorly understood. Here, using a comprehensive genome-wide analysis of H3K27ac mark and gene expression in mammary epithelial cells undergoing EMT, we found that ERK signalling is essential for the epigenetic reprogramming underlying hallmark gene expression and phenotypic changes of EMT. We show that the chemical inhibition of Erk signalling during EMT prevents the loss and gain of the H3K27ac mark at regulatory regions of epithelial and mesenchymal genes, respectively, and results in a transcriptome and epigenome closer to those of epithelial cells. Further computational analyses identified a distinct set of transcription factor motifs enriched at distal regulatory regions that are epigenetically remodelled by ERK signalling. Altogether, our findings reveal an ERK-dependent epigenetic remodelling of regulatory elements that results in a gene expression programme essential for driving EMT.

GLIAL-SECRETED FACTORS REGULATE NEURONAL GENE EXPRESSION AND FUNCTION

POSTER SESSION 02 - SECTION: GENE EXPRESSION & REGULATION IN NEURAL FUNCTION

Paul Turko[1], Juliane Schiweck[2], Piotr Niziolek[1], Francis O'Reilly[3], Sayaka Dantsuji[4], Nicolai Vonkuegelgen[4], Nils Rademacher[5], Helen Mcmillan[1], Cristina Kroon[2], Keenan Groberman[1], Marina Chekulaeva[4], Juri Rappsilber[3], Britta Eickholt[2], Imre Vida[1]
[1]Charité Universitätsmedizin Berlin, Institute Of Integrative Neuroanatomy, Berlin, Germany, [2]Charité Universitätsmedizin Berlin, Institute Of Biochemistry, Berlin, Germany, [3]Technische Universität, Bioanalytics, Institute Of Biotechnology, Berlin, Germany, [4]Max Delbrück Center for Molecular Medicine, Berlin Institute For Medical Systems Biology, Berlin, Germany, [5]Charité Universitätsmedizin Berlin, Neuroscience Research Center, Berlin, Germany

Glial cells secrete a wide variety of proteins and metabolites to the extracellular space (Dowell et al., 2009). We and others have shown the importance of these factors for neuron survival, morphological development, and excitatory synapse formation (Banker et al., 1980; Turko et al., 2018). However, our knowledge of precisely how these factors mediate their effects is incomplete. Our **aims** therefore are to further investigate the effects of glial-secreted factors on neuron physiology and to identify the roles of specific proteins on neuron function. We have employed a combination of **methods**, including cell sorting, RNA sequencing and mass spectrometry to explore the regulatory effects of glial-secreted factors on neuronal gene expression, and to identify secreted proteins interacting with distinct neuron types (Eichelbaum et al., 2012).
Our **results** demonstrate that glial-secreted factors exert a profound effect on neuronal gene expression, with hundreds of genes being significantly up or down regulated by the presence of glial-secreted factors. Interestingly, some gene expression changes are neuron-type specific, with glial cells regulating, for example, genes associated with synapse assembly in glutamatergic but not GABAergic neurons. Finally, we have identified several glial-secreted protein candidates which may physically interact with neurons to promote cell growth and survival. In **conclusion**, our results suggest that secreted factors are a central means by which glial cells can dynamically communicate with neurons to regulate their gene expression and function.

CAN THE BRAIN BE TAKEN AS A WHOLE WHEN CHOOSING HOUSEKEEPING GENES FOR STUDDING SEX DIFFERENCES?

POSTER SESSION 02 - SECTION: GENE EXPRESSION & REGULATION IN NEURAL FUNCTION

Florencia Dadam[1,2], Laura Vivas[1,3], Ximena Caeiro[1]
[1]Instituto de Investigación Médica Mercedes y Martin Ferreyra-INIMEC-CONICET-UNC, Homeostasis Hidrosalina E Hipertensión, Córdoba, Argentina, [2]Universidad Nacional de Córdoba, Facultad De Psicologia, Córdoba, Argentina, [3]Universidad Nacional de Córdoba, Facultad De Ciencias Exactas, Físicas Y Naturales, Córdoba, Argentina

Expression of sexual dimorphic genes at different brain areas are been extensively studied. But can the brain be taken as a whole when choosing housekeeping genes (HKG) for studying sex differences? Are there sex differences in HKG expression? Are these due to sex chromosome complement or hormonal factors? To analyze these questions, we used mice of the "four core genotypes" mouse model, in which the effect of gonadal sex (testes/ovaries) and SCC(XX/XY) are uncoupled. Brains were collected from gonadectomized mice and relative gene expression of basal *Gapdh, Cyc and 18s* genes at fore/hindbrain nuclei were assessed using q-PCR. Sex-dependent expressions of commonly used housekeeping genes at the SFO and AP brain levels were observed. The statistical analysis at the SFO of *Gapdh* and *Cyc* genes showed a female phenotype ($F(1,20)=6,05$; $p=0,02$/$F(1,12)=6,12$; $p=0,03$). Furthermore, a SCC effect on *Cyc* gene expression in the SFO as well as for *18s* at the AP were observed ($F(1,12)=5,75$; $p=0,03$/$F(1,12)=5,52$; $p=0,04$). At the NTS, OVLT and PVN no differences in gene expression were shown. Moreover, the analysis of the M-value (HKGs stability test- geNorm/Normfinder) for each HKG demonstrated not only the importance of taking into account sex as a factor (since the stability values were always much higher when males and females worked together) but also studying each area independently (obtaining in this way lower M-values than working all the brain tissue together). Our findings underscore the importance of empirical determination of reference genes to effectively and accurately normalize q-PCR data before quantifying target genes.

Sex chromosome complement involvement in angiotensin receptor sexual dimorphism.
This study aimed to define whether sex chromosome complement (SCC) may differentially modulate sex differences in relative gene expression of basal Agtr1a, Agtr2, and Mas1 receptors at fore/hindbrain nuclei and at medulla/cortical kidney. Samples were collected from gonadectomized male (XX and XY) and female (XX and XY) mice of the "four core genotypes" model. At brain level, a SCC effect at the area postrema was demonstrated. An increase in mRNA level of Agtr1a and Agtr1a/Agtr2 ratio in XY-SCC mice was associated with a decrease in Mas1 compared to XX-SCC mice. In the renal cortex, a SCC effect for Agtr2 and Mas1 was observed. Regardless of sex (male or female), XX-SCC mice expressed higher levels of mRNA Agtr2 and Mas1 than XY-SCC mice {$F(1,12) = 6,126, p < 0.05$; $F(1,21) = 5,143, p < 0.05$}. Furthermore, XX-female mice showed a significant increase in Mas1 expression compared to XY-female mice. These results reveal a SCC modulatory effect at central and kidney level on angiotensin receptor expression, with an enhancement of the vasodilatory arm in XX-mice and an increase in the vasoconstriction arm in XY-mice, which may underlie sex differences in the regulation of arterial pressure.

Angiotensin II AT receptors mediate neuronal sensitization and sustained blood pressure response induced by a single injection of amphetamine.
A single exposure to amphetamine induces neurochemical sensitization in striatal areas. The neuropeptide angiotensin II, through AT receptors (AT-R) activation, is involved in these responses. However, amphetamine-induced alterations can be extended to extra-striatal areas involved in blood pressure control and their physiological outcomes. Our aim for the present study was to analyze the possible role for AT-R in these events using a two-injection protocol and to further characterize the proposed AT-R antagonism protocol. Central effect of orally administered AT-R blocker (Candesartan, 3mg/kg p.o.×5days) in male Wistar rats was analyzed by spontaneous activity of neurons within locus coeruleus. In another group of animals

pretreated with the AT-R blocker or vehicle, sensitization was achieved by a single administration of amphetamine (5mg/kg i.p. - day 6) followed by a 3-week period off drug. On day 27, after receiving an amphetamine challenge (0.5mg/kg i.p.), we evaluated: (1) the sensitized c-Fos expression in locus coeruleus (LC), nucleus of the solitary tract (NTS), caudal ventrolateral medulla (A1) and central amygdala (CeAmy); and (2) the blood pressure response. AT-R blockade decreased LC neurons' spontaneous firing rate. Moreover, sensitized c-Fos immunoreactivity in TH+neurons was found in LC and NTS; and both responses were blunted by the AT-R blocker pretreatment. Meanwhile, no differences were found neither in CeAmy nor A1. Sensitized blood pressure response was observed as sustained changes in mean arterial pressure and was effectively prevented by AT-R blockade. Our results extend AT-R role in amphetamine-induced sensitization over noradrenergic nuclei and their cardiovascular output.

Effect of sex chromosome complement on sodium appetite and Fos-immunoreactivity induced by sodium depletion.
Previous studies indicate a sex chromosome complement (SCC) effect on the angiotensin II-sexually dimorphic hypertensive and bradycardic baroreflex responses. We sought to evaluate whether SCC may differentially modulate sexually dimorphic-induced sodium appetite and specific brain activity due to physiological stimulation of the rennin angiotensin system. For this purpose, we used the "four core genotype" mouse model, in which the effect of gonadal sex and SCC is dissociated, allowing comparisons of sexually dimorphic traits between XX and XY females as well as in XX and XY males. Gonadectomized mice were sodium depleted by furosemide (50 mg/kg) and low-sodium diet treatment; control groups were administered with vehicle and maintained on normal sodium diet. Twenty-one hours later, the mice were divided into two groups: one group was submitted to the water-2% NaCl choice intake test, while the other group was perfused and their brains subjected to the Fos-immunoreactivity (FOS-ir) procedure. Sodium depletion, regardless of SCC (XX or XY), induced a significantly lower sodium and water intake in females than in males, confirming the existence in mice of sexual dimorphism in sodium appetite and the organizational involvement of gonadal steroids. Moreover, our results demonstrate a SCC effect on induced brain FOS-ir, showing increased brain activity in XX-SCC mice at the paraventricular nucleus, nucleus of the solitary tract, and lateral parabrachial nucleus, as well as an XX-SCC augmented effect on sodium depletion-induced brain activity at two circumventricular organs, the subfornical organ and area postrema, nuclei closely involved in fluid and blood pressure homeostasis.

The effect of increased NaCl intake on rat brain endogenous μ-opioid receptor signalling.
Numerous studies demonstrate the significant role of central β-endorphin and its receptor, the μ-opioid receptor (MOR), in sodium intake regulation. The present study aimed to investigate the possible relationship between chronic high-NaCl intake and brain endogenous MOR functioning. We examined whether short-term (4 days) obligatory salt intake (2% NaCl solution) in rats induces changes in MOR mRNA expression, G-protein activity and MOR binding capacity in brain regions involved in salt intake regulation. Plasma osmolality and electrolyte concentrations after sodium overload and the initial and final body weight of the animals were also examined. After 4 days of obligatory hypertonic sodium chloride intake, there was clearly no difference in MOR mRNA expression and G-protein activity in the median preoptic nucleus (MnPO). In the brainstem, MOR binding capacity also remained unaltered, although the maximal efficacy of MOR G-protein significantly increased. Finally, no significant alterations were observed in plasma osmolality and electrolyte concentrations. Interestingly, animals that received sodium gained significantly less weight than control animals. In conclusion, we found no significant alterations in the MnPO and brainstem in the number of available cell surface MORs or de novo syntheses of MOR after hypertonic sodium intake. The increased MOR G-protein activity following acute sodium overconsumption may participate in the maintenance of normal blood pressure levels and/or in enhancing sodium taste aversion and sodium overload-induced anorexia.

Sex differences in body fluid homeostasis: Sex chromosome complement influences on bradycardic baroreflex response and sodium depletion induced neural activity.
Clinical and basic findings indicate that angiotensin II (ANG II) differentially modulates hydroelectrolyte and cardiovascular responses in male and female. But are only the activational and organizational hormonal effects to blame for such differences? Males and females not only differ in their sex (males are born with testes and females with ovaries) but also carry different sex chromosome complements and are thus influenced throughout life by different genomes. In this review, we discuss our recent studies in order to evaluate whether sex chromosome complement is in part responsible for gender differences previously observed in ANG II bradycardic-baroreflex response and sodium depletion-induced sodium appetite and neural activity. To test the hypothesis that XX or XY contributes to the dimorphic ANG II bradycardic-baroreflex response, we used the four core genotype mouse model, in which the effects of gonadal sex (testes or ovaries) and sex chromosome

complement (XX or XY) are dissociated. The results indicate that ANG II bradycardic-baroreflex sexual dimorphic response may be ascribed to differences in sex chromosomes, indicating an XX-sex chromosome complement facilitatory bradycardic-baroreflex control of heart rate. Furthermore, we evaluated whether genetic differences within the sex chromosome complement may differentially modulate the known sexually dimorphic sodium appetite as well as basal or induced brain activity due to physiological stimulation of the renin-angiotensin system by furosemide and low-sodium treatment. Our studies demonstrate an organizational hormonal effect on sexually dimorphic induced sodium intake in mice, while at the brain level (subfornical organ and area postrema) we showed a sex chromosome complement effect in sodium-depleted mice, suggesting a sex chromosome gene participation in the modulation of neural pathways underlying regulatory response to renin-angiotensin stimulation.

Early free access to hypertonic NaCl solution induces a long-term effect on drinking, brain cell activity and gene expression of adult rat offspring.
Exposure to an altered osmotic environment during a pre/postnatal period can differentially program the fluid intake and excretion pattern profile in a way that persists until adulthood. However, knowledge about the programming effects on the underlying brain neurochemical circuits of thirst and hydroelectrolyte balance, and its relation with behavioral outputs, is limited. We evaluated whether early voluntary intake of hypertonic NaCl solution may program adult offspring fluid balance, plasma vasopressin, neural activity, and brain vasopressin and angiotensinergic receptor type 1a (AT1a)-receptor gene expression. The manipulation (M) period covered dams from 1 week before conception until offspring turned 1-month-old. The experimental groups were (i) Free access to hypertonic NaCl solution (0.45 M NaCl), food (0.18% NaCl) and water [M-Na]; and (ii) Free access to food and water only [M-Ctrol]. Male offspring (2-month-old) were subjected to iv infusion (0.15 ml/min) of hypertonic (1.5M NaCl), isotonic (0.15M NaCl) or sham infusion during 20 min. Cumulative water intake (140 min) and drinking latency to the first lick were recorded from the start of the infusion. Our results indicate that, after systemic sodium overload, the M-Na group had increased water intake, and diminished neuronal activity (Fos-immunoreactivity) in the subfornical organ (SFO) and nucleus of the solitary tract. They also showed reduced relative vasopressin (AVP)-mRNA and AT1a-mRNA expression at the supraoptic nucleus and SFO, respectively. The data indicate that the availability of a rich source of sodium during the pre/postnatal period induces a long-term effect on drinking, neural activity, and brain gene expression implicated in the control of hydroelectrolyte balance.

Sex chromosome complement determines sex differences in aromatase expression and regulation in the stria terminalis and anterior amygdala of the developing mouse brain.
Aromatase, which converts testosterone in estradiol, is involved in the generation of brain sex dimorphisms. Here we used the "four core genotypes" mouse model, in which the effect of gonadal sex and sex chromosome complement is dissociated, to determine if sex chromosomes influence the expression of brain aromatase. The brain of 16 days old XY mouse embryos showed higher aromatase expression in the stria terminalis and the anterior amygdaloid area than the brain of XX embryos, independent of gonadal sex. Furthermore, estradiol or dihydrotestosterone increased aromatase expression in cultures of anterior amygdala neurons derived from XX embryos, but not in those derived from XY embryos. This effect was also independent of gonadal sex. The expression of other steroidogenic molecules, estrogen receptor-α and androgen receptor was not influenced by sex chromosomes. In conclusion, sex chromosomes determine sex dimorphisms in aromatase expression and regulation in the developing mouse brain.

THE FUNCTIONAL RELATIONSHIP BETWEEN C-JUN AND NNOS IN VSC 4.1 CELLS

POSTER SESSION 02 - SECTION: GENE EXPRESSION & REGULATION IN NEURAL FUNCTION

Prince Last Mudenda Zilundu[1], Yingying Zhou[2], Lihua Zhou[2]
[1]Ajman University, Basic And Dental Science, Ajman, United Arab Emirates, [2]Sun Yat-sen University, Human Anatomy, Guangzhou, China

Introduction Ventral Spinal Cord 4.1 (VSC 4.1) provides a good model to study motor neuron response to injury, especially the involvement of c-Jun and nNOS signaling pathways. This study was designed to explore the functional relationship between these signaling pathways. **Methods** Cell viability was tested using the CCK-8 kit. Hydrogen peroxide was used as a cell irritatant. c-Jun/JNK inhibitor SP600125 and nNOS-specific inhibitor 7-nitroindazole were used as neuroprotective agents when VSC 4.1 cells were exposed to hydrogen peroxide insult. The cellular responses to injury were evaluated by total nitric oxide assay, immunofluorescence and western blotting as well as coimmunoprecipitation. **Results** Increasing concentrations of hydrogen peroxide (0 to 1000μM) given over 24 hours resulted in a dose depended death of the motor neurons whereby concentrations above 600μM killed all the cells while above 80% survived dosages of 200μM or less. The cells pre-treated with neuroprotective treatments were spared death when incubated on hydrogen dosages of 50-200μM. c-Jun and nNOS as well as proapoptotic markers Bim and Caspase 3 were overexpressed in the VSC 4.1 cells after hydrogen peroxide insult but were all significantly reduced by neuroprotective treatments relative to vehicle control made from less than 1% DMSO in normal medium. Nitric oxide production was increased by injury and attenuated by neuroprotective treatments. We also observed coimmunoprecipitation of c-Jun and nNOS from injured VSC 4.1 cell lysates suggesting that an interaction between c-Jun and nNOS exists. **Conclusion** Taken together, these results indicate a functional relationship between c-Jun and nNOS warranting further research.

CYCLASE-ASSOCIATED PROTEIN 1 (CAP1) REPRESSES MRTF-SRF-DEPENDENT GENE EXPRESSION IN THE MOUSE BRAIN

POSTER SESSION 02 - SECTION: GENE EXPRESSION & REGULATION IN NEURAL FUNCTION

Sharof Khudayberdiev[1], Kerstin Weiß[1], Anika Heinze[1], Uwe Linne[2], Marco Rust[1]
[1]University of Marburg, Molecular Neurobiology Group, Institute Of Physiological Chemistry, Marburg, Germany, [2]University of Marburg, Mass Spectrometry Facility Of The Department Of Chemistry, Marburg, Germany

Serum response factor (SRF) is a ubiquitously expressed transcription factor essential for brain development and function. SRF activity is controlled by two classes of coactivators, myocardin-related transcription factors (MRTF) and ternary complex factors (TCF), which compete for SRF binding and introduce specificity into gene expression programs. To date, only few brain studies investigated regulatory mechanisms upstream of these coactivators, which mainly focused on TCF. Since an inhibitory function of monomeric actin (G-actin) towards MRTF-SRF signaling is well established, we hypothesized a role for the key actin-depolymerizing protein cofilin in this pathway. Surprisingly, cofilin was largely dispensable for neuronal MRTF-SRF activity. Instead, reporter assays combined with pharmacological and genetic approaches in isolated neurons from mutant mice identified cyclase-associated protein 1 (CAP1) as an important regulator of the MRTF-SRF pathway. Mechanistically, CAP1 promotes cytosolic MRTF retention and represses neuronal SRF activity by regulating cellular G-actin levels. RNAseq and mass spectrometry analysis of mice brain cortices deficient in CAP1 showed dysregulation of MRTF/SRF-dependent gene regulation, thus implying *in vivo* relevance of CAP1 in this process. Together, we identified CAP1 as a crucial repressor of the MRTF-SRF pathway in the brain.

SEX-BIASED RNA POPULATIONS ALONG THE HIPPOCAMPAL LONGITUDINAL AXIS AND THEIR PUTATIVE TRANSCRIPTIONAL AND POST-TRANSCRIPTIONAL REGULATORY NETWORKS

POSTER SESSION 02 - SECTION: GENE EXPRESSION & REGULATION IN NEURAL FUNCTION

Luciano Román Albasini, Wladimir Corrales, Juan Silva, Felipe Olave, Felipe Aguayo, Pablo González, Matías Alarcón Mardones, Julia Catalán Casanellas, Jenny Fiedler
Universidad de Chile, Biochemistry And Molecular Biology, Santiago, Chile

Numerous studies have unveiled sex differences across several aspects of health and disease. While multiple brain areas are known to display sex-biased transcriptomic signatures, the sex-biased transcriptomic profiles of the dorsal and ventral hippocampus –which have molecular and circuitry differences– has not been studied. By employing RNA sequencing, we report the sex biases in large- and mature micro-RNA populations of the dorsal and ventral hippocampus in adult rats. Furthermore, we aimed at discovering transcriptional and post-transcriptional regulatory interactions that may govern these sex differences in both hippocampal poles. In the dorsal hippocampus, 769 genes and 22 miRNAs had a female-biased expression, whereas 723 genes and 31 miRNAs displayed a male-biased expression. In the ventral hippocampus, 293 genes and 11 miRNAs showed a female-biased expression, while 264 genes and 22 miRNAs were male-biased. Overrepresentation analyses revealed that the female-biased genes in the dorsal hippocampus were functionally enriched in ubiquitin mediated proteolysis, while the male-biased genes were enriched in neuronal morphology modulation and actin dynamics. In the ventral hippocampus, the female-biased genes were overrepresented for inflammatory signaling pathways and the male-biased genes were enriched in glycine transport and actin dynamics. Next, we constructed regulatory networks based on predicted and validated transcriptional regulators and miRNA targets that were present in each sex-biased dataset, revealing discreet modules within the networks that were largely sex- and pole-specific Our results demonstrate a sex-biased transcriptomic profile in both hippocampal regions that may help understanding the sex differences in resilience/susceptibility to internal or external insults. INVESTIGATING THE DISEASE-CAUSING MECHANISMS OF NRROS-ASSOCIATED MICROGLIOPATHY

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Michael Sewell
University of Edinburgh, Uk Dri, Edinburgh, United Kingdom

Previously, our group and others have identified a fatal, incurable neurodevelopmental disorder caused by loss-of-function mutations in the microglial-associated protein negative regulator of reactive oxygen species (NRROS), leading to an aberrant microglial phenotype. However, the mechanisms mediating the impact of these mutations haven't been ascertained. Moreover, the biological function of NRROS isn't fully understood, with others showing that it regulates activation of latent microglial homeostatic mediator transforming growth factor beta 1 (TGF-β1). However, aspects of this regulation, such as whether it enables microglial-intrinsic and/or extrinsic activation, remain unclear. Here we show that a NRROS-deficient mouse model displays white matter pathology and microglial phenotypic changes, including increased CD45 and CD163 and lowered CD11b and P2RY12 expression. We then examined *in vitro* NRROS-deficient mouse microglia responses to exogenous TGF-β1. Additionally, we investigated the functional effects of NRROS deletion on microglia by assessing phagocytic capacity and responses to inflammatory stimuli. We also performed scRNAseq on CNS macrophages from P7 and P42 NRROS-deficient mice to examine whether microglial populations are affected uniformly. Our results demonstrate extensive abnormalities in NRROS knockout microglia, including a loss of homeostatic signature possibly due to defective TGF-β1 signalling, and which are associated with white matter dysfunction that will be further investigated through spatial transcriptomics. We will also explore *in vitro*, whether NRROS/TGF-β1 signalling is microglial-intrinsic/extrinsic, and if microglial elimination/repopulation can rescue disease progression. Our work may advance understanding of fundamental microglial biology aspects, which may pertain to other sporadic conditions across the human lifespan associated with microglial dysfunction.

Associations between major psychiatric disorder polygenic risk scores and blood-based markers in UK biobank.
Major depressive disorder (MDD), schizophrenia (SCZ), and bipolar disorder (BD) have both shared and discrete genetic risk factors, and are associated with peripheral abnormalities. The relationships between such genetic architectures and blood-based markers are, however, unclear. We investigated relationships between polygenic risk scores (PRS) for these disorders and peripheral markers in the UK Biobank cohort. We calculated polygenic risk scores for n = 367,329 (MDD PRS), n = 366,465 (SCZ PRS), and n = 366,383 (BD PRS) UK Biobank cohort subjects. We then examined associations between disorder PRS and 58 inflammatory/immune, hematological, bone, cardiovascular, hormone, liver, renal and diabetes-associated blood markers using two generalized linear regression models: 'minimally adjusted' controlling for variables such as age and sex, and 'fully adjusted' including additional lifestyle covariates: BMI, alcohol and smoking status, and medication intake. There were 38/58 MDD PRS, 32/58 SCZ PRS, and 20/58 BD PRS-blood marker associations detected for our minimally adjusted model. Of these, 13/38 (MDD PRS), 14/32 (SCZ PRS), and 10/20 (BD PRS) associations remained significant after controlling for lifestyle factors. Many were disorder-specific, with 8/13 unique MDD PRS associations identified. Several disorder-specific associations for MDD and SCZ were immune-related, with mostly positive and negative associations identified for MDD and SCZ PRS respectively. This study suggests that MDD, SCZ and BD have both shared and distinct peripheral markers associated with disorder-specific genetic risk. The results also implicate inflammatory dysfunction in MDD and SCZ, albeit with differences in patterns between the two conditions, and enrich our understanding of potential underlying pathophysiological mechanisms in major psychiatric disorders.

Metabolic Profiling of Live Cancer Tissues Using NAD(P)H Fluorescence Lifetime Imaging.
Altered metabolism is a hallmark of cancer, both resulting from and driving oncogenesis. The NAD and NADP redox couples play a key role in a large number of the metabolic pathways involved. In their reduced forms, NADH and NADPH, these

molecules are intrinsically fluorescent. As the average time for fluorescence to be emitted following excitation by a laser pulse, the fluorescence lifetime, is exquisitely sensitive to changes in the local environment of the fluorophore, imaging the fluorescence lifetime of NADH and NADPH offers the potential for label-free monitoring of metabolic changes inside living tumors. Here, we describe the biological, photophysical, and methodological considerations required to establish fluorescence lifetime imaging (FLIM) of NAD(P)H as a routine method for profiling the metabolism of living cancer cells and tissues.

Long non-coding RNAs (lncRNAs) are non-protein coding transcripts that have emerged as major regulators of cellular and molecular function in the central nervous system (CNS). In this study, we aimed to identify and characterize lncRNA that are de-regulated in the aging brain**.** We employed FACS to sort neuronal and non-neuronal nuclei from the hippocampus of 3- and 16-month-old mice and performed total RNA sequencing. Computational analysis of the sequencing results revealed several candidate lncRNAs. Further expression analysis identified a novel candidate lncRNA enriched in microglia, the resident immune cells of the CNS that play a central role in age-related CNS disorders. Knockdown of this candidate lncRNA in primary mouse microglia and in human iPSC-derived microglia led to an upregulation of inflammatory pathways and increased phagocytic activity. In conclusion, we identify a novel lncRNA that is deregulated in the aging brain and orchestrates microglia function.

THE S1PR2-CCL2-BDNF-TRKB PATHWAY MEDIATES NEUROINFLAMMATION, ALTERATIONS IN GABAERGIC NEUROTRANSMISSION AND MOTOR INCOORDINATION IN HYPERAMMONEMIC RATS

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Yaiza Mª Arenas Ortiz, Tiziano Balzano, Gergana Mincheva, Marta Llansola, Vicente Felipo
Research center of Príncipe Felipe, Neurobiology, Valencia, Spain

Aims: Chronic hyperammonemia and inflammation synergistically induce neurological impairment including motor incoordination in hepatic encephalopathy. Hyperammonemic rats show neuroinflammation in cerebellum which enhances GABAergic neurotransmission leading to motor incoordination. We aimed to identify underlying mechanisms. The aims were: 1) assess if S1PR2 is involved in microglia and astrocytes activation in cerebellum of hyperammonemic rats; 2) identify pathways by which enhanced S1PR2 activation induces neuroinflammation and alters neurotransmission; 3) assess if blocking S1PR2 reduces neuroinflammation and restores motor coordination in hyperammonemic rats. Methods: We performed ex vivo studies in cerebellar slices from control or hyperammonemic rats to identify pathways by which neuroinflammation enhances GABAergic neurotransmission in hyperammonemia. Neuroinflammation and neurotransmission were assessed by immunochemistry/immunofluorescence and western blot. The S1PR2 was blocked by intracerebral treatment with JTE-013 using osmotic mini-pumps. Motor coordination was assessed in the beam walking Catwalk and motorater. Results: Chronic hyperammonemia enhances S1PR2 activation in cerebellum by increasing its membrane expression. This increases CCL2, especially in Purkinje neurons. CCL2 activates CCR2 in microglia, leading to microglia activation, increased P2X4 membrane expression and BDNF in microglia. BDNF enhanced TrkB activation in neurons, increasing KCC2 membrane expression. This enhances GABAergic neurotransmission, leading to motor incoordination in hyperammonemic rats. Blocking the S1PR2 in hyperammonemic rats by intracerebral administration of JTE-013 normalizes the S1PR2-CCL2-CCR2-BDNF-TrkB-KCC2 pathway, reduces glial activation and restores motor coordination in hyperammonemic rats. Conclusions: Enhanced S1PR2-CCL2-BDNF-TrkB pathway activation mediates neuroinflammation and incoordination in hyperammonemia. The data raise a promising therapy for patients with hepatic encephalopathy using compounds targeting this pathway.

CHARACTERISATION OF A NOVEL NOX2 INHIBITOR, GSK2795039, USING IN VITRO MODELS OF MICROGLIAL ACTIVATION

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Janeen Laabei, David Loane, Marie Hanscom
Trinity College Dublin, Neuroscience In Biochemistry And Immunology, Dublin, Ireland

NADPH oxidase 2 (NOX2) is an enzyme complex responsible for reactive oxygen species (ROS) production in microglia. NOX2 also acts as a priming signal for NLRP3 inflammasome activation, which is implicated in microglial-mediated neuroinflammation during chronic neurodegeneration. GSK2795039 is a novel small molecule drug that inhibits NOX2 in an NADPH competitive manner. The goal of this in *vitro* study was to characterise GSK2795039 in models of microglial activation. Immortalised Microglial (IMG) cell line or primary microglia from p1 Wistar rat pups were pre-treated with GSK2795039 (NOX2 inhibitor; 1-40μM) or diphenyleneiodonium (DPI; broad antioxidant; 0.005-0.1μM) and stimulated with either lipopolysaccharide (LPS; 100ng/ml) or LPS (100ng/ml)/ATP(1mM) to induce NOX2/ROS and NLRP3 inflammasome activation. ROS production and cell viability were measured using CM-H2DCFDA and MTT assays, respectively. The conditioned media was analysed for IL-1β, TNF-α by ELISA, and levels of nitric oxide (NO) using a Griess assay. Protein expression of iNOS, Arginase 1 and NLRP3 were determined by Western immunoblot. In IMG and primary microglia, GSK2795039 attenuated LPS-induced ROS production, iNOS expression, NO and upregulated anti-inflammatory marker, Arginase-1. In the LPS/ATP model, GSK2795039 attenuated ROS, IL-1β release and NLRP3 expression. Thus, GSK2795039 attenuated pro-inflammatory activation of LPS-stimulated microglia and concurrently upregulated an anti-inflammatory response. GSK2795039 also inhibited NLRP3 inflammasome activation which may be due to reduced NOX2/ROS signalling. Preliminary results indicate that GSK2795039 may induce a phenotypic switch in microglia by reducing pro-inflammatory and upregulating anti-inflammatory responses. Thus, GSK2795039 may be a promising therapeutic drug for mitigating the damaging effects of microglial-mediated neuroinflammation

MICROGLIAL BRAIN COLONIZATION: LOCAL CROSSTALK WITH THE NEURAL ENVIRONMENT

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Cécile Bridlance[1], Nicolas Olivié[1], Edmond Dupont[2], Benjamin Mathieu[1], Sonia Garel[1,3], Morgane S. Thion[4]
[1]Institut de Biologie de l'ENS (IBENS), Ecole Normale Supérieure, CNRS, Inserm, Université Psl, Paris, France, [2]Centre Interdisciplinaire de Recherche en Biologie (CIRB), Collège de France, CNRS, Inserm, Université Psl, Paris, France, [3]Collège de France, Université Psl, Paris, France, [4]Institut de Biologie de l'ENS (IBENS), Ecole Normale Supérieure, CNRS, INSERM, Université Psl, Paris, France

Microglia, the brain resident macrophages, are instrumental for cerebral development, functioning and homeostasis. Generated in the embryonic yolk-sac, these immigrants colonize the central nervous system during early embryogenesis, proliferate, distribute themselves and self-renew throughout life. Their colonization follows a remarkable stereotypical spatiotemporal pattern which has been associated with specific microglial developmental functions. While little is known about the mechanisms that regulate their pattern of colonization, microglial survival, proliferation and maturation have been shown to rely on CSF-1 receptor signaling. Herein, we performed a detailed analysis of murine microglial colonization and highlighted two waves of global microglial proliferation, matching changes in numbers as well as some regional specificities. Moreover, two-photon live-imaging on acute brain slices allowed us to appreciate the dynamic of microglial colonization, showing little contribution of migration over local proliferation. Noteworthy, using conditional inactivation of *Csf-1* in specific neural populations, we elucidated the sources of CSF-1 during embryonic microglial colonization and highlighted its essential local, transient and dose-dependent roles. Consequently, we developed a specific embryonic microglial depletion model in which they are transiently locally deprived. Altogether, our study sheds light on how microglia proliferate and distribute to colonize the brain as well as on their focal dependency on the CSF-1 receptor pathway. Importantly, it provides a groundbreaking tool to study the local roles of microglia during development. Sonia Garel and Morgane S. Thion contributed equally to this work.

THE DARK MICROGLIAL SUBSET DISPLAYS ULTRASTRUCTURAL AND METABOLIC ALTERATIONS IN AN AGED MOUSE MODEL OF BETA-AMYLOID PATHOLOGY

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Marie-Kim St-Pierre[1,2,3], Micaël Carrier[1,3,4], Fernando Gonzalez Ibanez[2,3], Eva Simoncicova[3], Marie-Josée Wallman[4,5], Luc Vallières[1,6], Martin Parent[4,5], Marie-Ève Tremblay[1,2,3,7,8]
[1]Centre de recherche du CHU de Québec-Université Laval, Axe Neurosciences, Quebec, Canada, [2]Université Laval, Médecine, Quebec, Canada, [3]University of Victoria, Division Of Medical Sciences, Victoria, Canada, [4]Université Laval, Département De Psychiatrie Et De Neurosciences, Quebec, Canada, [5]CERVO Brain Research Center, Department Of Psychiatry And Neuroscience, Quebec, Canada, [6]Université Laval, Médecine Moléculaire, Quebec, Canada, [7]The University of British Columbia, Department Of Biochemistry And Molecular Biology, Vancouver, Canada, [8]McGill University, Department Of Neurology And Neurosurgery, Montreal, Canada

AIMS Recent technical advances helped to reveal the considerable heterogeneity of microglia, the resident immune cells of the central nervous system. One of these microglial subsets, the dark microglia (DM), was characterized by ultrastructural signs of cellular stress such as dilated endoplasmic reticulum (ER), altered mitochondria and loss of heterochromatin pattern. These dark cells were previously identified notably near amyloid beta plaques in age-matched APP-PS1 mice, a mouse model of amyloid beta deposition. However, their ultrastructural features and interactions with hallmarks of amyloid deposition (plaques, dystrophic neurites) were not yet investigated in aging. **METHODS** Using high-magnification chip mapping by scanning electron microscopy, we first analyzed the density of both typical and DM in the ventral hippocampus CA1 (*strata lacunosum-moleculare* and *radiatum*) of 20-month-old male WT *versus* APP-PS1 mice. **RESULTS** In the *stratum lacunosum-moleculare,* dark microglia represented nearly 43% of all microglial cells found near AD hallmarks. We found DM interacting more with dystrophic neurites, while contacting less healthy synaptic elements, myelinated axons and brain vasculature compared to typical microglia. **CONCLUSIONS** The present study further highlights the close interactions between DM and amyloid beta deposition hallmarks, suggesting a specialized involvement, whether beneficial or detrimental, compared to typical microglia in this context. Further investigations into the prevalence and parenchymal interactions of DM with Alzheimer's disease hallmarks will be performed in *post-mortem* brain samples from Alzheimer's patients and aged-matched controls. Studying DM close interactions with disease hallmarks could help us find new therapeutic targets modulating these cells in a context-dependent manner.

Psychological Stress as a Risk Factor for Accelerated Cellular Aging and Cognitive Decline: The Involvement of Microglia-Neuron Crosstalk.
The relationship between the central nervous system (CNS) and microglia is lifelong. Microglia originate in the embryonic yolk sac during development and populate the CNS before the blood-brain barrier forms. In the CNS, they constitute a self-renewing population. Although they represent up to 10% of all brain cells, we are only beginning to understand how much brain homeostasis relies on their physiological functions. Often compared to a double-edged sword, microglia hold the potential to exert neuroprotective roles that can also exacerbate neurodegeneration once compromised. Microglia can promote synaptic growth in addition to eliminating synapses that are less active. Synaptic loss, which is considered one of the best pathological correlates of cognitive decline, is a distinctive feature of major depressive disorder (MDD) and cognitive aging. Long-term psychological stress accelerates cellular aging and predisposes to various diseases, including MDD, and cognitive decline. Among the underlying mechanisms, stress-induced neuroinflammation alters microglial interactions with the surrounding parenchymal cells and exacerbates oxidative burden and cellular damage, hence inducing changes in microglia and neurons typical of cognitive aging. Focusing on microglial interactions with neurons and their synapses, this review discusses the disrupted communication between these cells, notably involving fractalkine signaling and the triggering receptor expressed on myeloid cells (TREM). Overall, chronic stress emerges as a key player in cellular aging by altering the microglial sensome, notably via fractalkine signaling deficiency. To study cellular aging, novel positron emission tomography radiotracers for TREM and the purinergic family of receptors show interest for human study.

Neuroendocrine, neuroinflammatory and pathological outcomes of chronic stress: A story of microglial remodeling.
Microglia, the resident macrophage cells of the central nervous system (CNS), are involved in a myriad of processes required to maintain CNS homeostasis. These cells are dynamic and can adapt their phenotype and functions to the physiological needs of the organism. Microglia rapidly respond to changes occurring in their microenvironment, such as the ones taking place during stress. While stress can be beneficial for the organism to adapt to a situation, it can become highly detrimental when it turns chronic. Microglial response to prolonged stress may lead to an alteration of their beneficial physiological functions, becoming either maladaptive or pro-inflammatory. In this review, we aim to summarize the effects of chronic stress exerted on microglia through the neuroendocrine system and inflammation at adulthood. We also discuss how these effects of chronic stress could contribute to microglial involvement in neuropsychiatric and sleep disorders, as well as neurodegenerative diseases.

Levodopa partially rescues microglial numerical, morphological, and phagolysosomal alterations in a monkey model of Parkinson's disease.
Parkinson's disease (PD) is the most common neurodegenerative motor disorder. The mechanisms underlying the onset and progression of Levodopa (L-Dopa)-induced dyskinesia (LID) during PD treatment remain elusive. Emerging evidence implicates functional modification of microglia in the development of LID. Thus, understanding the link between microglia and the development of LID may provide the knowledge required to preserve or promote beneficial microglial functions, even during a prolonged L-Dopa treatment. To provide novel insights into microglial functional alterations in PD pathophysiology, we characterized their density, morphology, ultrastructure, and degradation activity in the sensorimotor functional territory of the putamen, using 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) cynomolgus monkeys. A subset of MPTP monkeys was treated orally with L-Dopa and developed LID similar to PD patients. Using a combination of light, confocal and transmission electron microscopy, our quantitative analyses revealed alterations of microglial density, morphology and phagolysosomal activity following MPTP intoxication that were partially normalized with L-Dopa treatment. In particular, microglial density, cell body and arborization areas were increased in the MPTP monkeys, whereas L-Dopa-treated MPTP animals presented a microglial phenotype similar to the control animals. At the ultrastructural level, microglia did not differ between groups in their markers of cellular stress or aging. Nevertheless, microglia from the MPTP monkeys displayed reduced numbers of endosomes, compared with control animals, that remained lower after L-Dopa treatment. Microglia from MPTP monkeys treated with L-Dopa also had increased numbers of primary lysosomes compared with non-treated MPTP animals, while secondary and tertiary lysosomes remained unchanged. Moreover, a decrease microglial immunoreactivity for CD68, considered a marker of phagocytosis and lysosomal activity, was measured in the MPTP monkeys treated with L-Dopa, compared with non-treated MPTP animals. Taken together, these findings revealed significant changes in microglia during PD pathophysiology that were partially rescued by L-Dopa treatment. Albeit, this L-Dopa treatment conferred phagolysosomal insufficiency on microglia in the dyskinetic Parkinsonian monkeys.

Impact of TREM2R47H variant on tau pathology-induced gliosis and neurodegeneration.
Alzheimer's disease (AD) is characterized by plaques containing amyloid-β (Aβ) and neurofibrillary tangles composed of aggregated, hyperphosphorylated tau. Beyond tau and Aβ, evidence suggests that microglia play an important role in AD pathogenesis. Rare variants in the microglia-expressed triggering receptor expressed on myeloid cells 2 (TREM2) gene increase AD risk 2- to 4-fold. It is likely that these TREM2 variants increase AD risk by decreasing the response of microglia to Aβ and its local toxicity. However, neocortical Aβ pathology occurs many years before neocortical tau pathology in AD. Thus, it will be important to understand the role of TREM2 in the context of tauopathy. We investigated the impact of the AD-associated TREM2 variant (R47H) on tau-mediated neuropathology in the PS19 mouse model of tauopathy. We assessed PS19 mice expressing human TREM2CV (common variant) or human TREM2R47H. PS19-TREM2R47H mice had significantly attenuated brain atrophy and synapse loss versus PS19-TREM2CV mice. Gene expression analyses and CD68 immunostaining revealed attenuated microglial reactivity in PS19-TREM2R47H versus PS19-TREM2CV mice. There was also a decrease in phagocytosis of postsynaptic elements by microglia expressing TREM2R47H in the PS19 mice and in human AD brains. These findings suggest that impaired TREM2 signaling reduces microglia-mediated neurodegeneration in the setting of tauopathy.

Shedding Light on the Dark Side of the Microglia.
Microglia, the resident immune cells of the central nervous system, are not a homogeneous population; their morphology, molecular profile, and even their ultrastructure greatly vary from one cell to another. Recent advances in the field of neuroimmunology have helped to demystify the enigma that currently surrounds microglial heterogeneity. Indeed, numerous microglial subtypes have been discovered such as the disease-associated microglia, neurodegenerative phenotype, and Cd11c-positive developmental population. Another subtype is the dark microglia (DM), a population defined by its ultrastructural changes associated with cellular stress. Since their first characterization using transmission electron microscopy, they have been identified in numerous disease conditions, from mouse models of Alzheimer's disease, schizophrenia, fractalkine signaling deficiency to chronic stress, just to name a few. A recent study also identified the presence of cells with a similar ultrastructure to the DM in brain samples from schizophrenic patients, underlining the importance of understanding the function of these cells. In this minireview, we aim to summarize the current knowledge on the DM, from their initial ultrastructural characterization to their documentation in various pathological contexts across multiple species. We will also highlight the current limitations surrounding the study of these cells and the future that awaits the DM.

Microglial physiological properties and interactions with synapses are altered at presymptomatic stages in a mouse model of Huntington's disease pathology.
Huntington's disease (HD) is a dominantly inherited neurodegenerative disorder that affects cognitive and motor abilities by primarily targeting the striatum and cerebral cortex. HD is caused by a mutation elongating the CAG repeats within the Huntingtin gene, resulting in HTT protein misfolding. Although the genetic cause of HD has been established, the specific susceptibility of neurons within various brain structures has remained elusive. Microglia, which are the brain's resident macrophages, have emerged as important players in neurodegeneration. Nevertheless, few studies have examined their implication in HD.

Microglial Ultrastructure in the Hippocampus of a Lipopolysaccharide-Induced Sickness Mouse Model.
Sickness behavior is a set of behavioral changes induced by infections and mediated by pro-inflammatory cytokines. It is characterized by fatigue, decreased appetite and weight loss, changes in sleep patterns, cognitive functions, and lost interest in social activity. It can expedite recovery by conserving energy to mount an immune response involving innate immunity. To provide insights into microglial implication in sickness behavior with special focus on cognitive and social impairment, we investigated changes in their ultrastructure and interactions with synapses using a toxemia mouse model. Adult mice were injected with 1 mg/kg lipopolysaccharide (LPS) or saline, and assayed for signs of sickness behavior. LPS treated mice displayed reduced activity in open-field tests 24 h post-injection, while social avoidance and weight gain/loss were not significantly different between treatment groups. Microglia were investigated using electron microscopy to describe changes in their structure and function at nanoscale resolution. Microglial cell bodies and processes were investigated in the hippocampus CA1, a region responsible for learning and memory that is often impacted after peripheral LPS administration. Microglia in LPS treated animals displayed larger cell bodies as well as less complex processes at the time point examined. Strikingly, microglial processes in LPS injected animals were also more likely to contact excitatory synapses and contained more phagocytic material compared with saline injected controls. We have identified at the ultrastructural level significant changes in microglia-synapse interactions shortly after LPS administration, which draws attention to studying the roles of microglia in synaptic rewiring after inflammatory stimuli.

Visualizing Dark Microglia.
Dark microglia, a recently described phenotype, are found in high numbers in nonhomeostatic conditions (e.g., Alzheimer's disease pathology, aging, chronic stress). As a specific protein marker has not yet been defined, they cannot be studied using conventional cellular biology techniques. They are recognized by their unique ultrastructural features visible under electron microscopy. This nanoscale resolution imaging technique allows the identification of cells based on their ultrastructure or immunoreactivity to certain proteins. In this protocol, we describe the steps necessary for the preparation of high-quality brain tissues for transmission electron microscopy, the imaging, the identification of dark microglia, and the ultrastructural analysis of various parameters that can be studied in these cells.

Inflammatory mechanisms in neurodegeneration.
This review discusses the profound connection between microglia, neuroinflammation, and Alzheimer's disease (AD). Theories have been postulated, tested, and modified over several decades. The findings have further bolstered the belief that microglia-mediated inflammation is both a product and contributor to AD pathology and progression. Distinct microglia phenotypes and their function, microglial recognition and response to protein aggregates in AD, and the overall role of microglia in AD are areas that have received considerable research attention and yielded significant results. The following article provides a historical perspective of microglia, a detailed discussion of multiple microglia phenotypes including dark microglia, and a review of a number of areas where microglia intersect with AD and other pathological neurological processes. The overall breadth of important discoveries achieved in these areas significantly strengthens the hypothesis that neuroinflammation plays a key role in AD. Future determination of the exact mechanisms by which microglia respond to, and attempt to mitigate, protein aggregation in AD may lead to new therapeutic strategies.

Nonfunctional mutant Wrn protein leads to neurological deficits, neuronal stress, microglial alteration, and immune imbalance in a mouse model of Werner syndrome.
Werner syndrome (WS) is a premature aging disorder caused by mutations in a RecQ-family DNA helicase, WRN. Mice lacking part of the helicase domain of the WRN orthologue exhibit many phenotypic features of WS, including metabolic abnormalities and a shorter lifespan. Yet, little is known about the impact of WRN mutations on the central nervous system in both humans and mouse models of WS. In the current study, we have performed a longitudinal behavioral assessment on mice bearing a Wrn helicase deletion. Behavioral tests demonstrated a loss of motor activity and coordination, reduction in perception, increase in repetitive behavior, and deficits in both spatial and social novelty memories in Wrn mutant mice compared to age-matched wild type mice. These neurological deficits were associated with biochemical and histological changes in the brain of aged Wrn mutant mice. Microglia, resident immune cells that regulate neuronal plasticity and function in the brain, were hyper-ramified in multiple regions involved with the behavioral deficits of Wrn mutant mice. Furthermore, western analyses indicated that Wrn mutant mice exhibited an increase of oxidative stress markers in the prefrontal cortex. Supporting these findings, electron microscopy studies revealed increased cellular aging and oxidative stress features, among microglia and neurons respectively, in the prefrontal cortex of aged Wrn mutant mice. In addition, multiplex immunoassay of serum identified significant changes in the expression levels of several pro- and anti-inflammatory cytokines. Taken together, these findings indicate that microglial dysfunction and neuronal oxidative stress, associated with peripheral immune system alterations, might be important driving forces leading to abnormal neurological symptoms in WS thus suggesting potential therapeutic targets for interventions.

Temporal lobe epilepsy (TLE) is characterized by focal recurrent seizures generated in the temporal structures. TLE is often accompanied by neuronal death, gliosis, and synaptic reorganization. Sixty percent of patients do not respond to treatments, highlighting the urgency of better understanding the mechanisms involved in the pathogenesis to identify new therapeutic targets. **Aims:** Microglia develop a dual profile, pro and anti-inflammatory, and the balance between these two states influences disease progression. Our working hypothesis is that interactions between microglia and T cells drive a protective anti-inflammatory effect in the epileptic hippocampus. **Methods:** We used a unilateral intracortical kainate model of TLE in mice lacking T cells (CD3-/- mouse) or depleted in regulatory T cells (Treg). We performed *in vivo* electrophysiological recordings and immunostainings to test the effect of T cell absence on epileptic activity and hippocampal sclerosis. **Results:** We observed an increase of seizure frequency, an increase of neuronal death and a loss microglial anti-inflammatory response in the hippocampus of CD3-/- mouse. Treg have been shown to promote anti-inflammatory reactions in different models of neurological disorders. Depleting Treg by administrating anti-CD25 antibodies during early epileptogenesis led to a loss of the microglial anti-inflammatory response and to an increase of neuronal death and of seizure frequency in the hippocampus. **Conclusions:** These observations suggest that interactions between Treg and microglia have a protective role in TLE. These findings may allow the identification of new targets to enhance the endogenous anti-inflammatory response and ultimately improve the treatment of TLE.

The mGlu7 receptor provides protective effects against epileptogenesis and epileptic seizures.
Finding new targets to control or reduce seizure activity is essential to improve the management of epileptic patients. We hypothesized that activation of the pre-synaptic and inhibitory metabotropic glutamate receptor type 7 (mGlu7) reduces spontaneous seizures. We tested LSP2-9166, a recently developed mGlu7/4 agonist with unprecedented potency on mGlu7 receptors, in two paradigms of epileptogenesis. In a model of chemically induced epileptogenesis (pentylenetetrazole systemic injection), LSP2-9166 induces an anti-epileptogenic effect rarely observed in preclinical studies. In particular, we found a bidirectional modulation of seizure progression by mGlu4 and mGlu7 receptors, the latter preventing kindling. In the intra-hippocampal injection of kainic acid mouse model that mimics the human mesial temporal lobe epilepsy, we found that LSP2-9166 reduces seizure frequency and hippocampal sclerosis. LSP2-9166 also acts as an anti-seizure drug on established seizures in both models tested. Specific modulation of the mGlu7 receptor could represent a novel approach to reduce pathological network remodeling.

MICROGLIAL CASPASE-3 IS ESSENTIAL FOR MODULATING HIPPOCAMPAL NEUROGENESIS

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Rocío Ruiz, Isabel Alonso-Bellido, Mercedes Posada, Sandra Vázquez, María Cabanillas, Jesús Soldán, Rocío De Pablos, José Venero
Universidad de Sevilla, Bioquímica Y Biología Molecular, Sevilla, Spain

Adult hippocampal neurogenesis (AHN) is a process involved in numerous neurodegenerative diseases. Many researchers have described microglia as a key component in modulating this process, regulating the formation and migration of new neurons along the rostral migratory stream. Caspase-3 is a cysteine-aspartate-protease classically considered as one of the main effector caspases in the cell death program process. In addition to this classical function, we have identified the role of this protein as a modulator of microglial function; however, its action on neurogenic processes is unknown. The aim of the present study is to identify the role of caspase-3 in neurogenesis-related microglial functions. To address this study, caspase-3 conditional mutant mice in the microglia were used. Using this tool, we wanted to elucidate the role of this protein in microglial function in the hippocampus, the main region where adult neurogenesis takes place. After the deletion of caspase-3 in microglia, mutant mice showed a reduction of microglia in the hippocampus, showing a less active morphology. Using high-resolution image analysis, we also observed a reduction in the phagocytic capacity of microglia lacking caspase-3. Furthermore, we found a reduction in doublecortin-positive neurons in caspase-3 knockout mice, which corresponds to a reduction in neurogenic neurons. Behavioral analysis using object recognition and Y-maze tests showed altered memory and learning in the absence of caspase-3. Taken together, these results showed the essential role of caspase-3 in microglial function and highlight the relevant role of this specific microglial phenotype in the maintenance of AHN in the hippocampus.

MAGNETOFECTION IN HMC3 HUMAN MICROGLIA IS NOT AFFECTED BY DEFINED-MEDIUM CONDITIONS

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Melania Bica-Popi[1], Gabriela Chiritoiu[2], Cristian Munteanu[2], Violeta Ristoiu[1]

Aims: Serum-free microglia culture models supplemented with primary components of astrocyte-derived factors (defined-medium) are required for the cells *in vitro* to resemble the mature, resting microglial phenotype. Here we hypothesize that using magnetofection to deliver siRNA in HMC3 human microglia is equally effective in both serum-supplemented and defined-medium cultures. **Methods:** The polarization towards the resting phenotype of HMC3 microglial cells maintained in defined-medium was established by quantifying the degree of cell elongation across the cell nucleus. Additionally, extracellular acidification rate and oxygen consumption rate were measured using Seahorse XFe24 analyser. Magnetofection is a novel transfection method that allows the delivery of nucleic acids upon exploitation of magnetic force. The efficiency of magnetofection was assessed by siRNA molecule labelled with Alexa Fluor 594 and analysed quantitatively as mean integrated density per cell area. The efficacy of magnetofection was tested on Iba1 protein expression, by Western blot and LC-MS analysis, using a customized anti-Iba1 siRNA molecule. **Results:** The degree of cell elongation as well as the metabolic measurements confirmed that polarization occurs until 7 days of culturing the microglial cells in defined-medium. The siRNA delivery efficiency showed comparable results in terms of siRNA concentration and ratio between transfection reagent:siRNA. The siRNA delivery efficacy indicated a decrease in Iba1 expression, even though the results were not striking: surprisingly, we confronted a low level of Iba1 protein intrinsically expressed by HMC3 microglia. **Conclusions:** High-yield delivery of siRNA in HMC3 human microglia can be achieved by means of magnetofection, in both serum-supplemented and defined-medium cultures.

Silencing the Cytoskeleton Protein Iba1 (Ionized Calcium Binding Adapter Protein 1) Interferes with BV2 Microglia Functioning.
Iba1 (ionized calcium binding adapter protein 1) is a cytoskeleton protein specific only for microglia and macrophages, where it acts as an actin-cross linking protein. Although frequently regarded as a marker of activation, its involvement in cell migration, membrane ruffling, phagocytosis or in microglia remodeling during immunological surveillance of the brain suggest that Iba1 is not a simple cytoskeleton protein, but a signaling molecule involved in specific signaling pathways. In this study we investigated if Iba1 could also represent a drug target, and tested the hypothesis that its specific silencing with customized Iba1-siRNA can modulate microglia functioning. The results showed that Iba1-silenced BV2 microglia migrate less due to reduced proliferation and cell adhesion, while their phagocytic activity and P2x7 functioning was significantly increased. Our data are the proof of concept that Iba1 protein is a new microglia target, which opens a new therapeutic avenue for modulating microglia behavior.

THE POSSIBLE THERAPEUTIC ROLE OF ITACONATE AND MESACONATE ON THE DELETERIOUS EFFECTS OF INFLUENZA A VIRUS INFECTION IN THE BRAIN

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Melanie Ohm[1,2], Shirin Hosseini[2,3], Karsten Hiller[1], Martin Korte[2,3]
[1]TU Braunschweig, Department Of Bioinformatics And Biochemistry, Braunschweig, Germany, [2]TU Braunschweig, Department Of Cellular Neurobiology, Zoological Institute, Braunschweig, Germany, [3]Helmholtz Centre for Infection Research, Neuroinflammation And Neurodegeneration Group, Braunschweig, Germany

Numerous studies indicate that strong inflammatory responses in the periphery lead to infiltration of peripheral leukocytes into the central nervous system, resulting in activation of brain resident immune cells, neuroinflammation and even neurodegeneration. The inflammatory response is primarily a protective mechanism. However, excessive and chronic inflammation can lead to deleterious effects on neuronal cells. Indeed, neuroinflammation underlies the pathogenesis and accelerates the progression of many neurological disorders. Therefore, inflammatory signaling pathways have been implicated as potential therapeutic targets for many neurological diseases. A growing number of reports demonstrates that products of the cell metabolism play an important role in mediating the immune response. The TCA cycle-derived metabolite itaconate is strongly upregulated in activated macrophages and has been shown to act as an immunomodulator with anti-inflammatory functions. Mesaconate, an isomer of itaconate, also decreases the inflammatory response in macrophages. To investigate the immunomodulatory and therapeutic potential of itaconate and mesaconate in neuroinflammatory processes, the metabolites were administered in two mouse models: LPS-induced peripheral immune activation and influenza A virus infection. To analyze the extent of inflammation, pro-inflammatory cytokines were determined in the brain by ELISA. Interestingly, mice that received mesaconate in combination with influenza infection showed an improvement in the clinical score and lower cytokine levels compared to the corresponding control animals. Ongoing experiments address whether administration of itaconate or mesaconate may modulate microglial activation and neuronal structure and function. These results could lead to new therapeutic strategies to prevent immediate and delayed neurological manifestations associated with bacterial and viral infections.

EXPLORING THE POTENTIAL ROLES OF THE PIWI PATHWAY IN MICROGLIA AND NEUROINFLAMMATION

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Silvia Beatini, Roberta Pelizzoli, Davide De Pietri Tonelli
Istituto Italiano di Tecnologia (IIT), Neuroscience, Genova, Italy

Piwi proteins and the small noncoding RNAs interacting with them i.e., piRNAs (henceforth referred to as the Piwi pathway), are best known in gonads where they act as an RNA-mediated immune mechanism that safeguards genomic integrity and male fertility. Although accumulating evidence indicates that the Piwi pathway is also involved in neuroinflammation and neurodegeneration (Penning et al., 2022), mechanisms remain elusive. Our data indicates that the induction of an inflammatory state in murine microglia, the immune-resident cells of the brain, alters the expression of the Piwi pathway, suggesting that it might be involved and contribute to the mechanisms of microglia activation. As microglia are key players in neuroinflammation, which is considered a risk factor for a wide range of age-related diseases of the central nervous system, such as dementia, depression and neurodegeneration, this finding has potential implications for successful brain aging.

Influenza A virus (IAV) infections are primarily known to cause a self-limiting respiratory syndrome. It has rarely been systematically studied in what ways and with what long-term consequences the infection and/or the immune response to it might affect the nervous system. However, an expanded spectrum of cerebral manifestations has been reported following IAV infection. Evidence suggests that susceptibility to pulmonary infections caused by respiratory viruses increases with age. Indeed, a progressive decline in the integrity of the immune system, termed immunosenescence, is one of the prominent physiological changes during mammalian aging. Accordingly, we aimed to investigate whether age is a risk factor for the development of a more pronounced chronic immune response in the CNS of elderly individuals. Therefore, 15-month-old C57BL/6J mice were intranasally infected with non-neurotropic (H1N1 and H3N2) and neurotropic H7N7 IAV subtypes to determine potential long-term effects on hippocampal structure and function. Synapse loss detected at 30 dpi was associated with deficits in spatial learning and impaired synaptic plasticity. In addition, evidence of synaptic stripping by increased activated phagocytic microglia engulfing the postsynaptic compartment was detected in the hippocampus. While neuroinflammation induced by H7N7 IAV showed the strongest effect, systemic infection with H1N1 and H3N2 subtypes resulted in long-term impairment of hippocampal structure and function. Remarkably, the deficit in spatial learning at 120 dpi was still detectable in aged H7N7 IAV-infected mice, in contrast to fully recovered young mice. These results suggest that IAV infection has longer-lasting and more severe effects on hippocampal function in older animals.

Long-Term Consequence of Non-neurotropic H3N2 Influenza A Virus Infection for the Progression of Alzheimer's Disease Symptoms.
Influenza viruses until today are a leading cause of worldwide severe pandemics and represent a major threat to human and animal health. Although the primary target of influenza viruses is the lung, infection may manifest with acute and even chronic neurological complications (e.g., status epilepticus, encephalopathies, and encephalitis) potentially increasing the long-term risk for neurodegenerative diseases. We previously described that a peripheral influenza A virus (IAV) infection caused by non-neurotropic H3N2 (maHK68) variant leads to long-term neuroinflammation and synapse loss together with impaired memory formation in young adult mice. Processes of neuroinflammation have been associated with neurodegenerative diseases such as Alzheimer's disease (AD) and prolonged or excessive innate immune responses are considered a risk factor for AD. Here, the role of purely peripheral IAV infection for the development and progression of AD in a transgenic mouse model (APP/PS1) was investigated. At 2 months of age, mice were infected with H3N2 IAV and the detailed analysis of microglia morphology revealed neuroinflammation in the hippocampus already of 6 months old non-infected APP/PS1 mice together with impaired spatial learning, however, microglia activation, amyloid-β plaques load and cognitive impairments were even more pronounced in APP/PS1 mice upon H3N2 infection. Moreover, CA1 hippocampal dendritic spine density was reduced even at 120 dpi compared to wild-type and also to non-infected APP/PS1 mice, whereas neuronal cells number was not altered. These findings demonstrate that non-neurotropic H3N2 IAV infection as a peripheral immune stimulation may exacerbate AD symptoms possibly by triggering microglial hyperactivation.

The NLRP3 inflammasome inhibitor OLT1177 rescues cognitive impairment in a mouse model of Alzheimer's disease.
Numerous studies demonstrate that neuroinflammation is a key player in the progression of Alzheimer's disease (AD). Interleukin (IL)-1β is a main inducer of inflammation and therefore a prime target for therapeutic options. The inactive IL-1β precursor requires processing by the the nucleotide-binding oligomerization domain-like receptor family, pyrin domain

containing 3 (NLRP3) inflammasome into a mature and active form. Studies have shown that IL-1β is up-regulated in brains of patients with AD, and that genetic inactivation of the NLRP3 inflammasome improves behavioral tests and synaptic plasticity phenotypes in a murine model of the disease. In the present study, we analyzed the effect of pharmacological inhibition of the NLRP3 inflammasome using dapansutrile (OLT1177), an oral NLRP3-specific inhibitor that is safe in humans. Six-month-old WT and APP/PS1 mice were fed with standard mouse chow or OLT1177-enriched chow for 3 mo. The Morris water maze test revealed an impaired learning and memory ability of 9-mo-old APP/PS1 mice (= 0.001), which was completely rescued by OLT1177 fed to mice (= 0.008 to untreated APP/PS1). Furthermore, our findings revealed that 3 mo of OLT1177 diet can rescue synaptic plasticity in this mouse model of AD (= 0.007 to untreated APP/PS1). In addition, microglia were less activated (= 0.07) and the number of plaques was reduced in the cortex (= 0.03) following NLRP3 inhibition with OLT1177 administration. We also observed an OLT1177 dose-dependent normalization of plasma metabolic markers of AD to those of WT mice. This study suggests the therapeutic potential of treating neuroinflammation with an oral inhibitor of the NLRP3 inflammasome.

Langat virus infection affects hippocampal neuron morphology and function in mice without disease signs.
Tick-borne encephalitis virus (TBEV) is an important human pathogen that can cause the serious illness tick-borne encephalitis (TBE). Patients with clinical symptoms can suffer from severe meningoencephalitis with sequelae that include cognitive disorders and paralysis. While less than 30% of patients with clinical symptoms develop meningoencephalitis, the number of seropositive individuals in some regions indicates a much higher prevalence of TBEV infections, either with no or subclinical symptoms. The functional relevance of these subclinical TBEV infections and their influence on brain functions, such as learning and memory, has not been investigated so far.

Type I Interferon Receptor Signaling in Astrocytes Regulates Hippocampal Synaptic Plasticity and Cognitive Function of the Healthy CNS.
Type I interferon receptor (IFNAR) signaling is a hallmark of viral control and host protection. Here, we show that, in the hippocampus of healthy IFNAR-deficient mice, synapse number and synaptic plasticity, as well as spatial learning, are impaired. This is also the case for IFN-β-deficient animals. Moreover, antibody-mediated IFNAR blocking acutely interferes with neuronal plasticity, whereas a low-dose application of IFN-β has a positive effect on dendritic spine structure. Interfering with IFNAR signaling in different cell types shows a role for cognitive function and synaptic plasticity specifically mediated by astrocytes. Intriguingly, levels of the astrocytic glutamate-aspartate transporter (GLAST) are reduced significantly upon IFN-β treatment and increase following inhibition of IFNAR signaling. These results indicate that, besides the prominent role for host defense, IFNAR is important for synaptic plasticity as well as cognitive function. Astrocytes are at the center stage of this so-far-unknown signaling cascade.

Long-Term Neuroinflammation Induced by Influenza A Virus Infection and the Impact on Hippocampal Neuron Morphology and Function.
Acute influenza infection has been reported to be associated with neurological symptoms. However, the long-term consequences of an infection with neurotropic and non-neurotropic influenza A virus (IAV) variants for the CNS remain elusive. We can show that spine loss in the hippocampus after infection with neurotropic H7N7 (rSC35M) and non-neurotropic H3N2 (maHK68) in female C57BL/6 mice persists well beyond the acute phase of the disease. Although spine number was significantly reduced at 30 d postinfection (dpi) with H7N7 or H3N2, full recovery could only be observed much later at 120 dpi. Infection with H1N1 virus, which was shown previously to affect spine number and hippocampus-dependent learning acutely, had no significant long-term effects. Spine loss was associated with an increase in the number of activated microglia, reduced long-term potentiation in the hippocampus, and impairment in spatial memory formation, indicating that IAV-associated inflammation induced functional and structural alterations in hippocampal networks. Transcriptome analyses revealed regulation of many inflammatory and neuron- and glia-specific genes in H3N2- and H7N7-infected mice at day 18 and in H7N7-infected mice at day 30 pi that related to the structural and functional alterations. Our data provide evidence that neuroinflammation induced by neurotropic H7N7 and infection of the lung with a non-neurotropic H3N2 IAV result in long-term impairments in the CNS. IAV infection in humans may therefore not only lead to short-term responses in infected organs, but may also trigger neuroinflammation and associated chronic alterations in the CNS. In the acute phase of influenza infection, neuroinflammation can lead to alterations in hippocampal neuronal morphology and cognitive deficits. The results of this study now also provide evidence that neuroinflammation induced by influenza A virus (IAV) infection can induce longer-lasting, virus-specific alterations in neuronal connectivity that are still detectable 1 month after infection and are

associated with impairments in spatial memory formation. IAV infection in humans may therefore not only lead to short-term responses in infected organs, but may also trigger neuroinflammation and associated chronic alterations in the CNS.

Role of C-fibers in pain and morphine induced analgesia/hyperalgesia in rats.
Usual dosage of morphine (10 mg/kg) induces analgesia and ultra-low dose (ULD) of morphine (1 µg/kg); hyperalgesia, and C-fibers are also bearing µ-opioid receptors; here the importance of C-fibers on pain and morphine induced analgesia/hyperalgesia is questioned and investigated using pain evaluation methods and infant capsaicin treating for C-fibers lesioning.

The effects of trypsin on rat brain astrocyte activation.
Astrocytes are cells within the central nervous system which are activated in a wide spectrum of infections, and autoimmune and neurodegenerative diseases. In pathologic states, they produce inflammatory cytokines, chemokines, and nitric oxide (NO), and sometimes they induce apoptosis. Their protease-activated receptors (PARs) can be activated by proteases, e.g. thrombin and trypsin, which are important in brain inflammation. The current study aimed to investigate the effects of different concentrations of trypsin (1 to 100U/ml) on cultured astrocytes.

NANOPARTICLE-MEDIATED DELIVERY OF A NEW TSPO LIGAND SUPPRESSES INFLAMMATION IN LPS-STIMULATED MICROGLIA AND IN A MOUSE MODEL OF ALZHEIMER'S DISEASE

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Antonella Casamassa[1], Paola Brancaccio[1], Ilaria Piccialli[1], Anna Pannaccione[1], Ferdinando Fiorino[2], Giuseppe De Rosa[2], Lucio Annunziato[1], Giuseppe Pignataro[1]

The translocator protein 18kDa (TSPO) is a conserved outer mitochondrial membrane protein, implicated in inflammation, cell survival and proliferation. In the central nervous system, the expression of TSPO is markedly upregulated in activated microglia during various disease states such as Alzheimer's Disease. Synthetic as well as endogenous ligands with agonistic or antagonistic properties modulate the function of TSPO. Thus, TSPO ligands can act as putative therapeutic agents during neuroinflammatory processes. In the present study, we examined the effectiveness of a new TSPO ligand, named TEMNAP, in mitigating inflammatory processes associated to dementia. Lipopolysaccharide (LPS)-activated microglial cells were used as an *in vitro* model to study the anti-inflammatory effects of TEMNAP. In particular, we explored the efficacy of nanoparticle-mediated delivery of TEMNAP by investigating the molecular and the morphological properties of LPS-stimulated BV2 microglia. We demonstrated that the exposure of BV2 microglia to TEMNAP significantly reduced the LPS-induced microglia proliferation and strongly prevented the expression of the pro-inflammatory marker iNOS, as well as, the production of nitric oxide. In addition, we found that nanoparticle-mediated delivery of TEMNAP was more effective in preventing the LPS-induced proliferation of hyperactivated microglia and in reducing the upregulation of the M1 pro-inflammatory markers iNOS and CD86. Accordingly to our *in vitro* observations, *in vivo* experiments carried out in transgenic mice Tg2576, a well-known model of Alzheimer, confirmed the neuroprotective effects of TEMNAP systemically administered. Collectively, our results revealed a strong anti-inflammatory efficacy of the new compound TEMNAP.

Sumoylation of sodium/calcium exchanger in brain ischemia and ischemic preconditioning.
The small ubiquitin-like modifier (SUMO) conjugation (or SUMOylation) is a post-translational protein modification mechanism activated by different stress conditions that has been recently investigated in experimental models of cerebral ischemia. The expression of SUMOylation enzymes and substrates is not restricted to the nucleus, since they are present also in the cytoplasm and on plasma membrane and are involved in several physiological and pathological conditions. In the last decades, convincing evidence have supported the idea that the increased levels of SUMOylated proteins may induce tolerance to ischemic stress. In particular, it has been established that protein SUMOylation may confer neuroprotection during ischemic preconditioning. Considering the increasing evidence that SUMO can modify stability and expression of ion channels and transporters and the relevance of controlling ionic homeostasis in ischemic conditions, the present review will resume the main aspects of SUMO pathways related to the key molecules involved in maintenance of ionic homeostasis during cerebral ischemia and ischemic preconditioning, with a particular focus on the on Na/Ca exchangers.

Glial Na(+) -dependent ion transporters in pathophysiological conditions.
Sodium dynamics are essential for regulating functional processes in glial cells. Indeed, glial Na(+) signaling influences and regulates important glial activities, and plays a role in neuron-glia interaction under physiological conditions or in response to injury of the central nervous system (CNS). Emerging studies indicate that Na(+) pumps and Na(+) -dependent ion transporters in astrocytes, microglia, and oligodendrocytes regulate Na(+) homeostasis and play a fundamental role in modulating glial activities in neurological diseases. In this review, we first briefly introduced the emerging roles of each glial cell type in the pathophysiology of cerebral ischemia, Alzheimer's disease, epilepsy, Parkinson's disease, Amyotrophic Lateral Sclerosis, and myelin diseases. Then, we discussed the current knowledge on the main roles played by the different

glial Na(+) -dependent ion transporters, including Na(+) /K(+) ATPase, Na(+) /Ca(2+) exchangers, Na(+) /H(+) exchangers, Na(+) -K(+) -Cl(-) cotransporters, and Na(+) - HCO3- cotransporter in the pathophysiology of the diverse CNS diseases. We highlighted their contributions in cell survival, synaptic pathology, gliotransmission, pH homeostasis, and their role in glial activation, migration, gliosis, inflammation, and tissue repair processes. Therefore, this review summarizes the foundation work for targeting Na(+) -dependent ion transporters in glia as a novel strategy to control important glial activities associated with Na(+) dynamics in different neurological disorders. NCX1 Exchanger Cooperates with Calretinin to Confer Preconditioning-Induced Tolerance Against Cerebral Ischemia in the Striatum.
Recently, the Na(+)/Ca(+2) exchanger NCX1 and the calcium binding protein calretinin have emerged as new molecular effectors of delayed preconditioning in the brain. In the present study, we investigated whether NCX1 and calretinin cooperate within the preconditioned striatum to confer neurons greater resistance to degeneration. Confocal microscopy analysis revealed that NCX1 expression was upregulated in calretinin-positive interneurons in the rat striatum after tolerance induction. Consistently, coimmunoprecipitation assays performed on human SHSY-5Y cells, a neuronal cell line which constitutively expresses calretinin, revealed a binding between NCX1 and calretinin. Finally, silencing of calretinin expression, both in vitro and in vivo, significantly prevented preconditioning-induced neuroprotection. Interestingly, our biochemical and functional studies showed that the selective silencing of calretinin in brain cells significantly prevented not only the preconditioning-induced upregulation of NCX1 expression and activity but also the activation of the prosurvival protein kinase Akt, which is involved in calretinin and NCX1 protective actions. Collectively, our results indicate that the Na(+)/Ca(+2) exchanger NCX1 and the calcium binding protein calretinin cooperate within the striatum to confer tolerance against cerebral ischemia.

NCX1 is a new rest target gene: role in cerebral ischemia.
The Na(+)-Ca(2+) exchanger 1 (NCX1), a bidirectional transporter that mediates the electrogenic exchange of one calcium ion for three sodium ions across the plasma membrane, is known to be involved in brain ischemia. Since the RE1-silencing transcription factor (REST) is a key modulator of neuronal gene expression in several neurological conditions, we studied the possible involvement of REST in regulating NCX1 gene expression and activity in stroke. We found that: (1) REST binds in a sequence specific manner and represses through H4 deacetylation, ncx1 gene in neuronal cells by recruting CoREST, but not mSin3A. (2) In neurons and in SH-SY5Y cells REST silencing by siRNA and site-direct mutagenesis of REST consensus sequence on NCX1 brain promoter determined an increase in NCX1 promoter activity. (3) By contrast, REST overexpression caused a reduction in NCX1 protein expression and activity. (4) Interestingly, in rats subjected to transient middle cerebral artery occlusion (tMCAO) and in organotypic hippocampal slices or SH-SY5Y cells exposed to oxygen and glucose deprivation (OGD) plus reoxygenation (RX), the increase in REST was associated with a decrease in NCX1. However, this reduction was reverted by REST silencing. (5) REST knocking down, along with the deriving NCX1 overexpression in the deep V and VIb cortical layers caused a marked reduction in infarct volume after tMCAO. Double silencing of REST and NCX1 completely abolished neuroprotection induced by siREST administration. Collectively, these results demonstrate that REST, by regulating NCX1 expression, may represent a potential druggable target for the treatment of brain ischemia.

DETAILED ANALYSIS OF CORTICAL MICROGLIA MORPHOLOGY THROUGHOUT LIFE

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Sanziana Godeanu[1], Devin Clarke[2], Alexandru Deftu[3], Adrian Tudor Bălșeanu[1], Anja Scheller[4], Bogdan Catalin[1]
[1]University of Medicine and Pharmacy of Craiova, Experimental Research Centre For Normal And Pathological Aging, Craiova, Romania, [2]The University of Sussex, School Of Psychology And Sussex Neuroscience, Brighton, United Kingdom, [3]Pain Center, Department Of Anesthesiology, Lausanne, Switzerland, [4]University of Saarland, Department Of Molecular Physiology, Cipmm (center For Integrative Physiology And Molecular Medicine), Homburg, Germany

Aims. Microglia are long-lived cells that constantly monitor their microenvironment. In order to accomplish this task, microglia constantly change their morphologies under normal physiological conditions in both the short and long term. We investigated the morphological variation that microglia undergo across lifespan. **Methods.** Using semimanual and semiautomatic methods to quantify cortical microglia morphology. Data was obtained by confocal imaging the cortex of heterozygous TgH(CX3CR1-EGFP) mice. We were able to generate a detailed quantification of physiological morphologies of microglia at different time points of age, starting immediately postnatal (5, 10 and 20 days) and in young adult (20 weeks), early aged (58 and 84 weeks) and old aged (110 weeks) animals. **Results.** Basic microglia characteristics such as cellular density or the mean space occupied by each cell change over time. This is accompanied by a plethora of changes in the microglia ramifications, with its total length, number of branches also changes as time passes. Detailed cellular arbor analysis revealed differences in microglia morphology that are age-related, with mean branch length and the number of terminal processes changing the most over time. **Conclusions.** Our study provides insight into changes in microglia morphology across the lifespan and details the morphological appearance of microglia under normal conditions, with changes that are the result of the unique identity and nature of microglia.

Microglia, the brain resident macrophages, can adopt various cellular and transcriptional states, a remarkable feature initially associated to ageing and disease, but also found during normal postnatal development. In the embryonic brain, microglia transiently accumulate at stereotyped "hotspots" such as the corticostriatoamygdalar boundary (CSA), but their roles have remained elusive. Here, using transient depletion and genetic models, we showed that embryonic absence of microglia leads to a cavitary lesion at the CSA, a site where accumulating microglia share a common signature with the postnatal state previously identified as axon tract associated microglia (ATM). This embryonic ATM-like profile was observed at sites of morphogenetic stress that display fragilities during normal development - such as the CSA but also the subcallosal midline - and was strikingly induced by experimentally-driven mechanical damage. Remarkably, these cavitary lesions were transient, as they resorbed in concert with the progressive postnatal repopulation of microglia following embryonic depletion. At the molecular level, we found that core ATM factor Spp1/Osteopontin is partially required for brain integrity at the CSA and subcallosal midline. Taken together, our study reveals a novel role for embryonic microglia in the maintenance of brain integrity during morphogenesis and highlights a link between a specific microglial state and tissue cohesion, with major implications for our understanding of microglial functions in health and disease. * Alice Canzi and Cécile Bridlance contributed equally to this work ° Morgane S. MICROGLIAL P2X4 IN NEUROPATHIC PAIN AND ASSOCIATED COMORBIDITIES: A GENDER INDEPENDENT STORY?

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Damien Gilabert, Nathalie Linck, François Rassendren, Lauriane Ulmann
Université de Montpellier, CNRS, INSERM, Institut De Génomique Fonctionnelle, Montpellier, France

Aims P2X4 purinergic receptors are involved in spinal hyperexcitability during neuropathic pain. In males, it has been described that their activation by ATP in spinal reactive microglia leads to an autocrine release of BDNF (Brain Derived Neurotrophic Factor), responsible for the development of a hyperexcitability and a hyperalgesia. However, recent studies suggest that a P2X4-independent pathway is developed in females. Yet, detailed mechanisms of this potential dimorphism are not understood. Moreover, neuropathic pain is associated with chronic comorbidities such as anxiety and depression-like states that have been suggested to be due to microglia and P2X4 receptors. The aims of this study are 1/to determine whether microglial P2X4 is involved in neuropathic pain in female 2/in which extent P2X4 is involved in neuropathic pain associated comorbidities. **Methods** We perform neuropathy using WT, $P2X4^{-/-}$ and specific microglial P2X4 invalidated mice ($Cx3Cr1Cre^{ERT2}$ x $P2X4^{lox/lox}$ and $Sall1Cre^{ERT2}$ x $P2X4^{lox/lox}$) or inhibit specific P2X4 dependent pathway with pharmacological tools. **Results** Our results indicate a similar *de novo* expression of P2X4 in spinal microglia in male and female mice that is correlated with the neuropathy-induced mechanical hyperalgesia. The genetic deletion or the pharmacological inhibition of P2X4 also reverse hyperalgesia in both sexes. Whereas WT mice of both genders develop chronic anxio-depressive behaviors, microglial P2X4 invalidated mice do not present such comorbidities. **Conclusions** P2X4 in spinal microglia is required for the neuropathy-induced mechanical hyperalgesia in both sexes. Our results also indicate that P2X4 are involved in the development of associated psychiatric comorbidities.

Topographical memory analyzed in mice using the Hamlet test, a novel complex maze.
The Hamlet test is an innovative device providing a complex environment for testing topographic memory in mice. Animals were trained in groups for weeks in a small village with a central agora, streets expanding from it towards five functionalized houses, where they can drink, eat, hide, run, interact with a stranger mouse. Memory was tested by depriving mice from water or food and analyzing their ability to locate the Drink/Eat house. Exploration and memory were analyzed in different strains, gender, and after different training periods and delays. After 2 weeks training, differences in exploration patterns were observed between strains, but not gender. Neuroanatomical structures activated by training, identified using FosB/ΔFosB immunolabelling, showed an involvement of the hippocampus-subiculum-parahippocampal gyrus axis and dopaminergic structures. Training increased hippocampal neurogenesis (cell proliferation and neuronal maturation) and modified the amnesic efficacy of muscarinic or nicotinic cholinergic antagonists. Moreover, topographical disorientation in Alzheimer's disease was addressed using intracerebroventricular injection of amyloid β peptide in trained mice. When retested after 7 days, Aβ-treated mice showed memory impairment. The Hamlet test specifically allows analysis of topographical memory in mice, based on complex environment. It offers an innovative tool for various ethological or pharmacological research needs. For instance, it allowed to examine topographical disorientation, a warning sign in Alzheimer's disease.

Background: Perinatal inflammation is a leading cause of neurodevelopmental injuries including periventricular white matter injury (PWMI) in the premature newborn. Brain inflammation alters development through processes including activation of microglia toward a pro-inflammatory and neurotoxic phenotype causing white matter defect. Investigating microglial phenotype in the context of inflammatory insult could be an effective approach to find therapeutic targets. **Methods:** PWMI was induced by intra-peritoneal interleukine-1-beta (IL-1b) injections from P1 to P3. At P3, whole brain was dissociated (Miltenyi Biotec) and immunostained with fluorophore-conjugated antibodies (Sony Biotechnology, Biolegend, BD Biosciences) and a viability probe (BD). FACS analysis was done within 24h. After doublets and dead cells exclusion, the impact of IL-1b was evaluated in microglia, defined as $CD11b^{+}/CD45^{int}$ cells, on P2RY12, CX3CR1, and CD18 expression. In addition, intracellular presence of VGLUT1 was analyzed to evaluate the level of synaptic phagocytosis. Infiltrating myeloid cells, defined as $CD11b^{+}/CD45^{high}$ cells, were further characterized with CCR2, Ly-6G and Ly-6C expression, to evaluate polymorphonuclear neutrophils (PMNs) and monocytes (Mo) proportions. **Results:** In microglia, IL-1b increased CD11b, P2RY12 and CD18 and decreased CX3CR1. Intracellular VGLUT1 was higher in IL-1b than in control animals, suggesting that inflammation enhanced synaptic phagocytosis, that might be deleterious. IL-1b also leads to brain infiltration of myeloid cells, which express PMNs and Mo markers. **Conclusion:** Multi-parameters flow cytometry is a convenient tool to analyze microglia phenotype and function, and brain recruitment of immune cells in early cerebral inflammation. Further analysis could precise the phenotype variations along time, and the impact of myeloid infiltrate on PWMI.

3D MICROSCOPY REVEALS NEW DETAILS IN AMYLOID PLAQUE-MICROGLIA CROSSTALK IN ALZHEIMER'S DISEASE

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Maria Gotkiewicz, Heikki Tanila
University of Eastern Finland, A.i. Virtanen Institute For Molecular Sciences, Kuopio, Finland

Maria H. Gotkiewicz, Heikki Tanila.
A. I. Virtanen Institute, University of Eastern Finland, 70210 Kuopio, FINLAND **Background:** In the past years, research on Alzheimer's Disease (AD) has emphasized the role of microglia and neuroinflammation in the disease progression. **Aims:** We aimed to define morphological details of microglia clustered around different types of amyloid plaques (AP) and the types of contact they make with them. **Methods:** We cross-bred APP/PS1 mice with CX3CR1-GFP mice exhibiting green fluorescent microglia, and studied them at 6 and 13 months. We stained 100 µm sections at the dorsal hippocampus with anti-beta-amyloid D54D2 antibody. Sections were mounted with DAPI in the mounting medium. Z-stack imaging and 3D rendering was performed with ZEISS LSM800 Airyscan x63 objective. **Results:** We collected 3D images of 54 clusters in 13-month-old mice and 29 clusters in 6-month-old mice. We found that DAPI selectively stained the plaque core. We created our own scale for the DAPI + core intensity. The DAPI+ score correlated positively (Spearman rho) with the plaque diameter (13 months: r=0.63, p=0.0001; 6 months: r=0.43 p=0.02. We also observed that number of microglia in a cluster correlated positively with the plaque diameter. **Conclusion:** 3D imaging and rendering of AP microglia cluster shed new light on microglia reaction to APs. Images in 3D show details that are not visible in 2D light microscopy and might be crucial for understanding the function of microglia in AD. Intracerebral overexpression of miR-669c is protective in mouse ischemic stroke model by targeting MyD88 and inducing alternative microglial/macrophage activation.
Ischemic stroke is a devastating disease without a cure. The available treatments for ischemic stroke, thrombolysis by tissue plasminogen activator, and thrombectomy are suitable only to a fraction of patients and thus novel therapeutic approaches are urgently needed. The neuroinflammatory responses elicited secondary to the ischemic attack further aggravate the stroke-induced neuronal damage. It has been demonstrated that these responses are regulated at the level of non-coding RNAs, especially miRNAs.

Aim. Alterations in the Nerve Growth Factor (NGF) and its high-affinity Tropomyosin Receptor Kinase A (TrkA) signaling is thought to be a driving cause of the striking loss of cholinergic neurons in Alzheimer's disease (AD). However, being strongly multifactorial, AD cannot be simply recapitulated by the NGF-TrkA signaling disruption in neurons of the Central Nervous System (CNS), leading to hypothesize other NGF-responsive cell populations in the CNS. We identified neuroinflammation in an AD mouse model induced by NGF neutralization, pointing our attention to the immune cells resident in the CNS, microglia. Moreover, recently we also discovered the potent immunomodulatory properties of NGF via TrkA on microglia. Hence, our work aims to grasp the role of NGF-TrkA signaling in microglia and how this may contribute to neurodegeneration. **Results and Methods**. To achieve this, we have generated a transgenic mouse carrying a specific and tamoxifen-inducible TrkAKO in microglia. First, we report that microglia express TrkA *in vivo*, both via immunofluorescence staining on mouse brain slices and via mRNA/protein detection in microglia cells isolated from adult mouse brains, and that this TrkA expression is efficiently dampened by tamoxifen administration. Moreover, we report that knocking out TrkA in microglia leads to remarkable differences in microglial density and morphology in several brain and spinal cord areas. Transgenic mice have also revealed deficits in motor learning and a significantly reduced response to pain. **Conclusion**. This indicates the importance of TrkA signaling in microglia and calls for a closer look at their role in AD neurodegeneration.

MICROGLIA POLARIZATION AND ITS MODULATION BY ENVIRONMENTAL FACTORS

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Patrick Wolf[1,2], Chantal Fitterer[1], Thomas Grutter[2], Rémy Schlichter[1]
[1]University of Strasbourg CNRS UPR3212, Institut Des Neurosciences Cellulaires Et Intégratives, Strasbourg, France, [2]UMR 7199 CNRS/University of Strasbourg, Laboratoire De Conception Et Application De Molécules Bioactives, Illkirch, France

Microglia are the immune cells of the central nervous system (CNS). These cells are typically in a resting state, characterized by elongated, ramified processes and a small cellular body. They constantly probe their environment with cytoplasmic extensions and are “activated” in response to a variety of stimuli. Upon recruitment, these cells can acquire diverse phenotypes that display morphological and phenotypic changes. During the M1 state, considered neurotoxic, microglia retract their processes to adopt an amoeboid morphology promoting their multiplication and migration. In this state, they secrete cytotoxic and pro-inflammatory molecules. Conversely, in the M2 state, considered protective and anti-inflammatory, microglial cells have immunomodulatory functions. It was suggested that microglia play multiple and complex roles in the pathophysiology of numerous CNS diseases. While the M2 is beneficial, the M1 state precedes and underlies disease processes. In this context, the possibility of manipulating the activation of microglia and more importantly to trigger their passage from an M1 to an M2 state is a major therapeutic issue. We characterized the impact of the substrate and different soluble molecules on the phenotype of a murine microglial cell line. Our results indicate that some molecules (polymers, amino acids, etc.) induce morphological changes that may be associated with M1 or M2 states. Calcium imaging and molecular biology experiments are underway and should allow us to identify, in living cells, the resting state as well as the M1 and M2 states. Our study should ultimately make it possible to selectively control the functional states of microglia.

Bourgogne Franche-comté - Cnrs Umr 6265- Inrae - Agrosup Dijon, Dijon, France, [2]Institut de Pharmacologie Moléculaire et Cellulaire UMR 7275 CNRS, Université De Nice Sophia Antipolis, Valbonne, France, [3]AgroSup Dijon, Inserm Umr 1231, Dijon, France, [4]IGF, UM, INSERM, CNRS,, Neurosciences, MONTPELLIER, France

Microglia are brain resident immune cells. They are the first line of defense in CNS disturbances. In order to better understand the role of microglial function, we genetically ablate ASC, an essential component of intracellular inflammasome, in microglia in mouse. Mice expressing tamoxifen-inducible Cre-recombinase in CX3CR1^{+} cells were crossed with mice harboring conditional alleles for *Asc*. Treating progeny with tamoxifen generated *Asc*^{MgKO} mice in which ASC was deleted specifically in CX3CR1^{+} cells. Contrary to peripheral CX3CR1^{+} cells which are rapidly replaced by precursors, microglia present a slow turnover in the adult brain. Thus, 5-weeks after tamoxifen injections, the genetic recombination persisted in microglia while it was transient in periphery. We generated a transgenic mouse line with specific *Asc* gene deletion in microglia. After intraperitoneal injection of lipopolysaccharide, body weight and rectal temperature were higher in *Asc*^{MgKO} mice than controls. However, cell blood count revealed similar peripheral immune response in both groups. This indicates that *Asc*^{MgKO} mice were resistant to LPS challenge, and suggests that microglia are key factors that aggravate sepsis response. Furthermore, *Asc*^{MgKO} mice exhibited aberrant control of food intake during normal physiology. Food intake of *Asc*^{MgKO} mice was normal under standard diet but increased under high-fat-diet. This hyperphagic behaviour under HFD reveals that microglial ASC is involved in the acute homeostatic response to dietary fat, limiting excessive calorie intake during short-term HFD. These findings confirm that microglial inflammasome is implicated in the control of immune response, and reveal its contribution in the energy homeostasis regulation during normal physiology.

OPTOGENETIC INVESTIGATION OF MICROGLIA DYNAMICS DURING ZEBRAFISH BRAIN DEVELOPMENT

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Odessa Tanvé[1,2], Éric Bergeron[1], Gabriel Byatt[1,3], Mado Lemieux[1], Paul De Koninck[1,3]
[1]CERVO, Neurosciences Cellulaires Et Moléculaires, Québec, Canada, [2]Université Laval, Médecine, Québec, Canada, [3]Université Ulaval, Biochimie, Microbiologie Et Bio-informatique, Québec, Canada

Microglia are brain cells involved in different functions, such as immune response or brain development. Through their phagocytic activity, microglia can eliminate cells or prune synapses, thereby controlling the formation of neuronal networks. A potentially important influence in this process is the intestinal microbiota, which has been shown to modulate the microglia. To learn more on the impact of the gut microbiota on the phagocytic function of microglia during CNS development, we are establishing an optogenetic larval zebrafish model. We are using a cross between two transgenic lines to visualize glutamatergic neurons in red (DsRed) and microglia in green (GFP). Larvae from 3-16dpf (day post-fertilization), either rendered germ-free or colonized with specific bacteria, are imaged live using confocal or 2-photon microscopy. We are developing deep-learning based tools to categorize microglia morphology and quantify phagocytosis. Our preliminary results suggest that microglia change their morphology during the development of zebrafish brain circuits. In the optic tectum, they are minimally branched and very mobile in 3-5dpf larvae. At 5-6dpf, their protrusions are longer and more branched. At 7dpf, microglia are mostly immobile, while their branched protrusions are moving to scan the nearby environment. Phagocytic function is detected by the inclusion of DsRed from the neurons inside the microglia, as phagosome-like structures. We find that the extent of phagocytosis differentially changes over the 3-7dpf period. We are now comparing how this activity is affected by changes in gut microbiota. We aim to exploit this model to characterize the role of microglia in synaptic pruning.

Intro Air pollution affects the majority of the world's population and has been linked to over 7 million premature deaths per year. There is increasing evidence that exposure to air pollution *in utero* and in early childhood is associated with altered brain development. While oxidative stress and neuroinflammation are documented consequences of PM exposure, cell-specific mechanisms that may be triggered in response to air pollution exposure are less well defined. **Aims** We aimed to investigate the effect of urban (U)PM exposure on microglial-like BV2 and neural stem/precursor-like C17.2, two cell lines differing in source and maturity, to identify common and cell-specific mechanisms. **Methods** BV2 and C17.2 cells were treated with UPM (0-100µg/ml) for 24-72h. Cell health measurements (LDH, proliferation), neuroinflammation (cytokine expression) and oxidative stress (ROS production, NRF2 expression) were quantified. The effect of UPM exposure on mitochondrial function was also determined (TMRM, mitoTEMPO). **Results** We found that BV2 cells were more susceptible to UPM-mediated oxidative stress and cell death than immature C17.2 cells, evidence by a ~70% decrease in cell number in the 100µg/ml UPM-treated BV2 cells compared to control, whereas there was a ~20% decrease in the C17.2 cells. UPM exposure resulted in decreased mitochondrial TMRM intensity and increased mitochondrial ROS in BV2 cells, which could be prevented by mitoTEMPO antioxidant treatment. **Conclusions** UPM has cell-specific mechanistic outcomes dependent on cell type and maturity. Our data suggest that mitochondrial dysfunction may drive UPM-mediated cytotoxicity in BV2 cells, linked to inadequate antioxidant defences.

Early life exposure to air pollution impacts neuronal and glial cell function leading to impaired neurodevelopment.
The World Health Organisation recently listed air pollution as the most significant threat to human health. Air pollution comprises particulate matter (PM), metals, black carbon and gases such as ozone (O), nitrogen dioxide (NO) and carbon monoxide (CO). In addition to respiratory and cardiovascular disease, PM exposure is linked with increased risk of neurodegeneration as well as neurodevelopmental impairments. Critically, studies suggest that PM crosses the placenta, making direct in utero exposure a reality. Rodent models reveal that neuroinflammation, neurotransmitter imbalance and oxidative stress are triggered following gestational/early life exposure to PM, and may be exacerbated by concomitant mitochondrial dysfunction. Gestational PM exposure (potentiated by mitochondrial impairment in the metabolically active neonatal brain) not only impacts neurodevelopment but may sensitise the brain to subsequent cognitive impairment. Having reviewed this field, we conclude that strategies are urgently required to reduce exposure to PM during this sensitive developmental period.

IGF-1 GENE THERAPY ON DOPAMINERGIC NEURONS AND GLIAL CELLS INTERACTION IN EARLY COGNITIVE DEFICITS IN A NEURODEGENERATIVE ANIMAL MODEL

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Macarena Herrera[1], Leandro Champarini[1], Matias Javega Cometto[1], María Bellini[2], Claudia Hereñu[1]
[1]Instituto de Farmacología Experimental de Córdoba (IFEC)- Depto. Parkinson´s disease is a neurodegenerative disorder with a progressive dopaminergic (DA) neuronal loss and a variety of non-motor symptoms, such as cognitive dysfunctions. IGF-1 neuroprotective effects could be, in part, due to changes in the activity of neurons and glia. Aims: 1) to determine the early cognitive decline and the correlation of hippocampal changes in 6OHDA model, 2) to carry out therapeutic approaches with IGF-1 and 3) to analyze modifications on glial cells through different brain areas involved in the proposed circuit. Male Wistar rats were divided into 6 groups according to CPu bilaterally injection with 6OHDA or vehicle (SHAM) and the adenoviral therapy in hippocampus with RAd-DSRed or RAd-IGF1. At 3 weeks, rats were tested for behavioral tasks of cognitive performance and locomotor activity induced by amphetamine. Then rats were perfused, the brains fixed and IHC performed for TH and Iba-1 and GFAP for glial cells. Results: At 20 days post-lesion, memory deficits were observed in 6OHDA rats compared to SHAM rats. This cognitive decline was partially modified with IGF1 gene therapy. We observed changes in GFAP+ astrocytes mainly in the group with IGF-1 and changes of TH expression. IGF-1 gene therapy restored memory impairments and modified cellular activity. Knowledge of this potential therapeutic strategy with IGF-1 gene therapy motivates us to further studies under this experimental model

Intramuscular insulin-like growth factor-1 gene therapy modulates reactive microglia after traumatic brain injury.
Reactive gliosis is a key feature and an important pathophysiological mechanism underlying chronic neurodegeneration following traumatic brain injury (TBI). In this study, we have explored the effects of intramuscular IGF-1 gene therapy on reactive gliosis and functional outcome after an injury of the cerebral cortex. Young adult male rats were intramuscularly injected with a recombinant adenoviral construct harboring the cDNA of human IGF-1 (RAd-IGF1), with a control vector expressing green fluorescent protein (RAd-GFP) or PBS as control. Three weeks after the intramuscular injections of adenoviral vectors, animals were subjected to a unilateral penetrating brain injury. The data revealed that RAd-IGF1 gene therapy significantly increased serum IGF1 levels and improved working memory performance after one week of TBI as compared to PBS or RAd-GFP lesioned animals. At the same time, when we analyzed the effects of therapy on glial scar formation, the treatment with RAd-IGF1 did not modify the number of glial fibrillary acidic protein (GFAP) positive cells, but we observed a decrease in vimentin immunoreactive astrocytes at 7 days post-lesion in the injured hemisphere compared to RAd-GFP group. Moreover, IGF-1 gene therapy reduced the number of Iba1+ cells with reactive phenotype and the number of MHCII + cells in the injured hemisphere. These results suggest that intramuscular IGF-1 gene therapy may represent a new approach to prevent traumatic brain injury outcomes in rats.

Sex frailty differences in ageing mice: Neuropathologies and therapeutic projections.
It is well-established that females live longer than males. Paradoxically, women tend to have poorer health, a condition often named sex frailty. The aim of this study was to evaluate possible frailty predictors in older mice in a sex-specific manner, in order to employ these predictors to follow-up therapy efficiency. To further evaluate therapy effects, we also investigated the use of neurotrophic insulin-like growth factor 1 (IGF-1) gene therapy and its correlation with the expression of this frailty and emotional behaviour. In order to evaluate frailty, we employed two different approaches. We performed a frailty assessment through a 31-Item Clinical Frailty Index and through a Performance-Based 8-Item Frailty Index. Our results show that both indexes are in concordance to evaluate sex differences, but they do not correlate when evaluating IGF-1 therapy effects. Moreover, in order to reduce test-to-test variability for measures of dependent variables, we compared open field results

across studies assessing sex and treatment by means of the z-score normalization. The data show that regular open field parameters submitted to z-score normalization analysis could be a useful tool to identify sex differences in ageing mice after growth factor therapies. Taking this into account, sex is a factor that influences the incidence and/or nature of all major complex diseases; the main outcome of our investigation is the development of an efficient tool that compares the use of different frailty index calculations. This represents an important strategy in order to identify sex differences and therapy efficiency in ageing models.

Novel adenoviral IGF-1 administration modulates the association between depressive symptoms and aging: Does gender matter?
Depression is an illness of multifactorial origin and it seems to involve the dysregulation of many physiological processes. It also has been associated with age and a decreased in the expression of some neurotrophins. However, there are not unique animal models to assay depressive-like behavior, with male and females responding differently. In this study, we report the effects of gender on aged associated depressive signs as frailty, muscular strength and motor activity, as well as the role of intramuscular IGF-1 gene therapy in these processes. We found that male mice had higher general discomfort than females. Moreover, we observed that IGF-1 treatment did not modify this index in females. Regarding male mice, adenoviral IGF-1 injection reduced frailty scores compared to its adenoviral control. According to data, IGF-1 gene therapy had a positive effect on depressive associated hypo-locomotion activity as indicate by delta of total distance and the increment observed in time of mobility in male mice. This neurotrophic factor also increased the latency of time to fall in grip strength in male mice compared to female mice. Moreover, we observed that, while the therapy had no effect on the digging behavior, IGF-1 treatment diminished the latency to dig and increase the number of buried marbles in male mice, having no effect on female. The present study demonstrates that, in order to establish an animal model of depression both, gender and age are relevant variables/factors to consider. We also conclude that a frailty phenotype underlies depressive-like symptoms in an experimental mouse model. Furthermore, we demonstrated that intramuscular injection represents a less invasive, feasible and controllable route of IGF-1 gene delivery for the treatment of the depressive phenotype in old mice.

Aldehyde dehydrogenase 2 in the spotlight: The link between mitochondria and neurodegeneration.
Growing body of evidence suggests that mitochondrial dysfunctions and resultant oxidative stress are likely responsible for many neurodegenerative diseases, including Alzheimer's disease (AD) and Parkinson's disease (PD). Aldehyde dehydrogenase (ALDH) superfamily plays a crucial role in several biological processes including development and detoxification pathways in the organism. In particular, ALDH2 is crucial in the oxidative metabolism of toxic aldehydes in the brain, such as catecholaminergic metabolites (DOPAL and DOPEGAL) and the principal product of lipid peroxidation process 4-HNE. This review aims to deepen the current knowledge regarding to ALDH2 function and its relation with brain-damaging processes that increase the risk to develop neurodegenerative disorders. We focused on relevant literature of what is currently known at molecular and cellular levels in experimental models of these pathologies. The understanding of ALDH2 contributions could be a potential target in new therapeutic approaches for PD and AD due to its crucial role in mitochondrial normal function maintenance that protects against neurotoxicity.

Early IGF-1 Gene Therapy Prevented Oxidative Stress and Cognitive Deficits Induced by Traumatic Brain Injury.
Traumatic Brain Injury (TBI) remains a leading cause of morbidity and mortality in adults under 40 years old. Once primary injury occurs after TBI, neuroinflammation and oxidative stress (OS) are triggered, contributing to the development of many TBI-induced neurological deficits, and reducing the probability of critical trauma patients´ survival. Regardless the research investment on the development of anti-inflammatory and neuroprotective treatments, most pre-clinical studies have failed to report significant effects, probably because of the limited blood brain barrier permeability of no-steroidal or steroidal anti-inflammatory drugs. Lately, neurotrophic factors, such as the insulin-like growth factor 1 (IGF-1), are considered attractive therapeutic alternatives for diverse neurological pathologies, as they are neuromodulators linked to neuroprotection and anti-inflammatory effects. Considering this background, the aim of the present investigation is to test early IGF-1 gene therapy in both OS markers and cognitive deficits induced by TBI. Male Wistar rats were injected Cisterna Magna with recombinant adenoviral vectors containing the IGF-1 gene cDNA 15 min post-TBI. Animals were sacrificed after 60 min, 24 h or 7 days to study the advanced oxidation protein products (AOPP) and malondialdehyde (MDA) levels, to recognize the protein oxidation damage and lipid peroxidation respectively, in the TBI neighboring brain areas. Cognitive deficits were assessed by evaluating working memory 7 days after TBI. The results reported significant increases of AOPP and MDA levels at 60 min,

24 h, and 7 days after TBI in the prefrontal cortex, motor cortex and . In addition, at day 7, TBI also reduced working memory performance. Interestingly, AOPP, and MDA levels in the studied brain areas were significantly reduced after IGF-1 gene therapy that in turn prevented cognitive deficits, restoring TBI-animals working memory performance to similar values regarding control. In conclusion, early IGF-1 gene therapy could be considered a novel therapeutic approach to targeting neuroinflammation as well as to preventing some behavioral deficits related to TBI.

Early Cognitive Impairment Behind Nigrostriatal Circuit Neurotoxicity: Are Astrocytes Involved?
Cognitive dysfunction is one of the most severe nonmotor symptoms of nigrostriatal impairment. This occurs as a result of profound functional and morphological changes of different neuronal circuits, including modifications in the plasticity and architecture of hippocampal synapses. Such alterations can be implicated in the genesis and progression of dementia associated with neurodegenerative diseases including Parkinson-like symptoms. There are few studies regarding cognitive changes in nigrostriatal animal models. The aim of this study was to characterize the onset of memory deficit after induction of neurotoxicity with 6-hydroxydopamine (6-OHDA) and its correlation with hippocampal dysfunction. For this, we bilaterally microinjected 6-OHDA in dorsolateral Caudate-Putamen unit (CPu) and then, animals were tested weekly for working memory, spatial short-term memory, and motor performance. We evaluated tyrosine hydroxylase (TH) as a dopamine marker, aldehyde dehydrogenase 2 (ALDH2), a mitochondria detoxification enzyme and astrocyte glial fibrillar acid protein (GFAP) an immunoreactivity marker involved in different areas: CPu, substantia nigra, prefrontal cortex, and hippocampus. We observed a specific prefrontal cortex and nigrostriatal pathway TH reduction while ALDH2 showed a decrease-positive area in all the studied regions. Moreover, GFAP showed a specific CPu decrease and hippocampus increase of positively stained area on the third week after toxicity. We also evaluated the threshold to induce long-term potentiation in hippocampal excitability. Our findings showed that reduced hippocampal synaptic transmission was accompanied by deficits in memory processes, without affecting motor performance on the third-week post 6-OHDA administration. Our results suggest that 3 weeks after neurotoxic administration, astrocytes and ALDH2 mitochondrial enzyme modifications participate in altering the properties that negatively affect hippocampal function and consequently cognitive behavior.

Aims: VPS10P domain receptors are primarily recognized for their roles in intracellular sorting in neurons. They are crucial for maintaining neuronal integrity and viability, while their dysfunctions are linked to neurodegenerative disorders. Emerging evidence suggests that VPS10P receptors can also play important roles in non-neuronal cells, including microglia. Those cells acquire diverse functional properties depending on the brain's pathophysiological context. We hypothesized that SorLA, a member of the VPS10P family, shapes functional properties of microglia thereby influencing the pathogenesis of brain disorders. As microglia supports the progression of glioma, we explored the function of SorLA in experimental models of glioma. **Methods**: Available RNA-seq datasets and our *in vitro* experiments were examined to compare *SorLA* expression levels in microglia under various conditions. We evaluated the impact of pro- and anti-inflammatory factors on SorLA levels and compared the composition of secretomes of wild type (WT) and *SorLA*($^{-/-}$) murine microglia under control and pro-inflammatory conditions, by using unbiased mass spectrometry and targeted ELISA assays. **Results:** We confirmed a dependence of the *SorLA* expression in microglia on their pro- or anti-inflammatory activation states. The proteomics study revealed potential partners of SorLA, which likely participate in microglial responses to different pathological conditions. **Conclusions**: SorLA controls the pro- versus anti-inflammatory properties of microglia by regulating secretion of bioactive factors. Studies were supported by the National Science Center, Poland (2020/37/B/NZ3/00761, AM) and Foundation for Polish Science (POIR.04.04.00 00 5CEF/18 00, AM).

S-Palmitoylation of Synaptic Proteins as a Novel Mechanism Underlying Sex-Dependent Differences in Neuronal Plasticity. Although sex differences in the brain are prevalent, the knowledge about mechanisms underlying sex-related effects on normal and pathological brain functioning is rather poor. It is known that female and male brains differ in size and connectivity. Moreover, those differences are related to neuronal morphology, synaptic plasticity, and molecular signaling pathways. Among different processes assuring proper synapse functions are posttranslational modifications, and among them, S-palmitoylation (S-PALM) emerges as a crucial mechanism regulating synaptic integrity. Protein S-PALM is governed by a family of palmitoyl acyltransferases, also known as DHHC proteins. Here we focused on the sex-related functional importance of DHHC7 acyltransferase because of its S-PALM action over different synaptic proteins as well as sex steroid receptors. Using the mass spectrometry-based PANIMoni method, we identified sex-dependent differences in the S-PALM of synaptic proteins potentially involved in the regulation of membrane excitability and synaptic transmission as well as in the signaling of proteins involved in the structural plasticity of dendritic spines. To determine a mechanistic source for obtained sex-dependent changes in protein S-PALM, we analyzed synaptoneurosomes isolated from DHHC7-/- (DHHC7KO) female and male mice. Our data showed sex-dependent action of DHHC7 acyltransferase. Furthermore, we revealed that different S-PALM proteins control the same biological processes in male and female synapses.

DIESEL EXHAUST PARTICLES (DEP) IN THE ONSET AND PROGRESSION OF NEUROINFLAMMATION

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Giulia Terribile[1], Sara Di Girolamo[1], Claudia Verderio[2], Giulio Sancini[1]
[1]University of Milano-Bicocca, Department Of Medicine And Surgery, Monza, Italy, [2]CNR Institute of Neuroscience, Research Labs-university Milano-bicocca, Vedano al Lambro, Italy

Ambient air pollution (AP) is becoming a major health problem that affects millions of people worldwide. AP is contamination of the outdoor environment by any chemical, physical or biological agent that modifies the natural characteristics of the atmosphere. Pollutants of major public health concern include particulate matter (PM) of different size, mostly ascribed to diesel exhaust particles (DEP), organic compounds and metals. It is well known that AP causes respiratory and cardiovascular diseases, but recent extensive evidence indicates that it may also negatively affect the brain and contribute to central nervous system (CNS) diseases. AP is believed to exert its neurotoxic function through oxidative stress, glial activation and cerebrovascular damage. The aim of our study is to explore the effects of AP on CNS elements by focusing on microglia, brain cells of nonneural origin, as predominant regulators of neuroinflammation. To explore the effects of AP on microglia we treated, at different time-points, an immortalized line of murine microglia (i.e. BV2) and primary microglia with different concentration of a standard reference material of DEP. After the treatment, we evaluated viability, proliferation, cell morphology and intracellular calcium waves by means of calcium imaging technique. Our preliminary data indicate that DEP affect intracellular Ca^{2+} dynamics after a trigger of ATP and interfere with cell morphology and proliferation.

Hematopoietic stem cell transplantation (HSCT) is a treatment for various malignant and non-malignant blood diseases with over 50,000 procedures annually worldwide. Yet, despite its prevalence, it is still unclear how HSCT affects the brain. Here we performed HSCT in mice using the myeloablative chemotherapy compound busulfan. Histological and *in vivo* imaging showing gradual donor macrophage engraftment of the brain between 6 and 24 weeks post-HSCT becoming resident while having similar surveillant processes comparedto the microglia they replaced. Microglia density halved by 2 weeks and the cells doubled their process area along with the induction of broad senescence markers. All adult neurogenesis was permanently abolished within the first few days. At 6 weeks microglia Ki67 expression peaked which was co-labeled with cell cycle induction markers, a DNA damage marker while lack of DNA incorporation indicated microglia underwent cell cycle arrest at S-G1 phase, unable to pass to G2. In vivo monitoring of post-HSCT microglia recovery after chemical depletion showed a complete lack of regenerative capacity whereas peripheral macrophages engrafted ~95 percent of the brain. Our results suggest busulfan DNA crosslinking causes microglia cell cycle arrest, with the induction of senescence along an anti-apoptotic p21 pathway. After HSCT, the gradual loss of microglia, due to their inability to proliferate, causes a minimal microglia density threshold, allowing permissive engraftment of macrophages in the brain. This strong effect of busulfan induced microglia senescence provides a therapeutic strategy for future cell transplantation-based brain gene therapies.

LIVE-CELL OBSERVATION OF CYTOSOLIC DISC1 SUGGESTS ITS INTERACTIONS WITH CYTOSKELETON AND EXISTENCE OF DISC1 OLIGOMERS

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Keerthana Ramanathan
Universiteit Hasselt, Neuro/dynamic Bioimaging, Hasselt, Belgium

Disrupted In Schizophrenia (DISC1) gene, first identified in a Scottish pedigree is now regarded an important molecular lead to decoding etiology and molecular pathology of major mental illnesses. DISC1, being a scaffold protein, plays many distinct roles in the development and functioning of the brain. Microglia initiates the primary immune response to an injury or an invasion by pathogens in the CNS via phagocytosis, a process that involves continuous re-organization of cytoskeleton. An impairment in this process leads to onset of mental disorders. To probe a connection between impaired microglial phagocytosis and DISC1, we used advanced fluctuation microscopy techniques to quantify the diffusion and interaction of DISC1 in real-time in BV2 microglial cells. We expressed DISC1 in BV2 microglial cells to understand the cellular localization of DISC1 and we observed that that DISC1 diffuses rather slowly in cytoplasm. We also noted that diffusion of DISC1 is further reduced significantly near Actin enriched and Tubulin enriched regions of the cells, and is significantly faster in non-enriched regions of Actin and Tubulin, indicating an affinity for binding with these proteins. Our findings also suggested that DISC1 exists as an oligomer when interacting with Actin and Tubulin. However, further investigation is required to characterize the oligomeric state of DISC1 for interaction with the other proteins and to establish a link between DISC1 and microglial phagocytosis.

GAMMA-FREQUENCY OSCILLATIONS INDUCE CHANGES TO THE MORPHOLOGY AND ACTIVATION OF MICROGLIA

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Meg Elley, Jonathan Witton, Jonathan Brown
University of Exeter, Institute Of Biomedical And Clinical Sciences, Exeter, United Kingdom

Microglia are the immune cells of the central nervous system, which are responsible for mediating neuroinflammation in both health and disease. Their activity has been implicated in several neurological diseases such as dementia, and it is currently debated as to whether the inflammatory response observed in neurodegenerative disease is causative or compensatory. A recent series of studies has demonstrated that inducing neuronal network oscillations at the gamma frequency of 40 Hz is capable of reducing the neuropathology and cognitive deficits associated with dementia, which appears to occur as a result of microglia activation. To investigate the molecular mechanisms underlying this novel neuron-microglia interaction, we have developed an *ex vivo* assay, using hippocampal brain slices prepared from two mouse models (C57BL/6J and CX3CR1-GFP$^{+/-}$, which express GFP exclusively in microglia). This assay involves pharmacologically inducing gamma oscillations in the CA3 region of the hippocampus, fixing the brain tissue and then assessing microglia morphology following staining and mounting using two-photon microscopy. We have demonstrated that microglia morphology is altered in response to gamma oscillations, as microglia that have been exposed to these network oscillations have a significantly more amoeboid morphology than those in control conditions, where no oscillations were induced. These data suggest that sustained gamma oscillations result in the activation of microglia. Therefore, we have developed a new reduced model of gamma oscillation-microglia signalling that can be used to gain mechanistic understanding of this novel neuroimmune interaction.

Later but not early stages of familiar face recognition depend strongly on attentional resources: Evidence from event-related brain potentials.
In everyday life we usually recognise personally familiar faces efficiently and without apparent effort. This study examined to which extent the neural processes involved in recognising personally familiar faces depend on attentional resources by analysing event-related brain potentials. In two experiments, participants were presented with multiple ambient images of highly personally familiar and unfamiliar faces and pictures of butterflies, with a letter string superimposed on each image. Their task was either to indicate when a butterfly occurred (effectively ignoring the letter strings) or to indicate whether each letter string contained the letter X or N. Attentional resource load was manipulated in the letter task by presenting the target among different distractor letters (high load; Experiment 1) or by using only a single repeated letter in each string (low load; Experiment 2). ERPs revealed more negative amplitudes for familiar relative to unfamiliar faces under both high and low load conditions, both in the N250, reflecting the activation of perceptual face representations, and in the subsequent Sustained Familiarity Effect (SFE). Nonetheless, while the magnitude of the N250 effect was not substantially affected by attentional load, the SFE was still present but reduced in the high relative to the low load experiment. These findings suggest that perceptual face representations are activated independent of the demands of a competing task. However, the subsequent SFE, presumably reflecting more sustained activation needed to access identity-specific knowledge that can guide potential interactions, strongly relies on the availability of attentional resources.

NIMODIPINE REDUCES LPS-INDUCED MICROGLIAL ACTIVATION IN PRIMARY MIXED AND ISOLATED MICROGLIA CELL CULTURE

POSTER SESSION 02 - SECTION: MICROGLIA AND NEUROINFLAMMATION

István Pesti, Eszter Farkas, Károly Gulya
Albert Szent-Györgyi Medical School Faculty of Science and Informatics University of Szeged, Department Of Cell Biology And Molecular Medicine, Szeged, Hungary

Background: Microglia is the principal immune cell in the central nervous system. Microglial activation is an early response to brain ischemia which can induce an inflammatory response. Voltage-gated calcium channels (VGCCs) are implicated in microglia activation, which significantly contributes to the progression of neurodegenerative diseases. **Materials and methods**: Primary mixed cell cultures and isolated microglia cultures were prepared from the cortex of neonatal Sprague Dawley rats. On day 9, the plated cells were treated with LPS (20 ng/ml) or nimodipine (an L-type VGCC blocker) alone (5-10-20 uM), or in combination with LPS for 24 h. Microglial activation was evaluated by Iba1 immunolabeling (degree of arborization expressed by a transformation index - Ti) and Western blot analysis, and the visualization of phagocytotic activity with fluorescent microbeads. **Results:** Microglia displayed decreased area, perimeter and Ti in response to the LPS challenge, indicative of amoeboid transformation and activation. When the LPS-challenged cell cultures were treated with nimodipine, significantly more ramified cells were seen already at the lowest concentration. Increased Iba1 signal intensity in Western blot analysis confirmed microglial activation due to LPS treatment, which was decreased particularly by 10 and 20 uM nimodipine. Control microglia engulfed a few microbeads. In contrast, LPS challenge increased microglial phagocytic activity, which was significantly attenuated by nimodipine. **Conclusions**: Nimodipine is a potent vasodilator applied to alleviate vasospasm in acute cerebrovascular conditions. Our data suggest that nimodipine may be applicable in neuroinflammatory conditions including dementia, where neurodegeneration is believed to be linked to neurotoxic microglial activation.

FUNCTIONAL INTEGRATION OF GRAFTED HIPSC DERIVED DOPAMINE NEURONS IN A MOUSE MODEL OF PARKINSON'S DISEASE

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Bérengère Ballion[1], Sébastien Brot[1], Laure Belnoue[1,2], Afsaneh Gaillard[1]

Mainly characterized by a progressive degeneration of mesencephalic dopaminergic (DA) neurons of the substancia nigra pars compacta (SNc), Parkinson's disease (PD) induces major imbalances of basal ganglia loop activity resulting mainly in motor symptoms. Therapeutic proposals are multiple but among the most promising ones, the cell therapy is emerging as a major research axis. In this context, we propose to study the functional integration of an intranigral graft of DA progenitor neurons derived from human induced-pluripotent stem cells (DA-hiPSCs) in 6-OHDA RAG2-KO mouse model of PD. Nine months after 6-OHDA lesion and transplantation, we investigated the electrophysiological functionality of the identified grafted-DA neurons by performing unit extracellular recordings in anesthetized mice to compare their electrophysiological characteristics to SNc dopaminergic neurons collected in control intact mice. We have found essentially similar electrophysiological criteria (frequency -1 to 10 Hz-; typical waveform of biphasic action potential - large duration above 2 ms-; inflection on the positive phase) of described firing patterns (burst and irregular ones) in grafted-DA-hiPSCs and native-DA neurons. The dorsal striatum is the main target structure of DA nigral pathway. In lack of DA release, dorsolateral striatal medium spiny neuron (MSNs) activities are imbalanced. Additional experiments are underway to assesse recovery of MSNs in grafted mice. For this purpose, we will combine electrophysiological recordings of MSN activities and optogenetics to manipulate grafted-DA neuron (expressing photosensible ArchT channels) spontaneous activity. The results of these experiments will provide valuable insights regarding the neuroanatomical and functional integration of grafted neurons.

HOST TO GRAFT PROPAGATION OF ALPHA-SYNUCLEIN IN PARKINSON'S DISEASE: INTRA-NIGRAL VERSUS INTRA-STRIATAL TRANSPLANTATION

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Maëlig Patrigeon[1], Sébastien Brot[1], Marie-Laure Bonnet[1,2], Laure Belnoue[1,2], Afsaneh Gaillard[1]

Parkinson's disease (PD) is a neurodegenerative disorder characterized by the degeneration of nigro-striatal dopaminergic (DA) neurons and by an abnormal accumulation of aggregated α-synuclein (α-syn), the main protein component of Lewy bodies. Intrastriatal transplantation of DA neurons from fetal ventral mesencephalic (fVM) tissue in PD patients have provided proof-of-principle for the cell replacement strategy in this disorder. However, 10–22 years after transplantation, some of the grafted neurons contained Lewy bodies similar to those observed in the host brain. We hypothesize that the striatum represents an unfavorable environment for the development of transplanted neurons, making DA neurons more vulnerable to the disease process. Our project aims to investigate the host-to-graft propagation of α-syn by comparing two transplantation sites, the substantia nigra (SN) and the striatum. For this purpose, we set up two mouse models of PD by injecting AAV2-human α-synuclein A53T viral vector into the SN or the striatum of mice. In these models, DA progenitors originating from mouse fVM or human induced-pluripotent stem cells (iPSC) were transplanted into the SN or the striatum. The host-to-graft propagation of human and phosphorylated α-syn were quantified from 1 month up to 12 months after transplantation. The polarization of the inflammatory response was assessed in astrocytes and microglia to determine whether the inflammatory state is correlated with the level of α-syn propagation. Our preliminary results show 5 months after transplantation that the amount of human α-syn is higher in striatal grafts of striatal viral injected animals compared to other conditions, confirming our hypothesis.

Parkinson's disease (PD) is a neurodegenerative disorder associated with loss of dopaminergic (DA) neurons in the Substantia Nigra *pars compacta* (SNpc). **Cell replacement therapy** holds great promise for effective treatment of PD. Major advances have been made to generate **midbrain DA neurons** from human pluripotent stem cells. Before their use in clinical trials, extensive preclinical safety evaluations are required. One of the main issue to be addressed is the long-term therapeutic effectiveness of these cells. In most of transplantation studies using human cells, the maturation of DA neurons was analyzed over a relatively short period not exceeding 6 months. In present study, we generated midbrain DA progenitors from **human induced pluripotent stem cells (hiPSCs)** and grafted these cells into the SNpc in an animal model of PD. For the first time, we investigated the i**mpact of long-term transplantation up to 12 months** post-transplantation (mpt) and we report long-term survival and functionality of the grafted neurons. Indeed, intranigral grafted neurons express midbrain specific DA markers and allow the **reconstruction of degenerated nigrostriatal pathway**. Surprisingly, at 12 mpt, grafts still contained **immature neurons**, as evidenced by the presence of DCX+ cells. In addition, we observed a decrease in the proportion of SNpc DA neuron subtype compared to 6 mpt. Our results suggest that **longer-term evaluation** of the maturation of neurons derived from human stem cells is mandatory for the safe application of **cell therapy for PD**.

THE ROLE OF SEROTONERGIC RECEPTOR 5-HTR4 IN MOTOR SYMPTOMS AND L-DOPA-INDUCED DYSKINESIA IN PARKINSON'S DISEASE

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Demetra Ballardin[1,2], Alexander Seper[2,3], Jose Manuel Cruz Gamero[2], Heike Rebholz[1,2,3]
[1]GHU-Paris Psychiatrie et Neurosciences, Hôpital Sainte Anne, Paris, France, [2]Université de Paris, Institut De Psychiatrie Et Neuroscience De Paris, Paris, France, [3]Danube private university, Center Of Neurodegeneration, Faculty Of Medicine, Krems, Austria

Parkinson's disease (PD) is caused by a selective loss of midbrain dopaminergic neurons that results in dopamine denervation of the stratum, an imbalance of striatal output pathways and hypersensitivity of direct pathway medium spiny neurons (dMSNs). L-DOPA pharmacotherapy alleviates PD motor symptoms, but causes abnormal involuntary movements termed L-DOPA induced dyskinesia (LID). The serotonergic system has been implicated in LID, since striatal serotonergic terminals take up L-DOPA, convert it to dopamine and uncontrollably release it. We hypothesize that the postsynaptic 5-HT4 receptor represents an interesting player in dyskinesia modulation, due to its high striatal expression and ability of regulating not only the activity of medium spiny neurons but also dopaminergic release. Using the unilateral 6-OHDA PD mouse model, we assessed the effect of 5-HTR4 partial agonist RS 67333 on dyskinesia and locomotion of chronically L-DOPA treated mice. We showed that RS 67333 on its own has an anti-akinetic, i.e. rotational, effect on lesioned mice. Furthermore, the severity of LID is significantly reduced by administration of RS 67333. Immunohistological analysis did not show any significant changes in known dyskinesia markers in striatal neurons. Based on transcriptomic studies, 5-HTR4 appears to be preferentially expressed in indirect pathway neurons, prompting us to perform cell-specific analysis of dyskinesia markers in Drd1a-Cre-RFP and Drd2-Cre-GFP reporter mice. This should enable us to interrogate the mechanisms by which agonism of 5-HTR4 results in a significant reduction of LID in our mouse model.

CELL-TYPE SPECIFIC ALTERATION OF EXCITABILITY IN THE SUBSTANTIA NIGRA PARS RETICULATA OF PARKINSONIAN MICE

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Lorena Delgado Zabalza[1], Jérôme Baufreton[2], Cristina Miguelez[3], Maurice Garret[4]
[1]Neurodegeneratives Diseases Institute (IMN), Dopamine And Neuronal Assemblies, BORDEAUX, France, [2]Institute of Neurodegenerative Disease, Gironde, Bordeaux, France, [3]University of the Basque Country, Pharmacology, Leioa, Spain, [4]INCIA-UMR 5287, Cnrs/university Of Bordeaux, Bordeaux, France

The *substantia nigra pars reticulata* (SNr) is the main output nucleus of the basal ganglia (BG), a subcortical network involved in motor, cognitive and associative functions. Recently, parvalbumin-expressing SNr subpopulation has been associated with motor functions; however the impact of dopamine depletion on the excitability of motor-related SNr-PV neurons is unknown. By combining immunohistochemical and electrophysiological *in vitro* approaches in PVCre::Ai9T mice, we demonstrated that SNr-PV neurons exhibit different anatomical, molecular and electrophysiological profiles than non PV-expressing SNr neurons. Moreover, we revealed that only SNr-PV neurons lose their excitability in the unilateral 6-OHDA mouse model of PD, due to a reduction in NALCN-currents in these neurons. Finally, we have used chemogenetic approaches to improve motor symptoms in parkinsonian mice and to demonstrate a causative relationship between SNr-PV excitability and motor function.

Aims: Here we employ spatial transcriptomics to detect L-DOPA-induced gene expression changes in the forebrain sections of a mouse model of Parkinson's disease. **Methods:** Adult TIF-IA^{DATCreERT2} male mice with extensive loss of midbrain dopaminergic neurons underwent 14-day treatment with L-DOPA (18 mg/kg) or saline and behavioural testing. Brains were extracted 1 hour after the last dose of L-DOPA and processed to obtain spatial transcriptomic cDNA libraries. mRNA-Seq reads were analysed with the Space Ranger software package and a custom analysis pipeline adapting the Model-based Analysis of ChIP-Seq for validating transcript detection. **Results:** A total of 12 sections from 12 individual mice were used to construct spatially-barcoded cDNA libraries: 5 from each mutant treatment group and additional 2 from control animals that received saline. We observed induction of activity-dependent genes expression (e.g., *Fos*, *Junb*, *Egr2*) in the dorsal parts of the cortex and striatum but not the nucleus accumbens or olfactory tubercle of mutant mice treated with L-DOPA. Furthermore, we note that clustering of the of the gene expression results closely recapitulate the anatomical subdivisions in the forebrain. **Conclusions:** Our results show that L-DOPA evokes transcriptional changes in multiple cortical regions and the dorsal striatum in mice with loss of dopaminergic neurons. These observations indicate that treatment of L-DOPA affects, to a varying extent, diverse forebrain structures that regulate distinct motor and cognitive processes. This study was supported by the National Science Centre, Poland with a grant PRELUDIUM no. UMO-2020/37/N/NZ4/03672.

PHOSPHODIESTERASE 2A : FUNCTIONAL ROLE IN THE STRIATUM AND POTENTIALLY NEW THERAPEUTIC TARGET IN PARKINSON'S DISEASE

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Ségolène Bompierre, Cédric Yapo, Liliana Castro, Pierre Vincent
Sorbonne University, Institut De Biologie Paris Seine, PARIS, France

Aims: In Parkinson's disease (PD), the degeneration of dopaminergic neurons results in a deficit of dopamine. This situation is commonly treated pharmacologically by the administration of L-DOPA, a precursor of dopamine. However, after about 10 years of treatment, 80% of patients develop L-DOPA-induced dyskinesia (LID). In the dopamine depleted striatum, D1 type medium-sized spiny neurons (D1 MSN) become hyper-responsive to the stimulation of type 1 dopamine receptors. This hypersensitivity leads to an over-activation of the cAMP/PKA signaling pathway, resulting in the progressive development of LID. Our aim is to evaluate the potential of phosphodiesterase 2A (PDE2A), which degrades cAMP, to reduce D1 MSN hypersensitivity associated with LID. Because of its low affinity for cAMP, the stimulation of PDE2A activity through the nitric oxide (NO)/cGMP pathway could reduce excessive cAMP levels while preserving proper responses. **Methods**: Biosensor imaging reports the dynamics of cAMP/PKA signaling in MSNs in striatal brain slices from young mice, or adult mice in PD and dyskinetic situation. **Results**: In PD and dyskinetic mouse model, D1 MSN display a larger cAMP response to transient dopamine compared to normal mice. The larger cAMP response is similar to the response measured in immature brain. Interestingly, PDE2A activation by the NO/cGMP pathway efficiently reduces the amplitude of the dopamine response in PD and dyskinetic mouse model. **Conclusion**: the stimulation of PDE2A activity moderates excessive cAMP levels in the response to dopamine in dyskinetic mice. These results highlight the therapeutic potential of PDE2A stimulation in the treatment of LID.

HIPPOCAMPAL SLEEP SPINDLE DYNAMICS DURING REM SLEEP AND THEIR DISTINCT UNDERLYING PARVALBUMIN AND SYNAPTIC PROTEINS EXPRESSION IN THE RETICULO-THALAMIC NUCLEUS OF THE PARKINSONIAN RATS

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Ljiljana Radovanovic, Jasna Saponjic, Jelena Petrovic
Institute for Biological Research "Sinisa Stankovic" National Institute of Republic of Serbia, University of Belgrade, Department Of Neurobiology, Belgrade, Serbia

We investigated the alterations of reticulo-thalamic (RT) GABAergic parvalbumin (PV+) interneurons and synaptic re-organization underlying the altered hippocampal high voltage sleep spindle (HVS) dynamics during REM sleep in the rat models of Parkinson's disease (PD). Adult male Wistar rats were implanted for 6h sleep recording during light phase in four experimental groups: control (implanted controls), PD cholinopathy (bilateral lesion of *the nucleus pedunculopontinus tegmentalis*−PPT), hemiparkinsonism (unilateral lesion of *the nucleus substantiae nigrae pars compacta*−SNpc) and hemiparkinsonism with PD cholinopathy (unilateral SNpc/bilateral PPT lesion). Following 14 days of the surgical procedure we differentiated the Wake/NREM/REM 10s epochs, and the HVSs detection and extraction was done automatically (4.1–10 Hz band pass filter, 1s minimum duration) and visually validated. Hippocampal HVS dynamics were analyzed during 1h of NREM/REM sleep. Alterations of the PV+ interneurons and synaptic re-organization within the RT were determined by the parvalbumin, MAP2 and PSD-95 immunostaining. REM sleep is a predisposing state for the HVSs induction in all experimental models of PD neuropathology. Whereas the PD cholinopathy induced the prolongation and higher density of hippocampal HVSs, the hemiparkinsonism with PD cholinopathy increased the hippocampal HVSs intrinsic frequency during REM sleep. In contrast to the unaltered PV+ interneurons/partially enhanced MAP2/suppressed PSD-95 expression during PD cholinopathy, we evidenced the PV+ interneurons reduction/enhanced MAP2/no change of PSD-95 expression in the RT during hemiparkinsonism with PD cholinopathy. Distinct PV+ interneurons alteration and inhibition/excitation balance in the RT could be the underlying mechanisms of HVS generation/alteration during REM sleep in the parkinsonian rats.

Hippocampal and Reticulo-Thalamic Parvalbumin Interneurons and Synaptic Re-Organization during Sleep Disorders in the Rat Models of Parkinson's Disease Neuropathology.
We investigated the alterations of hippocampal and reticulo-thalamic (RT) GABAergic parvalbumin (PV) interneurons and their synaptic re-organizations underlying the prodromal local sleep disorders in the distinct rat models of Parkinson's disease (PD). We demonstrated for the first time that REM sleep is a predisposing state for the high-voltage sleep spindles (HVS) induction in all experimental models of PD, particularly during hippocampal REM sleep in the hemiparkinsonian models. There were the opposite underlying alterations of the hippocampal and RT GABAergic PV+ interneurons along with the distinct MAP2 and PSD-95 expressions. Whereas the PD cholinopathy enhanced the number of PV+ interneurons and suppressed the MAP2/PSD-95 expression, the hemiparkinsonism with PD cholinopathy reduced the number of PV+ interneurons and enhanced the MAP2/PSD-95 expression in the hippocampus. Whereas the PD cholinopathy did not alter PV+ interneurons but partially enhanced MAP2 and suppressed PSD-95 expression remotely in the RT, the hemiparkinsonism with PD cholinopathy reduced the PV+ interneurons, enhanced MAP2, and did not change PSD-95 expression remotely in the RT. Our study demonstrates for the first time an important regulatory role of the hippocampal and RT GABAergic PV+ interneurons and the synaptic protein dynamic alterations in the distinct rat models of PD neuropathology.

Prodromal local sleep disorders in a rat model of Parkinson's disease cholinopathy, hemiparkinsonism and hemiparkinsonism with cholinopathy.
We investigated the prodromal alterations of local sleep, particularly the motor cortical and hippocampal sleep, along with spontaneous locomotor activity in the rat models of Parkinson's disease (PD). We performed our experiments in adult, male

Wistar rats, chronically implanted for sleep recording and divided into four experimental groups: the control (implanted controls), the bilateral pedunculopontine tegmental nucleus (PPT) lesions (PD cholinopathy), the unilateral substantia nigra pars compacta (SNpc) lesions (hemiparkinsonism) and the unilateral SNpc/bilateral PPT lesions (hemiparkinsonism with PD cholinopathy). We followed their sleep, basal locomotor activity and spatial habituation for 14 days following the surgical procedures. Severe prodromal local sleep disturbances in the hemiparkinsonian rats were expressed as sleep fragmentation and distinct local NREM/REM EEG microstructure alterations in both the motor cortex and the hippocampus. Alongside the state-unrelated role of the dopaminergic control of theta oscillations and NREM/REM related sigma and beta oscillations, we demonstrated that the REM neurochemical regulatory substrate is particularly important in the dopaminergic control of beta oscillations. In addition, hippocampal prodromal sleep disorders in the hemiparkinsonian rats were expressed as NREM/REM fragmentation and the opposite impact of dopaminergic versus cholinergic control of the NREM delta and beta oscillation amplitudes in the hippocampus, likewise in the motor cortex versus the hippocampus. All these distinct prodromal local sleep disorders and the dopaminergic vs. cholinergic impact on NREM/REM EEG microstructure alterations are of fundamental importance for the further development and follow-up of PD-modifying therapies, and for the identification of patients who are at risk of developing PD.
Behav Brain Res, 2021; 397

32472657: Petrovic J, Radovanovic L, Saponjic J

Diversity of simultaneous sleep in the motor cortex and hippocampus in rats.

We investigated the homogeneity/heterogeneity of spontaneous sleep, simultaneously recorded in the motor cortex and the hippocampus of control rats, and particularly analysed simultaneous and non-simultaneous motor cortical and hippocampal non-rapid eye movement (NREM)/rapid eye movement (REM) sleep. We demonstrate that the sleep architectures of the motor cortex and hippocampus are different in control rats. There was an increase of NREM duration and a decrease of REM duration in the hippocampus versus the motor cortex. In terms of duration, NREM state is the most heterogeneous in the hippocampus, whereas the REM state is the most heterogeneous in the motor cortex. Whereas the hippocampal NREM duration was increased due to the prolongation of NREM episodes, the hippocampal REM duration decreased due to the decreased number of REM episodes. The heterogeneity of sleep in the motor cortex and hippocampus in control rats was particularly expressed through the inverse alteration of sigma amplitude during NREM sleep and beta/gamma amplitudes during REM sleep in the hippocampus, along with the delta, sigma, beta and gamma amplitudes only during non-simultaneous NREM/REM sleep in the hippocampus. We demonstrated the brain structure-related and NREM/REM state-related heterogeneity of the motor cortical and hippocampal local sleep in control rats. The distinctly altered local NREM/REM states, alongside their episode dynamics and electroencephalographic (EEG) microstructures, suggest the importance of both the local neuronal network substrate and the NREM/REM neurochemical substrate in the control mechanisms of sleep.

Functional and pharmacological analysis of agmatine administration in different cerebral ischemia animal models.

Agmatine (AgM, 100 mg/kg i.p.) effect was tested in parallel at two animal models of cerebral ischemia - rat MCAO model (60'/24 h, 60'/48 h, 90'/24 h, 90'/48 h) and gerbil global ischemia (10') model, administrated 5 min after reperfusion. Aim was to evaluate AgM effect on functional outcome 24 and 48 h after MCAO on neurological and sensor-motor function, and coordination in rats. AgM administration significantly reduced infarct volume, improved neurological score and improved post-ischemic oxidative status. Results of behavioral tests (cylinder test, beam walking test, and adhesive removal test) have shown very effective functional recovery after AgM administration. Efficiency of AgM administration in gerbils was observed in forebrain cortex, striatum, hippocampus, and cerebellum at the level of each examined oxidative stress parameter (nitric oxide level, superoxide production, superoxide dismutase activity, and index of lipid peroxidation) measured in four different time points starting at 3 h up to 48 h after reperfusion. The highest levels were obtained 6 h after the insult. The most sensitive oxidative stress parameter to AgM was nitric oxide. Additionally, we performed pharmacological analysis of AgM on rat isolated common carotid arteries. The findings imply that mixed population of potassium channels located on the smooth muscle cells was involved in common carotid artery response to AgM, with predominance of inward rectifying K channels. In our comparative experimental approach, judged by behavioral, biochemical, as well as pharmacological data, the AgM administration showed an effective reduction of ischemic neurological damage and oxidative stress, hence indicating a direction towards improving post-stroke recovery.

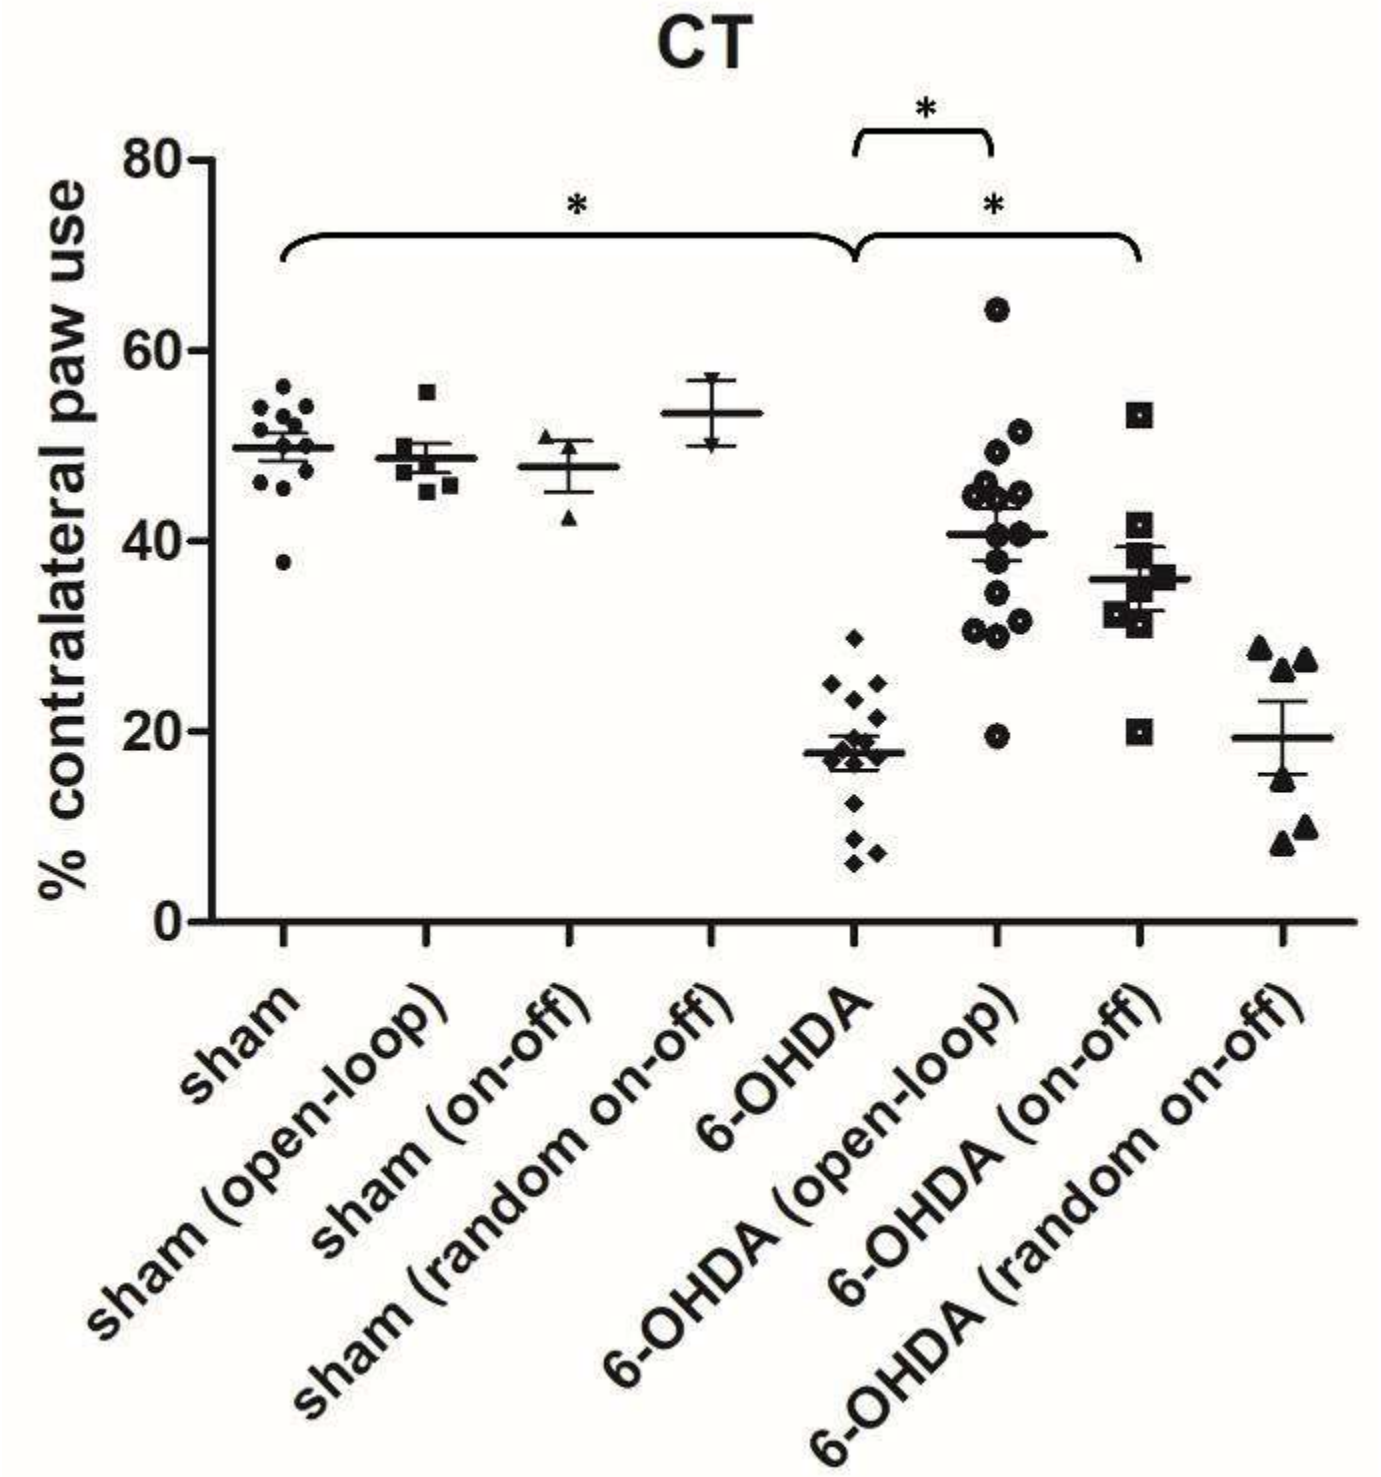
CONVENTIONAL OPEN-LOOP DBS AND ON-OFF CLOSED-LOOP DBS RESULT IN SIMILAR BEHAVIOURAL IMPROVEMENT IN PARKINSONIAN RATS

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Judith Evers[1], Jakub Orlowski[1], Madeleine Lowery[1], Hanne Jahns[2]
[1]UCD, School Of Electrical And Electronic Engneering, Dublin, Ireland, [2]School of Veterinary Medicine, Pathology, Dublin, Ireland

Aims: Closed-loop deep brain stimulation (DBS) has the potential automatically adjust the stimulation delivered to improve efficacy and reduce side effects in the treatment of medically refractory Parkinson's disease (PD). PD animal models provide an effective platform for testing different closed-loop algorithms before trialling in patients. Here we compared on-off closed-loop DBS to open-loop DBS in parkinsonian rats. Methods: A multi-electrode array (Microprobes) for stimulation and recording was implanted into the left subthalamic nucleus and 15 ug 6-OHDA (n=4), or vehicle only (n=3), were injected into the left medial forebrain bundle in 7 rats. Starting 3 weeks post-surgery, open-loop DBS, on-off closed-loop DBS based on recorded STN beta-power and random on-off stimulation were applied using W2100 system (Multichannel systems). Behaviour was assessed during the cylinder and stepping tests. Successful model creation was confirmed via apomorphine-induced rotation test and TH-immunocytochemistry, and electrode location was histologically confirmed. Data were analysed using linear mixed models (R Studio). Results: Contralateral paw use in parkinsonian rats was reduced to 20% in the cylinder test and 25% in the stepping test. Open-loop DBS and on-off closed-loop DBS, but not random on-off stimulation, improved motor function significantly (42%, 38%, 22% in cylinder test (Figure), 38%,38%, 30% in stepping test respectively).



Conclusions: Wireless closed-loop DBS is feasible in the rat and allows natural behaviour. On-off closed-loop stimulation was as effective as open-loop DBS in reducing motor symptoms of PD. In the future, the developed platform can be used to study more complex closed-loop algorithms, for example proportional control.

A systematic review of sacral nerve stimulation mechanisms in the treatment of fecal incontinence and constipation.
Sacral nerve stimulation (SNS) is now well established as a treatment for fecal incontinence (FI) resistant to conservative measures and may also have utility in the management of chronic constipation; however, mechanism of action is not fully understood. End organ effects of SNS have been studied in both clinical and experimental settings, but interpretation is difficult due to the multitude of techniques used and heterogeneity of reported findings. The aim of this study was to systematically review available evidence on the mechanisms of SNS in the treatment of FI and constipation.

Estimation of dispersive properties of encapsulation tissue surrounding deep brain stimulation electrodes in the rat.
The aim of this study was to estimate the electrical properties of the encapsulation tissue surrounding chronically implanted electrodes for deep brain stimulation in the rat. The impedance spectrum of a concentric bipolar microelectrode implanted in the rat brain was measured immediately following surgery and after 8 weeks of implantation. The experimental impedance data were used in combination with a finite element model of the rat brain using a parametric sweep method to estimate the electrical properties of the tissue surrounding the electrode in acute and chronic conditions. In the acute case, the conductivity and relative permittivity of the peri-electrode space were frequency independent with an estimated conductivity of 0.38 S/m and relative permittivity of 123. The electrical properties of the encapsulation tissue in the chronic condition were fitted to a dispersive Cole-Cole model. The estimated conductivity and relative permittivity in the chronic condition at 1 kHz were 0.028 S/m and 2×10, respectively. The estimated tissue properties can be used in combination with computational modeling as a basis for optimization of chronically implanted electrodes to increase the efficacy of long-term neural recording and stimulation.

Is there a nitrergic modulation of the rat external anal sphincter?
Nitric oxide is known to relax the internal anal sphincter, but its effect on the external anal sphincter (EAS) is unknown. The aim of this study was to investigate whether there is a nitrergic nerve plexus that modulates the EAS, similar to that found in oesophageal striated muscle. An in vitro ring preparation of rat anal canal was used to evaluate the effects of the nitric oxide synthase inhibitor N(ω)-nitro-L-arginine (L-NNA) and the NO donor sodium nitroprusside (SNP) on the EAS in conditions of neuromuscular blockade and the effect of SNP on nerve-evoked contractions. Immunohistological experiments were conducted to determine whether the neuronal isoform of nitric oxide synthase (nNOS) is present in the EAS. During direct muscle stimulation neither L-NNA (P = 0.32) nor SNP (P = 0.19) significantly changed the EF(50), which is the frequency at which 50% of maximal contraction is reached, compared with a time-dependent control. Nerve-evoked contractions were also not altered by addition of SNP to the tissue bath. Immunohistohistological experiments clearly showed co-localization of nNOS-positive nerve fibres at motor endplates of the oesophagus but not in the EAS. The internal anal sphincter was richly innervated by nitrergic fibres, but these did not extend into the EAS. In conclusion, there are no nitrergic motor fibres innervating the EAS, neurotransmission at the motor endplates is not affected by NO, and NO does not affect muscle force directly in conditions of neuromuscular blockade. There is, therefore, no evidence that EAS contraction is directly modulated by NO or by pudendal nitrergic fibres or diffusion from neighbouring nitrergic plexuses of the anal canal.

Acute lumbosacral nerve stimulation does not affect anorectal motor function in a rodent model.
Sacral nerve stimulation has become a first line treatment for fecal incontinence, however, its effect on the motor function of

the anorectum is uncertain. The aim of this study was to apply acute lumbosacral nerve stimulation in an animal model and to determine its effect on the external and internal anal sphincter forces, the rectoanal inhibitory and excitatory reflexes, and the slow wave frequency of the internal anal sphincter.

Reversal of sensory deficit through sacral neuromodulation in an animal model of fecal incontinence.
Sacral neuromodulation (SNM) is a treatment option for intractable fecal incontinence. The mechanism of action is unclear, however, increasing evidence for afferent somatosensory effects exists. This study's aim was to elucidate effects of acute SNM on the cerebral cortex in a rodent model of pudendal nerve injury.

Effects of stimulation frequency and intensity in sacral neuromodulation on anorectal inputs to the somatosensory cortex in an experimental model.
Although sacral neuromodulation (SNM) is an established treatment for faecal incontinence, stimulation parameters have been derived empirically and only one frequency (14 Hz) is employed clinically. The aim of this study was to test a range of stimulation frequencies to establish an optimal frequency of SNM for maximum augmentation of anal canal cortical evoked potentials (EPs) in an animal model.

STIMULATION OF GABA-Aα2/3, BUT NOT α1, RECEPTORS INHIBITS ESSENTIAL AND PARKINSONIAN-LIKE TREMORS IN RATS

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Barbara Kosmowska[1], Martyna Paleczna[1], Dominika Biała[1], Justyna Kadłuczka[1], Jadwiga Wardas[1], Jeffrey Witkin[2,3], James Cook[2,3], Dishary Sharmin[2], Monika Marcinkowska[4], Katarzyna Kuter-Nowak[1]

Tremors are common symptoms of many neurological diseases, like Parkinson's disease or essential tremor (ET). Unfortunately, current tremor pharmacotherapy is often ineffective, and the molecular basis is not yet fully understood. It is known, however, that the basal ganglia with the key dopamine and the GABA-regulated cerebello-thalamo-cortical loop are involved in parkinsonian tremor. Disturbances in GABAergic transmission are observed also in ET. Interestingly, $GABA_A$ receptors play an important role in the pathophysiology of both tremors. The study aimed to investigate the antitremor potential of $GABA_A$ positive allosteric modulators, zolpidem (selective for α1 subunits) and methyl 8-ethynyl-6-(pyridin-2-yl)-4H-benzo[f]imidazo[1,5-a][1,4]diazepine-3-carboxylate, MP-III-024 (α2/3) in two different rat tremor models. Harmaline (15 mg/kg) was used to model ET, while parkinsonian-like tremor, observed as tremulous jaw movements (TJMs), was induced by pimozide (1 mg/kg ip, 7 days). Zolpidem (0.34, 0.67, 1.01 mg/kg ip) was administered simultaneously with the model compounds, while MP-III-024 (3.2, 10 mg/kg ip) 30 min before them. Harmaline-induced tremor was measured using Force Plate Actimeters, and TJMs after pimozide were counted manually by an observer blind to treatments. Zolpidem did not influence harmaline-induced tremor or pimozide-induced TJMs. MP-III-024 significantly reduced harmaline tremor in both doses used, but the effect was stronger for the lower dose. Furthermore, MP-III-024 also inhibited pimozide-induced TJMs, at both doses. The obtained results suggest that stimulation of the α2/3, but not α1, subunit of the $GABA_A$ receptor can inhibit both ET and parkinsonian-like tremors. These findings encourage further research in this direction with the goal of developing new potential therapies.

The Pathophysiology and Treatment of Essential Tremor: The Role of Adenosine and Dopamine Receptors in Animal Models.
Essential tremor (ET) is one of the most common neurological disorders that often affects people in the prime of their lives, leading to a significant reduction in their quality of life, gradually making them unable to independently perform the simplest activities. Here we show that current ET pharmacotherapy often does not sufficiently alleviate disease symptoms and is completely ineffective in more than 30% of patients. At present, deep brain stimulation of the motor thalamus is the most effective ET treatment. However, like any brain surgery, it can cause many undesirable side effects; thus, it is only performed in patients with an advanced disease who are not responsive to drugs. Therefore, it seems extremely important to look for new strategies for treating ET. The purpose of this review is to summarize the current knowledge on the pathomechanism of ET based on studies in animal models of the disease, as well as to present and discuss the results of research available to date on various substances affecting dopamine (mainly D3) or adenosine A1 receptors, which, due to their ability to modulate harmaline-induced tremor, may provide the basis for the development of new potential therapies for ET in the future.

Blockade of adenosine A receptors inhibits Tremulous Jaw Movements as well as expression of zif-268 and GAD65 mRNAs in brain motor structures.
Tremor is one of the motor symptoms of Parkinson's disease (PD), present also in neuroleptic-induced parkinsonism. Tremulous Jaw Movements (TJMs) are suggested to be a well-validated rodent model of PD resting tremor. TJMs can be induced by typical antipsychotics and are known to be reduced by different drugs, including adenosine A receptor

antagonists. The aim of the present study was to search for brain structures involved in the tremorolytic action of SCH58261, a selective A receptor antagonist, in TJMs induced by subchronic pimozide. Besides TJMs, we evaluated in the same animals the expression of zif-268 mRNA (neuronal responsiveness marker), and mRNA levels for glutamic acid decarboxylase 65-kDa isoform (GAD65) and vesicular glutamate transporters 1 and 2 (vGluT1/2) in selected brain structures, as markers of GABAergic and glutamatergic neurons, respectively. We found that SCH58261 reduced the pimozide-induced TJMs. Pimozide increased the zif-268 mRNA level in the striatum, nucleus accumbens (NAc) core, and substantia nigra pars reticulata (SNr). Additionally, it increased GAD65 mRNA in the striatum and SNr, and vGluT2 mRNA levels in the subthalamic nucleus (STN). A positive correlation between zif-268, GAD65 and vGluT2 mRNAs and TJMs was found. SCH58261 reversed the pimozide-increased zif-268 mRNA in the striatum and NAc core and GAD65 mRNA in the striatum and SNr. In contrast, SCH58261 did not influence vGluT2 mRNA in STN. The present study suggests an importance of the striato-subthalamo-nigro-thalamic circuit in neuroleptic-induced TJMs. The tremorolytic effect of A receptor blockade seems to involve this circuit bypassing, however, STN.

Potential antipsychotic action of the selective agonist of adenosine A1 receptors, 5'-Cl-5'-deoxy-ENBA, in amphetamine and MK-801 rat models.
Disturbances of dopaminergic and glutamatergic transmissions have been suggested to be involved in the pathomechanisms underlying psychotic symptoms of schizophrenia. In line with this concept, hyperlocomotion induced by the dopaminomimetic amphetamine and the uncompetitive antagonist of NMDA receptors MK-801 (dizocilpine) in rodents is a generally established model for screening of new potential antipsychotic drugs. Since recent studies have indicated that receptors for adenosine may be targets for antipsychotic therapy, the aim of the present study was to investigate an influence of 5'-Cl-5'-deoxy-ENBA, a potent and selective adenosine A receptor agonist, on hyperlocomotion induced by amphetamine and MK-801.

Pramipexole Reduces zif-268 mRNA Expression in Brain Structures involved in the Generation of Harmaline-Induced Tremor.
Essential tremor is one of the most common neurological disorders, however, it is not sufficiently controlled with currently available pharmacotherapy. Our recent study has shown that pramipexole, a drug efficient in inhibiting parkinsonian tremor, reduced the harmaline-induced tremor in rats, generally accepted to be a model of essential tremor. The aim of the present study was to investigate brain targets for the tremorolytic effect of pramipexole by determination of the early activity-dependent gene zif-268 mRNA expression. Tremor in rats was induced by harmaline administered at a dose of 15 mg/kg ip. Pramipexole was administered at a low dose of 0.1 mg/kg sc. Tremor was measured by Force Plate Actimeters where four force transducers located below the corners of the plate tracked the animal's position on a Cartesian plane. The zif-268 mRNA expression was analyzed by in situ hybridization in brain slices. Harmaline induced tremor and increased zif-268 mRNA levels in the inferior olive, cerebellar cortex, ventroanterior/ventrolateral thalamic nuclei and motor cortex. Pramipexole reversed both the harmaline-induced tremor and the increase in zif-268 mRNA expression in the inferior olive, cerebellar cortex and motor cortex. Moreover, the tremor intensity correlated positively with zif-268 mRNA expression in the above structures. The present results seem to suggest that the tremorolytic effect of pramipexole is related to the modulation of the harmaline-increased neuronal activity in the tremor network which includes the inferior olive, cerebellar cortex and motor cortex. Potential mechanisms underlying the above pramipexole action are discussed.

Inhibition of Excessive Glutamatergic Transmission in the Ventral Thalamic Nuclei by a Selective Adenosine A1 Receptor Agonist, 5'-Chloro-5'-Deoxy-(±)-ENBA Underlies its Tremorolytic Effect in the Harmaline-Induced Model of Essential Tremor.
The primary cause of harmaline tremor, which is a model of essential tremor (ET) in animals, is excessive activation of olivocerebellar glutamatergic climbing fibers. Our recent study indicated that 5'-chloro-5'-deoxy-(±)-N6-(±)-(endo-norborn-2-yl)adenosine (5'Cl5'd-(±)-ENBA), a potent and selective adenosine A1 receptor (A1) agonist, inhibited harmaline tremor. The present study was aimed to evaluate the role of glutamatergic transmission system in 5'Cl5'd-(±)-ENBA tremorolytic action in the harmaline model in rats, by analyzing glutamate release in the motor nuclei of the thalamus and mRNA expression of glutamatergic neuron markers (vGlut1/2) in reference to the general neuronal activity marker (zif-268) in different brain structures. The extracellular glutamate level in the motor thalamus was evaluated by in vivo microdialysis and the vGlut1/vGlut2 and zif-268 mRNA expression was analyzed by in situ hybridization. The intensity of tremor was measured automatically using Force Plate Actimeters (FPAs). 5'Cl5'd-(±)-ENBA (0.5 mg/kg) given 30 min before harmaline (30 mg/kg) decreased the harmaline-induced excessive glutamate release in the motor thalamus and reversed harmaline-induced molecular effects, such as elevation of the vGlut1 mRNA expression in the inferior olive (IO) and decrease in the motor cortex, as well as an increase of the zif-268 mRNA expression in the IO, motor thalamus and motor cortex. Moreover, 5'Cl5'd-

(±)-ENBA reduced harmaline tremor by lowering its power in 9-15 Hz frequency band. Our findings show that A1 stimulation decreases glutamate release in the motor thalamic nuclei in the harmaline model of ET, suggesting that A1 receptors, especially in this structure, may be a potential therapeutic target in this disorder.

Adaptive down-regulation of the serotonin transporter in the 6-hydroxydopamine-induced rat model of preclinical stages of Parkinson's disease and after chronic pramipexole treatment.
Our recent study has indicated that a moderate lesion induced by bilateral 6-hydroxydopamine (6-OHDA) injections into the ventrolateral region of the caudate-putamen (CP) in rats, modeling preclinical stages of Parkinson's disease, induces a "depressive-like" behavior which is reversed by chronic treatment with pramipexole (PRA). The aim of the present study was to examine the influence of the above lesion and chronic PRA treatment on binding to the serotonin transporter (SERT) in different brain regions. As before, 6-OHDA (15 μg/2.5 μl) was administered bilaterally into the CP. PRA (1mg/kg) was injected subcutaneously twice a day for 2 weeks. Serotonergic and dopaminergic neurons of the dorsal raphe (DR) were immunostained for tryptophan hydroxylase and tyrosine hydroxylase, respectively, and were counted stereologically. Binding of [(3)H]GBR 12,935 to the dopamine transporter (DAT) and [(3)H]citalopram to SERT was analyzed autoradiographically. Intrastriatal 6-OHDA injections decreased the number of dopaminergic, but not serotonergic neurons in the DR. 6-OHDA reduced the DAT binding in the CP, and SERT binding in the nigrostriatal system (CP, substantia nigra (SN)), limbic system (ventral tegmental area (VTA), nucleus accumbens (NAC), amygdala, prefrontal cortex (PFCX), habenula, hippocampus) and DR. A significant positive correlation was found between DAT and SERT binding in the CP. Chronic PRA did not influence DAT binding but reduced SERT binding in the above structures, and deepened the lesion-induced losses in the core region of the NAC, SN, VTA and PFCX. The present study indicates that both the lesion of dopaminergic neurons and chronic PRA administration induce adaptive down-regulation of SERT binding. Moreover, although involvement of stimulation of dopaminergic transmission by chronic PRA in its "antidepressant" effect seems to be prevalent, additional contribution of SERT inhibition cannot be excluded.

Pramipexole at a Low Dose Induces Beneficial Effect in the Harmaline-induced Model of Essential Tremor in Rats.
The aim of the study was to examine the effects of preferential agonists of dopamine D3 receptors: pramipexole and 7-OH-DPAT on the harmaline-induced tremor in rats (a model of essential tremor, ET). To study receptor mechanisms of these drugs, rats were pretreated with dopamine D3 receptor antagonists--SB-277011-A and SR-21502, an antagonist of presynaptic D2/D3 receptors--amisulpride, or a nonselective antagonist of D2-like receptors, haloperidol, at a postsynaptic dose.

Alterations of BDNF and trkB mRNA expression in the 6-hydroxydopamine-induced model of preclinical stages of Parkinson's disease: an influence of chronic pramipexole in rats.
Our recent study has indicated that a moderate lesion of the mesostriatal and mesolimbic pathways in rats, modelling preclinical stages of Parkinson's disease, induces a depressive-like behaviour which is reversed by chronic treatment with pramipexole. The purpose of the present study was to examine the role of brain derived neurotrophic factor (BDNF) signalling in the aforementioned model of depression. Therefore, we investigated the influence of 6-hydoxydopamine (6-OHDA) administration into the ventral region of the caudate-putamen on mRNA levels of BDNF and tropomyosin-related kinase B (trkB) receptor. The BDNF and trkB mRNA levels were determined in the nigrostriatal and limbic structures by in situ hybridization 2 weeks after the operation. Pramipexole (1 mg/kg sc twice a day) and imipramine (10 mg/kg ip once a day)

were injected for 2 weeks. The lesion lowered the BDNF and trkB mRNA levels in the hippocampus [CA1, CA3 and dentate gyrus (DG)] and amygdala (basolateral/lateral) as well as the BDNF mRNA content in the habenula (medial/lateral). The lesion did not influence BDNF and trkB expression in the caudate-putamen, substantia nigra, nucleus accumbens (shell and core) and ventral tegmental area (VTA). Chronic imipramine reversed the lesion-induced decreases in BDNF mRNA in the DG. Chronic pramipexole increased BDNF mRNA, but decreased trkB mRNA in the VTA in lesioned rats. Furthermore, it reduced BDNF and trkB mRNA expression in the shell and core of the nucleus accumbens, BDNF mRNA in the amygdala and trkB mRNA in the caudate-putamen in these animals. The present study indicates that both the 6-OHDA-induced dopaminergic lesion and chronic pramipexole influence BDNF signalling in limbic structures, which may be related to their pro-depressive and antidepressant activity in rats, respectively.

CELL-TYPE SPECIFIC TRANSCRIPTIONAL CHANGES IN THE STRIATUM OF A 6-HYDROXYDOPAMINE MOUSE MODEL

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Lisbeth Harder[1], Leonardo Garma[1], Mónica Diez-Salguero[2], Juan Barba-Reyes[2], Ana Muñoz-Manchado[2]
[1]Karolinska Institutet, Department Of Medical Biochemistry And Biophysics, Division Of Molecular Neurobiology, Stockholm, Sweden, [2]Universidad de Cádiz, Departamento De Biomedicina, Biotecnología Y Salud Pública, Cádiz, Spain

The neurodegenerative movement disorder Parkinson's disease (PD) is the neuronal disorder with the fastest growing case numbers worldwide but disease mechanisms on cellular level are still not fully understood. One hallmark seen in human PD patients, neuronal loss in the substantia nigra (SN) causing a profound lack of dopaminergic signalling in the striatum, can be reproduced in mice using the neurotoxin 6-hydroxydopamine (6-OHDA). Applying single-cell RNA-sequencing to identify striatal cell populations, cell-type specific transcriptomic changes and the resulting alterations in gene regulatory patterns, can therefore allow valuable insides into cause and progression of PD. CD1 male mice, age 9-10 weeks, received intracranial unilateral injections with 6-OHDA or vehicle, either in the SN or the medial forebrain bundle (MFB). Thereby, the mice lose dopaminergic signalling in one half of the striatum, providing the possibility to compare changes within animals, as well as between groups. Striatal tissue was extracted 6-8 weeks after injection, cells were isolated, sequenced and six major cell classes were identified. A compositional analysis indicated alterations in the neuronal part of the data set after MFB lesion. Furthermore, differential expression analysis identified a set of statistically significant regulated genes in the striatum of mice receiving the 6-OHDA lesion. These preliminary findings indicate cell-type specific changes in the striatal gene regulation due to dopamine depletion and are a first step towards identifying new potential treatment targets.

Maternal thyroid hormone is required for parvalbumin neurone development in the anterior hypothalamic area.
Thyroid hormone (TH) is crucial for brain development and function. This becomes most evident in untreated congenital hypothyroidism, leading to irreversible mental retardation. Likewise, maternal hypothyroxinaemia, a lack of TH during pregnancy, is associated with neurological dysfunction in the offspring, such as autism and reduced intellectual capacity. In the brain, TH acts mainly through TH receptor α1 (TRα1). Consequently, mice heterozygous for a dominant-negative mutation in TRα1 display profound neuroanatomical abnormalities including deranged development of parvalbumin neurones. However, the exact timing and orchestration of TH signalling during parvalbumin neurone development remains elusive. In the present study, we dissect the development of parvalbumin neurones in the anterior hypothalamic area (AHA) in male mice using different mouse models with impaired pre- and postnatal TH signalling in combination with bromodeoxyuridine birth dating and immunohistochemistry. Our data reveal that hypothalamic parvalbumin neurones are born at embryonic day 12 and are first detected in the AHA at postnatal day 8, reaching their full population number at P13. Interestingly, they do not require TH postnatally because their development is not impaired in mice with impaired TH signalling after birth. By contrast, however, these neurones crucially depend on TH through TRα1 signalling in the second half of pregnancy, when the hormone is almost exclusively provided by the mother. For the first time, our findings directly link a maternal hormone to a neuroanatomical substrate in the foetal brain, and underline the importance of proper TH signalling during pregnancy for offspring mental health. Given the role of hypothalamic parvalbumin neurones in the central control of blood pressure, the present study advocates the inclusion of cardiovascular parameters in the current discussion on possible TH substitution in maternal hypothyroxinaemia.

Thermoregulatory and Cardiovascular Consequences of a Transient Thyrotoxicosis and Recovery in Male Mice.
Thyroid hormones play a major role in body homeostasis, regulating energy expenditure and cardiovascular function. Given that obese people or athletes might consider rapid weight loss as beneficial, voluntary intoxication with T4 preparations is a growing cause for thyrotoxicosis. However, the long-lasting effects of transient thyrotoxicosis are poorly understood. Here we examined metabolic, thermoregulatory, and cardiovascular function upon induction and recovery from a 2-week thyrotoxicosis

in male C57BL/6J mice. Our results showed that T4 treatment caused tachycardia, decreased hepatic glycogen stores, and higher body temperature as expected; however, we did not observe an increase in brown fat thermogenesis or decreased tail heat loss, suggesting that these tissues do not contribute to the hyperthermia induced by thyroid hormone. Most interestingly, when the T4 treatment was ended, a pronounced bradycardia was observed in the animals, which was likely caused by a rapid decline of T3 even below baseline levels. On the molecular level, this was accompanied by an overexpression of cardiac phospholamban and Serca2a mRNA, supporting the hypothesis that the heart depends more on T3 than T4. Our findings therefore demonstrate that a transient thyrotoxicosis can have pathological effects that even persist beyond the recovery of serum T4 levels, and in particular the observed bradycardia could be of clinical relevance when treating hyperthyroid patients.

In vivo Effects of Repeated Thyronamine Administration in Male C57BL/6J Mice.
Thyronamines are decarboxylated and deiodinated metabolites of thyroid hormones (THs). Of all possible thyronamine variants, only 3-iodothyronamine (3-TAM) and iodine-free thyronamine (TAM) have been detected in vivo. While intensive research has been done on the (patho-)physiological action of 3-TAM, the role of TAM has been studied less intensively.

Dwarfism and insulin resistance in male offspring caused by α1-adrenergic antagonism during pregnancy.
Maternal and environmental factors control the epigenetic fetal programming of the embryo, thereby defining the susceptibility for metabolic or endocrine disorders in the offspring. Pharmacological interventions required as a consequence of gestational problems, e.g. hypertension, can potentially interfere with correct fetal programming. As epigenetic alterations are usually only revealed later in life and not detected in studies focusing on early perinatal outcomes, little is known about the long-term epigenetic effects of gestational drug treatments. We sought to test the consequences of maternal α1-adrenergic antagonism during pregnancy, which can occur e.g. during hypertension treatment, for the endocrine and metabolic phenotype of the offspring.

Thyroid-Hormone-Induced Browning of White Adipose Tissue Does Not Contribute to Thermogenesis and Glucose Consumption.
Regulation of body temperature critically depends on thyroid hormone (TH). Recent studies revealed that TH induces browning of white adipose tissue, possibly contributing to the observed hyperthermia in hyperthyroid patients and potentially providing metabolic benefits. Here, we show that browning by TH requires TH-receptor β and occurs independently of the sympathetic nervous system. The beige fat, however, lacks sufficient adrenergic stimulation and is not metabolically activated despite high levels of uncoupling protein 1 (UCP1). Studies at different environmental temperatures reveal that TH instead causes hyperthermia by actions in skeletal muscle combined with a central body temperature set-point elevation. Consequently, the metabolic and thermogenic effects of systemic hyperthyroidism were maintained in UCP1 knockout mice, demonstrating that neither beige nor brown fat contributes to the TH-induced hyperthermia and elevated glucose consumption, and underlining that the mere presence of UCP1 is insufficient to draw conclusions on the therapeutic potential of browning agents.

CD5L Constitutes a Novel Biomarker for Integrated Hepatic Thyroid Hormone Action.
Pathological conditions of the thyroid hormone (TH) system are routinely diagnosed by using serum concentrations of thyrotropin (TSH), which is sufficient in most cases. However, in certain conditions, such as resistance to TH due to mutations in (RTHb) or TSH-releasing pituitary adenoma (TSHoma), TSH may be insufficient for a correct diagnosis, even in combination with serum TH concentrations. Likewise, under TH replacement therapy, these parameters can be misleading

and do not always allow optimal treatment. Hence, additional biomarkers to assess challenging clinical conditions would be highly beneficial. Data from untargeted multi-omics analyses of plasma samples from experimental thyrotoxicosis in human and mouse were exploited to identify proteins that might represent possible biomarkers of TH function. Subsequent mouse studies were used to identify the tissue of origin and the involvement of the two different TH receptors (TR). For in-depth characterization of the underlying cellular mechanisms, primary mouse cells were used. The analysis of the plasma proteome data sets revealed 16 plasma proteins that were concordantly differentially abundant under thyroxine treatment compared with euthyroid controls across the two species. These originated predominantly from liver, spleen, and bone. Independent studies in a clinical cohort and different mouse models identified CD5L as the most robust putative biomarker under different serum TH states and treatment periods. studies revealed that CD5L originates from proinflammatory M1 macrophages, which are similar to liver-residing Kupffer cells, and is regulated by an indirect mechanism requiring the secretion of a yet unknown factor from hepatocytes. In agreement with the role of TRα1 in immune cells and the TRβ-dependent hepatocyte-derived signaling, the regulation of expression depended on both TR isoforms. Our results identify several novel targets of TH action in serum, with CD5L as the most robust marker. Although further studies will be needed to validate the specificity of these targets, CD5L seems to be a promising candidate to assess TH action in hepatocyte-macrophage crosstalk.

Central Hypothyroidism Impairs Heart Rate Stability and Prevents Thyroid Hormone-Induced Cardiac Hypertrophy and Pyrexia.
Tachycardia, cardiac hypertrophy, and elevated body temperature are major signs of systemic hyperthyroidism, which are considered to reflect the excessive thyroid hormone (TH) action in the respective peripheral tissues. However, recent observations indicate that the central actions of TH also contribute substantially to cardiovascular regulation and thermogenesis. In this study, we dissect the individual contributions of peripheral TH action versus the central effects in body temperature regulation and cardiovascular functions by taking advantage of mice lacking the TH transporters monocarboxylate transporter 8 (MCT8) and organic anion transporting polypeptide 1C1 (OATP1C1) (double knock-out [dko]), which exhibit elevated serum triiodothyronine (T3) levels while their brain is in a profoundly hypothyroid state. We compared these animals with wild-type (WT) mice that were treated orally with T3 to achieve similarly elevated serum T3 levels, but are centrally hyperthyroid. For the studies, we used radiotelemetry, infrared thermography, gene expression profiling, Western blot analyses, and enzyme linked immunosorbent assays (ELISA) assays. Our analyses revealed mild hyperthermia and cardiac hypertrophy in T3-treated WT mice but not in dko animals, suggesting that central actions of TH are required for these hyperthyroid phenotypes. Although the average heart rate was unaffected in either model, the dko exhibited an altered heart rate frequency distribution with tachycardic bursts in active periods and bradycardic episodes during resting time, demonstrating that the stabilization of heart rate by the autonomic nervous system can be impaired in centrally hypothyroid animals. Our studies unravel distinct phenotypical traits of hyperthyroidism that depend on an intact central nervous system, and provide valuable insight into the cardiovascular pathology of the Allan-Herndon-Dudley syndrome, a condition caused by the lack of MCT8 in humans.

The Tissue Clock Network: Driver and Gatekeeper of Circadian Physiology: Circadian rhythms are integrated outputs of central and peripheral tissue clocks interacting in a complex manner - from drivers to gatekeepers.
In mammals, a network of cellular circadian clocks organizes physiology and behavior along the 24-h day cycle. The traditional hierarchical model of circadian clock organization with a central pacemaker and peripheral slave oscillators has recently been challenged by studies combining tissue-specific mouse mutants with transcriptome analyses. First, a surprisingly small number of tissue rhythms are lost when only local clocks are ablated and, second, transcriptional circadian rhythms appear to be regulated by a complex mix of local and systemic factors. As reviewed here, these findings suggest a more integrated model of clock network interaction with the central pacemaker as the main source of behavioral and systemic-physiological rhythms and peripheral clocks controlling some local rhythms while at the same time acting as gatekeepers that temporally adjust cellular responses to external stimuli.

3-Iodothyroacetic acid lacks thermoregulatory and cardiovascular effects in vivo.
3-Iodothyronamine (3-T1 AM) is an endogenous thyroid hormone derivative reported to induce strong hypothermia and bradycardia within minutes upon injection in rodents. Although 3-T1 AM is rapidly converted to several other metabolites in vivo, these strong pharmacological responses were solely attributed to 3-T1 AM, leaving potential contributions of downstream products untested. We therefore examined the cardiometabolic effects of 3-iodothyroacetic acid (TA1), the main

degradation product of 3-T1 AM.

DEEP PHENOTYPIC ANALYSIS OF ZEBRAFISH MODELS OF PARKINSON'S DISEASE

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Tanita Maria Tzotzolaki[1], Olivier Mirat[2], Claire Wyart[2], Flavia De Santis[1], Javier Terriente[1]

Parkinson's disease (PD) is a progressive disorder of the nervous system characterised by degeneration of dopaminergic neurons. While the pathogenesis remains unclear, there is evidence that changes in dopamine (DA) storage and release contribute to it. However, the precise effects on the dopaminergic circuitry are unknown. Here, pharmacological and genetic zebrafish models are used, involving incubation with the neurotoxicant MPTP or CRISPR/Cas9-induced knockout of PD-associated genes, respectively. The aim is to analyse the activity of the dopaminergic circuitry using genetically-encoded DA sensors. Using transgenesis, the $GRAB_{DA}$ and d.Light1.1 sensors are used to quantify the dynamics of DA signalling in wildtype conditions, in order to have an idea of the circuit activity. Subsequently, MPTP treatment is integrated to visualise the effects of dopaminergic neuron loss on the dopaminergic circuit. Additionally, a deep characterisation of locomotor patterns is conducted in the distinct PD models in order to identify any micromovement alterations compared to wildtype. Using high-throughput behavioural assays, swimming events of individual fish are recorded simultaneously at a high frequency over large timescales. Kinematic parameters are analysed in two manoeuvres: fast acoustovestibular escape responses, as well as slow forward swims and routine turns. Preliminary data currently point towards a long-latency escape response in PD mutants, which could be regarded as a delayed response. Moreover, mutants exhibit less swimming with higher tail beat amplitude compared to control. Ultimately, this work could help build a phenotypic profile of PD, which in the long term could enable screening of candidate chemicals for PD in zebrafish.

Performing movements and quickly adapting them is essential in the ever-changing environment we are living in. It is well established that this capital function recruits dopaminergic transmission in basal ganglia circuit. Indeed, the role of dopamine (DA) in these processes is illustrated by the consequences of its loss in Parkinson's disease (PD) patients, suffering from severe motor symptoms such as bradykinesia and akinesia. Despite years of research, the spatio-temporal dynamics of DA during motor control remain largely unknown. In this study, we investigate how DA impact the execution of dexterous movements in rats trained to perform a 'reach-to-grasp' motor task. Our first set of experiments aimed to assess the effect of the chronic lack of DA in a model of parkinsonism induced by 6-OHDA injection in the striatum of trained animals. This depletion in the dorso-lateral region shortly induced bradykinetic movements while akinesia appears in the following days of the lesion. Although the motor deficits quickly reached their peaks, they often did not persist in time and we observed a motor symptoms reversion which expression and timing depends on the size and location of the striatal DA depletion. We highlighted that this functional motor recovery requires DA signaling and relies on neuronal networks located in the striatal depleted area. We are currently investigating using fiber photometry the local adaptations of specific striatal populations that could underlie the motor restoration. We propose that those compensatory mechanisms occur early on PD to compensate for the slow decrease of DA.

DOPAMINE DYSREGULATION SYNDROME IN A MOUSE MODEL OF PARKINSON'S DISEASE

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Carina Plewnia[1], Debora Masini[2], Gilberto Fisone[1]

Treatment of Parkinson's disease (PD) is based on the use of dopaminergic drugs, such as L-Dopa and dopamine receptor agonists. These substances compensate for the lack of dopamine and counteract motor symptoms, but long-term treatment is accompanied by motor and non-motor complications. Among these latter conditions a neurobehavioral disorder similar to drug abuse, known as dopamine dysregulation syndrome (DDS), is attracting increasing interest because of its profound negative impact on the patients' quality of life. We used a PD mouse model based on a bilateral injection of 6-hydroxydopamine into the dorsal striatum to reproduce some of the features of DDS. Using the conditioned place preference paradigm, we found that L-Dopa induces place preference in PD mice, but not in control mice, suggesting that this drug acquires addictive-like properties following dopamine depletion. This effect is accompanied by abnormal signaling in dopamine D1 receptor (D1R) striatal projection neurons, leading to hyperactivation of the cAMP signaling cascade and accumulation of the transcription factor ΔFosB. Pharmacological inactivation of D1Rs abolished these effects and prevented the development of place preference, thereby counteracting the psychostimulant effect of L-Dopa. Interestingly, blockade of dopamine D2 receptors was also able to reduce the accumulation of ΔFosB and abolish place preference. Our results suggest that, in PD, combined activation of D1 and D2 receptors by L-Dopa results in DDS, and that this effect may be linked to abnormal accumulation of ΔFosB in striatal neurons.

Basal ganglia (BG) circuits play a key role in motor initiation and suppression and the loss of dopamine in these circuits triggers Parkinson's disease (PD) characterized by devastating motor impairments known as akinesia and bradykinesia. The supplement of DA, through the intake of the precursor levodopa, improves movements execution in the early stage of the disease but quickly triggers abnormal and involuntary movements known as levodopa-induced dyskinesias (LIDs). LIDs are very debilitating because refractory to any further drug treatments, hence understanding the neuronal mechanism of their generation is fundamental to develop new treatment strategies. Recent studies have shown that LIDs are caused by aberrant neuronal activity in the striatum, however how such striatal activity impacts on downstream BG circuits to generate LIDs is not known. The external globus pallidus (GPe) integrates striatal inputs and is an important hub nucleus that orchestrate normal and abnormal activity in BG circuit. In addition, arkypallidal GPe neurons, directly form a negative feedback loop to the striatum that powerfully control action inhibition in normal condition. Importantly, the activity and contribution of this action-suppressing loop during LIDs is totally unknown. In this work, we used optical methods (fiber photometry and miniscope) to monitor the calcium activity of arkypallidal neurons across different behavioral states: from healthy condition to the pathological state of PD and LIDs. Having characterized the abnormal change of activity of arkypallidal neurons during LIDs, we then used optogenetic manipulation to restore their activity and test their contribution to LIDs generation.

INVOLVEMENT OF 5-HT DESCENDING PATHWAY IN PAIN IN A MOUSE MODEL OF PARKINSONISM

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Parkinson disease (PD) is characterised by the dopamine (DA) depletion in basal ganglia (BG) especially in the substantia nigra and the striatum. PD is a multi-factory disorder leading to well-known motor symptoms but also to non-motor symptoms. The major one is chronic pain which is only partly explained by DA depletion in BG. The pain ascending signal coming from the periphery is strongly modulated by pain descending pathways and most particularly by serotonergic (5-HT) descending neurons coming from the nucleus raphe magnus (NRM) and acting at the level of the dorsal horn (DH) of the spinal cord. As the NRM seems to be affected by PD and as 5-HT is intricately involved in pain perception modulation, we hypothesized that this PD induced pain modulation may be associated to a modification of pain transmission by 5HT descending pathways. To assess this, we used a transgenic mice expressing cre-recombinase in 5-HT neurons in which we induced DA depletion with 6-OHDA intracerebral injection. After the validation of this model, we were able record the animal pain behaviour while optogenetically inhibiting specifically 5-HT descending pathways. We showed that unilateral DA depletion impairs bilaterally pain sensitivity. We showed then that 6-OHDA injection changes the role of 5-HT descending pathways on pain perception as 5-HT action shifted from an anti-nociceptive effect in Sham animal to proalgesic one in 6-OHDA. These results raise now the question of causes of this changes which will be investigated further to better understand and treat chronic pain syndromes in PD patients.

It is known that Parkinson's disease (PD) patients report sleep disturbances and decreased levels of melatonin. The sleep/wake rhythm is controlled by the biological clock, a group of neurons expressing clock genes. These genes regulate not only melatonin production but also innate immunity and mitochondrial function, which are affected in PD. Thus, chronodisruption may be an early stage of this disease. **Objectives:** to evaluate the connection between clock genes and PD and to assess whether melatonin administration can improve PD restoring the normal functioning of the biological clock. **Methods:** Parkinsonism was induced with MPTP in 24-120 hours post fertilization (hpf) zebrafish embryos. Melatonin was administered at doses of 1 µM**. Results:** Day-night melatonin rhythm disappeared in MPTP-treated embryos, which showed an advance in the activity phase and a parallel changes in the acrophases of Bmal1 and Per2 were detected. We also found an alteration in the mitochondrial dynamics and mitochondrial function with MPTP. In all cases, melatonin restored the normal phenotype and clock rhythm expression, normalizing the mitochondrial dynamics. **Conclusions:** The parkinsonian zebrafish shows state there is an alteration of the biological clock, which explain phenotype changes that are restored by treatment with melatonin.

In Vivo Determination of Mitochondrial Respiration in 1-Methyl-4-Phenyl-1,2,3,6-Tetrahydropyridine-Treated Zebrafish Reveals the Efficacy of Melatonin in Restoring Mitochondrial Normalcy.
Although mitochondria dysfunction is related to multiple diseases, no in vivo studies are available on mitochondrial respiration in animal parkinsonian models. Our aim is to analyze in vivo mitochondrial respiration, which reflects changes in mitochondrial bioenergetics more precisely than in vitro mitochondrial preparations. These experiments can be carried out in zebrafish embryos, which were treated with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) from 24 to 72 hours postfertilization (hpf). A reduction in electron transfer system capacity, ATP turnover, and increased proton leak were observed at 72 hpf in MPTP-treated embryos. These changes were followed by a significant oxidative stress due to inhibition in antioxidative defense and autophagy impairment. After removing MPTP from the treatment at 72 hpf, these bioenergetic deficiencies persisted up to 120 hpf. The administration of melatonin to zebrafish embryos at 72 hpf, when mitochondrial dysfunction is already present, restored the respiratory capacity and ATP production, reduced oxidative stress, and normalized autophagy after 48 h. Melatonin also counteracted mortality and embryonic malformations due to MPTP. Our results confirm for the first time the efficacy of melatonin in restoring parkinsonian phenotypes in animals.

L-DOPA-induced dyskinesia (LID) is a frequent complication of the medication for Parkinson's disease (PD). LID is a motor disorder that affects the patient's quality of life. Therefore, understanding the mechanisms underlying its development is key to prevent them. To this aim, we investigated the role of TrkB receptor in L-DOPA-induced dyskinesia in hemiparkinsonian mice treated chronically with L-DOPA administration. Repeated L-DOPA injections specifically increased full-length TrkB receptor mRNA and protein levels in the dopamine-depleted dorsal striatum as compared to the contralateral non-lesioned striatum or to the striatum of sham-operated animals. In addition, chronic L-DOPA treatment activated TrkB receptor as indicated by its increased tyrosine phosphorylation. Using specific D1 or D2 receptors agonists, we found that TrkB increase was D1 receptor-dependent. To determine the consequences of these effects we invalidated the TrkB gene in striatal neurons expressing D1 receptor, by injecting Cre-expressing adeno-associated viruses into mice with TrkB floxed gene, or by crossing these mice with Drd1-Cre transgenic mice. After unilateral lesion of dopamine neurons in both these mice lines, we found an aggravation of LID compared to the control groups. No change was found when TrkB deletion was induced in the indirect pathway A2A receptor-expressing neurons. Our study suggests that BDNF/TrkB signaling plays a protective role against the development of LID and that agonists specifically activating TrkB could reduce the severity of LID.

Parkinson's disease (PD) is characterized by a preferential degeneration of neurons accumulating with age neuromelanin in PD-vulnerable areas as substantia nigra (SN) and locus coeruleus (LC). Since this pigment is not naturally produced in most animals including rodents, we recently generated a neuromelanin-producing mouse model based on the tissue-specific constitutive expression of melanin-producing enzyme tyrosinase under the tyrosine hydroxylase promoter (Tg-TH-Tyr). As in humans, these animals age-dependently accumulate neuromelanin within catecholaminergic neurons. In parallel to its intracellular buildup, Tg-TH-Tyr mice exhibit an early degeneration of noradrenergic LC neurons that precedes nigral dopaminergic dysfunction, equivalent to prodromal PD, as well as PD-like motor and non-motor (i.e. olfactory, cognitive) deficits. Here we assessed whether Tg-TH-Tyr mice may also exhibit sleep alteration and REM sleep behaviour disorder (RBD), two documented prodromal manifestations of PD, likely linked to a degeneration of the LC/subcoeruleus area critical for REM sleep. For this goal, Tg-TH-Tyr and WT littermate mice (5 months old), prepared for polysomnography and video, were recorded for 58 weeks until natural death (5 Tg-6 WT). Preliminary results evidenced modifications of daily amounts and bout numbers of REM sleep, as their circadian distribution in Tg-TH-Tyr *vs.* WT mice, independently of the age factor. While clear occurrence of RBD was not detected by rapid video scrutinization, ongoing analyses of both EMG and EEG signals will allow to determine whether tonic/phasic motor events during REM sleep and the overall sleep quality are differentially affected by aging, along the presymptomatic PD period, in Tg-TH-Tyr *vs.* WT mice.

Chronic Levodopa therapy, the gold-standard treatment for Parkinson’s Disease (PD), leads to the emergence of involuntary movements, called levodopa-induced dyskinesia (LID). Cerebellar stimulation has been shown to decrease LID severity in PD patients. Here, in order to determine how cerebellar stimulation induces LID alleviation, we performed daily short trains of optogenetic stimulations of Purkinje cells (PCs) in freely moving LID mice. We demonstrated that these stimulations are sufficient to suppress LID or even prevent their development. This symptomatic relief is accompanied by the normalization of aberrant neuronal discharge in the cerebellar nuclei, the motor cortex, and the parafascicular thalamus. Inhibition of the cerebello-parafascicular pathway counteracted the beneficial effects of cerebellar stimulation. Moreover, cerebellar stimulation reversed plasticity in D1 striatal neurons and normalized the overexpression of FosB, a transcription factor causally linked to LID. These findings demonstrate LID alleviation and prevention by daily PCs’ stimulations, which restore the function of a wide brain motor network, and may be valuable for LID treatment.

ALTERED PARABRACHIAL NUCLEUS NOCICEPTIVE PROCESSING MAY UNDERLIE CENTRAL NEUROPATHIC PAIN IN PARKINSON'S DISEASE.

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Arnaud Pautrat, Racha Al Tannir, Véronique Coizet
Univ. Grenoble Alpes, Inserm U1216, Grenoble Institut Neurosciences, Grenoble, France

The presence of central neuropathic pain in Parkinson's disease suggests that the brain circuits that allow us to perceive and process pain could be dysfunctional in this disease. However, there is to date no clear pathophysiological mechanism to explain these specific symptoms. In the present work, we present evidence that the parabrachial nucleus, a low level primary nociceptive structure in the brainstem, and associated key structures in the basal ganglia, may be dysfunctional in Parkinson's disease. In rat models of Parkinson's disease with partial or total dopaminergic lesions of the substantia nigra pars compacta, we found that the subthalamic nucleus and the substantia nigra pars reticulata showed enhanced nociceptive responses with a Partial dopaminergic lesion while a Total dopaminergic lesion produced an increase in both the nociceptive responses and the baseline firing rate. At the level of the parabrachial nucleus, inhibited nociceptive responses and increased expression of $GABA_A$ receptors were found in the Total dopaminergic lesion group only. However, anatomical neuro-adaptations at the level of dendritic spine density and post-synaptic density were found in both dopaminergic lesion groups. We suggest that these neuro-adaptations are responsible for the substantial nociceptive rebound we found in the two groups after the pharmacological blockade of the substantia nigra pars reticulata. We propose that these neuro-adaptations follow increased inhibitory tone from the substantia nigra pars reticulata and may represent the mechanism generating central neuropathic pain in Parkinson's disease. **Keywords:** Basal Ganglia; Parabachial nucleus; Nociceptive processing; Parkinson's disease; Central neuropathic pain

SLEEP DISTURBANCES IN A MOUSE MODEL OF PARKINSON'S DISEASE

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Daniel Medeiros[1], Renan Mendes[2], Cleiton Aguiar[3], Gilberto Fisone[1]
[1]Karolinska Institutet, Neuroscience, Solna, Sweden, [2]University of Basel, Neuroscience, Basel, Switzerland, [3]Federal University of Minas Gerais, Department Of Physiology And Biophysics, Belo Horizonte, Brazil

A large spectrum of sleep disorders is frequently present in Parkinson's disease (PD). These co-morbidities significantly impair the patients' quality of life and are commonly refractory or exacerbated by standard anti-parkinsonian treatments. We studied sleep architecture in a mouse model of PD based on unilateral injection of the catecholamine neurotoxin 6-hydroxydopamine (6-OHDA) in the medial forebrain bundle. Electrodes for electroencephalogram and electromyogram were implanted over the left parietal cortex and the neck muscles of sham-lesion and 6-OHDA-lesion mice. The recording was performed for 24 hours and awake state, REM, and non-REM sleep were sorted using a MATLAB script. The 6-OHDA lesion mice showed reduced awaken state and increased non-REM sleep during the dark (active) phase of the sleep-wake cycle. In the same animals, we also observed a higher number of NREM episodes during the light (inactive) phase, indicative of sleep fragmentation. Notably, this effect was reversed by preserving the noradrenergic system using desipramine prior to the 6-OHDA injection. Levodopa and pramipexole, administered to 6-OHDA lesion mice for seven consecutive days, significantly augmented NREM sleep during the active period. The data show that the PD mouse model used in this study reproduces sleep abnormalities reminiscent of the excessive daytime sleepiness and sleep fragmentation frequently observed in PD patients. Importantly, they also show that loss of nigrostriatal dopamine is sufficient to produce excessive daytime sleepiness, whereas sleep fragmentation depends on noradrenaline dysfunction. Finally, the sleep disturbances found in the present PD model are refractory to, and even exacerbated by common anti-parkinsonian medications.

The Endocannabinoid System Activation as a Neural Network Desynchronizing Mediator for Seizure Suppression.
The understanding that hyper-excitability and hyper-synchronism in epilepsy are indissociably bound by a cause-consequence relation has only recently been challenged. Thus, therapeutic strategies for seizure suppression have often aimed at inhibiting excitatory circuits and/or activating inhibitory ones. However, new approaches that aim to desynchronize networks or compromise abnormal coupling between adjacent neural circuitry have been proven effective, even at the cost of enhancing local neuronal activation. Although most of these novel perspectives targeting circuitry desynchronization and network coupling have been implemented by non-pharmacological devices, we argue that there may be endogenous neurochemical systems that act primarily in the desynchronization component of network behavior rather than dampening excitability of individual neurons. This review explores the endocannabinoid system as one such possible pharmacological landmark for mimicking a form of "on-demand" desynchronization analogous to those proposed by deep brain stimulation in the treatment of epilepsy. This essay discusses the evidence supporting the role of the endocannabinoid system in modulating the synchronization and/or coupling of distinct local neural circuitry; which presents obvious implications on the physiological setting of proper sensory-motor integration. Accordingly, the process of ictogenesis involves pathological circuit coupling that could be avoided, or at least have its spread throughout the containment of other areas, if such endogenous mechanisms of control could be activated or potentiated by pharmacological intervention. In addition, we will discuss evidence that supports not only a weaker role played on neuronal excitability but the potential of the endocannabinoid system strengthening its modulatory effect, only when circuitry coupling surpasses a level of activation.

Sleep Disorders in Rodent Models of Parkinson's Disease.
Sleep disorders are frequently diagnosed in Parkinson's disease and manifested in the prodromal and advanced stages of the disease. These conditions, which in some cases affect more than 50% of Parkinson's disease (PD) patients, include

hypersomnia, often manifested as excessive daytime sleepiness, insomnia, characterized by delayed initiation and fragmentation of sleep at night, and disruption of rapid eye movement (REM) sleep, resulting in loss of atonia and dream enactment. Standard dopamine replacement therapies for the treatment of motor symptoms are generally inadequate to combat sleep abnormalities, which seriously affect the quality of life of PD patients. Rodent models still represent a major tool for the study of many aspects of PD. They have been primarily designed to eliminate midbrain dopamine neurons and elicit motor impairment, which are the traditional pathological features of PD. However, rodent models are increasingly employed to investigate non-motor symptoms, which are often caused by degenerative processes affecting multiple monoaminergic and peptidergic structures. This review describes how neurotoxic and genetic manipulations of rats and mice have been utilized to reproduce some of the major sleep disturbances associated with PD and to what extent these abnormalities can be linked to nondopaminergic dysfunction, affecting for instance noradrenaline, serotonin, and orexin transmission. Strengths and limitations are discussed, as well as the consistency of results obtained so far, and the need for models that better reproduce the multisystemic neurodegenerative nature of PD, thereby allowing to replicate the complex etiology of sleep-related disorders.

Focus on desynchronization rather than excitability: a new strategy for intraencephalic electrical stimulation.
Epilepsy is a severely debilitating brain disease, often associated with premature death, which has an urgent need for alternative methods of treatment. In fact, roughly 25% of patients with epilepsy do not have seizures satisfactorily controlled by pharmacological treatment, and 30% of these patients with treatment-refractory seizures are not even eligible for ablative surgery. Epilepsy is most readily identifiable by its seizures and/or paroxysmal events, mostly viewed as spontaneously recurrent and unpredictable, which are caused by stereotyped changes in neurological function associated with hyperexcitability and hypersynchronicity of the underlying neural networks. Treatment has strongly been based on the fixed goal of depressing neuronal activity, working under the veiled assumption that hyperexcitability would lead to synchronous neuronal activity and, therefore, to seizure. Over the last 20-30 years, the emergence of electrical (ES) of deep brain structures, a practicable option for treating patients with otherwise untreatable seizures, has broadened our understanding of anticonvulsant mechanisms that conceptually differ from those of pharmacological treatment. Conversely, the research on ES therapy applied to epilepsy is contributing significantly to untwine the phenomena of excitation from that of synchronization as potential target mechanisms for abolishing seizures and predicting paroxysmal events. This paper is, thus, an addendum to other reviews on the subject of ES therapy in epilepsy which focuses on the desynchronization effect ES has on epileptogenic neural networks rather than its effect on overall brain excitability.

Temporal rearrangement of pre-ictal PTZ induced spike discharges by low frequency electrical stimulation to the amygdaloid complex.
Epilepsy is a common neurological disease affecting over 40 million people worldwide. The foremost important challenge of epileptologists has been to control and predict the recurrent and spontaneous seizures of epileptic patients. The application of low frequency electrical stimulation (LFS) in deep brain structures has shown promising results in seizure control. However, the use of LFS as a probing strategy for seizure prediction, thus contributing to a closed loop solution, is still poorly explored.

Anatomically dependent anticonvulsant properties of temporally-coded electrical stimulation.
In the PTZ animal model of epilepsy, electrical stimulation applied to the amygdaloid complex may result in either pro-convulsive or anticonvulsant effect, depending on the temporal pattern used (i.e. periodic-PS and non-periodic-NPS electrical stimulation). Our hypothesis is that the anatomical target is a determinant factor for the differential effect of temporally-coded

patterns on seizure outcome. The threshold dose of PTZ to elicit forelimb clonus and generalized tonic-clonic seizure behavior was measured. The effect of amygdaloid complex PS on forelimb clonus threshold showed a pro-convulsive effect while NPS was anticonvulsant. NPS also significantly increased generalized tonic-clonic threshold; while PS, although at lower threshold levels, did not present statistical significance. Thalamus stimulation did not affect forelimb clonus threshold and showed similar anticonvulsant profiles for both PS and NPS on generalized tonic-clonic threshold. In summary, the anatomical target is a determinant factor on whether temporally-coded ES differentially modulates seizure outcome.

Seizure Susceptibility Corrupts Inferior Colliculus Acoustic Integration.
Evidence suggests that the pathophysiology associated with epileptic susceptibility may disturb the functional connectivity of neural circuits and compromise the brain functions, even when seizures are absent. Although memory impairment is a common comorbidity found in patients with epilepsy, it is still unclear whether more caudal structures may play a role in cognitive deficits, particularly in those cases where there is no evidence of hippocampal sclerosis. This work used a genetically selected rat strain for seizure susceptibility (Wistar audiogenic rat, WAR) and distinct behavioral (motor and memory-related tasks) and electrophysiological (inferior colliculus, IC) approaches to access acoustic primary integrative network properties. The IC neural assemblies' response was evaluated by auditory transient (focusing on bottom-up processing) and steady-state evoked response (ASSR, centering on feedforward and feedback forces over neural circuitry). The results show that WAR displayed no disturbance in motor performance or hippocampus-dependent memory tasks. Nonetheless, WAR animals exhibited significative impairment for auditory fear conditioning (AFC) along with no indicative of IC plastic changes between the pre-conditioning and test phases (ASSR coherence analysis). Furthermore, WAR's IC response to transient stimuli presented shorter latency and higher amplitude compared with Wistar; and the ASSR analysis showed similar results for WAR and Wistar animals under subthreshold dose of pentylenetetrazol (pro-convulsive drug) for seizure-induction. Our work demonstrated alterations at WAR IC neural network processing, which may explain the associated disturbance on AFC memory.

Deep brain stimulation probing performance is enhanced by pairing stimulus with epileptic seizure.
The unpredictability of spontaneous and recurrent seizures significantly impairs the quality of life of patients with epilepsy. Probing neural network excitability with deep brain electrical stimulation (DBS) has shown promising results predicting pathological shifts in brain states. This work presents a proof-of-principal that active electroencephalographic (EEG) probing, as a seizure predictive tool, is enhanced by pairing DBS and the electrographic seizure itself. The ictogenic model used consisted of inducing seizures by continuous intravenous infusion of pentylenetetrazol (PTZ - 2.5 mg/ml/min) while a probing DBS was delivered to the thalamus (TH) or amygdaloid complex to detect changes prior to seizure onset. Cortical electrophysiological recordings were performed before, during, and after PTZ infusion. Thalamic DBS probing, but not amygdaloid, was able to predict seizure onset without any observable proconvulsant effects. However, previously pairing amygdaloid DBS and epileptic polyspike discharges (day-1) elicited distinct preictal cortically recorded evoked response (CRER) (day-2) when compared with control groups that received the same amount of electrical pulses at different moments of the ictogenic progress at day-1. In conclusion, our results have demonstrated that the pairing strategy potentiated the detection of an altered brain state prior to the seizure onset. The EEG probing enhancement method opens many possibilities for both diagnosis and treatment of epilepsy.

Triggering Different Brain States Using Asynchronous Serial Communication to the Rat Amygdala.
Inputting information to the brain through direct electrical microstimulation must consider how underlying neural networks encode information. One unexplored possibility is that a single electrode delivering temporally coded stimuli, mimicking an asynchronous serial communication port to the brain, can trigger the emergence of different brain states. This work used a discriminative fear-conditioning paradigm in rodents in which 2 temporally coded microstimulation patterns were targeted at the amygdaloid complex. Each stimulus was a binary-coded "word" made up of 10 ms bins, with 1's representing a single pulse stimulus: A-1001111001 and B-1110000111. During 3 consecutive retention tests (i.e., day-word: 1-B; 2-A, and 3-B), only binary-coded words previously paired with a foot-electroshock elicited proper aversive behavior. To determine the neural substrates recruited by the different stimulation patterns, c-Fos expression was evaluated 90 min after the last retention test. Animals conditioned to word-B, after stimulation with word-B, demonstrated increased hypothalamic c-Fos staining. Animals conditioned to word-A, however, showed increased prefrontal c-Fos labeling. In addition, prefrontal-cortex and hypothalamic

c-Fos staining for, respectively, word-B- and word-A-conditioned animals, was not different than that of an unpaired control group. Our results suggest that, depending on the valence acquired from previous learning, temporally coded microstimulation activates distinct neural networks and associated behavior.

Sublayer- and cell-type-specific neurodegenerative transcriptional trajectories in hippocampal sclerosis.
Hippocampal sclerosis, the major neuropathological hallmark of temporal lobe epilepsy, is characterized by different patterns of neuronal loss. The mechanisms of cell-type-specific vulnerability and their progression and histopathological classification remain controversial. Using single-cell electrophysiology in vivo and immediate-early gene expression, we reveal that superficial CA1 pyramidal neurons are overactive in epileptic rodents. Bulk tissue and single-nucleus expression profiling disclose sublayer-specific transcriptomic signatures and robust microglial pro-inflammatory responses. Transcripts regulating neuronal processes such as voltage channels, synaptic signaling, and cell adhesion are deregulated differently by epilepsy across sublayers, whereas neurodegenerative signatures primarily involve superficial cells. Pseudotime analysis of gene expression in single nuclei and in situ validation reveal separated trajectories from health to epilepsy across cell types and identify a subset of superficial cells undergoing a later stage in neurodegeneration. Our findings indicate that sublayer- and cell-type-specific changes associated with selective CA1 neuronal damage contribute to progression of hippocampal sclerosis.

Motor symptoms of Parkinson’s disease (PD) result from the loss of nigrostriatal dopamine (DA) neurons and subsequent dysfunction of cortico-basal-ganglia (CBG) network. Recent anatomical and electrophysiological studies suggest that altered neuronal activity of the external globus pallidus (GPe) may be a critical mechanism contributing to the CBG network dysfunction because of its widespread projections to all BG nuclei and to the thalamus and the cortex. Yet, behavioural evidence supporting this view are scarce and the reported results are controversial. Here, we used unilateral 6-hydroxydopamine (6-OHDA) nigrostriatal DA lesion model of PD and optogenetic approach in mice to explore GPe contribution to the motor deficits of PD. We first examined whether photoinhibition of GPe neurons in normal BL6 mice using the inhibitory opsin IC++ could reproduce the classical motor deficits (ipsilateral circling, forelimb akinesia and locomotor hypoactivity) of 6-OHDA lesion. Bilateral GPe photoinhibition had no impact on spontaneous locomotor activity while unilateral photoinhibition induced few ipsilateral rotations, indicating that GPe may not be recruited in all testing conditions. We next examined whether photostimulation of GPe neurons could alleviate lesion-induced motor deficits. GPe photostimulation using the excitatory opsin ChR2(E123T/T159C) improved motor deficits at stimulation parameters ineffective in non-lesioned mice. Interestingly, selective photostimulation of parvalbumin (PV)-expressing neurons, which preferentially innervate BG output structures, was sufficient for restoring all motor deficits of 6-OHDA lesion. Collectively, these findings support the central role of GPe in the pathophysiology of PD and suggest that compensatory alterations of GPe activity, namely dyfunction of PV-neurons, may underly motor impairments.

Parkinson’s disease (PD) is an age-related neurodegenerative disorder characterized by a progressive loss of dopaminergic neurons in the substantia nigra (SN). Surviving neurons contain alpha-synuclein-positive intracellular inclusions mainly in nerve terminals. The aim of the present work is to investigate the effects of alpha-synuclein (alpha-syn) in the SN and striatum and its role on pathogenesis and symptomatology of PD. Methods: we used a rat model for Parkinson’s disease based on overexpression of alpha-syn with adeno-associated viral vectors. 1 µl of rAAV9-CMVie/SynP-wtsyn-WPRE (wt alpha-syn) was injected bilaterally in SN of 2 months Sprague Dawley male rats. After 2 months of alpha-syn overexpression open field and novel object recognition tests were realized. Animals were perfused and Tyrosine hydroxylase (TH) immunopositive striatal optical density, SNreticulata optical density and SNcompacta TH positive neuron density were measured. In addition, alpha-syn and alpha-syn -phosphorylated (p-alpha-syn) expression were observed by immunofluorescence. Results: behavioural tests had shown that alpha-syn animals have longer resting time and lower ability to recognize novel objects. Alpha-syn expression reached different brain regions in the rostro-caudal axis while p-alpha-syn expression remains near substantia nigra. TH immunostaining revealed a significant decrease of the TH-immunopositive striatal optical density, loss of TH-immunoreactive neurons in the SNcompacta and axodendritic network in the SNreticulata. Conclusions: These findings support the effectiveness of alpha-syn model to reproduce an animal model of PD. The morphological and behavioural description of this model could be a promising tool to investigate new strategies to implement against PD. With age, humans accumulate the dark-brown pigment neuromelanin (NM) inside catecholaminergic neurons reaching the highest levels in dopaminergic neurons of the substantia nigra pars compacta (SNC) which become susceptible to degeneration that later leads to Parkinson's disease (PD). It has been shown that during PD early stages dopaminergic neurons undergo homeostatic changes that submerge them in a "dormancy state" characterized by neuronal activity decrease and a loss of tyrosine-hydroxylase enzyme (TH) expression. We hypothesize that pacemaking of dopaminergic neurons (either optogenetically or chemogenetically) would alleviate early signs in an NM accumulating PD animal model. In DAT-Cre and TH-Cre mice we overexpressed the melanin-producing enzyme tyrosinase (hTyr) specifically in midbrain dopaminergic neurons along with the red light-sensitive opsin Chrimson or the excitatory DREADD receptor HM3d. After seven weeks of viral expression and NM accumulation, the mice were optically (635nm laser) or chemically (J60) stimulated during 4 weeks accordingly. We found that neurons in the ventral tegmental area and SNC accumulate NM differentially when they are non-stimulated (control), optically stimulated, or chemogenetically stimulated. Significantly fewer NM-positive neurons (NM+) were found in light stimulated dopaminergic regions compared to the control non-stimulated contralateral ones. Although both control and stimulated dopaminergic areas showed similar numbers of TH-positive cells (TH+), the total number of them is overall diminished compared to intact animals. In contrast, the DREADD stimulation led to a dramatic decrease in the number of TH+ neurons in the stimulated regions while the NM+ cells countings remained similar compared to control non-stimulated contralateral regions.

Background: Exercise is recommended for PD treatment, adjunct with pharmacotherapy. After partial degeneration of dopaminergic system surviving neurons can spontaneously compensate, to maintain almost normal system functioning but it strongly depends on the lesion size. Exercise could help to naturally move this threshold. The aim was to create reliable animal model to study potential neuroprotection, regeneration and compensation of the nigrostriatal dopaminergic system in PD. Comparison of medium vs large lesion resembling early vs late stage of PD will allow to determine when physiotherapeutic interventions are still possible and what kind of improvement can be expected. **Methods**: Regular training was performed for 4 weeks before and after unilateral 6-OHDA injection into the MFB (4 or 8 µg). Locomotor activity, asymmetric paw use and apomorphine induced rotation tests were assessed at different time points. **Results**: Locomotion of running lesioned animals was not different than their sham operated controls while sedentary rats showed decreased activity as compared to sedentary sham control. Asymmetric paw use resulted in lower ipsi/contra ratio in medium lesioned, exercised rats. Number of contralateral rotations in exercised medium lesioned animals was reduced. Medium lesion induced locomotor deficit was spontaneously compensated in contrast to large lesioned animals. **Conclusions:** Treadmill training may ameliorate some behavioral deficits but threshold of lesion size responsive to benefits of running is visible. The studies on exercise will bring us closer to understanding mechanisms prolonging independent functioning of patients in multiple neurodegenerative diseases. **Funding:** NCN 2019/35/B/NZ7/02862 and statutory funds of Maj Institute of Pharmacology, PAS, Poland.

Astrocyte support is important for the compensatory potential of the nigrostriatal system neurons during early neurodegeneration.
Glial pathology precedes symptoms of Parkinson's disease and multiple other neurodegenerative diseases. Prolonged impairment of astrocytic functions could increase the vulnerability of dopaminergic neurons in the substantia nigra (SN), accelerate their degeneration and affect ability to compensate for partial degeneration at the presymptomatic stages of the disease. The aim of this study was to investigate the astrocyte depletion in the SN, its impact on the dopaminergic system functioning and multiple markers of energy metabolism during the early stages of neurodegeneration and compensation. We induced death of 30% of astrocytes by chronic infusion of fluorocitrate (FC) into the SN, simultaneously activating microglia response but sparing the dopaminergic neurons. The FC effect was reversible after toxin withdrawal. Dopaminergic neurons were killed by 6-hydroxydopamine causing transient locomotor disability, reversed with time showing compensatory potential. Death of astrocytes diminished the capability of the dopaminergic system to compensate for the degeneration of neurons and caused a local energy deprivation by decreasing lactate and glycogen amount. Studied markers suggest a shift in the usage of energy substrates, via increased glycogenolysis and glycolysis markers, ketone bodies availability and fatty acid transport in remaining cells. Peroxisome proliferator-activated receptor-gamma coactivator 1α (PGC-1alpha) and AMP-activated protein kinase (AMPK), the energy sensors, showed different regulation between the cell-types. Increased neuronal expression of carnitine palmitoyltransferase 1c could play a role in the adaptation to metabolic stress in response to glia dysfunction. Astrocyte energetic support is one of the essential factors for neuronal compensatory mechanisms of dopaminergic system and might have a leading role in the presymptomatic Parkinson's disease stages. Beyond the GFAP-Astrocyte Protein Markers in the Brain.
The idea of central nervous system as one-man band favoring neurons is long gone. Now we all are aware that neurons and neuroglia are team players and constant communication between those various cell types is essential to maintain functional efficiency and a quick response to danger. Here, we summarize and discuss known and new markers of astroglial multiple functions, their natural heterogeneity, cellular interactions, aging and disease-induced dysfunctions. This review is focused on newly reported facts regarding astrocytes, which are beyond the old stereotypes. We present an up-to-date list of marker proteins used to identify a broad spectrum of astroglial phenotypes related to the various physiological and pathological nervous system conditions. The aim of this review is to help choose markers that are well-tailored for specific needs of further experimental studies, precisely recognizing differential glial phenotypes, or for diagnostic purposes. We hope it will help to categorize the functional and structural diversity of the astroglial population and ease a clear readout of future experimental results.

Overview of General and Discriminating Markers of Differential Microglia Phenotypes.
Inflammatory processes and microglia activation accompany most of the pathophysiological diseases in the central nervous system. It is proven that glial pathology precedes and even drives the development of multiple neurodegenerative conditions. A growing number of studies point out the importance of microglia in brain development as well as in physiological functioning. These resident brain immune cells are divergent from the peripherally infiltrated macrophages, but their precise discrimination is surprisingly difficult. Microglial heterogeneity in the brain is especially visible in their morphology and cell density in particular brain structures but also in the expression of cellular markers. This often determines their role in physiology or pathology of brain functioning. The species differences between rodent and human markers add complexity to the whole picture. Furthermore, due to activation, microglia show a broad spectrum of phenotypes ranging from the pro-inflammatory, potentially cytotoxic M1 to the anti-inflammatory, scavenging, and regenerative M2. A precise distinction of specific phenotypes is nowadays essential to study microglial functions and tissue state in such a quickly changing environment. Due to the overwhelming amount of data on multiple sets of markers that is available for such studies, the choice of appropriate markers is a scientific challenge. This review gathers, classifies, and describes known and recently discovered protein markers expressed by microglial cells in their different phenotypes. The presented microglia markers include qualitative and semi-quantitative, general and specific, surface and intracellular proteins, as well as secreted molecules. The information provided here creates a comprehensive and practical guide through the current knowledge and will facilitate the choosing of proper, more specific markers for detailed studies on microglia and neuroinflammatory mechanisms in various physiological as well as pathological conditions. Both basic research and clinical medicine need clearly described and validated molecular markers of microglia phenotype, which are essential in diagnostics, treatment, and prevention of diseases engaging glia activation.

Increased Beta-Hydroxybutyrate Level Is Not Sufficient for the Neuroprotective Effect of Long-Term Ketogenic Diet in an Animal Model of Early Parkinson's Disease. Exploration of Brain and Liver Energy Metabolism Markers.
The benefits of a ketogenic diet in childhood epilepsy steered up hope for neuroprotective effects of hyperketonemia in Parkinson's disease (PD). There are multiple theoretical reasons but very little actual experimental proof or clinical trials. We examined the long-term effects of the ketogenic diet in an animal model of early PD. A progressive, selective dopaminergic medium size lesion was induced by 6-OHDA injection into the medial forebrain bundle. Animals were kept on the stringent ketogenic diet (1% carbohydrates, 8% protein, 70% fat) for 3 weeks prior and 4 weeks after the brain operation. Locomotor activity, neuron count, dopaminergic terminal density, dopamine level, and turnover were analyzed at three time-points post-lesion, up to 4 weeks after the operation. Energy metabolism parameters (glycogen, mitochondrial complex I and IV, lactate, beta-hydroxybutyrate, glucose) were analyzed in the brain and liver or plasma. Protein expression of enzymes essential for gluconeogenesis (PEPCK, G6PC) and glucose utilization (GCK) was analyzed in the liver. Despite long-term hyperketonemia pre- and post-lesion, the ketogenic diet did not protect against 6-OHDA-induced dopaminergic neuron lesions. The ketogenic diet only tended to improve locomotor activity and normalize DA turnover in the striatum. Rats fed 7 weeks in total with a restrictive ketogenic diet maintained normoglycemia, and neither gluconeogenesis nor glycogenolysis in the liver was responsible for this effect. Therefore, potentially, the ketogenic diet could be therapeutically helpful to support the late compensatory mechanisms active via glial cells but does not necessarily act against the oxidative stress-induced parkinsonian neurodegeneration itself. A word of caution is required as the stringent ketogenic diet itself also carries the risk of unwanted side effects, so it is important to study the long-term effects of such treatments. More detailed metabolic long-term studies using unified diet parameters are required, and human vs. animal differences should be taken under

consideration.

Pharmacological manipulation of endocannabinoid system represents a promising therapy to alleviate L-3,4-dihydroxyphenylalanine (L-DOPA)-induced dyskinesia (LID) in Parkinson's disease (PD). We investigated here whether CBD (10, 30 and 60 mg/kg) and HUF-101 (1, 3 and 30 mg/kg), a fluorinated CBD analogue, would induce antidyskinetic effects. Unilateral striatal 6-hydroxydopamine-lesioned rats received L-DOPA (10 mg/kg, s.c.) for one week, developing severe axial, limb, locomotor and orofacial abnormal involuntary movements (AIMs). Following that, the animals were treated with CBD or HUF-101 (i.p.) before L-DOPA for two weeks. Independent groups received a combination of CBD with antagonists of the Transient Receptor Potential Vanniloid-1 (CPZ), cannabinoid type 1 (AM251), cannabinoid type 2 (AM630) or Peroxisome Proliferator-Activated type gamma (GW9662) receptors. An inverted U-shaped curve was observed in the CBD effect, the 30 mg/kg dose was effective in decreasing AIMs. HUF-101 at 3 and 30 mg/kg doses present antidyskinetic effects. Both, CBD and HUF-101 do not interfere in motor benefits produced by L-DOPA. AM251 or GW9662 reversed the antidyskinetic effect of CBD and AM630 had no action in this effect. CPZ (5 mg/kg) potentiated the anti-dyskinetic effect of CBD (30mg/kg) and was able to reduce AIMs in association with a subeffective dose of CBD (60 mg/kg). In-tube solid-phase microextraction was used for determination of anandamide (AEA) and 2-arachidonoylglycerol (2-AG) in rat striatum. The decrease of LID by CBD was associated with an increase in the endocannabinoids AEA and 2-AG, which may be a possible mechanism of CBD prior to L-DOPA treatment to prevent the onset of LID.

Cannabidiol has therapeutic potential for myofascial pain in female and male parkinsonian rats.
The musculoskeletal orofacial pain is a complex symptom of Parkinson's disease (PD) resulting in stomatognathic system dysfunctions aggravated by the disease rigidity and postural instability. We tested the effect of cannabidiol (CBD), a non-psychotomimetic constituent of Cannabis sativa, in PD-related myofascial pain. Wistar adult female and male rats orofacial allodynic and hyperalgesic responses were tested by Von Frey and formalin tests, before and 21 days past 6-OHDA lesion. Algesic response was tested after masseter muscle injection of CBD (10, 50, 100 µg in 10 µL) or vehicle. Males compared to females in all estrous cycles' phases presented reduced orofacial allodynia and hyperalgesia. According to the estrous cycle's phases, females presented distinct orofacial nociceptive responses, being the estrus phase well-chosen for nociceptive analysis after 6-OHDA lesion (phase with fewer hormone alterations and adequate length). Dopaminergic neuron lesion decreased mechanical and inflammatory nociceptive thresholds in females and males in a higher proportion in females. CBD local treatment reduced the increased orofacial allodynia and hyperalgesia, in males and females. The female rats were more sensitive to CBD effect considering allodynia, responding to the lowest dose. Although females and males respond to the effect of three doses of CBD in the formalin test, males showed a superior reduction in the hyperalgesic response. These results indicate that hemiparkinsonian female in the estrus phase and male answer differently to the different doses of CBD therapy and nociceptive tests. CBD therapy is effective for parkinsonism-induced orofacial nociception.

Tetracycline repurposing in neurodegeneration: focus on Parkinson's disease.
The prevalence of Parkinson's disease, which affects millions of people worldwide, is increasing due to the aging population. In addition to the classic motor symptoms caused by the death of dopaminergic neurons, Parkinson's disease encompasses a wide range of nonmotor symptoms. Although novel disease-modifying medications that slow or stop Parkinson's disease

progression are being developed, drug repurposing, which is the use of existing drugs that have passed numerous toxicity and clinical safety tests for new indications, can be used to identify treatment compounds. This strategy has revealed that tetracyclines are promising candidates for the treatment of Parkinson's disease. Tetracyclines, which are neuroprotective, inhibit proinflammatory molecule production, matrix metalloproteinase activity, mitochondrial dysfunction, protein misfolding/aggregation, and microglial activation. Two commonly used semisynthetic second-generation tetracycline derivatives, minocycline and doxycycline, exhibit effective neuroprotective activity in experimental models of neurodegenerative/ neuropsychiatric diseases and no substantial toxicity. Moreover, novel synthetic tetracyclines with different biological properties due to chemical tuning are now available. In this review, we discuss the multiple effects and clinical properties of tetracyclines and their potential use in Parkinson's disease treatment. In addition, we examine the hypothesis that the anti-inflammatory activities of tetracyclines regulate inflammasome signaling. Based on their excellent safety profiles in humans from their use for over 50 years as antibiotics, we propose the repurposing of tetracyclines, a multitarget antibiotic, to treat Parkinson's disease.

Temporomandibular inflammation regulates the matrix metalloproteinases MMP-2 and MMP-9 in limbic structures.
Temporomandibular disorder (TMD) is characterized by acute or chronic orofacial pain, which can be associated with inflammatory processes in the temporomandibular joint (TMJ) and emotional disorders. Peripheral and central sensitization in painful orofacial processes is common, and it can be triggered by peripheral inflammatory challenge with consequent neuroinflammation phenomena. Such neuroinflammation comes from inflammatory products from supportive cells, blood-brain barrier, and extracellular matrix. Here, we evaluated the possible recruitment of limbic structures for modified matrix metalloproteinases (MMPs) expression and activity during temporomandibular inflammation-induced orofacial persistent pain. The inflammatory process in TMJs of rats was induced by Freund's Complete Adjuvant (CFA) administration. The activity and expression of MMPs-2 and 9 were assessed by in situ zymography and conventional zymography, respectively. A glial colocalization with the MMPs was performed using immunofluorescence. The results evidenced both short- and long-term alterations on MMP-2 and -9 expression in the limbic structures following CFA-induced temporomandibular inflammation. The gelatinolytic activity was increased in the central amygdala, hippocampus, hypothalamus, ventrolateral periaqueductal gray (vlPAG), superior colliculus, and inferior colliculus. Finally, an increase of colocalization of MMP-2/GFAP and MMP-9/GFAP in CFA-induced inflammation groups was observed when compared with saline groups in the central amygdala and vlPAG. It is possible to suggest that glial activation is partly responsible for the production of gelatinases in the persistent orofacial pain, and it is involved in the initiation and maintenance of this process, indicating that inhibition of MMPs might be pursued as a potential new therapeutic target for TMD.

Upregulation of FosB/ΔFosB in limbic circuits after tooth exodontia-induced occlusal instability in an experimental model of unpredictable chronic stress.
Psychological stress and occlusal alterations are contributing etiologic factors for temporomandibular and muscular disorders in the orofacial area. The neural modulation recruited for this relationship, however, is not elucidated. The aim of this study was to investigate potential central mechanisms involved in the exodontia-induced occlusal instability associated with unpredictable chronic stress (UCS). Male adult Wistar rats were submitted to occlusal instability (unilateral molar teeth extraction) and/or to a UCS protocol and treated with diazepam or vehicle. The anxiety-like behavior was evaluated by elevated plus maze (EPM) and open field (OF) tests. Limbic structures such as the central nucleus of the amygdala (CeA), paraventricular nucleus of the hypothalamus (PVN), dorsal periaqueductal gray matter (dPAG) and nucleus accumbens core (NAc) were analyzed for expression of FosB/ΔFosB (immediate early genes) by immunohistochemistry. Exodontia and/or UCS decreased the time spent in the open arms at the EPM and the distance travelled at the OF, and increased the immobility time at the OF, suggesting anxiety-like behavior. In addition, exodontia induction resulted in an upregulation of FosB/ΔFosB in the CeA, PVN and dPAG, while UCS and exodontia + UCS upregulate FosB/ΔFosB immunoreactivity in the CeA, PVN, dPAG and NAc. Treatment with diazepam decreased the expression of FosB/ΔFosB in all analyzed structures of animals subject to UCS and exodontia + UCS, while promoted a reduction in the FosB/ΔFosB expression in the CeA, PVN and dPAG in animals subject to exodontia. Our findings showed an anxiogenic effect of exodontia and UCS, which is

correlated with intranuclear neuron activation of limbic structures in a spatially dependent manner and that is prevented by the administration of diazepam.

Propargylglycine decreases neuro-immune interaction inducing pain response in temporomandibular joint inflammation model.
The mechanisms underlying temporomandibular disorders following orofacial pain remain unclear. Hydrogen sulfide (HS), a newly identified gasotransmitter, has been reported to modulate inflammation. Cystathionine γ-lyase (CSE) is responsible for the systemical production of HS, which exerts both pro- and antinociceptive effects through inflammation. In the current study, we investigated whether the endogenous HS production pathway contributes to arousal and maintenance of orofacial inflammatory pain, through the investigation of the effects of a CSE inhibitor, propargyglycine (PAG), in a rat CFA (Complete Freund Adjuvant)-induced temporomandibular inflammation model to mimic persistent pain in the orofacial region. For this, rats received either CFA or saline in the temporomandibular joints (TMJs), and after 3 or 14 days, they received a single injection of PAG or saline and were evaluated for nociception with the von Frey and formalin test. Also, pro-inflammatory cytokines, tumor necrosis factor-α (TNF-α), and interleukin-1β (IL-1β) were analyzed in TMJs and trigeminal ganglion (TG). In this last one, glial cells reactivity was also verified. Endogenous HS production rate were measured in both, TMJ and TG. Our results indicated decreased allodynia and hyperalgesic responses in rats submitted to CFA after injection of PAG. Moreover, PAG inhibited leucocyte migration to temporomandibular synovial fluid after 3 and 14 days of inflammation. PAG was able to reduce levels of CBS, CSE, TNF-α, and IL-1β in the TMJ and TG, after 13 days of CFA injection. The observed increased activation of glial cells in the trigeminal ganglia on the 14th day of inflammation can be prevented by the highest dose of PAG. Finally, CBS and CSE expression, and endogenous HS production rate in the TMJ and TG was found higher in rats with persistent temporomandibular inflammation compared to rats injected with saline and PAG was able to prevent this elevation. Our results elucidated the molecular mechanisms by which HS exerts its pro-inflammatory and pro-nociceptive role in the orofacial region by alterations in both local tissue and TG.

Beneficial effects of benzodiazepine on masticatory muscle dysfunction induced by chronic stress and occlusal instability in an experimental animal study.
Psychological stress and occlusal alteration are important etiologic factors for temporomandibular/masticatory muscular disorders. In particular, the exact physiologic mechanism underlying the relation by occlusal alteration and temporomandibular disorders remains unclear. Our purpose was to test the hypothesis that benzodiazepine therapy is able to prevent metabolic and vascular changes in the medial pterygoid muscle of rats under chronic stress after 14 days of unilateral exodontia. Adult Wistar rats were submitted to unpredictable chronic mild stress (10 days) and/or unilateral exodontia and their plasma and medial pterygoid muscles were removed for analysis. A pre-treatment with diazepam was used to verify its effect on stress. The parameters evaluated included anxiety behavior, plasma levels of corticosterone, metabolic activity by succinate dehydrogenase, capillary density by laminin staining and ultrastructural findings by transmission electron microscopy. Occlusal instability induced anxiety-like behavior on elevated plus-maze test and diazepam administration blocked the appearance of this behavior. Unilateral exodontia promoted in the contralateral muscle an increase of oxidative fibers and capillaries and modification of sarcoplasmic reticulum. Chronic stress caused increased glycolytic metabolism, reduced capillary density and morphological changes in mitochondria on both sides. Association of both factors induced a glycolytic pattern in muscle and hemodynamic changes. Pharmacological manipulation with diazepam inhibited the changes in the medial pterygoid muscle after stress. Our results reveal a preventive benzodiazepine treatment for stress and occlusal instability conditions affecting masticatory muscle disorders. In addition, provide insights into the mechanisms by which chronic stress and exodontia might be involved in the pathophysiology of masticatory muscular dysfunctions.

Time-dependent analysis of nociception and anxiety-like behavior in rats submitted to persistent inflammation of the temporomandibular joint.
Temporomandibular disorder (TMD) is prevalent in dental clinics and can involve problems with the masticatory muscles or the temporomandibular joints (TMJ). The pain of TMD is frequently associated with inflammation in the TMJs, but it's etiology is considered to be multifactorial and includes biologic, behavioral, environmental, social, emotional and cognitive factors. The purpose of this investigation was to evaluate the anxiety-like behavior in rats exposed to temporomandibular inflammation via injection of Freund's Adjuvant (CFA) with the elevated plus maze (EPM) and light/dark box (LDB) tests and

to evaluate nociceptive behavior with the von Frey test at different periods. Moreover, this study measured TMJ inflammation using plasma extravasation (Evans blue test) and the intraarticular infiltration of polymorphonuclear neutrophils (myeloperoxidase quantification). The results showed that rats that were submitted to TMJ inflammation exhibited a decreased number of entries into the open arms of the EPM and a decrease in the time spent in the light compartment and in the number of transitions in the LDB. Additionally, the number of entries in closed arms in the EPM, used as indicator of locomotor activity, did not alter between treatments. Furthermore, increases in mechanical sensitivity and increases in plasma extravasation in the joint tissue occurred throughout the inflammation process, along with an increase in myeloperoxidase in the synovial fluid of TMJ. Our results suggest that the temporomandibular inflammation induced by CFA produced anxiety-like behaviors in rats and induced nociceptive behavior across different periods of inflammation.

Cannabidiol increases the nociceptive threshold in a preclinical model of Parkinson's disease.
Medications that improve pain threshold can be useful in the pharmacotherapy of Parkinson's disease (PD). Pain is a prevalent PD's non-motor symptom with a higher prevalence of analgesic drugs prescription for patients. However, specific therapy for PD-related pain are not available. Since the endocannabinoid system is expressed extensively in different levels of pain pathway, drugs designed to target this system have promising therapeutic potential in the modulation of pain. Thus, we examined the effects of the 6-hydroxydopamine- induced PD on nociceptive responses of mice and the influence of cannabidiol (CBD) on 6-hydroxydopamine-induced nociception. Further, we investigated the pathway involved in the analgesic effect of the CBD through the co-administration with a fatty acid amide hydrolase (FAAH) inhibitor, increasing the endogenous anandamide levels, and possible targets from anandamide, i.e., the cannabinoid receptors subtype 1 and 2 (CB1 and CB2) and the transient receptor potential vanilloid type 1 (TRPV1). We report that 6-hydroxydopamine- induced parkinsonism decreases the thermal and mechanical nociceptive threshold, whereas CBD (acute and chronic treatment) reduces this hyperalgesia and allodynia evoked by 6-hydroxydopamine. Moreover, ineffective doses of either FAAH inhibitor or TRPV1 receptor antagonist potentialized the CBD-evoked antinociception while an inverse agonist of the CB1 and CB2 receptor prevented the antinociceptive effect of the CBD. Altogether, these results indicate that CBD can be a useful drug to prevent the parkinsonism-induced nociceptive threshold reduction. They also suggest that CB1 and TRPV1 receptors are important for CBD-induced analgesia and that CBD could produce these analgesic effects increasing endogenous anandamide levels.

Nociceptive Response to L-DOPA-Induced Dyskinesia in Hemiparkinsonian Rats.
Non-motor symptoms are increasingly identified to present clinical and diagnostic importance for Parkinson's disease (PD). The multifactorial origin of pain in PD makes this symptom of great complexity. The dopamine precursor, L-DOPA (L-3,4-dihydroxyphenylalanine), the classic therapy for PD, seems to be effective in pain threshold; however, there are no studies correlating L-DOPA-induced dyskinesia (LID) and nociception development in experimental Parkinsonism. Here, we first investigated nociceptive responses in a 6-hydroxydopamine (6-OHDA)-lesioned rat model of Parkinson's disease to a hind paw-induced persistent inflammation. Further, the effect of L-DOPA on nociception behavior at different times of treatment was investigated. Pain threshold was determined using von Frey and Hot Plate/Tail Flick tests. Dyskinesia was measured by abnormal involuntary movements (AIMs) induced by L-DOPA administration. This data is consistent to show that 6-OHDA-lesioned rats had reduced nociceptive thresholds compared to non-lesioned rats. Additionally, when these rats were exposed to a persistent inflammatory challenge, we observed increased hypernociceptive responses, namely hyperalgesia. L-DOPA treatment alleviated pain responses on days 1 and 7 of treatment, but not on day 15. During that period, we observed an inverse relationship between LID and nociception threshold in these rats, with a high LID rate corresponding to a reduced nociception threshold. Interestingly, pain responses resulting from CFA-induced inflammation were significantly enhanced during established dyskinesia. These data suggest a pro-algesic effect of L-DOPA-induced dyskinesia, which is confirmed by the correlation founded here between AIMs and nociceptive indexes. In conclusion, our results are consistent with the notion that central dopaminergic mechanism is directly involved in nociceptive responses in Parkinsonism condition.

Levadopa Induced Dyskinesia (LID) is a series of abnormal involuntary movements that may arise after treating parkinsonian patients with levodopa. We used a deep-learning opensource package to track posture and movement of a rodent model of LID. Thereafter we used an unsupervised clustering algorithm to classify the subcomponents of movements. Our investigation into pharmacological components of this distinct episode demonstrated a causal role for D2 receprot in producing a distinct set of abnormal movements. We have followed up our behavioral study with in-vivo recordings of striatal activity to unravel the mechanism underlying D2-receptor modulation the mentioned behavioral episode.

Background: There is no available therapy counteracting Parkinson's disease (PD). Astrocyte dysfunction and microglia activation lead to neuroinflammation and consequently to degeneration of dopaminergic neurons. However, the exact mechanism is unknown. One of the proposed approaches to improve neuronal survival is to shift the glial phenotype towards a neuroprotective state. The aim of our project was to study the potential of zolpidem - a $GABA_A\alpha1$ receptor agonist and Compound 21 (C21) – an agonist of angiotensin type 2 receptor (AT2R) to modulate glial phenotype. Additionally we assessed how a selective depletion of microglia (PLX3397) influences motor behavior in rats. **Methods:** 6-ODHA was injected into the medial forebrain bundle to induce medium lesion of dopaminergic neurons. Fluorocitrate (FC) was infused for 7 days into the substantia nigra to promote astrocyte degeneration and microglia activation. Zolpidem and C21 were administered for 7 days after the surgery and PLX3397 7 days prior to and after the surgery. Locomotor activity was measured three and six days after the surgery using ACTIFRAME-SYSTEM and compensatory potential was calculated. **Results:** Lesion-induced behavioral deficit was spontaneously compensated 6 days after the surgery. Only in rats treated with FC, C21 improved motor behavior 3 days after the surgery. Neither zolpidem nor microglia depletion affected motor dysfunction. **Conclusions:** Improvement of motor behavior after AT2R activation suggests that C21 may possess astroprotective properties. To unravel, whether this effect is associated with glial phenotype shift requires further studies. **Funding:** Supported by the National Science Centre grant OPUS14 2017/27/B/NZ7/00289.

Beyond the GFAP-Astrocyte Protein Markers in the Brain.
The idea of central nervous system as one-man band favoring neurons is long gone. Now we all are aware that neurons and neuroglia are team players and constant communication between those various cell types is essential to maintain functional efficiency and a quick response to danger. Here, we summarize and discuss known and new markers of astroglial multiple functions, their natural heterogeneity, cellular interactions, aging and disease-induced dysfunctions. This review is focused on newly reported facts regarding astrocytes, which are beyond the old stereotypes. We present an up-to-date list of marker proteins used to identify a broad spectrum of astroglial phenotypes related to the various physiological and pathological nervous system conditions. The aim of this review is to help choose markers that are well-tailored for specific needs of further experimental studies, precisely recognizing differential glial phenotypes, or for diagnostic purposes. We hope it will help to categorize the functional and structural diversity of the astroglial population and ease a clear readout of future experimental results.

RNase MCPIP1 regulates hepatic peroxisome proliferator-activated receptor gamma via TXNIP/PGC-1alpha pathway.
Monocyte chemoattractant protein-1-induced protein-1 (MCPIP1) acts as an endonuclease that degrades selected mRNAs, viral RNAs and pre-miRNAs. MCPIP1 inhibits adipogenesis by degradation of C/EBPβ mRNA and adipogenesis-related miRNA, however its role in the regulation of hepatic lipid homeostasis is unknown. In this study, we investigated the role of MCPIP1 in the regulation of lipid metabolism in hepatocytes. C57BL/6 mice were fed a high-fat diet (HFD) for 2-20 weeks and next primary hepatocytes and adipose tissue were isolated. For in vitro experiments we used murine primary hepatocytes, control HepG2 cells and HepG2 with overexpressed or silenced MCPIP1. We found that Mcpip1 levels were lower in primary hepatocytes isolated from HFD-fed mice than in control cells starting at 4 weeks of a HFD. Level of Mcpip1 was also depleted in visceral fat isolated from obese and glucose-intolerant mice characterized by fatty liver disease. We showed that MCPIP1 overexpression in HepG2 cells treated with oleate induces the level and activity of peroxisome proliferator-activated receptor γ (PPARγ). This phenotype was reverted upon silencing of MCPIP1 in HepG2 cells and in primary hepatocytes lacking Mcpip1 protein. MCPIP1 activated the PPARγ transcription factor via the thioredoxin-interacting protein (TXNIP)/peroxisome

proliferator-activated receptor γ coactivator 1- α (PGC-1α) pathway. MCPIP1 contributes to lipid metabolism in hepatocytes by regulating the TXNIP/PGC-1α/PPARγ pathway.

Background: Parkinson's disease (PD) is a progressive movement disorder, and the second most common neurodegeneration without effective treatment, stemming the need for further research. Repetitive transcranial magnetic stimulation (rTMS) refers to a non-invasive stimulation protocol designed to modulate neuronal excitability, by applying magnetic pulses delivered in predefined patterns. This type of brain stimulation has been applied to several neurological and psychiatric diseases to alleviate motor and cognitive symptoms. Aim: We aimed to evaluate the effect of intermittent theta-burst stimulation (iTBS), a highly effective excitatory protocol of rTMS with shorter stimulation duration, on motor dysfunction in the 6-hydroxydopamine (6-OHDA) model of Parkinson's disease. Methods: Two-month-old male Wistar rats were divided into 4 experimental groups: controls, rats injected unilaterally with 6-OHDA (10 µg/kg) into the right SNpc, 6-OHDA rats subjected to iTBS protocol (2 times/day/three weeks), and iTBS sham group. To evaluate the therapeutic effect of iTBS in the 6-OHDA model, we performed the Rotarod test, Cylinder test, and Open field test. Results: Animals treated with iTBS showed significant improvement of motor deficit which reflected in increased time on Rotarod, compared to the 6-OHDA and sham group ($p < 0.01$). The iTBS treated rats also used the impaired forelimbs more than the 6-OHDA rats ($p < 0.01$) during lateral exploration. Finally, iTBS-treated rats exhibited reduced anxiety-like behavior when compared to 6-OHDA and sham groups ($p < 0. 01$). Conclusions: Administrations of iTBS showed a considerable beneficial effect on the motor behavior of hemiparkinsonian rats, which could candidate this protocol as a potential therapeutic strategy for PD.

Immunotoxicology of cadmium: Cells of the immune system as targets and effectors of cadmium toxicity.
Cadmium (Cd) has been listed as one of the most toxic substances affecting numerous tissues/organs, including the immune system. Due to variations in studies examining Cd effects on the immune system (exposure regime, experimental systems, immune endpoint measured), data on Cd immunotoxicity in humans and experimental animals are inconsistent. However, it is clear that Cd can affect cells of the immune system and can modulate some immune responses. Due to the complex nature of the immune system and its activities which are determined by multiple interactions, the underlying mechanisms involved in the immunotoxicity of this metal are still vague. Here, the current knowledge regarding the interaction of Cd with cells of the immune system, which may affect immune responses as well as potential mechanisms of consequent biological effects of such activities, is reviewed. Tissue injury caused by Cd-induced effects on innate cell activities depicts components of the immune system as mediators/effectors of Cd tissue toxicity. Cd-induced immune alterations, which may compromise host defense against pathogenic microorganisms and homeostatic reparative activities, stress this metal as an important health hazard.

Immunomodulation by heavy metals as a contributing factor to inflammatory diseases and autoimmune reactions: Cadmium as an example.
Cadmium (Cd) represents a unique hazard because of the long biological half-life in humans (20-30 years). This metal

accumulates in organs causing a continuum of responses, with organ disease/failure as extreme outcome. Some of the cellular and molecular alterations in target tissues can be related to immune-modulating potential of Cd. This metal may cause adverse responses in which components of the immune system function as both mediators and effectors of Cd tissue toxicity, which, in combination with Cd-induced alterations in homeostatic reparative activities may contribute to tissue dysfunction. In this work, current knowledge concerning inflammatory/autoimmune disease manifestations found to be related with cadmium exposure are summarized. Along with epidemiological evidence, animal and in vitro data are presented, with focus on cellular and molecular immune mechanisms potentially relevant for the disease susceptibility, disease promotion, or facilitating development of pre-existing pathologies.

Theta burst stimulation ameliorates symptoms of experimental autoimmune encephalomyelitis and attenuates reactive gliosis.
Multiple sclerosis (MS) is a chronic neurodegenerative disease caused by inflammatory processes in the central nervous system (CNS). Decades of research led to discovery of several disease-modifying therapeutics strategies with moderate success. Experimental autoimmune encephalomyelitis (EAE) is currently the most commonly used experimental model for MS and for studying various therapeutic approaches. Repetitive transcranial magnetic stimulation (rTMS) is a non-invasive neurostimulation technique with multiple beneficial effects on healthy as well as CNS with pathology. However, the molecular and cellular mechanisms of rTMS on acute EAE are scarce. Our study demonstrated beneficial effects of theta-burst stimulation (TBS), an experimental paradigm of rTMS, on disease course of acute EAE. TBS treatment attenuated reactive gliosis, restored myelin sheet and down-regulated expression of vimentin in EAE rats. These effects were reflected through reduced clinical parameters, shorter duration of illness and days spent in paralysis. Based on our research, rTMS deserves further considerations for its neuroprotective effect on EAE, and is an excellent candidate for further research and points that it could be used for more than for simple symptomatic therapy.

Proinflammatory effects of environmental cadmium boost resistance to opportunistic pathogen Aspergillus fumigatus: Implications for sustained low-level pulmonary inflammation?
Cadmium (Cd) is one of the most toxic environmental heavy metals to which the general population is exposed mainly via the oral route. Owing to its immunomodulatory potential, orally acquired Cd affects antimicrobial immune defense in several organs, including the lungs. While there are data concerning Cd and viral and bacterial pulmonary infections, effects on fungal infections are not studied yet. In the present study, the effect of the Cd (5 mg/L for 30 days, in drinking water, the average daily Cd intake 0.641 ± 0.089 mg/kg) on the immune response of rats to pulmonary A. fumigatus infection was examined. Data obtained showed that orally acquired cadmium does not affect the elimination of the fungus in immunocompetent rats owing to the preservation of some aspects of innate immune responses (lung leukocyte infiltration and NBT reduction) and an increase in other (increased numbers of mucus-producing goblet cells, MPO release). Cd does not affect an IFN-γ response in lung leukocytes during the infection (despite suppression of cytokine production in cells of lung-draining lymph nodes), while it stimulates IL-17 and suppresses IL-10 response to the fungus. As a result, the elimination of the fungus occurs in a milieu with the prevailing proinflammatory response in Cd-exposed animals that preserved fungal elimination from the lungs, though with more intense injury to the lung tissue. Therefore, the proinflammatory microenvironment in the lungs created by Cd that sustains inflammatory/immune response to the fungus to which humans are exposed for a lifetime, raises a concern of orally acquired Cd as a risk factor for the development of chronic low-grade pulmonary inflammation.

Downregulation of CD73/AR-Mediated Adenosine Signaling as a Potential Mechanism of Neuroprotective Effects of Theta-Burst Transcranial Magnetic Stimulation in Acute Experimental Autoimmune Encephalomyelitis.
Multiple sclerosis (MS) is a chronic neurodegenerative disease caused by autoimmune-mediated inflammation in the central nervous system. Purinergic signaling is critically involved in MS-associated neuroinflammation and its most widely applied animal model-experimental autoimmune encephalomyelitis (EAE). A promising but poorly understood approach in the treatment of MS is repetitive transcranial magnetic stimulation. In the present study, we aimed to investigate the effect of continuous theta-burst stimulation (CTBS), applied over frontal cranial bone, on the adenosine-mediated signaling system in EAE, particularly on CD73/AR/AR in the context of neuroinflammatory activation of glial cells. EAE was induced in two-month-old female DA rats and in the disease peak treated with CTBS protocol for ten consecutive days. Lumbosacral spinal cord was analyzed immunohistochemically for adenosine-mediated signaling components and pro- and anti-inflammatory factors.

We found downregulated IL-1β and NF- κB- and upregulated IL-10 pointing towards a reduction in the neuroinflammatory process in EAE animals after CTBS treatment. Furthermore, CTBS attenuated EAE-induced glial eN/CD73 expression and activity, while inducing a shift in AR expression from glia to neurons, contrary to EAE, where tight coupling of eN/CD73 and AR on glial cells is observed. Finally, increased glial AR expression following CTBS supports anti-inflammatory adenosine actions and potentially contributes to the overall neuroprotective effect observed in EAE animals after CTBS treatment.

Dermatotoxicity of oral cadmium is strain-dependent and related to differences in skin stress response and inflammatory/immune activity.

Adverse effects of non-occupational exposure to cadmium (Cd) are increasingly acknowledged. Since our previous study has showed that orally acquired Cd affects skin, the contribution of genetic background to dermatotoxicity of oral cadmium was examined in two rat strains, Albino Oxford (AO) and Dark Agouti (DA), which differed in response to chemicals. While similar accumulation of Cd in the skin of both strains was noted, the skin response to the metal differed. DA rat individuals mounted antioxidant enzyme defense in the skin already at lower Cd dose, in contrast to AO rats which reacted to higher metal dose solely (and less pronounced), implying higher susceptibility of DA strain to Cd dermatotoxicity. Epidermal cells from both strains developed stress response, but higher intensity of antioxidant response in AO rats implied this strain`s better ability to defend against Cd insult. Cd induced epidermal cells' proinflammatory cytokine response only in DA rats. Increased IL-10 seems responsible for the lack of response in AO rats. Differences in the pattern of skin/epidermal cell responsiveness to cadmium give a new insight into repercussion of genetic variability to dermatotoxicity of orally acquired cadmium, bearing relevance for variations in the link between dietary cadmium and inflammation-based skin pathologies.

NEUROPROTECTIVE EFFECTS OF L-THEANINE AGAINST TRAMADOL INDUCED PARKINSON'S LIKE SYMPTOMS IN EXPERIMENTAL RATS

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Khadga Raj Aran
ISF College of Pharmacy, Pharmacology, Moga, India

Abstract Parkinson's disease (PD) is a chronic neurodegenerative disorder triggered by degeneration of dopaminergic neurons in substantia nigra pars compacta (SNpc). Experimental Animals: Wistar Rats (180-200 g). Drugs and Chemicals: Tramadol, L- theanine, Naloxone and Sinemet. Experimental procedure: The animals were divided into 7 groups. Behavioral observations were done on 1, 7, 14, 21 and 28 day after tramadol treatment. On 29 day, animals were sacrificed and striatum was isolated for biochemical, neuroinflammation, histopathological and neurotransmitters analysis. Administration of tramadol (50 mg/ kg, i.p.) for 28 days in rats produces impaired motor functions and locomotor activity as evidenced by rotarod, open field, narrow beam walk and grip strength performance. In addition, there was increased oxidative stress (MDA, nitrite) and neuroinflammatory markers (TNF-α, IL-1β and IL-17) and decreased levels of catecholamines, GABA and glutamate. The treatment drug L-theanine at dose (25, 50, 100 mg/kg) significantly and dose- dependently improved alterations in motor impairments and locomotor activity, attenuated oxidative stress, neuroinflammatory markers and restored catecholamines, GABA and glutamate level in striatum. Chronic tramadol administration produces impaired motor functions, increased oxidative stress, neuroinflammation and altered neurotransmitters level was significantly ameliorated by L-theanine, through antioxidant, anti-inflammatory and neuroprotective mechanisms.

Neuroprotective Effect of Fucoxanthin against Intracerebroventricular Streptozotocin (ICV-STZ) Induced Cognitive Impairment in Experimental Rats.
Alzheimer's disease (AD) is a neurological disorder characterized by loss of memory and cognitive functions caused by oxidative stress, neuroinflammation, change in neurotransmitter levels, and excessive deposition of Aβ plaques. Fucoxanthin is a carotenoid with potential antioxidant, anti-inflammatory, and neuroprotective actions.

Spermine protects aluminium chloride and iron-induced neurotoxicity in rat model of Alzheimer's disease via attenuation of tau phosphorylation, Amyloid-β (1-42) and NF-κB pathway.
Alzheimer's disease (AD) is the most prevalent type of dementia, characterized by a gradual decline in cognitive and memory functions of the aged peoples. Long-term exposure to heavy metals (aluminium and iron) cause neurotoxicity by amyloid plaques accumulation, tau phosphorylation, increased oxidative stress, neuroinflammation, and cholinergic neurons degeneration, contributes to the development of AD-like symptoms. The present research work is designed to investigate the neuroprotective effect of spermine in aluminium chloride (AlCl), and iron (Fe) induced AD-like symptoms in rats. Rats were administered of AlCl (100 mg/kg p.o.) alone and in combination with iron (120 µg/g, p.o.) for 28 days. Spermine (5 and 10 mg/kg) through intraperitoneal (i.p.) route was given for 14 days. The recognition and spatial memory impairment were tasted using Morris water maze (MWM), actophotometer, and Novel Object Recognition test (NORT). All the rats were sacrificed on day 29, brains were isolated, and tissue homogenate was used for neuroinflammatory, biochemical, neurotransmitters, metals concentration, and nuclear factor-kappa B (NF-κB) analysis. In the present study, AlCl and iron administration elevated oxidative stress, cytokines release, dysbalanced neurotransmitters concentration, and biochemical changes. Rats treated with spermine dose-dependently improved the recognition and spatial memory, attenuated proinflammatory cytokine release, and restored neurotransmitters concentration and antioxidant enzymes. Spermine also mitigated the increased beta-amyloid (Aβ42), with downregulation of tau phosphorylation. Furthermore, spermine augmented the hippocampal levels of B cell leukaemia/lymphoma-2 (Bcl-2), diminished nuclear factor-kappa B (NF-κB) and caspase-3 (casp-3) expression. Moreover, spermine exhibited the neuroprotective effect through anti-inflammatory, antioxidant, neurotransmitters restoration, anti-apoptotic Aβ42 concentration.

Protective effects of cerebrolysin against chemotherapy (carmustine) induced cognitive impairment in Albino mice.
Chemotherapy-induced cognitive impairment (CICI) comprises different neurological problems, including difficulty in learning new things, concentrating and making decisions that affect daily life activities. Clinical reports indicate that around 70% of cancer patients receiving chemotherapy suffer from cognitive impairment. The purpose of the present study is to examine the effects of widely used anticancer medication (Carmustine) on cognitive function using mice model and investigation of the neuroprotective effects of Cerebrolysin (CBN). Cerebrolysin (CBN) is a mixture of several neurotrophic factors and active peptides with anti-inflammatory, antioxidant, and neuroprotective actions. Our study aimed to establish a mice model of Carmustine (BCNU)-induced cognitive deficits and determine the protective effects of CBN. BCNU (10 mg/kg, i.v.) was administered to mice for 28 days, and behavioral parameters were measured on a weekly basis. CBN (44 and 88 mg/kg, i.p.) was administered daily from day 1 to 28 to BCNU treatment mice. All animals were sacrificed on day 29 and brain hippocampus tissues were used for biochemical, neuroinflammatory, neurotransmitters analysis. BCNU administration animals showed impaired cognition and memory, confirmed from behavioral analysis. Further, BCNU increased oxidative stress, inflammatory cytokines release and altered neurotransmitters concentration as compared to the control group (< 0.01). However, mice treated with CBN (44 and 88 mg/kg, i.p.) significantly and dose-dependently improved cognitive functions, reduced oxidative stress markers, inflammatory cytokines and restored neurotransmitters concentration as compared to BCNU administered mice (< 0.05). The finding of current study suggested that CBN could be the promising compound to reverse cognitive impairment associated with use of chemotherapy.

l-Theanine ameliorates motor deficit, mitochondrial dysfunction, and neurodegeneration against chronic tramadol induced rats model of Parkinson's disease.
Parkinson's disease (PD) is the second most prevalent progressive neurodegenerative disease, characterized by loss of dopaminergic neurons in substantia nigra, with deficiency of dopamine in the striatum. Tramadol is safe analgesic but long-term use confirmed to elevate oxidative stress, neuroinflammation, mitochondrial dysfunction, in brain leads to motor deficits. l-Theanine is an active constituent of green tea which prevents neuronal loss, mitochondrial failure and improves dopamine, gamma-aminobutyric acid (GABA), serotonin levels and in the central nervous system (CNS) via antioxidant, anti-inflammatory, and neuromodulatory properties. In the present study, tramadol was injected intraperitoneally to Wister rats for 28 days at a dose of 50 mg/kg. l-Theanine (25, 50, and 100 mg/kg) was administered orally 3 h before tramadol administration from day 14 to day 28. Behavioral analyses including rotarod, narrow beam walk, open field, and grip strength were used to evaluate motor coordination on a weekly basis. On the day 29, all Wistar rats were sacrificed and striatum homogenates were used for biochemical (lipid peroxidation, nitrite, glutathione, glutathione peroxidase activity, superoxide dismutase, catalase, mitochondrial complex I, IV, and cyclic adenosine monophosphate), neuroinflammatory markers (tumor necrosis factor-α, interleukin-1β, and interleukin-17), and neurotransmitters (dopamine, norepinephrine, serotonin, GABA, and glutamate) analysis. Chronic tramadol treatment caused motor deficits reduced antioxidant enzymes level, increased striatal proinflammatory cytokines release, dysbalanced neurotransmitters, and reduced mitochondrial complex activity I, IV, and cAMP activity. However, l-theanine administration attenuated behavioral, biochemical, neuroinflammatory, neurotransmitters, and mitochondrial activity indicated it as a promising neuroprotective potential against degenerative changes in experimental model of PD.

Allicin ameliorates aluminium- and copper-induced cognitive dysfunction in Wistar rats: relevance to neuro-inflammation, neurotransmitters and Aβ analysis.
Alzheimer's disease (AD) is a multifactorial neurological disorder associated with neuropathological and neurobehavioral changes, like cognition and memory loss. Pathological hallmarks of AD comprise oxidative stress, formation of insoluble β-amyloid (Aβ) plaques, intracellular neurofibrillary tangles constituted by hyperphosphorylated tau protein (P-tau), neurotransmitters dysbalanced (DA, NE, 5-HT, GABA and Glutamate) and metal deposition. Chronic exposure to metals like aluminium and copper causes accumulation of Aβ plaques, promotes oxidative stress, neuro-inflammation, and degeneration of cholinergic neurons results in AD-like symptoms. In the present study, rats were administered with aluminium chloride (200 mg/kg p.o) and copper sulfate (0.5 mg/kg p.o) alone and in combination for 28 days. Allicin (10 and 20 mg/kg i.p) was administered from day 7 to day 28. Spatial and recognition memory impairment analysis was performed using Morris water maze, Probe trial, and Novel Object Recognition test. Animals were sacrificed on day 29, brain tissue was isolated, and its homogenate was used for biochemical (lipid peroxidation, nitrite, and glutathione), neuro-inflammatory (IL-1β, IL-6 and TNF-α), neurotransmitters (DA, NE, 5-HT, GABA and Glutamate), Aβ level, Al concentration estimation, and Na/K-ATPase activity.

In the present study, aluminium chloride and copper sulfate administration increased oxidative stress, inflammatory cytokines release, imbalanced neurotransmitters' concentration, and promoted β-amyloid accumulation and Na/K-ATPase activity. Treatment with allicin dose-dependently attenuated these pathological events via restoration of antioxidants, neurotransmitters concentration, and inhibiting cytokine release and β-amyloid accumulation. Moreover, allicin exhibited the neuroprotective effect through antioxidant, anti-inflammatory, neurotransmitters restoration, attenuation of neuro-inflammation and β-amyloid-induced neurotoxicity.

Current understanding on molecular drug targets and emerging treatment strategy for novel coronavirus-19.
SARS-CoV-2 is an enveloped positive-sense RNA virus, contain crown-like spikes on its surface, exceptional of large RNA genome, and a special replication machinery. Common symptoms of SARS-CoV-2 include cough, common cold, fever, sore throat, and a variety of severe acute respiratory disease (SARD) such as pneumonia. SARS-CoV-2 infects epithelial cells, T-cells, macrophages, and dendritic cells and also influences the production and implantation of pro-inflammatory cytokines and chemokines. Repurposing of various drugs during this emergency condition can reduce the rate of mortality as well as time and cost. Two druggable protein and enzyme targets have been selected in this review article due to their crucial role in the viral life cycle. The eukaryotic translation initiation factor (eIF4A), cyclophilin, nucleocapsid protein, spike protein, Angiotensin-converting enzyme 2 (ACE2), 3-chymotrypsin-like cysteine protease (3CLpro), and RNA-dependent RNA polymerase (RdRp) play significant role in early and late phase of SARS-CoV-2 replication and translation. This review paper is based on the rationale of inhibiting of various SARS-CoV-2 proteins and enzymes as novel therapeutic approaches for the management and treatment of patients with SARS-CoV-2 infection. We also discussed the structural and functional relationship of different proteins and enzymes to develop therapeutic approaches for novel coronavirus SARS-CoV-2.

Metals associated neurodegeneration in Parkinson's disease: Insight to physiological, pathological mechanisms and management.
Parkinson's disease (PD) is a deliberately progressive neurological disorder, arises due to degeneration of dopaminergic neurons in the substantia nigra pars compacta (SNpc). The loss of dopaminergic nerves and dopamine deficiency leads to motor symptoms characterized by rigidity, tremor, and bradykinesia. Heavy metals and trace elements play various physiological and pathological roles in the nervous system. Excessive exposure to toxic metals like mercury (Hg), lead (Pb), copper (Cu), zinc (Zn), iron (Fe), manganese (Mn), aluminium (Al), arsenic (As), cadmium(cd), and selenium (Se) cross the blood-brain barrier to enter into the brain and leads to dopaminergic neuronal degeneration. Excessive concentrations of heavy metals in the brain promote oxidative stress, mitochondrial dysfunction, and the formation of α-synuclein leads to dopaminergic neuronal damage. There is increasing evidence that heavy metals normally present in the human body in minute concentration also cause accumulation to initiate the free radical formation and affecting the basal ganglia signaling. In this review, we explored how these metals affect brain physiology and their roles in the accumulation of toxic proteins (α-synuclein and Lewy bodies). We have also discussed the metals associated with neurotoxic effects and their prevention as management of PD. Our goal is to increase the awareness of metals as players in the onset and progression of PD.

Oxiracetam and Zinc Ameliorates Autism-Like Symptoms in Propionic Acid Model of Rats.
Autism spectrum disorder (ASD) is a complex neurodevelopmental disorder characterized by restrictive behaviour, deficit in social skills and interaction. The multifactorial etiology, complex pathophysiology and different combination of symptoms (unusual speech patterns, frequent repetition of phrases) make it difficult to treat. Thus, present study aimed to find the protective effects of oxiracetam alone and in combination with zinc on brain behavioral, biochemical, pro-inflammatory cytokines and neurotransmitters level. Rats were administered with propionic acid (250 mg/kg p.o.) for 3 days and immediately on next day treatment were given with oxiracetam (25, 50 mg/kg i.p), zinc (4 mg/kg) as well as oxiracetam (25 mg/kg i.p) in combination with zinc (4 mg/kg p.o). Behavioral parameters were performed from 22th to 28th day. On 29th day, all the animals were sacrificed by cervical dislocation and the brain was preserved for biochemical (LPO, GSH, nitrite, mitochondrial complex I, IV and cAMP), neuroinflammatory (TNF-α, IL-1β, IL-6) and neurotransmitters (5-HT, GABA, glutamate and acetylcholine) analysis. The propionic acid administration showed memory impairment, restrictive behavior, increased proinflammatory cytokines level, biochemical and neurotransmitters alteration. However, treatment with oxiracetam alone and in combination with zinc significantly attenuated behavioral, biochemical, inflammatory cytokines and restored neurotransmitters level. The finding of present study demonstrated that oxiracetam alone and in combination with zinc afforded superior anti-autistic effect through antioxidant, anti-inflammatory and anti-excitotoxic mechanisms and could serve as attractive strategy in managing autism.

Neurobehavioral Consequences Associated with Long Term Tramadol Utilization and Pathological Mechanisms.
Tramadol is a synthetic analog of codeine used to treat pain of moderate to severe intensity and is reported to have neurotoxic potential. At therapeutic dose, tramadol does not cause major side effects in comparison to other opioid analgesics, and is useful for the management of neurological problems like anxiety and depression. Long term utilization of tramadol is associated with various neurological disorders like seizures, serotonin syndrome, Alzheimer's disease and Parkinson's disease. Tramadol produces seizures through inhibition of nitric oxide, serotonin reuptake and inhibitory effects on GABA receptors. Extensive tramadol intake alters redox balance through elevating lipid peroxidation and free radical leading to neurotoxicity and produces neurobehavioral deficits. During Alzheimer's disease progression, low level of intracellular signalling molecules like cGMP, cAMP, PKC and PKA affect both learning and memory. Pharmacologically tramadol produces actions similar to Selective Serotonin Reuptake Inhibitors (SSRIs), increasing the concentration of serotonin, which causes serotonin syndrome. In addition, tramadol also inhibits GABAA receptors in the CNS has been evidenced to interfere with dopamine synthesis and release, responsible for motor symptoms. The reduced level of dopamine may produce bradykinesia and tremors which are chief motor abnormalities in Parkinson's Disease (PD).

Mitochondrial dysfunctioning and neuroinflammation: Recent highlights on the possible mechanisms involved in Traumatic Brain Injury.
Traumatic brain injury (TBI) is the injury to the vasculature of brain while trauma caused by physical, chemical and biological stimuli. TBI is the leading cause of mortality and morbidity around the world. In this, primary insult leads to secondary injury through the involvement and initiation of various pathological processes. The most citable includes excitotoxicity, Blood Brain Barrier (BBB) dysfunction, inflammation, mitochondrial dysfunction, oxidative stress, calcium efflux, microglial mediated release of proinflammatory mediators (cytokine, chemokines, interleukin, tissue necrosis factor etc.). The morphological changes in TBI are proportional to mitochondrial dysfunctioning and microglial activation, which play an assorted role in neurodegeneration following traumatic brain injury. It is also assumed that the release of nitric oxide, activation of microglial cells plays a diversive role in maintaining the physiological and pathological balance. This review cites different pathophysiological mechanisms that are involved in progenesis of secondary injury after primary insult. These targets further are useful to explore the deep molecular mechanisms and to analyse the effectiveness of available drugs. Moreover, the present review reflects the underlying inflammatory cascade responsible for neuronal loss and neurological deficit in TBI.

EFFECT OF A COMBINATION TREATMENT OF BEE VENOM PHARMACOPUNCTURE IN GB34 AND L-DOPA IN A MOUSE MODEL OF PARKINSON'S DISEASE

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Minsook Ye[1], Kyungsoo Kim[1], Mun Young Lee[1], Insop Shim[2]
[1]The Catholic University of Korea, Integrative Medicine, Seoul, Korea, Republic of, [2]Kyung Hee University, Physiology, Seoul, Korea, Republic of

Aim: L-DOPA-induced dyskinesias (LID) remain a major problem of long-term therapy of Parkinson's disease. After several years, however, the patients develop l-dopa–induced dyskinesia, or abnormal involuntary movements. Previous studies reported that bee venom (BV) had neuroprotective effect in mouse model of Parkinson's disease (PD). The present study aimed to investigate whether bee venom (BV) pharmacopuncture in GB34 would have synergistic effects with L-3,4-dihydroxyphenylalanine (L-DOPA)and antidyskinetic effects caused by L-dopa as well. **Methods:** MPTP (30 mg/kg) was injected intraperitoneally for 5 consecutive days. Then, 1 week after the last MPTP injection, L-dopa (15mg/kg) to test synergistic effects with BV pharmacopuncture in GB34. After the final treatments, behavioral changes were assessed in all mice using pole test. The antidyskinetic effects of BV in GB34 on pathological movements triggered by L-dopa were investigated by testing abnormal involuntary movements (AIMs) and measuring the expression of TH (tyrosine hydroxylase), Iba-1 in the substantia nigra and activation of FosB in striatum. **Results:** BV pharmacopuncture in GB34 synergistically improved the motor function when L-dopa was co-administered. In addition, it significantly reversed MPTP-induced improved expression of Iba-1, TH in the SN and FosB in the striatum. Furthermore, BV pharmacopuncture in GB34 significantly lowered AIMs and controlled abnormal levels. **Conclusion:** BV pharmacopuncture in GB34 lowered the effective dose of L-dopa and alleviated LID. These findings suggest that BV in GB34 may be used as an adjunct therapy to enhance the efficacy of l-dopa and alleviate its adverse effects in patients with PD.

ASSESSMENT OF REPETITIVE AND COMPULSIVE BEHAVIOURS INDUCED BY PRAMIPEXOLE IN RATS: EFFECT OF ALPHA-SYNUCLEIN-INDUCED NIGROSTRIATAL DEGENERATION

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Mélina Decourt, Eric Balado, Haritz Jiménez-Urbieta, Maureen Francheteau, Pierre-Olivier Fernagut, Marianne Benoit-Marand
Inserm - University of Poitiers, Laboratoire De Neurosciences Expérimentales Et Cliniques-Inec, Poitiers, France

Parkinson’s disease is characterized by the degeneration of *substantia nigra pars compacta* dopaminergic neurons, leading to motor and cognitive symptoms. Pramipexole (PPX, D2/D3 dopaminergic agonist) is effective to treat motor symptoms but induces non-motor side effects called impulse control disorders developing in 30% of treated patients. Several risk factors are known such individual vulnerability traits, medications and neurodegenerative process. Here, we explored the impact of nigrostriatal degeneration induced by bilateral injection of a viral vector expressing human mutated alpha-synuclein (AAV-2 hA53Talpha-syn) and chronic PPX treatment on repetitive and compulsive-like behaviours with spontaneous hoarding task and operant post-training signal attenuation task (PTSA). Our results highlight that PPX increases the time spent interacting with food (similar to punding behaviour) at the expense of hoarding in the same way in sham and lesioned rats. In PTSA task, the combination of nigrostriatal lesion and PPX decreased the number of completed trials and increased the number of uncompleted trials. The lesion led to an increased compulsive-like behaviour after attenuation, and PPX shifted the overall behavioural output towards an increased proportion of compulsive lever-presses. Given the magnitude of the behavioural effects and the lack of strong interaction between PPX and nigral degeneration, these results suggest that extra-nigral pathology may be critical to increase the vulnerability to develop compulsive-like behaviours following treatment.

SEROTONERGIC AND DOPAMINERGIC NEURONS IN DORSAL RAPHE NUCLEUS: FROM PHYSIOLOGY TO PARKINSON'S DISEASE PATHOLOGY.

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Laura Boi[1], Yvonne Johansson[1,2], Gilad Silberberg[1], Gilberto Fisone[1]
[1]Karolinska Institutet, Neuroscience, Solna, Sweden, [2]University College London, Sainsbury Wellcome Centre For Neural Circuits And Behaviour, London, United Kingdom

The Dorsal Raphe Nucleus (DRN) contains different populations of serotonergic ($DRN_{5\text{-}HT}$) and dopaminergic (DRN_{DA}) neurons. Because of their anatomic and genetic features, attempts to target these populations are difficult and have often generated contrasting results. Parkinson's Disease (PD) is associated with non-motor comorbidities, which may involve the $DRN_{5\text{-}HT}$ and DRN_{DA}. To test this possibility, we first investigated the electrophysiological and morphological properties of $DRN_{5\text{-}HT}$ and DRN_{DA} in physiological conditions and in a mouse model of PD. Wild-type and DAT-tdTomato mice were bilaterally injected in the Dorsal Striatum with vehicle or 6-hydroxydopamine (6-OHDA). Three weeks later, mice were deeply anaesthetized and midbrain slices were prepared for whole-cell patch-clamp recordings of DRN neurons. Recorded neurons were stained and classified as $DRN_{5\text{-}HT}$ or DRN_{DA} using immunohistochemistry. We found that in control mice, $DRN_{5\text{-}HT}$ and DRN_{DA} neurons differ in many of their electrophysiological and morphological profiles. In 6-OHDA lesioned mice, $DRN_{5\text{-}HT}$ showed changes in the excitability and smaller and more circular cell bodies. DRN_{DA} neurons in lesioned mice had altered action potential properties as well as morphological changes such as swelling of cell bodies and increased dendritic branching. Our study identifies several electrophysiological properties that can be used to differentiate $DRN_{5\text{-}HT}$ and DRN_{DA} neurons. Importantly, both populations are affected by the 6-OHDA lesion. Taking into account the involvement of DRN in affective and sleep disorders, the present results provide useful information to determine the relative contribution of $DRN_{5\text{-}HT}$ and DRN_{DA} to non-motor comorbidities in PD.

Neuroinflammation in L-DOPA-induced dyskinesia: beyond the immune function.
Neuroinflammation is a main component of Parkinson's disease (PD) neuropathology, where unremitting reactive microglia and microglia-secreted soluble molecules such as cytokines, contribute to the neurodegenerative process as part of an aberrant immune reaction. Besides, pro-inflammatory cytokines, predominantly TNF-α, play an important neuromodulatory role in the healthy and diseased brain, being involved in neurotransmitter metabolism, synaptic scaling and brain plasticity. Recent preclinical studies have evidenced an exacerbated neuroinflammatory reaction in the striatum of parkinsonian rats that developed dyskinetic responses following L-DOPA administration. These findings prompted investigation of non-neuronal mechanisms of L-DOPA-induced dyskinesia (LID) involving glial cells and glial-secreted soluble molecules. Hence, besides the classical mechanisms of LID that include abnormal corticostriatal neurotransmission and maladaptive changes in striatal medium spiny neurons (MSNs), here we review studies supporting a role of striatal neuroinflammation in the development of LID, with a focus on microglia and the pro-inflammatory cytokine TNF-α. Moreover, we discuss several mechanisms that have been involved in the development of LID, which are directly or indirectly under the control of TNF-α, and might be abnormally affected by its chronic overproduction and release by microglia in PD. It is proposed that TNF-α may contribute to the altered neuronal responses occurring in LID by targeting receptor trafficking and function in MSNs, but also dopamine synthesis in preserved dopaminergic terminals and serotonin metabolism in serotonergic neurons. Therapeutic approaches specifically targeting glial-secreted cytokines may represent a novel target for preventing or treating LID.

Boosting phagocytosis and anti-inflammatory phenotype in microglia mediates neuroprotection by PPARγ agonist MDG548 in Parkinson's disease models.
Microglial phenotype and phagocytic activity are deregulated in Parkinson's disease (PD). PPARγ agonists are

neuroprotective in experimental PD, but their role in regulating microglial phenotype and phagocytosis has been poorly investigated. We addressed it by using the PPARγ agonist MDG548.

Microglial Phagocytosis and Its Regulation: A Therapeutic Target in Parkinson's Disease?
The role of phagocytosis in the neuroprotective function of microglia has been appreciated for a long time, but only more recently a dysregulation of this process has been recognized in Parkinson's disease (PD). Indeed, microglia play several critical roles in central nervous system (CNS), such as clearance of dying neurons and pathogens as well as immunomodulation, and to fulfill these complex tasks they engage distinct phenotypes. Regulation of phenotypic plasticity and phagocytosis in microglia can be impaired by defects in molecular machinery regulating critical homeostatic mechanisms, including autophagy. Here, we briefly summarize current knowledge on molecular mechanisms of microglia phagocytosis, and the neuro-pathological role of microglia in PD. Then we focus more in detail on the possible functional role of microglial phagocytosis in the pathogenesis and progression of PD. Evidence in support of either a beneficial or deleterious role of phagocytosis in dopaminergic degeneration is reported. Altered expression of target-recognizing receptors and lysosomal receptor CD68, as well as the emerging determinant role of α-synuclein (α-SYN) in phagocytic function is discussed. We finally discuss the rationale to consider phagocytic processes as a therapeutic target to prevent or slow down dopaminergic degeneration.

Immunomodulatory drugs alleviate l-dopa-induced dyskinesia in a rat model of Parkinson's disease.
Thalidomide and closely related analogues are used clinically for their immunomodulatory and antiangiogenic properties mediated by the inhibition of the proinflammatory cytokine tumor necrosis factor α. Neuroinflammation and angiogenesis contribute to classical neuronal mechanisms underpinning the pathophysiology of l-dopa-induced dyskinesia, a motor complication associated with l-dopa therapy in Parkinson's disease. The efficacy of thalidomide and the more potent derivative 3,6'-dithiothalidomide on dyskinesia was tested in the 6-hydroxydopamine Parkinson's disease model.

Trimethyl Chitosan Hydrogel Nanoparticles for Progesterone Delivery in Neurodegenerative Disorders.
Progesterone is a sex hormone which shows neuroprotective effects in different neurodegenerative disorders, including Parkinson's disease, stroke, and Alzheimer's disease. However, the pharmacokinetic limitations associated with the peripheral administration of this molecule highlight the need for more efficient delivery approaches to increase brain progesterone levels. Since the nose-to-brain administration of mucoadhesive hydrogel nanoparticles is a non-invasive and convenient strategy for the delivery of therapeutics to the central nervous system, in this work, progesterone-loaded hydrogel nanoparticle formulations have been prepared, characterized, and tested in vivo. Nanoparticles, loaded with different progesterone concentrations, have been obtained by polyelectrolyte complex formation between trimethyl chitosan and sodium alginate, followed by ionotropic gelation with sodium tripolyphosphate as a cross-linking agent. All formulations showed a mean diameter ranging from 200 nm to 236 nm, a polydispersity index smaller than 0.23, and a high progesterone encapsulation efficiency (83-95%). The zeta potential values were all positive and greater than 28 mV, thus ensuring nanoparticles stability against aggregation phenomena as well as interaction with negative sialic residues of the nasal mucosa. Finally, in vivo studies on Sprague-Dawley male rats demonstrated a 5-fold increase in brain progesterone concentrations compared to basal progesterone level after 30 min of hydrogel nanoparticle inhalation.

Treatment with gut bifidobacteria improves hippocampal plasticity and cognitive behavior in adult healthy rats.
At the present time, gut microbiota inspires great interest in the field of neuroscience as a function of its role in normal physiology and involvement in brain function. This aspect suggests a specific gut-brain pathway, mainly modulated by gut microbiota activity. Among the multiple actions controlled by microbiota at the brain level, neuronal plasticity and cognitive function represent two of the most interesting aspects of this cross-talk communication. We address the possible action of two-months implementation of gut Bifidobacteria using a mixture of three different strains (B-MIX) on hippocampal plasticity and related cognitive behavior in adult healthy Sprague Dawley rats. B-MIX treatment increases the hippocampal BDNF with a parallel gain in dendritic spines' density of hippocampal CA1 pyramidal neurons. Electrophysiological experiments revealed a significant increment of HFS-induced LTP formation on the CA1 hippocampal region in B-MIX treated rats. All these effects are accompanied by a better cognitive performance observed in B-MIX treated animals with no impairments in locomotion activity. Therefore, in adult rats, the treatment with different strains of bifidobacteria is able to markedly enhance neuronal plasticity and the CNS function influencing cognitive behavior, an effect that may suggest a potential therapeutic treatment in

brain diseases associated with cognitive functions.

Neuroprotection by the Immunomodulatory Drug Pomalidomide in the LRRK2 Genetic Model of Parkinson's Disease.
The search for new disease-modifying drugs for Parkinson's disease (PD) is a slow and highly expensive process, and the repurposing of drugs already approved for different medical indications is becoming a compelling alternative option for researchers. Genetic variables represent a predisposing factor to the disease and mutations in leucine-rich repeat kinase 2 (LRRK2) locus have been correlated to late-onset autosomal-dominant PD. The common fruit fly melanogaster carrying the mutation LRRK2 loss-of-function in the WD40 domain (LRRK2), is a simple model of PD and is a valid tool to first evaluate novel therapeutic approaches to the disease. Recent studies have suggested a neuroprotective activity of immunomodulatory agents in PD models. Here the immunomodulatory drug Pomalidomide (POM), a Thalidomide derivative, was examined in the LRRK2 genetic model of PD. Mutant and wild type flies received increasing POM doses (1, 0.5, 0.25 mM) through their diet from day 1 post eclosion, until postnatal day (PN) 7 or 14, when POM's actions were evaluated by quantifying changes in climbing behavior as a measure of motor performance, the number of brain dopaminergic neurons and T-bars, mitochondria integrity. LRRK2 flies displayed a spontaneous age-related impairment of climbing activity, and POM significantly and dose-dependently improved climbing performance both at PN 7 and PN 14. LRRK2 fly motor disability was underpinned by a progressive loss of dopaminergic neurons in posterior clusters of the protocerebrum, which are involved in the control of locomotion, by a low number of T-bars density in the presynaptic bouton active zones. POM treatment fully rescued the cell loss in all posterior clusters at PN 7 and PN 14 and significantly increased the T-bars density. Moreover, several damaged mitochondria with dilated cristae were observed in LRRK2 flies treated with vehicle but not following POM. This study demonstrates the neuroprotective activity of the immunomodulatory agent POM in a genetic model of PD. POM is an FDA-approved clinically available and well-tolerated drug used for the treatment of multiple myeloma. If further validated in mammalian models of PD, POM could rapidly be clinically tested in humans.

Modeling Parkinson's Disease Neuropathology and Symptoms by Intranigral Inoculation of Preformed Human α-Synuclein Oligomers.
The accumulation of aggregated α-synuclein (αSyn) is a hallmark of Parkinson's disease (PD). Current evidence indicates that small soluble αSyn oligomers (αSynOs) are the most toxic species among the forms of αSyn aggregates, and that size and topological structural properties are crucial factors for αSynOs-mediated toxicity, involving the interaction with either neurons or glial cells. We previously characterized a human αSynO (H-αSynO) with specific structural properties promoting toxicity against neuronal membranes. Here, we tested the neurotoxic potential of these H-αSynOs in vivo, in relation to the neuropathological and symptomatic features of PD. The H-αSynOs were unilaterally infused into the rat substantia nigra pars compacta (SNpc). Phosphorylated αSyn (p129-αSyn), reactive microglia, and cytokine levels were measured at progressive time points. Additionally, a phagocytosis assay in vitro was performed after microglia pre-exposure to αsynOs. Dopaminergic loss, motor, and cognitive performances were assessed. H-αSynOs triggered p129-αSyn deposition in SNpc neurons and microglia and spread to the striatum. Early and persistent neuroinflammatory responses were induced in the SNpc. In vitro, H-αSynOs inhibited the phagocytic function of microglia. H-αsynOs-infused rats displayed early mitochondrial loss and abnormalities in SNpc neurons, followed by a gradual nigrostriatal dopaminergic loss, associated with motor and cognitive impairment. The intracerebral inoculation of structurally characterized H-αSynOs provides a model of progressive PD neuropathology in rats, which will be helpful for testing neuroprotective therapies.

Advances in modelling alpha-synuclein-induced Parkinson's diseases in rodents: Virus-based models versus inoculation of exogenous preformed toxic species.
Aggregates of alpha-synuclein (αSyn) have been described in Parkinson's disease (PD) patients, and recent evidence has suggested that the most toxic αSyn species in PD are small soluble aggregates including oligomers, prefibrils, protofibrils. The physiological function of αSyn is still highly debated, with a possible role in synaptic vesicle trafficking and release at the presynaptic compartment, and in the regulation of gene expression in the nucleus. Emerging evidence indicate that most of αSyn functions are related with the crucial ability to bind biological membranes, which is associated with structural conversion from a disordered monomer to an α-helical enriched structure. Conformational properties of αSyn can be modulated by a number of factors including post-translational modifications, gene duplication and triplication-driven overexpression, single point mutations, environmental changes, which affect membrane binding and the protein propensity to aggregate in toxic species. The recognized toxic role of αSyn in PD has laid the rational for purposing of αSyn-based, neuropathologically

relevant preclinical models of PD. Different approaches have led to the establishment of transgenic models, viral vector-based models, and more recently models based on the intracerebral inoculation of exogenous αSyn preformed fibrils/oligomers. Here, we overview and compare viral vector-based models of αSyn overexpression and models obtained by direct intracerebral infusion of in vitro preformed αSyn species. The advantages and pitfalls associated with these different approaches are discussed.

Metabolomics Fingerprint Induced by the Intranigral Inoculation of Exogenous Human Alpha-Synuclein Oligomers in a Rat Model of Parkinson's Disease.
Parkinson's disease (PD) is considered a synucleinopathy because of the intraneuronal accumulation of aggregated α-synuclein (αSyn). Recent evidence points to soluble αSyn-oligomers (αSynO) as the main cytotoxic species responsible for cell death. Given the pivotal role of αSyn in PD, αSyn-based models are crucial for the investigation of toxic mechanisms and the identification of new therapeutic targets in PD. By using a metabolomics approach, we evaluated the metabolic profile of brain and serum samples of rats infused unilaterally with preformed human αSynOs (HαSynOs), or vehicle, into the substantia nigra pars compacta (SNpc). Three months postinfusion, the striatum was dissected for striatal dopamine (DA) measurements via High Pressure Liquid Chromatography (HPLC) analysis and mesencephalon and serum samples were collected for the evaluation of metabolite content via gas chromatography mass spectrometry analysis. Multivariate, univariate and correlation statistics were applied. A 40% decrease of DA content was measured in the HαSynO-infused striatum as compared to the contralateral and the vehicle-infused striata. Decreased levels of dehydroascorbic acid, myo-inositol, and glycine, and increased levels of threonine, were found in the mesencephalon, while increased contents of fructose and mannose, and a decrease in glycine and urea, were found in the serum of HαSynO-infused rats. The significant correlation between DA and metabolite content indicated that metabolic variations reflected the nigrostriatal degeneration. Collectively, the metabolomic fingerprint of HαSynO-infused rats points to an increase of oxidative stress markers, in line with PD neuropathology, and provides hints for potential biomarkers of PD.

RATHER A FANTASTIC DRUG THAN A FANTASTIC BEAST: DOXY (DOXYCYCLINE) WORKS AS AN ANTI-DYSKINETIC DRUG TO PARTIALLY LESIONED HEMIPARKINSONIAN MICE DUE TO ITS ANTI-INFLAMMATORY PROPERTIES.

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Pharmacologic manipulation of neuroinflammation is a promising strategy to alleviate L-DOPA-induced dyskinesia (LID). Recently, our group has demonstrated that anti-inflammatory drugs alleviate LID in hemiparkinsonian mice. Here we addressed the hypothesis that LID could be reversed by doxycycline (Doxy) in doses that present anti-inflammatory actions without affecting bacterial structure. To this aim, we used 6-OHDA-lesioned C57BL/6 hemiparkinsonian mice that present a partial lesion of the nigrostriatal pathway and treated them with L-DOPA (L-DOPA 25 mg/kg + benserazide 10 mg/kg i.p. for 21 days). These animals developed severe axial, limb and orofacial abnormal involuntary movements (AIMs). Following this period, the animals were exposed to doxy (20 or 40 mg/kg s.c.) for 5 more days. Sub-chronic treatment with Doxy at both doses significantly reduced the stablished L-DOPA-induced AIMs without affecting the locomotor activity improved by L-DOPA. As expected, Doxy at 40 mg/kg had a more robust effect over AIMs compared to Doxy 20 mg/kg. However, since doxy 20 mg/kg (the lower dose without antibiotic activity) also caused a significant decrease of AIMs, we chose this dose for molecular analysis. After confirmation of LID attenuation, we performed immunohistochemistry (for COX-2-immunoreactive cells) and ELISA (for cytokines TNF-α, IL-1β and IL-6 and for COX-2 metabolite PGE2) in the lesioned dorsal striatum of hemiparkinsonian mice. LID decrease was accompanied by the reduction of COX-2 expression, PGE2 and the cytokines TNF-α and IL-1β. Overall, we conclude that sub-antibiotic doses of doxy are responsible for anti-inflammatory actions that are mandatory for LID attenuation and might be an interesting alternative way to use doxy as treatment for LID in Parkinson's disease.

Caffeine Improves GABA Transport in the Striatum of Spontaneously Hypertensive Rats (SHR).
The spontaneously hypertensive rat (SHR) is an excellent animal model that mimics the behavioral and neurochemical phenotype of attention-deficit/hyperactivity disorder (ADHD). Here, we characterized the striatal GABA transport of SHR and investigated whether caffeine, a non-selective antagonist of adenosine receptors, could influence GABAergic circuitry. For this purpose, ex vivo striatal slices of SHR and Wistar (control strain) on the 35th postnatal day were dissected and incubated with [3H]-GABA to quantify the basal levels of uptake and release. SHR exhibited a reduced [3H]-GABA uptake and release, suggesting a defective striatal GABAergic transport system. GAT-1 appears to be the primary transporter for [3H]-GABA uptake in SHR striatum, as GAT-1 selective blocker, NO-711, completely abolished it. We also verified that acute exposure of striatal slices to caffeine improved [3H]-GABA uptake and release in SHR, whereas Wistar rats were not affected. GABA-uptake increase and cAMP accumulation promoted by caffeine was reverted by A1R activation with N6-cyclohexyl adenosine (CHA). As expected, the pharmacological blockade of cAMP-PKA signaling by H-89 also prevented caffeine-mediated [3H]-GABA uptake increment. Interestingly, a single caffeine exposure did not affect GAT-1 or A1R protein density in SHR, which was not different from Wistar protein levels, suggesting that the GAT-1-dependent transport in SHR has a defective functional activity rather than lower protein expression. The current data support that caffeine regulates GAT-1 function and improves striatal GABA transport via A1R-cAMP-PKA signaling, specifically in SHR. These results reinforce that caffeine may have therapeutic use in disorders where the GABA transport system is impaired.

The Chemically-Modified Tetracycline COL-3 and Its Parent Compound Doxycycline Prevent Microglial Inflammatory Responses by Reducing Glucose-Mediated Oxidative Stress.

We used mouse microglial cells in culture activated by lipopolysaccharide (LPS) or α-synuclein amyloid aggregates (αSa) to study the anti-inflammatory effects of COL-3, a tetracycline derivative without antimicrobial activity. Under LPS or αSa stimulation, COL-3 (10, 20 µM) efficiently repressed the induction of the microglial activation marker protein - and the stimulated-release of the pro-inflammatory cytokine TNF-α. COL-3's inhibitory effects on TNF-α were reproduced by the tetracycline antibiotic doxycycline (DOX; 50 µM), the glucocorticoid dexamethasone, and apocynin (APO), an inhibitor of the superoxide-producing enzyme NADPH oxidase. This last observation suggested that COL-3 and DOX might also operate themselves by restraining oxidative stress-mediated signaling events. Quantitative measurement of intracellular reactive oxygen species (ROS) levels revealed that COL-3 and DOX were indeed as effective as APO in reducing oxidative stress and TNF-α release in activated microglia. ROS inhibition with COL-3 or DOX occurred together with a reduction of microglial glucose accumulation and NADPH synthesis. This suggested that COL-3 and DOX might reduce microglial oxidative burst activity by limiting the glucose-dependent synthesis of NADPH, the requisite substrate for NADPH oxidase. Coherent with this possibility, the glycolysis inhibitor 2-deoxy-D-glucose reproduced the immunosuppressive action of COL-3 and DOX in activated microglia. Overall, we propose that COL-3 and its parent compound DOX exert anti-inflammatory effects in microglial cells by inhibiting glucose-dependent ROS production. These effects might be strengthened by the intrinsic antioxidant properties of DOX and COL-3 in a self-reinforcing manner.

Cannabidiol has therapeutic potential for myofascial pain in female and male parkinsonian rats.
The musculoskeletal orofacial pain is a complex symptom of Parkinson's disease (PD) resulting in stomatognathic system dysfunctions aggravated by the disease rigidity and postural instability. We tested the effect of cannabidiol (CBD), a non-psychotomimetic constituent of Cannabis sativa, in PD-related myofascial pain. Wistar adult female and male rats orofacial allodynic and hyperalgesic responses were tested by Von Frey and formalin tests, before and 21 days past 6-OHDA lesion. Algesic response was tested after masseter muscle injection of CBD (10, 50, 100 µg in 10 µL) or vehicle. Males compared to females in all estrous cycles' phases presented reduced orofacial allodynia and hyperalgesia. According to the estrous cycle's phases, females presented distinct orofacial nociceptive responses, being the estrus phase well-chosen for nociceptive analysis after 6-OHDA lesion (phase with fewer hormone alterations and adequate length). Dopaminergic neuron lesion decreased mechanical and inflammatory nociceptive thresholds in females and males in a higher proportion in females. CBD local treatment reduced the increased orofacial allodynia and hyperalgesia, in males and females. The female rats were more sensitive to CBD effect considering allodynia, responding to the lowest dose. Although females and males respond to the effect of three doses of CBD in the formalin test, males showed a superior reduction in the hyperalgesic response. These results indicate that hemiparkinsonian female in the estrus phase and male answer differently to the different doses of CBD therapy and nociceptive tests. CBD therapy is effective for parkinsonism-induced orofacial nociception.

Contributive Role of TNF-α to L-DOPA-Induced Dyskinesia in a Unilateral 6-OHDA Lesion Model of Parkinson's Disease.
Our present objective was to better characterize the mechanisms that regulate striatal neuroinflammation in mice developing L-DOPA-induced dyskinesia (LID). For that, we used 6-hydroxydopamine (6-OHDA)-lesioned mice rendered dyskinetic by repeated intraperitoneal injections of 3,4-dihydroxyphenyl-L-alanine (L-DOPA) and quantified ensuing neuroinflammatory changes in the dopamine-denervated dorsal striatum. LID development was associated with a prominent astrocytic response, and a more moderate microglial cell reaction restricted to this striatal area. The glial response was associated with elevations in two pro-inflammatory cytokines, tumor necrosis factor-α (TNF-α) and interleukin-1β. Treatment with the phytocannabinoid cannabidiol and the transient receptor potential vanilloid-1 (TRPV-1) channel antagonist capsazepine diminished LID intensity and decreased TNF-α levels without impacting other inflammation markers. To possibly reproduce the neuroinflammatory component of LID, we exposed astrocyte and microglial cells in culture to candidate molecules that might operate as inflammatory cues during LID development, i.e., L-DOPA, dopamine, or glutamate. Neither L-DOPA nor dopamine produced an inflammatory response in glial cell cultures. However, glutamate enhanced TNF-α secretion and GFAP expression in astrocyte cultures and promoted Iba-1 expression in microglial cultures. Of interest, the antidyskinetic treatment with cannabidiol + capsazepine reduced TNF-α release in glutamate-activated astrocytes. TNF-α, on its own, promoted the synaptic release of glutamate in cortical neuronal cultures, whereas cannabidiol + capsazepine prevented this effect. Therefore, we may assume that the release of TNF-α by glutamate-activated astrocytes may contribute to LID by exacerbating corticostriatal glutamatergic inputs excitability and maintaining astrocytes in an activated state through a self-reinforcing mechanism.

Cannabidiol prevents LPS-induced microglial inflammation by inhibiting ROS/NF-κB-dependent signaling and glucose

consumption.
We used mouse microglial cells in culture activated by lipopolysaccharide (LPS, 10 ng/ml) to study the anti-inflammatory potential of cannabidiol (CBD), the major nonpsychoactive component of cannabis. Under LPS stimulation, CBD (1-10 μM) potently inhibited the release of prototypical proinflammatory cytokines (TNF-α and IL-1β) and that of glutamate, a noncytokine mediator of inflammation. The effects of CBD were predominantly receptor-independent and only marginally blunted by blockade of CB2 receptors. We established that CBD inhibited a mechanism involving, sequentially, NADPH oxidase-mediated ROS production and NF-κB-dependent signaling events. In line with these observations, active concentrations of CBD demonstrated an intrinsic free-radical scavenging capacity in the cell-free DPPH assay. Of interest, CBD also prevented the rise in glucose uptake observed in microglial cells challenged with LPS, as did the inhibitor of NADPH oxidase apocynin and the inhibitor of IκB kinase-2, TPCA-1. This indicated that the capacity of CBD to prevent glucose uptake also contributed to its anti-inflammatory activity. Supporting this view, the glycolytic inhibitor 2-deoxy-d-glucose (2-DG) mimicked the antioxidant/immunosuppressive effects of CBD. Interestingly, CBD and 2-DG, as well as apocynin and TPCA-1 caused a reduction in glucose-derived NADPH, a cofactor required for NADPH oxidase activation and ROS generation. These different observations suggest that CBD exerts its anti-inflammatory effects towards microglia through an intrinsic antioxidant effect, which is amplified through inhibition of glucose-dependent NADPH synthesis. These results also further confirm that CBD may have therapeutic utility in conditions where neuroinflammatory processes are prominent.

Cannabidiol and Cannabinoid Compounds as Potential Strategies for Treating Parkinson's Disease and L-DOPA-Induced Dyskinesia.
Parkinson's disease (PD) and L-DOPA-induced dyskinesia (LID) are motor disorders with significant impact on the patient's quality of life. Unfortunately, pharmacological treatments that improve these disorders without causing severe side effects are not yet available. Delay in initiating L-DOPA is no longer recommended as LID development is a function of disease duration rather than cumulative L-DOPA exposure. Manipulation of the endocannabinoid system could be a promising therapy to control PD and LID symptoms. In this way, phytocannabinoids and synthetic cannabinoids, such as cannabidiol (CBD), the principal non-psychotomimetic constituent of the Cannabis sativa plant, have received considerable attention in the last decade. In this review, we present clinical and preclinical evidence suggesting CBD and other cannabinoids have therapeutic effects in PD and LID. Here, we discuss CBD pharmacology, as well as its neuroprotective effects and those of other cannabinoids. Finally, we discuss the modulation of several pro- or anti-inflammatory factors as possible mechanisms responsible for the therapeutic/neuroprotective potential of Cannabis-derived/cannabinoid synthetic compounds in motor disorders.

Microglial glutamate release evoked by α-synuclein aggregates is prevented by dopamine.
When activated, microglial cells have the potential not only to secrete typical proinflammatory mediators but also to release the neurotransmitter glutamate in amounts that may promote excitotoxicity. Here, we wished to determine the potential of the Parkinson's disease (PD) protein α-Synuclein (αS) to stimulate glutamate release using cultures of purified microglial cells. We established that glutamate release was robustly increased when microglial cultures were treated with fibrillary aggregates of αS but not with the native monomeric protein. Promotion of microglial glutamate release by αS aggregates (αSa) required concomitant engagement of TLR2 and P2X7 receptors. Downstream to cell surface receptors, the release process was mediated by activation of a signaling cascade sequentially involving phosphoinositide 3-kinase (PI3K) and NADPH oxidase, a superoxide-producing enzyme. Inhibition of the Xc- antiporter, a plasma membrane exchange system that imports extracellular l-cystine and exports intracellular glutamate, prevented the release of glutamate induced by αSa, indicating that system Xc- was the final effector element in the release process downstream to NADPH oxidase activation. Of interest, the stimulation of glutamate release by αSa was abrogated by dopamine through an antioxidant effect requiring D dopamine receptor activation and PI3K inhibition. Altogether, present data suggest that the activation of microglial cells by αSa may possibly result in a toxic build-up of extracellular glutamate contributing to excitotoxic stress in PD. The deficit in dopamine that characterizes this disorder may further aggravate this process in a vicious circle mechanism.

Long Withdrawal of Methylphenidate Induces a Differential Response of the Dopaminergic System and Increases Sensitivity to Cocaine in the Prefrontal Cortex of Spontaneously Hypertensive Rats.
Methylphenidate (MPD) is one of the most prescribed drugs for alleviating the symptoms of Attention Deficit/Hyperactivity Disorder (ADHD). However, changes in the molecular mechanisms related to MPD withdrawal and susceptibility to consumption of other psychostimulants in normal individuals or individuals with ADHD phenotype are not completely understood. The aims of the present study were: (i) to characterize the molecular differences in the prefrontal dopaminergic system of SHR and Wistar strains, (ii) to establish the neurochemical consequences of short- (24 hours) and long-term (10 days) MPD withdrawal after a subchronic treatment (30 days) with Ritalin® (Methylphenidate Hydrochloride; 2.5 mg/kg orally), (iii) to investigate the dopaminergic synaptic functionality after a cocaine challenge in adult MPD-withdrawn SHR and Wistar rats. Our results indicate that SHR rats present reduced [3H]-Dopamine uptake and cAMP accumulation in the prefrontal cortex (PFC) and are not responsive to dopaminergic stimuli in when compared to Wistar rats. After a 24-hour withdrawal of MPD, SHR did not present any alterations in [3H]-Dopamine Uptake, [3H]-SCH 23390 binding and cAMP production; nonetheless, after a 10-day MPD withdrawal, the results showed a significant increase of [3H]-Dopamine uptake, of the quantity of [3H]-SCH 23390 binding sites and of cAMP levels in these animals. Finally, SHR that underwent a 10-day MPD withdrawal and were challenged with cocaine (10 mg/kg i.p.) presented reduced [3H]-Dopamine uptake and increased cAMP production. Wistar rats were affected by the 10-day withdrawal of MPD in [3H]-dopamine uptake but not in cAMP accumulation; in addition, cocaine was unable to induce significant modifications in [3H]-dopamine uptake and in cAMP levels after the 10-day withdrawal of MPD. These results indicate a mechanism that could explain the high comorbidity between ADHD adolescent patients under methylphenidate treatment and substance abuse in adult life.

Are cyclooxygenase-2 and nitric oxide involved in the dyskinesia of Parkinson's disease induced by L-DOPA?
Inflammatory mechanisms are proposed to play a role in L-DOPA-induced dyskinesia. Cyclooxygenase-2 (COX2) contributes to inflammation pathways in the periphery and is constitutively expressed in the central nervous system. Considering that inhibition of nitric oxide (NO) formation attenuates L-DOPA-induced dyskinesia, this study aimed at investigating if a NO synthase (NOS) inhibitor would change COX2 brain expression in animals with L-DOPA-induced dyskinesia. To this aim, male Wistar rats received unilateral 6-hydroxydopamine microinjection into the medial forebrain bundle were treated daily with L-DOPA (21 days) combined with 7-nitroindazole or vehicle. All hemi-Parkinsonian rats receiving l-DOPA showed dyskinesia. They also presented increased neuronal COX2 immunoreactivity in the dopamine-depleted dorsal striatum that was directly correlated with dyskinesia severity. Striatal COX2 co-localized with choline-acetyltransferase, calbindin and DARPP-32 (dopamine-cAMP-regulated phosphoprotein-32), neuronal markers of GABAergic neurons. NOS inhibition prevented L-DOPA-induced dyskinesia and COX2 increased expression in the dorsal striatum. These results suggest that increased COX2 expression after L-DOPA long-term treatment in Parkinsonian-like rats could contribute to the development of dyskinesia.

Alpha-synuclein (α-syn), being the main protein in Lewy bodies, plays a key role in the pathological hallmarks of Parkinson's disease (PD). However, the mechanisms underlying the degeneration of dopaminergic (DA) neurons and the involvement of α-syn and neuroinflammation in this process remain unclear. We aimed to investigate the temporal relationship between α-syn overexpression, motor impairment, glial activation and nigrostriatal degeneration in a PD mouse model. Mice received uni or bilateral intranigral injection of adeno-associated viral vectors (AAV) encoding human α-syn (AAV-hα-syn) and were sacrificed 15, 60 or 120 days post-injection. At these time points, motor behavioural tests and immunohistochemistry for DA degeneration (TH) and neuroinflammation (microglia (Iba-1) and astrocytes (GFAP)) were carried out. Uni or bilateral intranigral injection of AAV-hα-syn led to significant nigral α-syn aggregation at day 15 post-surgery, reaching the peak at day 60. Significant reductions in striatal and nigral TH^+ fibres were observed 60 and 120 days post-surgery, whereas the number of nigral TH^+ cells was unchanged. Behavioural analysis revealed motor impairments highly correlated to striatal TH loss 60 days after the viral transduction. In both models, a significant nigral microglial activation was observed 60 and 120 days post-injection, but no striatal or nigral astroglial activation was found. Although these preliminary data indicate that the AAV-mediated overexpression of α-syn in the mouse *substantia nigra* is appropriate to model PD-like pathology, additional time points need to be explored to elucidate whether the neuroinflammation contributes to DA degeneration. INVOLVEMENT OF STRIATO-PALLIDAL DARPP32 IN SLEEP REGULATION

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Clarissa Pisanò[1], Emanuela Santini[2], Gilberto Fisone[2]
[1]Karolinska Institutet, Neuroscience, Solna, Sweden, [2]Karolinska Institutet, Department Of Neuroscience, Stockholm, Sweden

Aim: DARPP32 is highly enriched in the striatal formation and has been intensively studied for its role in the regulation of the activity of the striato-nigral and striato-pallidal projection neurons, belonging to the direct and indirect pathway. The present study investigates the involvement of DARPP32 in different types of striato-pallidal driven behaviors, including locomotion and motor coordination, sleep, and cognition. Methods: *Animals:* we used a mouse strain where DARPP32 is specifically depleted in the A2A expressing striato-pallidal neurons. *Behavioral tests:* The motor phenotype was studied using the open-field and rotarod test. The novel object recognition test and the water Y maze were used to examine cognition and memory. Anxiety and obsessive behaviors were assessed by light-dark box, elevated plus maze and marble burying test. *Sleep analysis:* sleep architecture was analyzed by EEG and EMG recording using a MATLAB script. Results: Depletion of DARPP32 in A2A expressing neurons increases basal exploratory behavior in the open-field. This effect is accompanied by a significant increase in wakefulness and decrease in slow-wave sleep during the active period of the 24hr light-dark cycle. The other behavioral tests did not show impairment in cognition or learning. Conclusion: Our findings show that DARPP32 deficiency in striato-pallidal neurons increases motor behavior and reduces sleep during the active period of the sleep-wake cycle. Further studies will be necessary to clarify the possible involvement of dysregulated striato-pallidal DARPP32-dependent transmission in pathological states associated with sleep disruption, including neurodegenerative and psychiatric disorders.

NOP Receptor Ligands and Parkinson's Disease.
Nociceptin/Orphanin FQ (N/OFQ) and its NOP receptor are highly expressed in motor areas of the rodent, nonhuman, and human primate brain, such as primary motor cortex, thalamus, globus pallidus, striatum, and substantia nigra. Endogenous N/OFQ negatively regulates motor behavior and dopamine transmission through NOP receptors expressed by dopaminergic neurons of the substantia nigra compacta. Consistent with the existence of an N/OFQ tone over dopaminergic transmission, blockade of NOP receptor antagonists increases striatal dopamine release. In this chapter, we will review the evidence linking the N/OFQ-NOP receptor system to Parkinson's disease (PD). We will first discuss data showing that the central N/OFQ-NOP receptor system undergoes plastic changes in different basal ganglia nuclei following dopamine depletion. Then we will show that NOP receptor antagonists relieve motor deficits in different rodent and nonhuman primate models of PD. Mechanistically, NOP receptor blockade in substantia nigra reticulata results in rebalancing of the inhibitory GABAergic and excitatory glutamatergic inputs impinging on nigro-thalamic GABAergic neurons, leading to thalamic disinhibition. We will also present data showing that, in addition to motor symptoms, N/OFQ also plays a role in the parkinsonian neurodegeneration. In fact, NOP receptor antagonists possess neuroprotective/neurorescue properties in in vitro and in vivo models of PD.

Anti-Parkinsonian and anti-dyskinetic profiles of two novel potent and selective nociceptin/orphanin FQ receptor agonists.
We previously showed that nociceptin/orphanin FQ opioid peptide (NOP) receptor agonists attenuate the expression of levodopa-induced dyskinesia in animal models of Parkinson's disease. We now investigate the efficacy of two novel, potent and chemically distinct NOP receptor agonists, AT-390 and AT-403, to improve Parkinsonian disabilities and attenuate dyskinesia development and expression.

Striatal and nigral muscarinic type 1 and type 4 receptors modulate levodopa-induced dyskinesia and striato-nigral pathway

activation in 6-hydroxydopamine hemilesioned rats.
Acetylcholine muscarinic receptors (mAChRs) contribute to both the facilitation and inhibition of levodopa-induced dyskinesia operated by striatal cholinergic interneurons, although the receptor subtypes involved remain elusive. Cholinergic afferents from the midbrain also innervate the substantia nigra reticulata, although the role of nigral mAChRs in levodopa-induced dyskinesia is unknown. Here, we investigate whether striatal and nigral M1 and/or M4 mAChRs modulate dyskinesia and the underlying striato-nigral GABAergic pathway activation in 6-hydroxydopamine hemilesioned rats. Reverse microdialysis allowed to deliver the mAChR antagonists telenzepine (M1 subtype preferring), PD-102807 and tropicamide (M4 subtype preferring), as well as the selective M4 mAChR positive allosteric modulator VU0152100 in striatum or substantia nigra, while levodopa was administered systemically. Dyskinetic movements were monitored along with nigral GABA (and glutamate) and striatal glutamate dialysate levels, taken as neurochemical correlates of striato-nigral pathway and cortico-basal ganglia-thalamo-cortical loop activation. We observed that intrastriatal telenzepine, PD-102807 and tropicamide alleviated dyskinesia and inhibited nigral GABA and striatal glutamate release. This was partially replicated by intrastriatal VU0152100. The M2 subtype preferring antagonist AFDX-116, used to elevate striatal acetylcholine levels, blocked the behavioral and neurochemical effects of PD-102807. Intranigral VU0152100 prevented levodopa-induced dyskinesia and its neurochemical correlates whereas PD-102807 was ineffective. These results suggest that striatal, likely postsynaptic, M1 mAChRs facilitate dyskinesia and striato-nigral pathway activation in vivo. Conversely, striatal M4 mAChRs can both facilitate and inhibit dyskinesia, possibly depending on their localization. Potentiation of striatal and nigral M4 mAChR transmission leads to powerful multilevel inhibition of striato-nigral pathway and attenuation of dyskinesia.

Safinamide inhibits in vivo glutamate release in a rat model of Parkinson's disease.
To investigate whether the reversible MAO-B inhibitor and sodium channel blocker safinamide impairs glutamate release under parkinsonian conditions in vivo, and this effect is dependent on MAO-B inhibition, safinamide (and rasagiline as a comparator) were administered to 6-hydroxydopamine hemilesioned rats, a model of Parkinson's disease, and haloperidol-treated rats, a model of neuroleptic-induced parkinsonism. A microdialysis probe was implanted in the dopamine-depleted dorsolateral striatum, globus pallidus, subthalamic nucleus or substantia nigra reticulata of 6-hydroxydopamine hemilesioned rats. Glutamate and GABA release was stimulated by reverse dialysis of veratridine, and safinamide or rasagiline were acutely administered before veratridine at doses inhibiting MAO-B >50%. A microdialysis probe was implanted in the substantia nigra reticulata of naïve rats to monitor glutamate and GABA release following acute haloperidol and safinamide administration. Safinamide inhibited the veratridine-evoked glutamate release in the globus pallidus and subthalamic nucleus but not in the striatum and substantia nigra. Moreover, it reduced pallidal and nigral GABA release. Conversely, rasagiline failed to modify the veratridine-induced glutamate and GABA release in the basal ganglia. Safinamide also inhibited the haloperidol-induced nigral glutamate release. MAO-B inhibitors safinamide and rasagiline differ in their abilities to inhibit depolarization-evoked glutamate release in the basal ganglia of parkinsonian rats. The ineffectiveness of rasagiline suggests that MAO-B inhibition does not contribute to the antiglutamatergic activity of safinamide. The glutamate-inhibiting action of safinamide within the subthalamo-external pallidal loop, which shows abnormal activity in Parkinson's disease, might contribute to its therapeutic actions of improving motor performance without provoking troublesome dyskinesia.

Regulator of G-Protein Signalling 4 (RGS4) negatively modulates nociceptin/orphanin FQ opioid receptor signalling: Implication for l-Dopa-induced dyskinesia.
Regulator of G-protein signalling 4 (RGS4) is a signal transduction protein that accelerates intrinsic GTPase activity of Gα and Gα subunits, suppressing GPCR signalling. Here, we investigate whether RGS4 modulates nociceptin/orphanin FQ (N/OFQ) opioid (NOP) receptor signalling and if this modulation has relevance for l-Dopa-induced dyskinesia.

6-Hydroxydopamine lesion and levodopa treatment modify the effect of buspirone in the substantia nigra pars reticulata.
l-DOPA-induced dyskinesia (LID) is considered a major complication in the treatment of Parkinson's disease (PD). Buspirone (5-HT partial agonist) have shown promising results in the treatment of PD and LID, however no 5-HT-based treatment has been approved in PD. The present study was aimed to investigate how the substantia nigra pars reticulata (SNr) is affected by buspirone and whether it is a good target to study 5-HT antidyskinetic treatments.

Discovery and Structure-Activity Relationships of Nociceptin Receptor Partial Agonists That Afford Symptom Ablation in Parkinson's Disease Models.
A novel series of C(3)-substituted piperdinylindoles were developed as nociceptin opioid receptor (NOP) partial agonists to explore a pharmacological hypothesis that NOP partial agonists would afford a dual pharmacological action of attenuating Parkinson's disease (PD) motor symptoms and development of levodopa-induced dyskinesias. SAR around the C-3 substituents investigated effects on NOP binding, intrinsic activity, and selectivity and showed that while the C(3)-substituted indoles are selective, high affinity NOP ligands, the steric, polar, and cationic nature of the C-3 substituents affected intrinsic activity to afford partial agonists with a range of efficacies. Compounds , , and with agonist efficacies between 25% and 35% significantly attenuated motor deficits in the 6-OHDA-hemilesioned rat model of PD. Further, unlike NOP antagonists, which appear to worsen dyskinesia expression, these NOP partial agonists did not attenuate or worsen dyskinesia expression. The NOP partial agonists and their SAR reported here may be useful to develop nondopaminergic treatments for PD.

Safinamide Differentially Modulates In Vivo Glutamate and GABA Release in the Rat Hippocampus and Basal Ganglia.
Safinamide has been recently approved as an add-on to levodopa therapy for Parkinson disease. In addition to inhibiting monoamine oxidase type B, it blocks sodium channels and modulates glutamate (Glu) release in vitro. Since this property might contribute to the therapeutic action of the drug, we undertook the present study to investigate whether safinamide inhibits Glu release also in vivo and whether this effect is consistent across different brain areas and is selective for glutamatergic neurons. To this aim, in vivo microdialysis was used to monitor the spontaneous and veratridine-induced Glu and GABA release in the hippocampus and basal ganglia of naive, awake rats. Brain levels of safinamide were measured as well. To shed light on the mechanisms underlying the effect of safinamide, sodium currents were measured by patch-clamp recording in rat cortical neurons. Safinamide maximally inhibited the veratridine-induced Glu and GABA release in hippocampus at 15 mg/kg, which reached free brain concentrations of 1.89-1.37 M. This dose attenuated veratridine-stimulated Glu (but not GABA) release in subthalamic nucleus, globus pallidus, and substantia nigra reticulata, but not in striatum. Safinamide was ineffective on spontaneous neurotransmitter release. In vitro, safinamide inhibited sodium channels, showing a greater affinity at depolarized (IC = 8 M) than at resting (IC = 262 M) potentials. We conclude that safinamide inhibits in vivo Glu release from stimulated nerve terminals, likely via blockade of sodium channels at subpopulations of neurons with specific firing patterns. These data are consistent with the anticonvulsant and antiparkinsonian actions of safinamide and provide support for the nondopaminergic mechanism of its action.

Leucine-rich repeat kinase 2 (LRRK2) inhibitors differentially modulate glutamate release and Serine935 LRRK2 phosphorylation in striatal and cerebrocortical synaptosomes.
Mutations in leucine-rich repeat kinase 2 () gene have been pathogenically linked to Parkinson's disease, and pharmacological inhibition of LRRK2 is being pursued to tackle nigro-striatal dopaminergic neurodegeneration. However, LRRK2 kinase inhibitors may have manifold actions, affecting not only pathological mechanisms in dopaminergic neurons but also physiological functions in nondopaminergic neurons. Therefore, we investigated whether LRRK2 kinase inhibitors differentially modulate dopamine and glutamate release from the mouse striatum and cerebral cortex. Spontaneous and KCl-evoked [H]-dopamine and glutamate release from superfused synaptosomes obtained from wild-type and LRRK2 knock-out, kinase-dead or G2019S knock-in mice was measured. Two structurally unrelated inhibitors, LRRK2-IN-1 and GSK2578215A, were tested. LRRK2, phosphoSerine1292 and phosphoSerine935 LRRK2 levels were measured in all genotypes, and target engagement was evaluated by monitoring phosphoSerine935 LRRK2. LRRK2-IN-1 inhibited striatal glutamate but not dopamine release; GSK2578215A inhibited striatal dopamine and cortical glutamate but enhanced striatal glutamate release. LRRK2-IN-1 reduced striatal and cortical phosphoSerine935 levels whereas GSK2578215A inhibited only the former. Neither LRRK2 inhibitor affected neurotransmitter release in LRRK2 knock-out and kinase-dead mice; however, they facilitated dopamine without affecting striatal glutamate in G2019S knock-in mice. GSK2578215A inhibited cortical glutamate release in G2019S knock-in mice. We conclude that LRRK2-IN-1 and GSK2578215A modulate exocytosis by blocking LRRK2 kinase activity, although their effects vary depending on the nerve terminal examined. The G2019S mutation unravels a dopamine-promoting action of LRRK2 inhibitors while blunting their effects on glutamate release, which highlights their positive potential for the treatment of PD, especially of LRRK2 mutation carriers.

Parkinson's disease (PD) is a complex neurodegenerative disease, characterized by both motor and non-motor symptoms. In MPTP model of PD, we previously showed that glucocorticoids (GCs), through their receptor GR in astrocytes, regulate degeneration of dopamine neurons in substantia nigra through connexin-43 hemichannel activity. In addition, we showed the number of astrocytes expressing GR was significantly lower in substantia nigra of PD samples compared to controls suggesting that GR activity is affected in PD (Cell Death and Differentiation, 2019). To dissect further the role of GR in astrocytes in PD pathology, we have undertaken experiments to study its role in alpha-synuclein pathology, using mice conditionally inactivated for GR gene specifically in parenchymal astrocytes. Stereotaxic injection of AAV human A53T alpha-synuclein viral vector in substantia nigra resulted, after 8 weeks, in greater dopamine neuronal loss with increased glial reactivity in astrocytic GR mutant mice compared to controls, suggesting astrocyte GR modulates alpha-synuclein pathology. As GC-GRs are known to affect profoundly mood and cognition, firstly we verified whether astrocytic GR mutant mice have behavioral, cognitive or motor anomalies. The results showed increased anxiety-like behavior and reduced motor performance in astrocytic GR mutant mice with no change observed in cognitive tests. Interestingly, expression of A53T alpha-synuclein in prefrontal cortex of astrocytic GR mutant and control mice resulted in impairment of working memory only in the mutant mice. We are investigating the cellular and biochemical mechanisms through which astrocyte GR regulates cognitive processes in face of alpha-synuclein pathology.

Aims Prosaposin (PSAP) is a pleiotropic protein with neurotrophic feature and interacts with progranulin (PGRN) when trafficking in cells. PSAP is genetically linked to Parkinson's disease (PD). Encapsulated-cell biodelivery (ECB) is an effective way for therapeutic factor delivery. The objective of the study is to examine the therapeutic potential of PSAP, PGRN, and PSAP/PGRN complex delivered by ECB devices in α-synuclein-induced parkinsonism. ***Methods*** ARPE-19 cells overexpressing PSAP, PGRN, and PSAP/PGRN complex were encapsulated to generate corresponding factor-secreting ECB devices. AAV-α-synuclein was injected in the right substantia nigra of rats. Meanwhile, control ECB, ECB-PSAP, ECB-PGRN, and ECB-PSAP-PGRN devices were implanted into the right striatum of AAV-α-synuclein-injected rats. Open field test was conducted at 6-, 10-, and 14wks after surgery, followed by apomorphine rotation test at 14wks. Postmortem immunohistochemical stainings were performed to examine dopaminergic marker alterations. ***Results*** ECB devices were tested to be actively secreting corresponding factors before implantation. Overexpression of α-synuclein was detected in the substantia nigra and striatum and caused behavior deficiencies and dopaminergic degeneration in rats. ECB-PSAP and ECB-PSAP-PGRN protected rats from locomotion deterioration. ECB-PSAP prevented rats from rotating to the contralateral side induced by apomorphine. ECB-PSAP protected dopamine transporter (DAT) and vesicle monoamine transporter levels, and ECB-PSAP-PGRN protected DAT levels. However, ECB-PGRN did not show neuroprotective effect. ***Conclusions*** PSAP with or without PGRN delivered by ECB devices counteracted behavior impairments and dopaminergic loss induced by intranigral AAV-α-synuclein overexpression. Thus, PSAP replenishment might be beneficial in halting PD progression.

Parkinson´s Disease (PD) is a neurodegenerative disorder characterized by neuron loss in different brain areas, especially dopaminergic neurons in the Substancia Nigra (SN). The alterations cause motor symptoms such as tremor, rigidity and bradykinesia. It is not until these symptoms appear that the pathology can be diagnosed, when the neuron loss in SN is over 60%, due to a lack of early stage biomarkers that allow the diagnosis. The trigger of the degeneration remains unknown but some features have been associated with neuron death, such as the presence of Lewy bodies. These structures are formed by the accumulation of alpha-synuclein and its presence could lead to mitochondrial dysfunction, inducing oxidative stress and cell death. The aim of this study is to identify PD biomarkers in blood samples. In order to achieve this purpose, we have stablished a rodent model based on the overexpression of alpha-synuclein by injecting adeno-associated virus in the SN. Animals were tested four, eight and twelve weeks after the injection showing intact motor and non-motor performance, however, alterations in mitochondrial activity were observed in blood samples three months after the injection. With the current study we identified potential early stage PD biomarkers that could allow a sooner diagnosis of the disease. This project is financed by PIBA19-0038; PUE21-03; Bikaintek program: 007-B2/2020; COLAB20/07; GIU19/339. This research was conducted in the scope of the Transborder Joint Laboratory (LTC) “non-motor CoMorbidities in Parkinson’s Disease (CoMorPD)”. No conflict of interest.

Loss of GSK 3beta function leads to neuronal function in Shaggy strain of drosophila. Loss of neural function invariably leads to neurodegenerative diseases such as Parkinson's disease (PD). Natural compounds with antioxidant properties such as flavonoids is thought to be involved in protection against cellular oxidative stress. Oxidative stress is believed to be a major factor for the onset of PD. In this study, we have investigated oxidative status in transgenic *Drosophila* model of PD. Our results revealed elevated levels of reactive oxygen species (ROS) in shaggy PD model flies compared to control. We have demonstrated for the first time the ameliorating potential of synergistic natural antioxidants quercetin and curcumin PD model flies. Feeding of transgenic flies with co-administration of curcumin and quercetin for 5 days significantly improved their climbing ability and circadian rhythm of locomotor activity which was associated with reduction in levels of ROS and enhancement in the activities of catalase (CAT) and superoxide dismutase (SOD). The co-administration treatment protected against transgenic flies and delayed the onset of PD-like symptoms which appears to be mediated by suppression of oxidative stress.

GLYCATION OF ALPHA-SYNUCLEIN MODULATES AGGREGATION AND PARKINSON'S DISEASE-LIKE PHENOTYPES

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Tiago Outeiro
University Medical Center Goettingen, Experimental Neurodegeneration, Goettingen, Germany

Posttranslational modifications (PTMs) are major determinants of protein folding, localization and function. Glycation is a non-enzymatic PTM that is increased in the brains of hyperglycemic patients, such as those affected by type 2 diabetes (T2D). Since it typically leads to irreversible changes in protein properties and behavior, it has attracted a great deal of attention in the last years. Alpha-synuclein (aSyn) can be glycated at lysine residues, thereby reducing fibril formation *in vitro* and modulating aggregation in cells. However, the molecular basis for these effects is unclear. To elucidate this, we are investigating the effect of different physiologically-relevant glycating agents on the aggregation of aSyn. The dicarbonyl methylglyoxal (MGO) and the sugar ribose modify aSyn to the greatest extent, and these glycation agents are the most efficient inhibitors of fibril formation. Glycation primarily inhibits elongation rather than nucleation of aSyn, and has only a modest effect on the level of oligomerization. Furthermore, glycated aSyn is not significantly incorporated into fibrils. In vivo, MGO-glycation alters dopaminergic pathways, consistent with alterations observed in PD. Our results are not only relevant for other aSyn PTMs, but also for understanding PTMs affecting other fibrillogenic proteins, and may thus open novel avenues for therapeutic intervention in protein aggregation disorders.

ROLE OF PARKINSONISM-ASSOCIATED PROTEIN FBXO7 IN SYNAPTIC INTEGRITY OF THE STRIATUM & OLFACTORY BULB

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Jingbo Wang, Judith Stegmüller
Uniklinik RWTH Aachen, Neurology, Aachen, Germany

F-box protein only protein 7 (FBXO7) is a subunit of the SCF (SKP1/cullin-1/F-box protein) E3 ubiquitin ligase complex that plays an important role in the ubiquitin proteasome system. Mutations in *FBXO7* are associated with autosomal recessive juvenile parkinsonism, also known as Parkinsonian-pyramidal syndrome (PARK15) characterized by motor and non-motor dysfunctions. Here, we investigated the role of Fbxo7 in early pathological changes of the synapse in parkinsonism in the PARK15 mouse model by examining the basal ganglia and the olfactory bulb. First, we analyzed the striatal synaptic integrity and the proteome of the PARK15 mice by immunohistochemistry and mass spectrometry, respectively. In PARK15 mice, we found astrocytosis and microgliosis, increased complement system and dopamine transporters, as well as abnormal regulation of endocytic and exocytic proteins. Second, owing to the finding that PARK15 is associated with hyposmia, we performed immunohistochemical analysis of the olfactory bulb of PARK15 mice and found an increase in astrocytes, microglia, complement system and Vgat, but a decrease in Vglut1, tyrosine hydroxylase. In conclusion, our study demonstrated that loss of Fbxo7 resulted in activated dopaminergic pathway, complement system and immune system, and inhibited endocytosis and exocytosis in the striatum, and activated GABAergic pathway, complement system and immune system, and inhibited glutamatergic pathway and dopaminergic pathway in olfactory bulb.

EXOSOMAL MIR-128 IS ALTERED IN THE PARKINSON'S PATIENT PLASMA AND PROTECTS THE NEURONS AGAINST APOPTOSIS AND MAINTAINS SYNAPTIC INTEGRITY IN PARKINSON'S DISEASE MODELS

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Pallabi Bhattacharyya, Subhas Biswas
CSIR- Indian Institute of Chemical Biology, Cell Biology & Physiology, Kolkata, India

Aim: Parkinson's disease (PD) is a progressive motor neuron disorder of the mid-brain. We aim at identifying specific brain-enriched exosomal miRNAs circulating in the PD patient blood (plasma) and characterizing their role in PD pathogenesis. **Methods**: 1.Exosome isolation; 2.qRT-PCR; 3.Immunoblotting; 4.Flow cytometry; 5.Confocal imaging **Results**: We collected blood samples from PD patients and age-matched controls and isolated exosomes from the respective plasma. Interestingly, we found a decrease in the expression of exosomal miR-128 in the PD patient plasma. Next, we treated SH-SY5Y and PC-12 cells with 6-OHDA (neurotoxin) which showed a decrease in the miR-128 expression upon treatment. Flow cytometry revealed that miR-128 over-expression could reduce the percentage of dying cells from 6-OHDA treatment. Since earlier reports from our lab showed that 6-OHDA can induce neuronal apoptosis via activation of the transcription factor FoxO3a, we decided to check the effect of miR-128 on apoptosis via FoxO3a activation, which revealed that 6-OHDA-mediated FoxO3a activation was significantly reversed upon over-expression of miR-128. Interestingly, miR-128 over-expression could also lead to down-regulation of early pro-apoptotic proteins like FasL and PUMA and attenuate the downstream activation of caspases-8 and -9 by 6-OHDA. Furthermore, miR-128 over-expression could not only improve neurite length formation, but also increase the expressions of synaptic proteins Synaptophysin and PSD-95 which was reduced during 6-OHDA treatment. **Conclusion**: We identified neuron-enriched miR-128 which was characteristically reduced in the PD patient plasma-derived exosomes and determined for the first time, its comprehensive role in neuronal apoptosis and maintenance of synaptic integrity in context to PD.

[1]UMR - S1172 – LilNCog - Lille Neuroscience & Cognition, Univ. Lille, Inserm, CHU Lille, Medical Pharmacology Department, Lille, France, [2]UMR - S1172 – LilNCog - Lille Neuroscience & Cognition, Univ. Lille, Inserm, CHU Lille, University Of Pharmacology, Lille, France

Aims Parkinson's disease is characterized by a progressive degeneration of dopaminergic neurons, a pathological accumulation of alpha-synuclein and a chronic neuroinflammation. Loss-of-function mutations in the GBA gene encoding lysosomal glucocerebrosidase are common genetic factor for Parkinson's disease. However, how glucocerebrosidase deficiency contributes to Parkinson's disease pathophysiology is poorly understood. The research project aims to study the impact of the loss of glucocerebrosidase activity on the susceptibility of dopaminergic neurons exposed to cell death stimuli. **Methods**
Conduritol-beta-epoxide (CBE) was used to inhibit glucocerebrosidase activity in Human dopaminergic LUHMES cells. LUHMES cells were exposed to various cell-death inductors leading to apoptosis, autophagy, ferroptosis or mitochondrial respiratory chain alteration death. Cell viability, reactive oxygen species production and protein levels are assessed using resazurin, flow cytometry and western blot. **Results** Short-term inhibition of glucocerebrosidase activity didn't impact LUHMES cells susceptibility to inductors of neuronal death. Interestingly, prolonged inhibition of glucocerebrosidase activity decreased the sensitivity of dopaminergic LUHMES cells towards autophagic cell death and RSL3-induced ferroptosis. Ongoing experiments aim to determine the basis of the observed neuroprotective effect caused by long-term inhibition of glucocerebrosidase. **Conclusions**
Our data suggest that glucocerebrosidase deficiency in neurons decreases their susceptibility to cellular death suggesting that others mechanisms intrinsic to neurons of other cells such as microglia may increase the susceptibility of dopaminergic neurons to cell death. Ongoing experiments should determine whether the link between glucocerebrosidase and neurodegeneration could involve excessive activation of microglial cells.

Cannabidiol (CBD) is a non-psychoactive phytocannabinoid with interesting pharmacological properties that may have therapeutic utility for CNS-related disorders. In particular, CBD has been reported to have analgesic, anti-inflammatory, anti-convulsant, anti-dyskinetic and anxiolytic effects (dos Santos Pereira et al, Glia, 2020). Some studies also suggested that CBD might operate as a neuroprotectant. The present work aimed to determine whether CBD has the capacity to prevent dopamine (DA) cell death as it might occur in Parkinson disease (PD). For that, we established mouse primary midbrain cultures under experimental conditions in which DA neurons degenerate spontaneously and progressively by ferroptosis, a mode of cell death reported to contribute to PD neurodegeneration (Angelova et al, Cell Death Differ, 2020). We found that CBD efficiently protected DA neurons under such conditions. CBD effects were long lasting, not dependent on cell culture age and observable in a range of concentrations comprised between 0.2-1µM. Antagonists of CB1 (AM 251), CB2 (SCH 336) and PPARy (GW 9662) receptors as well as of TRPV1 channels (capsazepine) failed to curtail CBD neuroprotection, suggesting that CBD operated through receptor-independent mechanisms. Live-cell imaging of reactive oxygen species with DHR-123 revealed that CBD efficiently curtailed intracellular oxidative stress. The iron chelator desferrioxamine, the inhibitor of lipid peroxidation Trolox and the ferroptosis inhibitor liproxstatin-1, all reproduced CBD neuroprotective effects, confirming that CBD operated by curtailing iron-dependent ferroptosis. Overall, our data indicate that CBD has the potential to interfere efficiently with ferroptosis pathways that could possibly intervene in PD neurodegeneration.

PEGASUS: A NOVEL DOPAMINE AGONIST WITH NEUROPROTECTIVE EFFECT

POSTER SESSION 02 - SECTION: PARKINSON'S DISEASE AND MOVEMENT DISORDERS

Rosana Chehin[1,2], Agustin Pernicone[2], Verónica Manzano[1], Esteban Vera Pingitore[1], Martin Luong[3], Cesar Ávila[1], Adriana Kolender[3], Florencia González-Lizárraga[1], Rodrigo Tomas-Grau[1], Silvina Chaves[1], Oscar Varela[3], Diego Ploper[1]

Aims: continuous and safe delivery of dopamine across the blood brain barrier (BBB) is a main obstacle for successful substitution therapy in Parkinson's disease. However, the presence of the neurotransmitter does not interfere the progression of neuronal death. Our aim is taking advantage of the well-known capacity of doxycycline (DOXY) to cross the BBB together with its neuroprotective activity to obtain a DOXY-DOPA hybrid molecule that we call Pegasus. **Methods**: *Pegasus* was synthetized by removal of the dimethylamino function at C4 and introducing an amino group at C-9, which was covalently linked via a linker to dopamine. Activation of dopaminergic receptors was performed by cAMPNOMAD Cells (Innoprot). Cytotoxicity was studied by MTT assay in SH-SY5Y/Bv2 cell lines. Neuroprotective properties were studied as follows: *i)* inhibition of α-Synuclein (AS) aggregation by ThT assay; *ii)* antioxidant capability by CellRox™ assay; *iii)* inhibition of proinflammatory cytokine IL-1β release by microglial cells; *iv*) antiapoptotic properties on HEK293T Cytochrome C-tGFP cell line, and *v*) influence on lysosomal biogenesis in SH-SY5Y cells with LysoTraker™ assay. **Results and conclusion:** *Pegasus* activated dopaminergic receptors 10-fold less efficiently than dopamine but resulted in improved theoretical ability to cross the BBB. *Pegasus* did not show toxicity in two different cell lines, and efficiently inhibited AS amyloid aggregation as well as LPS or AS fibrils-induced neuroinflammation. The new molecule also preserved antioxidant properties, characteristic of tetracyclines, and did not interfere with lysosomes biogenesis. We present *Pegasus* as a dopamine agonist with neuroprotective activity, and an ideal candidate for further preclinical studies.

BLUE LIGHT MODULATES TASK-DEPENDENT SUBCORTICO-CORTICAL CONNECTIVITY DURING AN AUDITORY ATTENTIONAL TASK

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Ilenia Paparella[1], Islay Campbell[1], Roya Sharifpour[1], Alexander Berger[1,2,3], Ekaterina Koshmanova[1], Elise Beckers[1,4], Nasrin Mortazavi[1], Pierre Maquet[1], Siya Sherif[1], Gilles Vandewalle[1]
[1]University of Liège, Cyclotron Research Centre, Liège, Belgium, [2]Université Catholique de Louvain (UCLouvain), Institute Of Neuroscience (ions), Bruxelles, Belgium, [3]Synergia Medical SA, Synergia Medical Sa, Mont-Saint-Guibert, Belgium, [4]Alzheimer Centre Limburg, School For Mental Health And Neuroscience, Faculty Of Health, Medicine And Life Sciences, Maastricht University, Maastricht, Netherlands

Aim: Exposure to blue light stimulates alertness and performance by affecting a widespread set of task-dependent brain regions. Light information is considered to reach first subcortical regions which in turn affects non-visual regional cortical activity. Here, we aimed to provide an empirical demonstration of this putative scenario in humans. **Methods:** Fourteen healthy young subjects (24.3y ± 3; 9 women) completed an attentional oddball task consisting in detecting rare (20%) deviant tones (100Hz) among more frequent (80%) standard (500Hz) ones. While performing the task, participants were exposed to 30s-blocks of blue-enriched (61 $\mu W/cm^2$) or orange monochromatic light (5.28 10^{12} photons/cm^2/s) interleaved by ~15s darkness periods. We used Dynamic Causal Modeling (DCM) to investigate the effective connectivity between areas significantly involved in the task. **Results:** Standard univariate analysis showed that the left intraparietal sulcus (IPS), involved in attention, and the inferior colliculus (IC), a brainstem nuclei part of the auditory pathway involved in multisensory integration, were significantly recruited by deviant tone detection ($p<.001$ uncorrected). Bayesian model selection and averaging of several DCMs in which light conditions modulated either the connection between IC to IPS, between IPS to IC, or both, revealed that the model with best posterior probability consisted in the model where blue, but not orange light, strengthened IC-to-IPS connection ($t=2.48$, $p=.02$). **Conclusion:** Our results provide empirical data suggesting that blue light affects cognitive activity by modulating task-dependent information flow from subcortical to cortical areas. Psycho-social factors associated with mental resilience in the Corona lockdown.
The SARS-CoV-2 pandemic is not only a threat to physical health but is also having severe impacts on mental health. Although increases in stress-related symptomatology and other adverse psycho-social outcomes, as well as their most important risk factors have been described, hardly anything is known about potential protective factors. Resilience refers to the maintenance of mental health despite adversity. To gain mechanistic insights about the relationship between described psycho-social resilience factors and resilience specifically in the current crisis, we assessed resilience factors, exposure to Corona crisis-specific and general stressors, as well as internalizing symptoms in a cross-sectional online survey conducted in 24 languages during the most intense phase of the lockdown in Europe (22 March to 19 April) in a convenience sample of N = 15,970 adults. Resilience, as an outcome, was conceptualized as good mental health despite stressor exposure and measured as the inverse residual between actual and predicted symptom total score. Preregistered hypotheses (osf.io/r6btn) were tested with multiple regression models and mediation analyses. Results confirmed our primary hypothesis that positive appraisal style (PAS) is positively associated with resilience ($p < 0.0001$). The resilience factor PAS also partly mediated the positive association between perceived social support and resilience, and its association with resilience was in turn partly mediated by the ability to easily recover from stress (both $p < 0.0001$). In comparison with other resilience factors, good stress response recovery and positive appraisal specifically of the consequences of the Corona crisis were the strongest factors.

Preregistered exploratory subgroup analyses (osf.io/thka9) showed that all tested resilience factors generalize across major socio-demographic categories. This research identifies modifiable protective factors that can be targeted by public mental health efforts in this and in future pandemics.

Rhythm is a fundamental component of the auditory world, present even during the prenatal life. While there is evidence that some auditory capacities are already present before birth, whether and how the premature neural networks process auditory rhythm is yet not known. We investigated the neural response of premature neonates at 30-34 weeks gestational age to violations from rhythmic regularities in an auditory sequence using high-resolution electroencephalography and event-related potentials. Unpredicted rhythm violations elicited a fronto-central mismatch response, indicating that the premature neonates detected the rhythmic regularities. Next, we examined the cortical effective connectivity underlying the elicited mismatch response using dynamic causal modeling. We examined the connectivity between cortical sources using a set of 16 generative models that embedded alternate hypotheses about the role of the frontal cortex as well as backward fronto-temporal connection. Our results demonstrated that the processing of rhythm violations was not limited to the primary auditory areas, and as in the case of adults, encompassed a hierarchy of temporo-frontal cortical structures. The result also emphasized the importance of top-down (backward) projections from the frontal cortex in explaining the mismatch response. Our findings demonstrate a sophisticated cortical structure underlying predictive rhythm processing at the onset of the thalamocortical and cortico-cortical circuits, two months before term.

By interfering with the normal sequence of mechanisms serving the brain maturation, premature birth and perinatal stress can alter peri-natal experiences, with potential long-term consequences on the child development. The early characterization of brain functioning is thus of critical interest in premature infants who are at high risk of atypical outcomes. We aimed to characterize the resting-state activity in infants studied at the equivalent age of pregnancy term (n=20, gestational age at birth: 25-31weeks) and longitudinally 2-months later (n=12), using high-density electroencephalography (EEG; recording duration: 2.8-8.3mins). The temporal dynamics of brain activity were characterized by parsing it into “microstates”, defined as sequences of short-lasting scalp topographies (Michel & Koenig, NeuroImage, 2018). K-means clustering algorithm identified 7 dominant microstate templates that explained more than 50% of the signal variance across infants. While the duration of all microstates decreased between the two ages, their occurrence frequency mainly increased. Furthermore, the coverage of 4/7 microstates changed with development. These suggest both an acceleration of the temporal dynamics and an evolution in the spatiotemporal organization of brain activity with maturation. This preliminary work highlights the potential of microstates characterization to investigate resting-state functional networks in infants. This approach may provide clinically-useful quantitative measures of the developing brain activity, and help to evaluate atypical deviations related to early

insults.

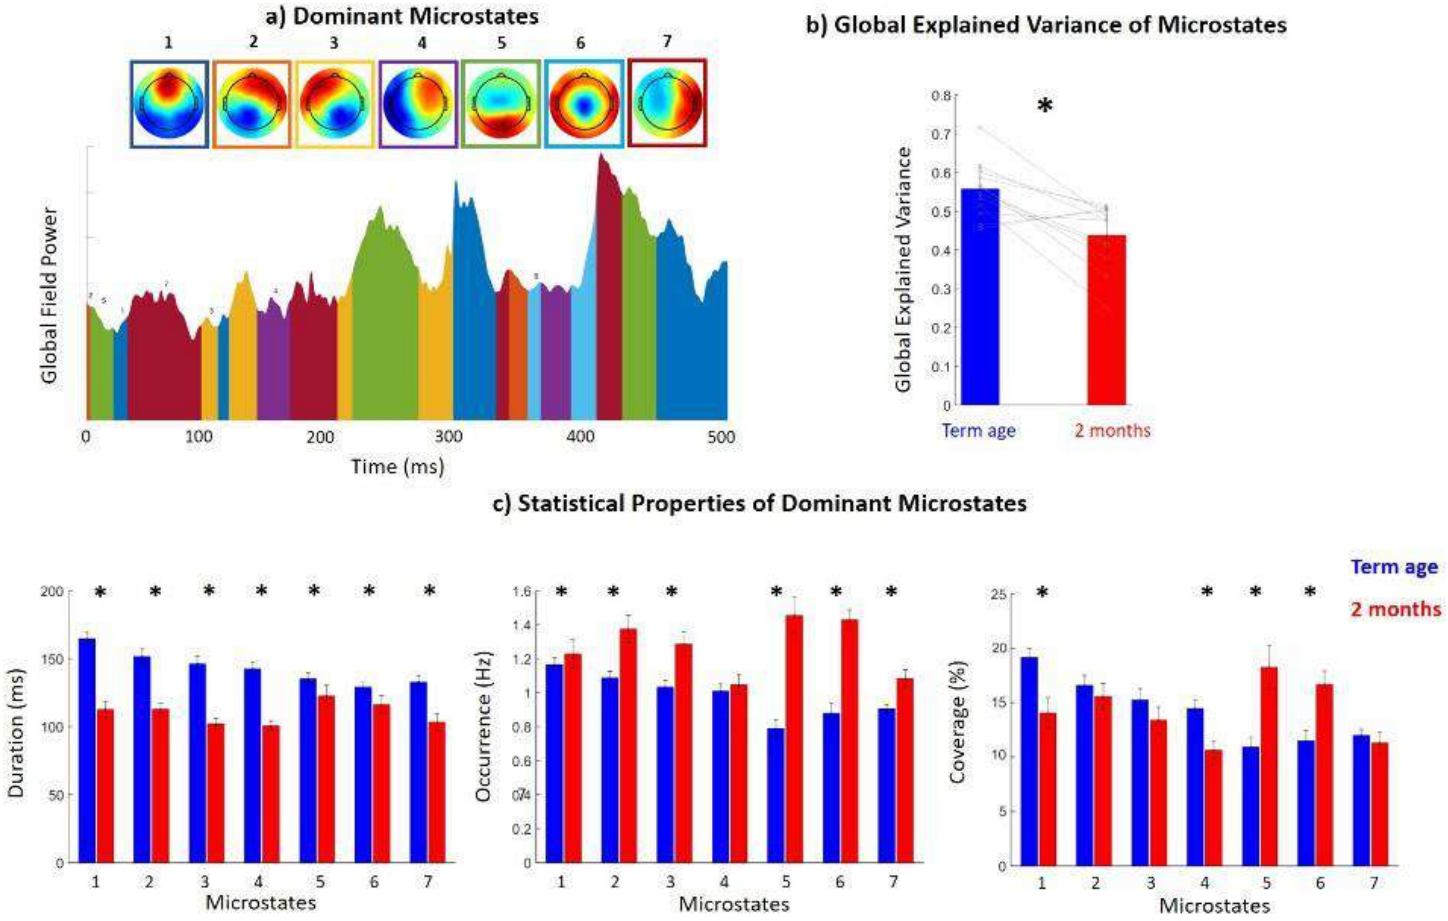

Figure. a) Continuous activity was parsed into 7 dominant microstates identified across all infants. These templates were back fitted to each infant recording and individual characteristics were measured. **b)** The microstates explained the global variance better at term-age than 2-month later (n=12). **c)** Metrics of Duration (i.e. average time a microstate lasts before changing to a new one), Occurrence (i.e. rate per second) and Coverage (i.e. proportion along recording time) were measured for each microstate and compared across ages (* paired t-test: $p<0.05$).

UNCOVERING THE FUNCTIONAL CONNECTIVITY OF THE HUMAN CORTICAL FACE NETWORK WITH CONCURRENT VISUAL FREQUENCY TAGGING AND INTRACEREBRAL ELECTRICAL STIMULATION

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Luna Angelini[1], Bruno Rossion[1,2,3], Angélique Volfart[4], Corentin Jacques[2], Louis Maillard[3], Sophie Colnat-Coulbois[5], Jacques Jonas[3]
[1]Université de Lorraine, CNRS, CRAN, Health, Biology And Signal, Nancy, France, [2]Université Catholique de Louvain, Institute Of Research In Psychological Science, Louvain-la-Neuve, Belgium, [3]Université de Lorraine, Chru-nancy, Service De Neurologie, Nancy, France, [4]Queensland University of Technology, School Of Psychology And Counselling, Brisbane, Australia, [5]Université de Lorraine, CHRU-Nancy, Service De Neurochirurgie, Nancy, France

The neural basis of human face recognition has been extensively studied for decades, but the functional organization of the cortical face network remains largely unknown. Here we apply direct electrical stimulation (DES) through intracerebral electrodes (SEEG) combined with fast periodic visual stimulation (FPVS) to define the cortical face network functional connectivity. Electrodes implanted intracerebrally in drug-resistant epilepsy patients allow us to stimulate a local node of the network and record the functional activity of other implanted regions, with high spatial and temporal resolution.
We describe this original combination of techniques in one case: CJ, a right-handed 43-year-old woman with refractory focal epilepsy, excellent face recognition ability and key implantations in face-selective regions of the right lateral FG and the ventral ATL. The patient observed 60-second stimulation sequences of natural images of familiar faces alternating at a 6Hz rate, while focal stimulation (1,2mA at 55Hz) was applied to the face-selective right latFG for 10s. During stimulation, we found a reduction of significant 6Hz responses to famous faces not only locally (right latFG), but also in remote face-responsive electrodes of the right and left vATL. Interestingly, the stimulations that lead to significant electrophysiological effects, which suggest functional connectivity, were also associated with the clearest behavioural effects: during the stimulation, the patient could not recognize the famous faces displayed on the screen. This original combination of techniques appears to be effective and its application on a wide sample of individual brains could provide key information regarding the connectivity of well-defined functional brain networks.

EFFECT OF STATIC TRANSCRANIAL MAGNETIC STIMULATION OVER LEFT-DLPFC ON FATIGUE PRODUCED BY HUMAN GAIT

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Pablo Arias, Mariña Naya, Aranza Vila, Antonio Madrid, Javier Cudeiro
University of A Coruña, Neurocom Lab, A Coruña, Spain

Aims: We search for a role of left dorsolateral prefrontal cortex (DLPFC) on gait fatigue. For this purpose, we stimulated left DLPFC with a 0.5T magnet while participants walking. Static magnetic fields applied over the cortex are reported to reduce cortical excitability. **Methods:** 12 healthy participants (age-range [20-29 yrs]; 6 women) walked over a level-treadmill during 25 bouts of 5 min/each (15 secs rest in between), in two different sessions. Fatigue perception was recorded with a visual analogue scale (VAS, 0=not fatigue at all, 10=exhausted) every 5 min (we also recorded kinematics and muscle activity continuously). While walking, left DLPFC was stimulated with a real/sham magnet each session, sessions order counterbalanced across participants. Walking repetitions #2, 3, 24 and 25 also included the concurrent execution of a cognitive task (Stroop: color interfering or reading). Treadmill walking speed matched each participant's preferred walking speed, calculated over-ground in a previous session. **Results:** While walking at 4.6 Km/h (SE 0.1) along sessions, fatigue perception increased in a lineal manner ($p<0.001$), from ≈0 to 4.2 in the 10 points VAS. Fatigue perception and its increase along sessions did not differ for real/sham sessions ($p=0.437$ and $p=0.821$). The Stroop interference mildly modulated fatigue perception ($p=0.002$), not differently for early (#2 and 3) and late (#24 and 25) repetitions, and did not interact with the DLPFC stimulation mode either. **Conclusions:** Increasing cognitive demands and while walking has weak effects on fatigue perception.

RESPONSES TO LOCAL AND GLOBAL DEVIANCE IN SUBCORTICAL STRUCTURES

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Audrey Mazancieux[1], Franck Mauconduit[2], Alexis Amadon[2], Jan Willem De Gee[3], Tobias Donner[4], Florent Meyniel[1]
[1]CEA, INSERM, Unicog, Neurospin,, Gif sur Yvette Cedex, France, [2]CEA, CNRS,, Baobab, Neurospin,, Gif sur Yvette Cedex, France, [3]Baylor College of Medicine, Houston, TX, USA., Department Of Neuroscience, Houston, United States of America, [4]University Medical Center Hamburg-Eppendorf,, Section Computational Cognitive Neuroscience, Department Of Neurophysiology And Pathophysiology, Hamburg, Germany

The ability to detect deviance in the environment is crucial in order to adapt our behavior. Deviance detection recruits the sympathetic nervous system, particularly the arousal system mainly driven by noradrenaline through the activity of the Locus Coeruleus (LC). However in humans, it is unclear whether the recruitment of this arousal system is specific or if it also relates to other systems such as dopamine, acetylcholine, and serotonin systems. Here, we performed a systematic mapping of response to deviants in subcortical structures using dedicated fMRI methods. Twenty participants performed the local-global task, an extension of a classical auditory oddball task that discriminates the bottom-up and top-down mechanisms of deviance detection. The auditory sequence exhibited two types of deviance as a lack of repetition, both locally (within a pattern of sound) and globally (across patterns). . During the task, pupil size was also recorded (indirect measure of the LC activity). We showed that the response to global deviants is very much distributed: it is found in the LC but also in many regions involving other neuromodulators, other subcortical nuclei, and cortical areas. Activity in the subject-specific LC region increased for both types of global deviants (locally standard or locally deviant patterns), like pupil size but unlike activity in an atlas-based LC region.Responses to global deviants were uncorrelated between the LC activity and pupil size. We discuss our results in terms of a hierarchy of processes involved in deviance detection. Moreover, our results validate a method to investigate neuromodulator-specific subcortical structures.

WHAT IS AROUSAL? AN AUTOMATED ANALYSIS OF A CORPUS OF 48.000 SCIENTIFIC ARTICLES

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Magdalena Sabat[1,2], Charles De Dampierre[3], Catherine Tallon-Baudry[2,3,4]
[1]Laboratoire des systèmes perceptifs, Département D'études Cognitives, École Normale Supérieure, Psl University, Paris, France, [2]Laboratoire de Neurosciences Cognitives et Computationelles, Inserm, Ecole Normale Supérieure, Université PsI, Paris, France, [3]Ecole Normale Supérieure, Department Of Cognitive Science, Paris, France, [4]Ecole Normale Supérieure, Inserm, Paris, France

Arousal refers to brain and body modulations within the awake state. Historically arousal has been associated with different neuromodulatory systems, and, in consequence, to different aspects of the general body and brain states. Different measurements have been used as a proxy: from heart rate and respiratory rhythm to skin conductance, or, more recently, pupil diameter. Despite the heterogeneity of measures, arousal is often conceptually seen as uni-dimensional, reflecting an "internal state". While some authors have attempted at bringing attention to the problems and limitations of the notion of arousal, the term has been and is still widely used: as of February 2022 sixty thousand scientific articles mention the term 'arousal' (Pubmed). Proper systematization of the concept would require pondering over tens of thousands of individual uses. Here, we use modern natural language processing tools which facilitate extraction of semantic meaning across very large datasets, without having to manually analyze the text. Using automatic term extraction and word embedding we recover semantic clusters within an arousal-related literature data set of ~48.000 abstracts. In contrast with the classical view of arousal, the semantic clusters seem to point to a heterogeneous, multi-dimensional concept of arousal. We further characterize the clusters by assessing the prevalence of neuromodulators and measurement-related terms in abstracts and titles of papers associated with each cluster. Finally, we attempt to relate the semantic associations with the brain using automatic fMRI meta-analytic tools.

WHAT IS THE CONTRIBUTION OF CEREBROVASCULAR REACTIVITY TO MEASURES OF HAEMODYNAMIC LAGS IN PATIENTS WITH LEFT HEMISPHERE STROKE?

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Andra Braban[1], Robert Leech[2], Kevin Murphy[3], Fatemeh Geranmayeh[1]
[1]Imperial College London, Clinical Language And Cognition Group (clc), Department Of Brain Sciences, Hammersmith Campus, London, United Kingdom, [2]King's College London, Centre For Neuroimaging Science, London, United Kingdom, [3]Cardiff University, Cardiff University Brain Research Imaging Centre (cubric), Department Of Psychology, Cardiff, United Kingdom

Resting-state fMRI is increasingly used to study post-stroke recovery. Recent evidence suggests that haemodynamic response (HRF) is impaired following stroke, showing temporal signal delays ('lag') which can correlate with behavioural outcomes, functional connectivity, and cerebral perfusion measures. **Aims:** To investigate the relationship between haemodynamic delays and cerebrovascular reactivity (CVR) in patients after a left hemisphere infarct. **Methods:** Voxelwise Lag maps were calculated relative to the mean grey-matter reference signal for 58 patients and 27 heathy controls, sub-acutely (~2wks) and chronically (~4m) post-stroke, using both a resting-state and a breath-holding fMRI task. The latter produced measures of CVR induced by hypercapnia. **Results:** Voxelwise cross-correlation between lag maps derived from the resting-state and breath-hold fMRI showed a moderately high spatial correlation (mean *r=0.46-0.55*) of lag between the two brain states, both at a whole brain level and within regions we have previously shown reduced CVR (lesion and perilesional tissue). Across both brain states there was a relative haemodynamic lead in primary sensorimotor cortices. Breath-hold derived lag showed no significant correlation at group level with CVR maps (mean *r=-0.03-0.06*). Lag maps were highly replicable irrespective of the choice of reference signal (whole-brain grey matter, right hemisphere, or left hemisphere). **Conclusions:** The lack of correlation between lag and CVR and the high spatial correlation of lag maps derived from the two brain states would suggest that alterations in CVR post stroke have negligible effect on the temporal lag in the HRF. We argue that the lag is predominantly driven by differential neural network dynamics.

SINGLE SESSION OF PREFRONTAL THETA BURST STIMULATION MODULATES METABOLIC ACTIVITY

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Ines Jani[1], Lauri Tuominen[1], Cecelia Shvetz[1], Abir Gebara[1], Juho Joutsa[2], Sara Tremblay[1]

Background: Intermittent theta burst stimulation (iTBS) to the left dorsolateral prefrontal cortex (DLPFC) has emerged as a new treatment for depression. Effects of iTBS in humans however are not well understood. In this sham controlled double blind randomized cross-over study, we tested the effects of a single session of neuronavigated DLPFC iTBS on [18F]FDG uptake. **Methods**: Planned unblinding and interim analyses were carried out on 8 healthy individuals (6 females, age 27.5 ± 8.2). Subjects underwent standard 3 minute iTBS stimulation and a sham stimulation on separate days. [18F]FDG was injected immediately after both stimulations. [18F]FDG emission data was collected 40 minutes after injection for 30 minutesusing a Siemens PET/MRI scanner. Standardized uptake value ratios (SUVRs) were computed using preprocessed [18F]FDG scans. Difference between iTBS and sham in SUVRs were calculated. Effects of stimulation were analyzed using voxel-wise one sample t-tests. All tests were thresholded at voxel-wise p-values < 0.01, uncorrected. **Results**: Compared to sham stimulation, iTBS decreased [18F]FDG uptake in the subgenual anterior cingulate cortex, the anterior insula, and the left caudate. **Conclusions**: To our knowledge this is the first iTBS PET/MRI study. Our interim analysis suggests that a single session of iTBS is sufficient to modulate the metabolic activity of the core depression network. These results are in line with previous studies and if confirmed in the final sample, they will help design more personalized iTBS treatments in clinical populations.

PHENOMENOLOGY AND FUNCTIONAL SIGNIFICANCE OF THE VERTEX POTENTIAL

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Richard Somervail[1,2], Eros Quarta[3], Diego Benusiglio[2], Sofija Perovic[2,4], Rory Bufacchi[2], Alexandra Battaglia-Mayer[4], Giandomenico Iannetti[1,2]
[1]University College London, Department Of Neuroscience, Physiology And Pharmacology, London, United Kingdom, [2]Istituto Italiano di Tecnologia, Neuroscience And Behaviour Laboratory, Clns, Rome, Italy, [3]Sapienza University of Rome, Department Of Physiology And Pharmacology, Rome, Italy, [4]Sapienza University of Rome, Department Of Psychology, Rome, Italy

Living in rapidly changing and potentially dangerous environments has shaped animal brains toward high sensitivity to sudden sensory events - often signaling threats or affordances requiring swift motor reactions. Unsurprisingly, such events elicit one of the largest electrocortical responses recordable from the scalp of several animals: the widespread Vertex Potential (VP). While often assumed to reflect sensory-specific processing, we have shown that the VP instead largely reflects *supramodal* neural activity, sensitive to the *behavioural-relevance* of the eliciting stimulus. Specifically the VP amplitude is determined by the magnitude of sensory changes, rather than their absolute intensity, and this sensitivity is conserved across sensory modalities and species. Additionally highly similar VPs are elicited regardless of the direction of this sensory change (i.e. increases or decreases of sensory intensity). All together, these results suggest that, rather than reflecting the canonical “lemniscal” sensory processing in primary sensory regions, the VP instead reflects a supramodal, widespread activation of cortex mediated by the non-specific “extralemniscal” projections from non-specific thalamic nuclei (and associated subcortical structures, such as the locus coeruleus and reticular activating system). We hypothesise that the negative-positive sequence of waves composing the VP reflects a process similar to the cortical up and down states observed during slow-wave sleep, presumably to set the cortex into a more reactive state, allowing the organism to better prepare swift motor reactions. We present novel electrophysiological data from monkeys and mice to test these ideas, using simultaneous surface and invasive recordings of cortex, and sudden sensory stimuli of several modalities.

Brain Responses to Surprising Stimulus Offsets: Phenomenology and Functional Significance.
Abrupt increases of sensory input (onsets) likely reflect the occurrence of novel events or objects in the environment, potentially requiring immediate behavioral responses. Accordingly, onsets elicit a transient and widespread modulation of ongoing electrocortical activity: the Vertex Potential (VP), which is likely related to the optimisation of rapid behavioral responses. In contrast, the functional significance of the brain response elicited by abrupt decreases of sensory input (offsets) is more elusive, and a detailed comparison of onset and offset VPs is lacking. In four experiments conducted on 44 humans, we observed that onset and offset VPs share several phenomenological and functional properties: they (1) have highly similar scalp topographies across time, (2) are both largely comprised of supramodal neural activity, (3) are both highly sensitive to surprise and (4) co-occur with similar modulations of ongoing motor output. These results demonstrate that the onset and offset VPs largely reflect the activity of a common supramodal brain network, likely consequent to the activation of the extralemniscal sensory system which runs in parallel with core sensory pathways. The transient activation of this system has clear implications in optimizing the behavioral responses to surprising environmental changes.

Waves of Change: Brain Sensitivity to Differential, not Absolute, Stimulus Intensity is Conserved Across Humans and Rats.
Living in rapidly changing environments has shaped the mammalian brain toward high sensitivity to abrupt and intense sensory events-often signaling threats or affordances requiring swift reactions. Unsurprisingly, such events elicit a widespread electrocortical response (the vertex potential, VP), likely related to the preparation of appropriate behavioral reactions. Although the VP magnitude is largely determined by stimulus intensity, the relative contribution of the differential and absolute components of intensity remains unknown. Here, we dissociated the effects of these two components. We systematically varied the size of abrupt intensity increases embedded within continuous stimulation at different absolute

intensities, while recording brain activity in humans (with scalp electroencephalography) and rats (with epidural electrocorticography). We obtained three main results. 1) VP magnitude largely depends on differential, and not absolute, stimulus intensity. This result held true, 2) for both auditory and somatosensory stimuli, indicating that sensitivity to differential intensity is supramodal, and 3) in both humans and rats, suggesting that sensitivity to abrupt intensity differentials is phylogenetically well-conserved. Altogether, the current results show that these large electrocortical responses are most sensitive to the detection of sensory changes that more likely signal the sudden appearance of novel objects or events in the environment.

Movement of environmental threats modifies the relevance of the defensive eye-blink in a spatially-tuned manner.
Subcortical reflexive motor responses are under continuous cortical control to produce the most effective behaviour. For example, the excitability of brainstem circuitry subserving the defensive hand-blink reflex (HBR), a response elicited by intense somatosensory stimuli to the wrist, depends on a number of properties of the eliciting stimulus. These include face-hand proximity, which has allowed the description of an HBR response field around the face (commonly referred to as a defensive peripersonal space, DPPS), as well as stimulus movement and probability of stimulus occurrence. However, the effect of stimulus-independent movements of objects in the environment has not been explored. Here we used virtual reality to test whether and how the HBR-derived DPPS is affected by the presence and movement of threatening objects in the environment. In two experiments conducted on 40 healthy volunteers, we observed that threatening arrows flying towards the participant result in DPPS expansion, an effect directionally-tuned towards the source of the arrows. These results indicate that the excitability of brainstem circuitry subserving the HBR is continuously adjusted, taking into account the movement of environmental objects. Such adjustments fit in a framework where the relevance of defensive actions is continually evaluated, to maximise their survival value.

HEART RATE DECELERATION AS A BIOMARKER OF IMPLICIT PROCESSING: A DEMONSTRATION OF ITS SENSITIVITY IN A REAL-WORLD TEACHING TASK

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Camilla Moliterni[1,2], Xiao-Fei Yang[1,2,3], Christina Kundrak[1,2,3], Mary Helen Immordino-Yang[1,2,3,4]
[1]University of Southern California, Center For Affective Neuroscience, Development, Learning And Education, Los Angeles, United States of America, [2]University of Southern California, Brain And Creativity Institute, los angeles, United States of America, [3]University of Southern California, Rossier School Of Education, los Angeles, United States of America, [4]University of Southern California, Neuroscience Graduate Program, Loa Angeles, United States of America

Heart rate deceleration (HRD) following the presentation of new stimulus is a component of the orienting response (Lacey & Lacey, 1974). HRD magnitude varies depending on the attentional requirement of the task, increasing when attention is drawn outward and diminishing when internally focused reflection is required, such as mentalizing and moral reasoning (Yang, 2013). Here we provide a proof-of-concept study of the utility of HRD as a biomarker for reflective thinking using a real-world teaching task. While grading work from a familiar student (compared to an unknown student), teachers spontaneously engage in more internally focused reflection to consider the rich history of social interactions, and therefore we predicted less HRD.19 secondary teachers (10 females, aged 28-57 years) designed and administered subject-specific assignments to their students. We collected students' answers and created matched controls, which we told teachers were from unknown students. Teachers viewed for the first time 10 students' answers and 10 controls during continuous pulse oximetry recording. Following a 2-second fixation, each answer was presented for 20 seconds, during which teachers evaluated answer quality and assigned a grade. For each trial, we calculated heart rate change relative to the pre-trial fixation, and averaged changes over a 6-second window after stimulus onset to capture HRD to the stimulus. As hypothesized, teachers showed less HRD when evaluating their own students' answers compared to equivalent answers from unknown students ($t(18)=2.08$; one-tailed $p=.03$)[CK1] . Our findings suggest that HRD is a useful biomarker to reveal differences in reflective processing during real-world social tasks.

A ROLE OF PARAHIPPOCAMPAL CORTEX IN FORWARD-LOOKING CHOICES DURING MULTI-STEP REINFORCEMENT LEARNING IN HUMANS

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Fabien Cerrotti[1], Alexandre Salvador[1], Sabrine Hamroun[1], Mael Lebreton[2], Stefano Palminteri[1]
[1]Laboratoire de Neurosciences Cognitives et Computationnelles, Département D'Études Cognitives, Paris, France, [2]Paris School of Economics, Paris-jourdan Sciences Économiques, Paris, France

Many real-life decisions involve a tension between short-term and long-term outcomes. In the reinforcement learning framework, an optimal solution to this trade off consists in computing forward-looking (or prospective) values using a model of the environment (model-based RL). Experimentally, this trade-off is often instantiated by multi-step decision-making problems, where decisions taken at an initial stage concomitantly generate an outcome and the transition to a new state. In the present study we wanted to compare the neural correlates of choices involving a forward-looking value computation. To do so we administered a new version of a two-step learning task to subjects (N=28) undergoing fMRI scanning. Analysis of the behavioral results during and after learning revealed that subjects learned both the reward values associated to each state and an explicit model of the task (i.e., state-transition probabilities). Turning to the neural data, we directly contrasted neural activity of choices in the first stage (involving a prospective component) to those in the second stage (without a prospective component) at the options onset. Results (significant after controlling for multiple comparisons) indicated that the parahippocampal cortex (BA37) was more activated in forward-looking choices. Another set of areas, including the bilateral orbitofrontal cortex (BA11) was more activated in short-term choices. Our results shed new light on the neural bases of model-based reinforcement learning by suggesting a specific role of the parahippocampal cortex in forward planning and OFC in choices involving immediate rewards.

CORTICAL GREY MATTER AND ITS RELATIONSHIP TO COGNITIVE PERFORMANCE AND METABOLIC PARAMETERS IN ADULTS WITH EARLY-TREATED PHENYLKETONURIA

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Raphaela Muri[1,2,3,4], Stephanie Abgottspon[1,3,4], Christian Rummel[2], Michael Rebsamen[2], Michel Hochuli[1], Bernadette Jansma[5], Roland Wiest[2,4], Roman Trepp[1], Regula Everts[1,4,6]

Background: Despite strict dietary adherence, the gold-standard treatment of phenylketonuria (PKU) seems unable to prevent damages to brain structure and function. How structural characteristics of the brain relate to cognitive outcomes in adult patients is still unknown.
Aims: We investigated cortical thickness (CT) and cortical surface area (CSA) in adults with PKU and their relationship to metabolic parameters and cognitive functions.
Methods: Twenty-three adult patients with early-treated PKU and fifty-one healthy controls were included. Surface-based morphometry was derived from T1-weighted MRI using FreeSurfer, and general intelligence, executive functions, and attention were assessed. In patients, concurrent plasma phenylalanine (Phe), tyrosine, and tryptophan levels were measured.
Results: Patients showed a thinner cortex than controls primarily in temporal, parietal, and occipital regions-of-interest (ROIs) (d=0.47 to 0.67), while group differences in CSA were more pronounced in frontal areas (d=0.47 to 0.73). Phe and tyrosine were negatively related to CT of occipital (r=-.46) and frontal ROIs (r=-.46), respectively. Conversely, tryptophan was positively related to a parietal ROI (r=.44). In patients, executive functions correlated with CT and CSA of frontal ROIs (r=-.59 to .56), and attention was associated with CT of temporal, parietal, and occipital ROIs (r=-.50 to .47). In controls, attention was correlated with CT of parietal and occipital ROIs (r=.29 to .30).
Conclusions: Our results reflect the heterogeneity of grey matter characteristics in adults with early-treated PKU and suggest that PKU has a widespread impact on cortical architecture. Such structural changes are partially related to metabolic control and cognitive performance in adults with PKU.

DOES THE VERTEX POTENTIAL REFLECT THE RAPID SUCCESSION OF CORTICAL DOWN AND UP STATES?

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Sofija Perovic[1,2], Richard Somervail[1,3], Giandomenico Iannetti[1,3]
[1]Istituto Italiano di Tecnologia, Neuroscience And Behaviour Laboratory, Clns, Rome, Italy, [2]Sapienza University of Rome, Department Of Psychology, Rome, Italy, [3]University College London, Department Of Neuroscience, Physiology And Pharmacology, London, United Kingdom

Sudden sensory changes elicit a transient, large and widespread biphasic negative-positive deflection in the ongoing EEG: the Vertex Potential (VP). The VP has a number of transient behavioural effects, such as a multidirectional modulation of motor output. Here, we tested whether the VP affects already early sensory processing, which we probed by recording early somatosensory evoked potentials (SEPs). We elicited the VP using sudden auditory stimuli delivered at variable intervals (0.1-0.17 Hz), while participants were continuously receiving median nerve somatosensory stimuli at 9.5 Hz. We grouped single-trial SEPs as a function of the phase of the average VP waveform, and thereby provided a dynamic evaluation of the VP-dependent modulation of early somatosensory processing. We observed that the N20 component, which represents the arrival of the first thalamocortical volley, was unaffected by the VP phase. In contrast, the amplitude of the P45 component, which reflects later cortical processing, was reduced during the negative and enhanced during the positive VP wave. Crucially, these effects were enhanced when single-trial SEPs were grouped accounting for the trial-by-trial latency jitter of the VP (i.e. using the phase of single-trial VPs), compared to when they were aligned to the onset of the auditory stimulus. These results provide strong evidence that the VP exerts phase-dependent modulation of early lemniscal sensory processing. The biphasic nature of this modulation is reminiscent of the effects on early sensory processing of slow waves in non-REM sleep, suggesting that the negative-positive VP waves reflects a rapid succession of cortical down-state and up-state.

A leftward bias negatively correlated with performance is selectively displayed by domestic chicks during rule reversal (not acquisition).
In order to face a constantly changing environment, animals need to be able to update their knowledge of the world on the basis of new information. Often, this means to inhibit a previously acquired response and flexibly change their behaviour to produce a new response. Here, we measured such abilities in young domestic chicks, employing a Colour Reversal Learning Task. During the acquisition phase, 17 one-week-old male chicks had to learn to peck on one of two coloured boxes to obtain a food reward. After reaching criterion, chicks underwent a reversal phase in which the previously learned colour-reward contingency was swapped. As expected from the literature, chicks performed better in the acquisition phase with respect to the reversal phase. Results moreover highlighted the presence of a lateralized bias selectively during reversal: chicks performed better if the stimulus rewarded was located in the left hemispace (processed by the right hemisphere). Interestingly, the bias correlated with the individual difficulty, i.e., it was stronger in those chicks which needed more trials to complete the reversal session. The present study contributes evidence in support of behavioural flexibility in young chicks, along with a novel perspective on lateralized mechanisms that might underlie such ability.

LINK BETWEEN DORSOMEDIAL PREFRONTAL CORTEX AND ANTERIOR INSULA METABOLISM AND FMRI CORRELATES OF MOTIVATED BEHAVIOR

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Nicolas Clairis[1], Arthur Barakat[1], Carmen Sandi[2]
[1]EPFL, Behavioral Genetics Laboratory - Brain Mind Institute (bmi) - Sciences De La Vie (sv), Lausanne, Switzerland, [2]EPFL, Laboratory Of Behavioural Genetics, Brain Mind Institute, Lausanne, Switzerland

Aims: Individuals continuously decide whether it is worth exerting effort to obtain rewards. Research on the physiological mechanisms that explain inter-individual differences in motivated behavior is essential to comprehend its neural underpinnings. A network encompassing the dorsomedial prefrontal cortex (dmPFC) and the anterior insula (aIN) plays a major role in several aspects of motivated behavior (i.e., exploration/exploitation tradeoff, saliency, uncertainty, effort, cognitive control). Here, we aim to understand how the metabolic state of the dmPFC and the aIN, in terms of concentrations of different metabolites (Glutamine, Glutamate and GABA), relates to differences in the brain activity associated to different aspects of motivated behavior and decision-making. Methods: The metabolic profile from healthy participants (25-40 years old) is acquired with proton magnetic resonance spectroscopy (^{1}H-MRS) in a 7T scanner. Immediately afterwards, participants perform two binary choice tasks while acquiring functional magnetic resonance imaging (fMRI). These tasks involve choices between options associated to different levels of monetary incentive, either to win or to lose, and of physical (squeezing a handgrip) or mental (2-back task) effort. Results: Our experiment allowed us to identify key metabolites (Glutamine/Glutamate, GABA) in the dmPFC and in the aIN relating to differences in the activity of the fMRI brain correlates of motivated behavior, in particular regarding the processing of different types of efforts, and, therefore, to differences in motivational profiles, assessed with computational modelling. Conclusion: Our results pave the way for a new approach of motivated behavior and brain imaging, by bridging baseline ^{1}H-MRS with fMRI BOLD activity.

Individual Brain Charting dataset extension, second release of high-resolution fMRI data for cognitive mapping.
We present an extension of the Individual Brain Charting dataset -a high spatial-resolution, multi-task, functional Magnetic Resonance Imaging dataset, intended to support the investigation on the functional principles governing cognition in the human brain. The concomitant data acquisition from the same 12 participants, in the same environment, allows to obtain in the long run finer cognitive topographies, free from inter-subject and inter-site variability. This second release provides more data from psychological domains present in the first release, and also yields data featuring new ones. It includes tasks on e.g. mental time travel, reward, theory-of-mind, pain, numerosity, self-reference effect and speech recognition. In total, 13 tasks with 86 contrasts were added to the dataset and 63 new components were included in the cognitive description of the ensuing contrasts. As the dataset becomes larger, the collection of the corresponding topographies becomes more comprehensive, leading to better brain-atlasing frameworks. This dataset is an open-access facility; raw data and derivatives are publicly available in neuroimaging repositories.

Major neurotransmitter systems in dorsal hippocampus and basolateral amygdala control social recognition memory.
Social recognition memory (SRM) is crucial for reproduction, forming social groups, and species survival. Despite its

importance, SRM is still relatively little studied. Here we examine the participation of the CA1 region of the dorsal hippocampus (CA1) and the basolateral amygdala (BLA) and that of dopaminergic, noradrenergic, and histaminergic systems in both structures in the consolidation of SRM. Male Wistar rats received intra-CA1 or intra-BLA infusions of different drugs immediately after the sample phase of a social discrimination task and 24-h later were subjected to a 5-min retention test. Animals treated with the protein synthesis inhibitor, anisomycin, into either the CA1 or BLA were unable to recognize the previously exposed juvenile (familiar) during the retention test. When infused into the CA1, the β-adrenoreceptor agonist, isoproterenol, the D1/D5 dopaminergic receptor antagonist, SCH23390, and the H2 histaminergic receptor antagonist, ranitidine, also hindered the recognition of the familiar juvenile 24-h later. The latter drug effects were more intense in the CA1 than in the BLA. When infused into the BLA, the β-adrenoreceptor antagonist, timolol, the D1/D5 dopamine receptor agonist, SKF38393, and the H2 histaminergic receptor agonist, ranitidine, also hindered recognition of the familiar juvenile 24-h later. In all cases, the impairment to recognize the familiar juvenile was abolished by the coinfusion of agonist plus antagonist. Clearly, both the CA1 and BLA, probably in that order, play major roles in the consolidation of SRM, but these roles are different in each structure vis-à-vis the involvement of the β-noradrenergic, D1/D5-dopaminergic, and H2-histaminergic receptors therein.

HOW COGNITIVE CONTROL IS REPRESENTED IN THE BRAIN: AN EEG REPRESENTATIONAL SIMILARITY ANALYSIS STUDY

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Giada Viviani[1,2], Antonino Visalli[2], Antonino Vallesi[1,2,3], Ettore Ambrosini[1,2]
[1]University of Padua, Padova Neuroscience Center, Padova, Italy, [2]University of Padua, Deparment Of Neuroscience, Padua, Italy, [3]Fondazione Ospedale San Camillo IRCCS, Fondazione Ospedale San Camillo Irccs, Lido di Venezia (VE), Italy

Aims: Cognitive control is a fundamental human ability that allows pursuing specific relevant goals. Several theories postulate that cognitive control relies on neural representations. However, univariate approaches that have been classically used to investigate it are not suitable for studying such representations. Therefore, the aim of our EEG study was to explore how cognitive control representations are encoded at the neural level and to investigate the contribute of different theory-based representations. Methods: To this aim, we used Representational Similarity Analysis (RSA) to model theory-based representations and correlate them to the observed brain patterns.
We designed a spatial Stroop task, in which both list-wide and item-specific proportion of congruency were manipulated, respectively, to measure the effects of proactive and reactive control on Stroop interference resolution. We assessed the similarity between control-related representational models and temporal and spatial multivariate patterns of EEG activity, while controlling for low-level confounding effects. Results: RSA revealed specific spatiotemporal EEG correlates not only of low-level sensorial, motor, and cognitive representations, but also of both proactive and reactive control representations. Specifically, significant similarities were found between proactive control representational models and pre-stimulus multivariate patterns of EEG activity, as well as between reactive control representational models and post-stimulus multivariate patterns of EEG activity, in line with theoretical accounts of Stroop interference resolution. Conclusions: Our results suggest that RSA better informs cognitive control theory by revealing the dynamics of its neural representations. Indeed, temporal and spatial RSA patterns provided insights into cognitive control theory-based representations but also into low-level representations.

It is not always positive: emotional bias in young and older adults.
Healthy ageing has been associated with a bias toward positive information and greater psychological well-being. However, to what extent this positivity bias also applies to prioritizing positive information under emotional competition is unclear. Old and young adults performed a word-face interference task, in which they responded to the valence of positive and negative target-words while ignoring happy or angry distractor-faces that could be affectively congruent or incongruent. A control condition with scrambled neutral distractor-faces was also used. Findings showed small facilitation effects with faster responses when targets and distractors were affectively congruent and large interference effects with slower responses when targets and distractors were affectively incongruent compared to the control condition. Importantly, whereas for younger adults there was a similar pattern of interference from happy and angry distractor-faces, for older adults there was greater interference from angry distractor-faces. The present findings are discussed in the context of emotional bias literature. Psychol Res, 2021;

EEG-neurofeedback and executive function enhancement in healthy adults: A systematic review.
Electroencephalographic (EEG)-neurofeedback training (NFT) is a promising technique that supports individuals in learning to modulate their brain activity to obtain cognitive and behavioral improvements. EEG-NFT is gaining increasing attention for its potential "peak performance" applications on healthy individuals. However, evidence for clear cognitive performance enhancements with healthy adults is still lacking. In particular, whether EEG-NFT represents an effective technique for enhancing healthy adults' executive functions is still controversial. Therefore, the main objective of this systematic review is to assess whether the existing EEG-NFT studies targeting executive functions have provided reliable evidence for NFT effectiveness. To this end, we conducted a qualitative analysis of the literature since the limited number of retrieved studies did not allow us meta-analytical comparisons. Moreover, a second aim was to identify optimal frequencies as NFT targets for

specifically improving executive functions. Overall, our systematic review provides promising evidence for NFT effectiveness in boosting healthy adults' executive functions. However, more rigorous NFT studies are required in order to overcome the methodological weaknesses that we encountered in our qualitative analysis.

PSYCHOBIOLOGICAL APPROACH TO STRESS AND ANXIETY: A VIRTUAL REALITY STUDY UNCOVERING NEURAL AND PHYSIOLOGICAL READOUTS OF STRESS ANTICIPATION AND THEIR CAPACITY TO PREDICT PERFORMANCE

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Catherine Bratschi, Jonathan Benhaiem, João Rodrigues, Carmen Sandi
EPFL, Life Sciences, Lausanne, Switzerland

Aim. Anticipating potential threats is essential for an organism to maximize its chances of survival. When exposed to a stressor, organisms undergo physiological, behavioral and neural responses. Repeated activations of these responses, either triggered by a threatening or a non-threatening event, can be detrimental to health. Sustaining high levels of anxiety and stress is maladaptive for the organism. Therefore, it is important to identify and characterize predictive biomarkers of individual differences in stress vulnerability. The present study aims to characterize anticipatory anxiety and stress responses based on locomotion, brain activity and physiological markers including respiration, cortisol and heart rate variability (HRV), to predict performance in completing a stressful task. **Methods**. Physiological recordings (respiration, electrocardiogram, photoplethysmogram, electrodermal activity), motion capture, salivary cortisol and EEG were collected before, during and after immersion in virtual reality scenarios, including a modified version of the Trier Social Stress Test (TSST) and two scenarios inspired by the animal literature to capture behavioral responses related to stress and anxiety. **Results**. We found that data on locomotor responses during novelty exploration reliably predicts interindividual differences in HRV triggered by exposure to a threatening VR environment. Several features from locomotor response commonly considered in rodent studies significantly contributed to our HRV predictive model and indicated a trade-off between area exploration and remaining in a safe environment. **Conclusion**. These findings pave the way for further research on biofeedback manipulation and development of phenotyping techniques to detect stress-vulnerable individuals.

Aims: Evidence for sleep-dependent changes in micro-structural neuroplasticity remains scarce, despite the fact that it is a mandatory corelate of the reorganization of learning-related functional networks. We investigated the effects of post-training sleep on structural neuroplasticity markers measuring standard diffusion tensor imaging mean diffusivity (MD) and the revised biophysical neurite orientation dispersion and density imaging (NODDI) free water fraction (FWF) and neurite density (NDI) parameters that enable disentangling whether MD changes result from modifications in neurites or in other cellular components (e.g., glial cells). **Methods:** 34 healthy adults (18-30y) were scanned using diffusion weighted imaging [DWI] on Day1 before and after 40-minutes route learning (navigation) in a virtual environment, then were sleep deprived (SD) or slept normally (RS) for the night. After recovery sleep for 2 nights, they were scanned again (Day4) before and after 40-minutes route learning (navigation) in an extended environment. Sleep-related microstructural changes were computed on DTI (MD) and NODDI (NDI and FWF) parameters in the cortical ribbon and subcortical regions of interest (ROIs). **Results and conclusions:** Results disclosed navigation learning-related decreased DWI parameters in the cortical ribbon (MD, FWF) and subcortical (MD, FWF, NDI) areas. Post-learning sleep-related changes were found at Day4 in the extended learning session (pre- to post-relearning percentage changes; see Figure) in the caudate nucleus (FWF and NDI: RS decrease vs. SD increase) and the hippocampus (NDI: RS decrease vs. SD increase), suggesting a sleep-related remodelling of neurites and glial cells subtending learning and memory processes in basal ganglia and hippocampal structures.

The mouse prefrontal cortex (PFC) lacks a definition. Further, the function(s) of the PFC remains to be established, regardless of species. Traditionally, subregions of the PFC have been delineated based on cytoarchitectural features. Based on recent large-scale mapping of the connectivity of the mouse cortex, a prefrontal module has been identified. The cortical subregions within this module (anterior cingulate (ACA), prelimbic area (PL), infralimbic area (ILA), orbitofrontal cortex (OFC)) display particularly high interconnectivity to each other than to other cortical regions. Hodology thus gives support for the presence of a distinct prefrontal region (module) in the mouse brain. However, how hodology and cytoarchitectural features relate to function is highly unclear. We here use a series of auditory tasks and high-density (Neuropixels probes) recordings in a head-restrained mice to establish functional maps of the mouse PFC. Thousands of single units and the local field potential (LFP) activity were recorded across the layers and the proposed subregions of the PFC. The exact location of the individual electrodes was mapped after tissue clearing and reconstruction of the probe location. At first, we focused on spontaneous activity and used functional connectivity and intrinsic timescales to establish a hierarchical organization of PFC regions. We next used auditory stimuli to engage the subregions of the PFC while mice either passively listen to sounds or engage in distinct tasks. The presented data will focus on how functions segregate across the PFC during distinct auditory tasks, and how different prefrontal functions relate to traditional delineations of the PFC.

Motor skill learning is fundamental for behavioral adaptation as it leads to automatization and refinement of common behaviors. Dorsal striatum has been described as central to motor learning with a differential global implication of the dorsomedial striatum (DMS) and the dorsolateral striatum (DLS) in the learning process. Aim: Our aim is to determine whether and how specific striatal neuronal ensembles encode the acquisition and consolidation of a motor skill. Methods and Results: Here, using ex vivo two-photon calcium imaging, we report the existence of striatal ensembles formed by highly active (HA) cells, which arise from distinct spatiotemporal reorganization in DMS and DLS networks over the course of motor learning. The overall activity of DMS decreases during the early phase, with few and sparsely distributed HA cells. In contrast, the DLS shows a progressive and long-lasting formation of HA cell clusters. In both territories, the HA cells have specific properties and are correlated with the learning performance of the mice. These two types of network reorganization arise from distinct levels of plasticity: early reinforcement of synaptic connections from cingulate cortex on DMS HA cells, followed by late and long-lasting anatomical rearrangements of somatosensory projections to the DLS. Using an AAV cFos-TRAP strategy combined with chemogenetics, we further demonstrate that silencing HA cells in DMS or DLS strongly impairs the individual performance. Conclusion: We therefore conclude that discrete domains of HA neuronal ensembles encode early acquisition in DMS and long-lasting retention of motor skill learning in DLS.

DEVELOPMENTAL CHANGES OF THE PULVINO-CORTICAL FUNCTIONAL CONNECTIVITY

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Mathilda Froesel[1], Simon Clavagnier[1], Holly Rayson[2], Maëva Gacoin[1], Alice Massera[2], Pier Francesco Ferrari[2], Suliann Ben Hamed[1]
[1]Institut des Sciences Cognitives Marc Jeannerod (ISC-MJ), Neural Bases Of Spatial Cognition And Action Umr5229 Cnrs, Bron, France, [2]Institut des Sciences Cognitives Marc Jeannerod (ISC-MJ), Laboratory Of Social Neuroscience And Comparative Umr5229 Cnrs, Bron, France

The pulvinar is a complex posterior thalamic nucleus involved in numerous cognitive and socio-emotional functions. However, although we know that the pulvinar, and notably the dorsal part, acts as a key functional hub for these functions and that pulvino-cortical functional connectivity (PCFC) dysfunctions are reported in the context of neurodevelopmental disorder (ADHD and ASD), little is known about changes in functional pulvinar connectivity across development, how this relates to the emergence of specific higher-level cognitive and socio-emotional functions, or how factors in the early social environment may impact this development. Here, we aimed to characterize PCFC across childhood, adolescence and early adulthood, and consider the impact of early social deprivation (ESD) on this connectivity, as ESD is linked to increased levels of ADHD and “quasi-autistic” patterns of behaviour. To this aim, we utilized a macaque model of ESD to longitudinally examine changes in PCFC using resting-state fMRI. We found that connectivity became more adult-like from childhood into adulthood, with prefrontal cortex, anterior cingulate cortex, pre-supplementary motor area, and insula connectivity increasing with age, and lateral sulcus, superior temporal sulcus, intraparietal sulcus and posterior cingulate cortex connectivity decreasing. Changes were particularly marked in cortical areas associated with vocal production and social auditory perception suggesting that development of pulvino-cortical networks play a crucial role in the refinement of cognitive and socio-emotional skills during this period. Effects of early social adversity are currently being analysed.

EARLY SOCIAL ADVERSITY IN NON-HUMAN PRIMATES INTERFERES WITH THE DEVELOPMENTAL TRAJECTORY OF AMYGDALO-CORTICAL FUNCTIONAL CONNECTIVITY

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Simon Clavagnier[1], Holly Rayson[2], Mathilda Froesel[3], Maëva Gacoin[3], Alice Massera[4], Pier Francesco Ferrari[5], Suliann Ben Hamed[1]
[1]UMR5229 Institut des sciences cognitives Marc Jeannerod, Neural Bases Of Spatial Cognition And Action, BRON CEDEX, France, [2]Institut des Sciences Cognitives Marc Jeannerod (ISC-MJ) CNRS UMR 5229, Laboratory Of Social Neuroscience And Comparative Development, Bron, France, [3]Institut des Sciences Cognitives Marc Jeannerod (ISC-MJ), Neural Bases Of Spatial Cognition And Action Umr5229 Cnrs, Bron, France, [4]Institut des Sciences Cognitives Marc Jeannerod (ISC-MJ), Laboratory Of Social Neuroscience And Comparative Umr5229 Cnrs, Bron, France, [5]CNRS/Université Claude Bernard Lyon, Institut Des Sciences Cognitives Marc Jeannerod, Lyon, France

Neuroimaging of the non-human social primate brain has been instrumental to forge our current understanding of primate social cognition. However, little is known to date on how this cognitive function develops from childhood into adolescence, and how early social adversity (ESA) interferes with typical brain functional developmental trajectories. Here, we used a longitudinal neuroimaging protocol and collected anesthetized resting-state fMRI data in 21 juvenile monkeys (10 peer-reared, 11 mother-reared), at three time points (av. 2.7 years -childhood; av. 3.8 years -adolescence; av. 5.0 years -early adulthood). We focus on the amygdala, a subcortical structure which plays a key role in socioemotional and attentional processing. In the left and right amygdala, we quantified the functional connectivity between this structure and the rest of the brain. We applied a linear mixed-effects modelling approach to dissociate sources of variability associated with age from those associated with ESA. We show a progressive refinement of the amygdalo-cortical connectivity through adolescence, from a broad distributed pattern to a more adult-like restrained pattern. Independently from this age effect, we show that the peer-reared group, as compared to the mother-reared group, retains part of its functional connectivity with the medial posterior parietal cortex (precuneus), the mid-cingulate and specific premotor and prefrontal regions. We propose that altered amygdalo-cortical functional connectivity in the peer-reared group accounts for the specific differences in affect-biased attention and high emotional reactivity observed in this group.

A HEAD-FIXED ASSAY FOR LARVAL ZEBRAFISH TO STUDY BEHAVIORAL STATE CHANGES ACROSS MULTIPLE TIMESCALES

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Thomas Soares Mullen, Adrien Jouary, Edite Figueiras, Alexandre Laborde, Joaquim António Contradanças, Michael Orger
Champalimaud Centre for the Unknown, Neuroscience, Lisboa, Portugal

Animals produce spontaneous patterns of behaviour that are modulated by internal states on timescales that range from seconds to hours. A challenge to studying the underlying neural mechanisms has been that these states are difficult to elicit in a controlled and reliable form in preparations amenable to large-scale physiology. We developed an assay to evoke a simple behavioural cycle repeatedly in head-fixed larval zebrafish. A photochemical, noxious stimulus results in a brief nocifensive response and a sustained period of immobility, which is followed by a stereotyped transition into rhythmic swimming behaviour. We characterised these behavioural states and assigned key temporal signatures to transitions in the bout kinematics. We see that the duration of the immobility period correlates with the time to establish rhythmic swimming. Swim bouts during the rhythmic swimming state occur more frequently and with less variation in timing and kinematics than observed during spontaneous swimming, before any presentation of aversive stimuli. While all fish showed a state of rhythmic swimming, some fish did not repeat a single stereotyped bout type but had multiple modes and would alternate between low and high amplitude forward swims. This assay was developed in an arena that was designed to be compatible with light-sheet imaging. Therefore, all behaviour was recorded, while also imaging neural activity in the brain using panneurally expressed GCaMP. Using this data, we hope not only to map neural states onto behavioural states, but also to shed light on the mechanisms by which these internal states switch over long timescales.

LEAKY INTEGRATION OF PAST NEURONAL AND BEHAVIORAL STATES BY HIPPOCAMPAL ASTROCYTES

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Peter Rupprecht, Christopher Lewis, Fritjof Helmchen
University of Zurich, Brain Research Institute, Zurich, Switzerland

Recent years have seen a surge of research on astrocytes and their possible roles for computations and memory processes. However, a systematic study of natural activity patterns of astrocytes in the context of distinct behavioral, neuromodulatory, and neuronal network states is still lacking. Here, we perform simultaneous two-photon calcium imaging of astrocyte and neuronal populations in the hippocampus of head-fixed mice – together with recordings of locomotion, body movements, and pupil diameter – to investigate their behavioral, neuromodulatory and neuronal state dependence. We find that astrocytic activity in vivo, albeit exhibiting localized activation patterns, is dominated by a global mode that is largely maintained within and across hippocampal layers. This global activity pattern is highly correlated with the *current* pupil diameter. In addition, the global mode can also be well explained as a leaky integration of *past* neuronal activity and *past* body movement. The time constants of integration define a temporal sequence, with neuronal activity, motor movement and pupil changes preceding astrocytic activity in this order with consistent delays on the order of seconds. Furthermore, we find that integration of such past events in individual astrocytes occurs in a specific spatio-temporal pattern, starting in their distal processes followed by a slow propagation to the soma region. Together, our data provide evidence for a role of hippocampal astrocytes in the integration of past events, and put forward a quantitative description of the spatio-temporal integration in the context of behavioral, modulatory and neuronal signals.

INVESTIGATING HIPPOCAMPAL SYNAPTIC DEFICITS IN THE SUB-CHRONIC PHENCYCLIDINE RAT MODEL FOR SCHIZOPHRENIA

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Ningyuan Sun
University of Manchester, Faculty Of Biology, Medicine And Health, Manchester, United Kingdom

Background: Schizophrenia is a complex neuropsychiatric disorder characterised by three main symptom domains, namely positive, negative, and cognitive deficits. Recent evidence suggests that the cognitive impairments associated with schizophrenia (CIAS) are the main determinant of functional outcomes. However, to date, there is no licenced treatment for CIAS. N-methyl-D-aspartate (NMDA) receptor antagonist rodent models are routinely used to model CIAS and provide a reliable model for investigating underlying mechanisms. **Methods:** Animals received either phencyclidine (scPCP) 2 mg/kg or vehicle bi-daily for 7 days followed by a 7 day washout period prior to behavioural testing (novel object recognition). Synaptic function in the CA1 region of the dorsal hippocampus was then assessed by acute electrophysiology under urethane anaesthesia *in vivo*. CA3-evoked field excitatory postsynaptic potential (fEPSP) in CA1 were analysed to investigate differences in synaptic connectivity and short/long-term synaptic plasticity. **Results:** The scPCP group showed expected novel object recognition deficits in behavioural testing. Our electrophysiology data shows that whilst short-term plasticity (paired-pulse facilitation) was similar between two groups, synaptic connectivity (input-output function) was significantly decreased in the scPCP group. Early data from ongoing experiments show that: (a) both groups support long-term synaptic potentiation in CA1 following high-frequency stimulation; and (b) depotentiation of fEPSP slope and amplitude after LTP induction appears similar between groups, with both reversing towards the baseline. Full results will be presented on the poster. **Conclusion:** In summary, our data indicate that the well-established cognitive deficit in the scPCP rat model is accompanied by a complex change in hippocampal synaptic networks.

SOCIAL PLAY DURING ADOLESCENCE IS CRITICAL FOR THE DEVELOPMENT OF PREFRONTAL INHIBITORY SYNAPSES IN RATS

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Ate Bijlsma[1], Corette Wierenga[2], Vanderschuren[1]
[1]Utrecht University, Population Health Sciences, Utrecht, Netherlands, [2]Utrecht University, Cell Biology, Neurobiology And Biophysics, Utrecht, Netherlands

Experience-dependent organization of neuronal connectivity is critical during brain development. We recently demonstrated that social play, a form of social interaction that is abundant during development, is essential for fine-tuning of inhibitory synapses the prefrontal cortex (PFC) in rats. Here we asked how social play deprivation (SPD) during adolescence affects the developmental time course of two subregions of the PFC: the mPFC and OFC. Rats were social play deprived from postnatal day (PND) 21-42 by housing with a conspecific, while separated by a perforated screen. To address PFC circuit changes, spontaneous excitatory, inhibitory and miniature inhibitory postsynaptic currents (sEPSCs; sIPSCs; mIPSCs) were recorded in layer 5 pyramidal neurons in mPFC and OFC slices from young (PND 21), adolescent (PND 42) and adult (PND 85) rats. Our data reveal that the mPFC and OFC develop in a differential manner. GABAergic and glutamatergic synaptic inputs onto L5 pyramidal cells are already abundant in the OFC at P21 while these are much reduced in the mPFC. IPSC frequency in the mPFC gradually increased between P21 and P85, while IPSC frequency in the OFC remained stable between P21 and P42, after which a sharp increase was seen in adulthood. SPD did not affect glutamatergic development in either brain region, but SPD differentially affects the development of inhibitory synapses in these two brain regions. This suggests that the deprivation results in a direct reduction in mPFC inhibitory synapses, which leads to subsequent changes in the OFC.

A databank for intracellular electrophysiological mapping of the adult somatosensory cortex.
Neurons in the supragranular layers of the somatosensory cortex integrate sensory (bottom-up) and cognitive/perceptual (top-down) information as they orchestrate communication across cortical columns. It has been inferred, based on intracellular recordings from juvenile animals, that supragranular neurons are electrically mature by the fourth postnatal week. However, the dynamics of the neuronal integration in adulthood is largely unknown. Electrophysiological characterization of the active properties of these neurons throughout adulthood will help to address the biophysical and computational principles of the neuronal integration.

EMERGENCE OF STRUCTURE IN HIPPOCAMPAL NETWORK DYNAMICS DURING LEARNING OF A DELAYED NON-MATCH TO SAMPLE TASK

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Coralie-Anne Mosser, Mohammad Yaghoubi, Andres Nieto-Posadas, Thomas Gisiger, Zeeshan Haqqee, Emmanuel Wilson, Mark Brandon, Sylvain Williams
Douglas Hospital Research Center, McGill University, Psychiatry, Montréal, Canada

Recent technical advances enable the recording of large neuronal populations during behavior resulting in increasingly complex datasets. We have established the McGill-Mouse-Miniscope platform (www.m3platform.org) to combine miniscope calcium imaging with standardized touchscreen-based behavioral testing. Our mission is to curate an open-source and standardized framework for acquiring, analyzing, and accessing high-quality data of the neuronal dynamics that underly behavior and cognition throughout the brain in mice. Each experiment provides up to 1000 simultaneously recorded neurons from a single brain region over the course of ~3 months as animals learn and master the task. To highlight the feasibility of this approach, we have collected hippocampal CA1 and CA3 recordings during the delayed trial-unique nonmatching-to-location (TUNL) task. In this task, a square is presented in one of five positions on the touchscreen. A nose poke to this square starts a delay period. Following this delay, two squares are displayed, and the mouse must choose the nonmatching square to receive reward. As expected, CA1 and CA3 neurons are spatially modulated, however, they are also sensitive to other behavioral and task-related features that allow for decoding behavioral performance from neuron activity. Approximately 10% of hippocampal neurons participate in sequences that tile the delay period, which are unique to the sample square location, the fidelity of sequence predicts performance, and delay sequence cells are reliably activated during reward. We are now examining how this structure emerges in both regions during the initial learning of this task, and how network activity restructures when memory load is changed.

Conjunctive spatial and self-motion codes are topographically organized in the GABAergic cells of the lateral septum.
The hippocampal spatial code's relevance for downstream neuronal populations-particularly its major subcortical output the lateral septum (LS)-is still poorly understood. Here, using calcium imaging combined with unbiased analytical methods, we functionally characterized and compared the spatial tuning of LS GABAergic cells to those of dorsal CA3 and CA1 cells. We identified a significant number of LS cells that are modulated by place, speed, acceleration, and direction, as well as conjunctions of these properties, directly comparable to hippocampal CA1 and CA3 spatially modulated cells. Interestingly, Bayesian decoding of position based on LS spatial cells reflected the animal's location as accurately as decoding using the activity of hippocampal pyramidal cells. A portion of LS cells showed stable spatial codes over the course of multiple days, potentially reflecting long-term episodic memory. The distributions of cells exhibiting these properties formed gradients along the anterior-posterior and dorsal-ventral axes of the LS, directly reflecting the topographical organization of hippocampal inputs to the LS. Finally, we show using transsynaptic tracing that LS neurons receiving CA3 and CA1 excitatory input send projections to the hypothalamus and medial septum, regions that are not targeted directly by principal cells of the dorsal hippocampus. Together, our findings demonstrate that the LS accurately and robustly represents spatial, directional as well as self-motion information and is uniquely positioned to relay this information from the hippocampus to its downstream regions, thus occupying a key position within a distributed spatial memory network.

The McGill-Mouse-Miniscope platform: A standardized approach for high-throughput imaging of neuronal dynamics during behavior.
Understanding the rules that govern neuronal dynamics throughout the brain to subserve behavior and cognition remains one of the biggest challenges in neuroscience research. Recent technical advances enable the recording of increasingly larger neuronal populations to produce increasingly more sophisticated datasets. Despite bold and important open-science and data-sharing policies, these datasets tend to include unique data acquisition methods, behaviors, and file structures.

Discrepancies between experimental protocols present key challenges in comparing data between laboratories and across different brain regions and species. Here, we discuss our recent efforts to create a standardized and high-throughput research platform to address these issues. The McGill-Mouse-Miniscope (M3) platform is an initiative to combine miniscope calcium imaging with standardized touchscreen-based animal behavioral testing. The goal is to curate an open-source and standardized framework for acquiring, analyzing, and accessing high-quality data of the neuronal dynamics that underly cognition throughout the brain in mice, marmosets, and models of disease. We end with a discussion of future developments and a call for users to adopt this standardized approach.

Dietary fat exacerbates postprandial hypothalamic inflammation involving glial fibrillary acidic protein-positive cells and microglia in male mice.
In humans, obesity is associated with brain inflammation, glial reactivity, and immune cells infiltration. Studies in rodents have shown that glial reactivity occurs within 24 hr of high-fat diet (HFD) consumption, long before obesity development, and takes place mainly in the hypothalamus (HT), a crucial brain structure for controlling body weight. Here, we sought to characterize the postprandial HT inflammatory response to 1, 3, and 6 hr of exposure to either a standard diet (SD) or HFD. HFD exposure increased gene expression of astrocyte and microglial markers (glial fibrillary acidic protein [GFAP] and Iba1, respectively) compared to SD-treated mice and induced morphological modifications of microglial cells in HT. This remodeling was associated with higher expression of inflammatory genes and differential regulation of hypothalamic neuropeptides involved in energy balance regulation. DREADD and PLX5622 technologies, used to modulate GFAP-positive or microglial cells activity, respectively, showed that both glial cell types are involved in hypothalamic postprandial inflammation, with their own specific kinetics and reactiveness to ingested foods. Thus, recurrent exacerbated postprandial inflammation in the brain might promote obesity and needs to be characterized to address this worldwide crisis.

Biphasic Impact of Prenatal Inflammation and Macrophage Depletion on the Wiring of Neocortical Inhibitory Circuits.
The etiology of neurodevelopmental disorders is linked to defects in parvalbumin (PV)-expressing cortical interneurons and to prenatal immune challenges. Mouse models of maternal immune activation (MIA) and microglia deficits increase the postnatal density of PV interneurons, raising the question of their functional integration. Here, we show that MIA and embryonic depletion of macrophages including microglia have a two-step impact on PV interneurons wiring onto their excitatory target neurons in the barrel cortex. In adults, both challenges reduced the inhibitory drive from PV interneurons, as reported in neurodevelopmental disorders. In juveniles, however, we found an increased density of PV neurons, an enhanced strength of unitary connections onto excitatory cells, and an aberrant horizontal inhibition with a reduced lateral propagation of sensory inputs in vivo. Our results provide a comprehensive framework for understanding the impact of prenatal immune challenges onto the developmental trajectory of inhibitory circuits that leads to pathological brain wiring.

Microglia in CNS development: Shaping the brain for the future.
Microglial cells are the resident macrophages of the central nervous system (CNS) and are mainly known for their roles in neuropathologies. However, major recent developments have revealed that these immune cells actively interact with neurons in physiological conditions and can modulate the fate and functions of synapses. Originating from myeloid precursors born in the yolk sac, microglial cells invade the CNS during early embryonic development. As a consequence they can potentially influence neuronal proliferation, migration and differentiation as well as the formation and maturation of neuronal networks, thereby contributing to the entire shaping of the CNS. We review here recent evidence indicating that microglial cells are indeed involved in crucial steps of the CNS development, including neuronal survival and apoptosis, axonal growth, migration of neurons, pruning of supernumerary synapses and functional maturation of developing synapses. We also discuss current hypotheses proposing that diverting microglial cells of their physiological functions, by promoting the expression of an immune phenotype during development, may be central to neurodevelopmental disorders such as autism, schizophrenia and epilepsy.

Aims : Loss of consciousness is associated with the disruption of long-range thalamo-cortical and cortico-cortical brain communication. We tested the hypothesis that deep brain stimulation (DBS) of central thalamus might restore both arousal and awareness following consciousness loss. Methods : We modelled unconsciousness using finely tuned anesthesia in primates (Barttfeld et al., PNAS, 2015; Uhrig et al., Anesthesiology, 2018). Under propofol anesthesia, the implanted DBS leads stimulated either central thalamus or a control structure, the ventro-lateral thalamic nucleus. We monitored the effects of DBS on both behavior and brain activity using functional MRI (fMRI) and EEG. We investigated both the cortical dynamics of spontaneous resting-state activity and the brain evoked activity by the “local-global” auditory paradigm. Results : During anesthesia, central thalamic stimulation induced arousal in an on-off manner and increased fMRI activity in prefrontal, parietal and cingulate cortices. Moreover, DBS restored a broad dynamic repertoire of spontaneous resting-state activity, previously described as a signature of consciousness. None of these effects were obtained during the stimulation of the control site in the ventro-lateral thalamus. Finally, DBS restored a broad hierarchical response to auditory violations that was disrupted under anesthesia. Conclusions : DBS restored the two dimensions of consciousness, arousal and conscious access, following consciousness loss, paving the way to its therapeutical translation in patients with disorders of consciousness.

THE 6-ZONE TRACK: A NOVEL SPATIAL MEMORY TEST FOR AWAKE HEAD-FIXED CA2+ IMAGING

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Manuel Mittag, Falko Fuhrmann, Fabrizio Musacchio, Martin Fuhrmann
German Center for Neurodegenerative Diseases (DZNE), Neuroimmunology And Imaging, Bonn, Germany

Two-photon Ca^{2+} imaging is one of the state-of-the-art methods to record the activity of large neuronal populations in awake and behaving animals. Despite the emergence of miniature microscopes – which allow imaging of freely moving animals – many experimental systems still rely on head-fixation for better controlled conditions. Spatial memory tests in head-fixed configuration are still missing. Here, we introduce the novel 6-zone track, a spatial memory test that allows testing for different aspects and features of spatial memory processing in awake head-fixed mice. For this, we utilize a 360 cm long linear treadmill equipped with textures, separating the track into six reward zones with unique textual patterns and uniform transition zones. The local cues guide the mice along the track and allow them to identify zones associated with reward. The 6-zone track can be flexibly set-up in different ways – by introduction of fake reward zones or a delayed start – in order to test for working memory or different types of reference memory. Food-restricted and habituated mice were able to learn the tasks within a testing period of five days and showed significant improvements in several performance parameters. These parameters could be used to measure efficiency as well as specificity and thereby distinguish behavioral phenotypes. For these reasons we are convinced that the 6-zone track will be a an efficient tool to routinely perform spatial memory tests in head-fixed mice in combination with *in vivo* two-photon Ca^{2+} imaging.

Background – The development of vascular cognitive impairment (VCI) and heart failure with preserved ejection fraction (HFpEF) is associated with the presence of comorbidities (obesity, diabetes, hypertension, aging). Microvascular dysfunction and subsequent rarefaction may be a key pathological step for the development of HFpEF and VCI. **Aim** - To study the impact of combined vascular risk factors on cerebral blood flow (CBF) and cognition in a rat model of comorbidities with HFpEF. **Methods** – Cognitive function of Lean (Ln, n=15) and Obese (Ob, n=14) ZSF1 rats was studied using a series of behavioural tasks. At 33-34 weeks old, CBF was measured over the barrel cortex via a thinned skull window using laser speckle contrast imaging (LSCI). Neurovascular coupling (NVC) was assessed by whisker stimulation (5Hz, 30sec). Animals were sacrificed at 34-35w for plasma and brain analyses. **Results** – Cardiac hypertrophy was observed in Ob vs Ln (heart-to-tibia: Ln=0.03; Ob=0.04g/mm; $p<0.0001$). At 31w, short-term memory was impaired in Ob vs Ln rats ($p<0.01$) in the novel object recognition task ($p_{group}<0.01$). Furthermore, spatial learning was impaired in Ob vs Ln in the Barnes maze at 22 and 32w ($p_{group}<0.05$; $p_{time\ x\ group}<0.0001$), as well as long-term memory in the probe trial ($p_{group}<0.05$). Although no difference was observed in baseline CBF, NVC was decreased in Ob vs Ln rats (Ln=23.7±1.6; Ob=18.8±1.4, $p<0.05$). **Conclusion** – Cognitive function and NVC were impaired in a HFpEF model. The development of cerebral microvascular dysfunction and rarefaction and their underlying mechanisms are being assessed in a longitudinal study.

NEURAL SUBSTRATES OF LATENT LEARNING IN THE RETROSPLENIAL CORTEX

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Ana Carolina Bottura De Barros, Colm Dowling, Philip Graemer, Michael Kohl
University of Glasgow, School Of Psychology And Neuroscience, Glasgow, United Kingdom

Latent learning occurs when associations are formed between stimuli in the absence of explicit reinforcement. It is thought to be critical for the creation of internal models of the world's structure used in decision making. But how stimulus representations are encoded in neural activity in the absence of direct reinforcement is still unclear. Silencing retrosplenial cortex (RSC) activity during the preexposure phase of a sensory preconditioning drastically impairs task performance, demonstrating the necessity of RSC for non-spatial latent learning. This makes RSC a suitable brain area to study neural activity in latent learning. Here, we set out to understand what task variables are encoded in RSC activity and how these change over the course of a latent learning task. We use head-mounted, miniature microscopes to chronically image calcium activity in GCaMP7s-expressing RSC neurons in freely moving, adult mice performing a non-spatial sensory preconditioning task. We relate neural activity from individual neurons in the superficial layers of RSC to task variables and show how stimulus representations evolve over the course of the task. Our results expand the current understanding of latent learning and its involvement in the creation of internal models required for model-based learning.

IMPACT OF COGNITIVE TRAINING IN RESTING STATE NETWORKS IN THE TGF344-AD RAT MODEL

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Guadalupe Soria[1,2], Emma Muñoz-Moreno[3], Xavier López-Gil[3], Federico Varriano[1], Raúl Tudela[2]
[1]University of Barcelona, Laboratory Of Surgical Neuroanatomy, Barcelona, Spain, [2]Consorcio de Investigación Biomédica en Red de Bioinginería, Biomateriales y Nanomedicina, Ciber-bbn, Madrid, Spain, [3]Institut d'Investigacions Biomèdiques August Pi i Sunyer, Experimental 7t Mri Unit, Magnetic Resonance Imaging Core Facility, Barcelona, Spain

Introduction
TgF344-AD rat model (TG) of Alzheimer's disease shows time-dependent alterations revealing dysfunction in resting state networks (default mode, sensorimotor, somatosensorial [Tudela et al., 2019]). Our aim was to study the impact of cognitive training during 8 months on somatosensory networks and other resting state networks in wild type (WT) and TG rats. Methods: Training and delayed non-matched to sample (DMNS) test were performed in WT and TG rats starting at 3 months of age until 11 months, when MRI was acquired. rs-fMRI was acquired in a 7T scanner periodically to evaluate different resting state networks. The standard deviation of the time-series (Amplitude) of the component was computed for each subject and the differences between groups were evaluated using mixed ANOVA (genotype and treatment as between factors and time as within-group factor of variation). Differences were considered significant if $p< 0,05$. Results: Cognitive stimulation, by DNMS task performed between, 3 and 11 months had a positive effect in TgF344-AD rats compared to non-trained TG animals in resting state networks related with sensorial processing such as somatosensory S1, S2 and insular cortices (Figure1). While trained TgF344-AD rats showed a similar temporal evolution than their WT littermates, non-trained TgF344-AD animals revealed alterations in the amplitude of these networks. Conclusion: Our preliminary results point to a positive impact of early cognitive training in specific resting state networks in the TgF344-AD rat model of Alzheimer's

disease, which could prevent from the cognitive decline induced by the pathology at later time-

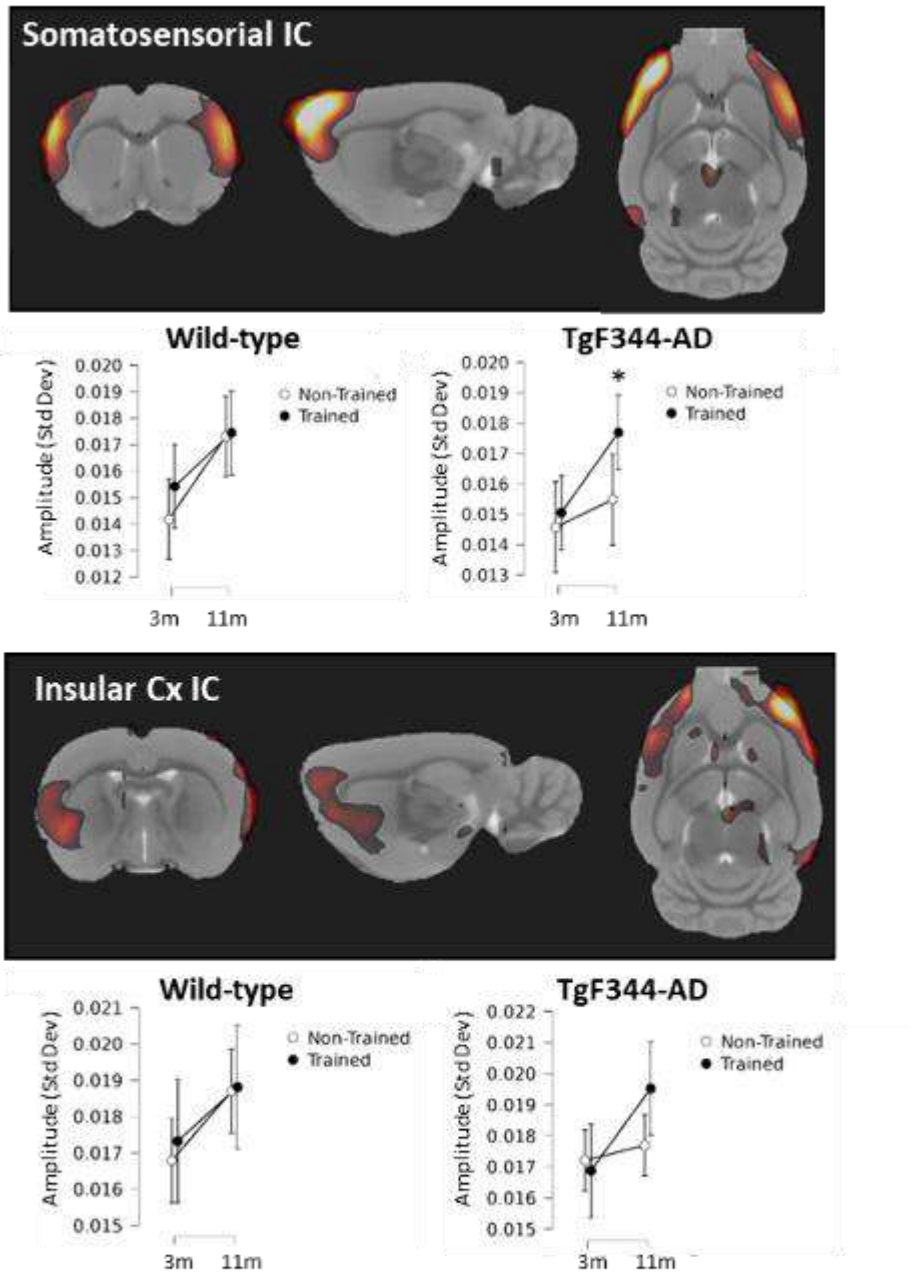

Figure 1. Somatosensorial and Insular cortices independent components (IC) and the corresponding longitudinal changes in the amplitude of the time series in trained and non-trained WT and TG animals. * Indicates significant difference $p<0,05$ vs non-trained group

points.

VENTRAL PALLIDUM ACTIVATION DIFFERENTIALLY MODULATES THE MEDIODORSAL THALAMUS AND THE LATERAL HABENULA OF RATS

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Epistimi-Anna Makedona, Hamid Azimi, Pilar Vaca Sánchez, Michael Harvey, Gregor Rainer
University of Fribourg, Department Of Medicine, Fribourg, Switzerland

The Default Mode Network (DMN) is a collection of mainly cortical brain areas, the simultaneous activation of which is typically associated with mental inward focus and disengagement from environmental stimuli. Recent convergent literature suggests that the basal forebrain plays a major role in DMN regulation and more specifically, has implicated the ventral pallidum (VP) as a key brain region that triggers and maintains cortical DMN activation. Here, we investigate which efferent neural pathways mediate DMN regulation by VP. While the VP projects to a plethora of regions, particularly robust projections target the mediodorsal thalamus (MD) and the lateral habenula (LHb). Based on the apparent connectivity of MD and LHb with areas linked to the DMN, we hypothesize that VP impacts DMN activation through projections to these areas. To elucidate this, we optogenetically manipulated VP in different stimulation frequencies while recording single-unit and multi-unit activity in the MD and LHb. Towards this, we employed an AAV-hSyn1-hChR2 construct and activated the general population of neurons in the VP, which led to robust suppression in both MD and LHb. The inhibitory effect correlated positively with the stimulation frequency. Notably, while both areas were downregulated during VP activation, the prominent rebound excitation following the laser pulse and the low baseline activity of LHb resulted in an overall excitation of the latter relative to pre-stimulation baseline. Our preliminary findings indicate robust VP-induced regulation of MD and LHb and suggest therefore two candidate pathways by which VP might affect DMN activity.

MORPHOLOGICAL ANALYSIS OF TWO SULCI IN THE VENTROLATERAL FRONTAL CORTEX OF THE CHIMPANZEE (PAN TROGLODYTES) BRAIN

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Trisanna Sprung-Much[1], Dirk Jan Ardesch[2], Claude Lepage[1], Michael Petrides[1], William Hopkins[3]
[1]McGill University, Montreal Neurological Institute, Montreal, Canada, [2]Vrije Universiteit Amsterdam, Complex Trait Genetics, Amsterdam, Netherlands, [3]The University of Texas MD Anderson Cancer Center, Comparative Medicine, Bastrop, United States of America

In the language dominant hemisphere of the human brain, the ventrolateral frontal cortex is necessary for speech production (Broca's area). Investigations of the homologous region in the brains of non-human primates are, therefore, relevant for understanding the evolution of language and related functional processes. In the present study, we examined the morphology of the fronto-orbital sulcus (*fo*) and the opercular sulcus (*op*) (Figure 1), which are characteristic features of the ventrolateral and neighbouring orbitofrontal cortex of the chimpanzee (*Pan troglodytes*) brain. Cortical surfaces were reconstructed from 77 in-vivo MRI scans (3T) from the National Chimpanzee Brain Resource, and the two sulci of interest were labelled manually to examine their morphological features and relations to each other. Morphological patterns were then categorized across hemispheres and individuals. The results demonstrate that the *fo* can be subdivided into a ventral component that remains on the orbital surface and a more dorsal component that extends onto the ventrolateral surface. Both the dorsal and ventral *fo* can exist as a single branch or can bifurcate. The *op* extends from the lateral fissure and its position varies considerably along the anterior-posterior axis. In the majority of cases, a gyral bridge separates the *fo* from the *op*, although this bridge can, occasionally, be submerged, resulting in the superficial joining of these two sulci. These results contribute to a better understanding of the structural organization of a region that, in the human brain, evolved to play a critical role in language

functions.

INTERACTIONS BETWEEN THE EDINGER-WESTPHAL AND DORSAL RAPHE NUCLEI PROMOTE PARENTAL NESTING

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Ana Marta Capaz
Paris Brain Institute, Laboratory Of Structural Plasticity, Paris, France

Preparatory nesting is an essential parental care behavioral adaption, as it anticipates the need to provide protection for the upcoming litter. Nevertheless, the neural mechanisms regulating it are largely unknown. We showed previously that the CART-expressing neurons in the Edinger-Westphal Nucleus (EWcp) are necessary for the expression of preparatory nest building behavior in pregnant female mice. However, the downstream regions that these neurons contact, as well as their inputs promoting such behavior are yet unknown. The Dorsal Raphe Nucleus (DR) is also known to be needed for the expression of nest building and maternal care behaviors. Therefore, we hypothesized that the 2 nuclei might interact to promote parental nesting. Here, we aimed to elucidate how the two nuclei interact, and whether the EWcp-DRN system might play a role in the plasticity of nesting behavior, its variability among individuals and its gender-specific expression.

REGULATION OF SOCIAL BEHAVIORS BY THE LATERAL SEPTUM

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Francisco Javier De Los Santos Bernal[1,2], Robson Scheffer Teixeira[3], Letizia Moscato[1], Hanna Van Den Munkhof[1,2], Haena Choi[2], Tatiana Korotkova[1,2]
[1]Max Planck Institute, Metabolism Research, Köln, Germany, [2]University of Cologne, Institute Of Vegetative Physiology, Cologne, Germany, [3]University of Cologne, Institut For Vegetative Physiology, Faculty Of Medicine, Cologne, Germany

Social behaviors, conflictive or cooperative, are crucial for the survival and reproduction. Neural circuit mechanisms underlying the regulation of various social behaviors remain largely elusive. Further, little is known about how the brain computes choices when competing stimuli for mutually exclusive behaviors occur simultaneously. Aggression and feeding-related behaviors are regulated by the lateral septum (LS), which is connected with hypothalamic areas, the prefrontal cortex and hippocampus. We previously showed that somatostatin-expressing (Sst) neurons in the LS promote food-seeking (Carus-Cadavieco et al., Nature 2017). Here we investigated functions of two cell populations in the LS, Sst-, and neurotensin-expressing (NT) cells, in social interactions, from stressful to rewarding, as well as feeding-related behaviors. Combining opto-, chemogenetics and calcium imaging in behaving mice, we found differential neuronal activity in the LS selectively changing during different stages of social behaviors. Optogenetic activation of NT cells resulted in increased social interaction, accompanied by decreased dominant behavior to conspecifics. Simultaneously, activation of NT cells in the LS decreased food intake in the absence of conspecifics. Subsecond analysis of behavior using MoSeq, an unsupervised machine learning algorithm, upon chemogenetic activation of NT cells, revealed changes of multiple behavioral modules on a subsecond scale. Conversely, optogenetic activation of Sst cells in LS promoted food approach and decreased social interactions. Taken together, our results suggest that Sst- and NT-expressing populations in LS complementary regulate multiple aspects of innate behaviors. We gratefully acknowledge support by the ERC Consolidator Grant (772994, FeedHypNet, to T.K.) and DFG (SFB1089 and EXC2030-CECAD, 233886668-GRK1960).

CHEMOGENETIC MANIPULATIONS OF PARVALBUMIN INTERNEURONS AS AN ANIMAL MODEL OF SCHIZOPHRENIA: IMPLICATIONS ON BEHAVIOR AND ELECTROPHYSIOLOGY

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Kristyna Maleninska, Dominika Radostová, Martina Janíková, David Levcik, Jan Svoboda, Hana Brožka, Ales Stuchlik
Institute of Physiology CAS, Laboratory Of Neurophysiology Of Memory, Prague, Czech Republic

In schizophrenia, the power of gamma oscillation is abnormally increased during resting states and fails to upregulate during cognitively demanding tasks. As parvalbumin interneruons (PVIs) participates in generation of gamma oscillations, their altered function could therefore participate in development of schizophrenia. Also, changes in PVIs were confirmed in post mortem studies in schizophrenia patients. In our study we aimed to explore the effect of brain-wide chemogenetic inhibition of PVIs on brain wave oscillations and on behavioral in PV-cre mice. The animals were transduced by AAV PHP.eB capsids with double floxed hM4D(Gi) DREADD receptors coupled with mCherry via the left jugular vein. In two different mice cohorts we either studied changes of gamma and other band oscillations in prefrontal cortex and hippocampus or observed changes in schizophrenia-like behavior. The electrophysiological measurements revealed higher network excitability in the dorsal hippocampus in the alpha band in contrast with activity in the prefrontal cortex where the alpha activity was reduced. In preliminary behavior data, we found group and sex differences in elevated plus maze test, open-field and prepulse inhibition task. In conclusion, the animal model of schizophhrenia based on chemogenetic inhibition of PVIs seems to be promising for further studies of various schizophrenia-like symptoms and disruptions in behavior and electrophysiology. This work was supported by Czech Science Foundation (GACR) grants 20-00939S and 21-16667K.

Selective deficits in attentional set-shifting in mice induced by maternal immune activation with poly(I:C).
Maternal immune activation has been identified as a significant risk factor for schizophrenia. Using rodent models, past work has demonstrated various behavioral and brain impairments in offspring after immune-activating events. We applied 5 mg/kg of poly(I:C) on gestation day 9 to pregnant mouse dams, whose offspring were then stressed during puberty. We show impairments in attentional set-shifting in a T-maze, and a decreased number of parvalbumin-positive interneurons in the hippocampus as a result of peripubertal stress specifically in females.

Is short-term memory capacity (7±2) really predicted by theta to gamma cycle length ratio?
Several studies suggest that EEG parameters, reflecting top-down processes in the brain, may predict cognitive performance, e.g. short-term memory (STM) capacity. According to Lisman and Idiart's model, STM capacity is predicted by theta and gamma EEG waves and their ratio. This model suggests that the more periods of gamma band waves fit into one period of theta band waves, the more information can be stored. We replicated the study by Kaminski et al. (2011), which recorded spontaneous EEG activity and measured verbal STM capacity with a modified digit span task from the Wechsler battery. Our study included more subjects and two EEG recording sessions. We discuss the possible limits of EEG correlates of STM capacity as EEG parameters were not stable across the two measurements and no correlation was found between the theta/gamma ratio and performance in the digit span task.

Selective impairment of timing in a NMDA hypofunction animal model of psychosis.
Schizophrenia is severe neuropsychiatric disease, which is commonly accompanied not only by positive or negative symptoms, but also by cognitive impairment. To study neuronal mechanisms underlying cognitive distortions and mechanisms underlying schizophrenia, animal pharmacological models of cognitive symptoms are commonly used. Between various cognitive impairments in schizophrenia patients, disturbed time perception has often been reported. Here, we examined temporal and spatial cognition in a modified Carousel maze task in the animal model of schizophrenia induced by

non-competitive NMDA-receptor antagonists MK-801. Male Long-Evans rats (n = 18) first learned to avoid the aversive sector on a rotating arena in both dark and light intervals. We verified that during dark, rats used temporal cues, while during light they relied predominantly on spatial cues. We demonstrated that the timing strategy depends on the stable rotation speed of the arena and on the repositioning clues such as aversive stimuli. During testing (both in light and dark intervals), half of the rats received MK-801 and the control half received saline solution. We observed dose-dependent disruptions of both temporal and spatial cognition. Namely, both doses of MK-801 (0.1 and 0.12 mg/kg) significantly impaired timing strategy in the dark and increased locomotor activity. MK-801 dose 0.1 mg/kg, but not 0.12, also impaired spatial avoidance strategy in light. We found that the timing strategy is more sensitive to NMDA antagonist MK-801 than the spatial strategy. To conclude, a modified version of the Carousel maze is a useful and sensitive tool for detecting timing impairments in the MK-801 induced rodent model of schizophrenia.

Behavioral Alterations and Decreased Number of Parvalbumin-Positive Interneurons in Wistar Rats after Maternal Immune Activation by Lipopolysaccharide: Sex Matters.
Maternal immune activation (MIA) during pregnancy represents an important environmental factor in the etiology of schizophrenia and autism spectrum disorders (ASD). Our goal was to investigate the impacts of MIA on the brain and behavior of adolescent and adult offspring, as a rat model of these neurodevelopmental disorders. We injected bacterial lipopolysaccharide (LPS, 1 mg/kg) to pregnant Wistar dams from gestational day 7, every other day, up to delivery. Behavior of the offspring was examined in a comprehensive battery of tasks at postnatal days P45 and P90. Several brain parameters were analyzed at P28. The results showed that prenatal immune activation caused social and communication impairments in the adult offspring of both sexes; males were affected already in adolescence. MIA also caused prepulse inhibition deficit in females and increased the startle reaction in males. Anxiety and hypolocomotion were apparent in LPS-affected males and females. In the 28-day-old LPS offspring, we found enlargement of the brain and decreased numbers of parvalbumin-positive interneurons in the frontal cortex in both sexes. To conclude, our data indicate that sex of the offspring plays a crucial role in the development of the MIA-induced behavioral alterations, whereas changes in the brain apparent in young animals are sex-independent.

A Rat Model of Alzheimer's Disease Based on Abeta42 and Pro-oxidative Substances Exhibits Cognitive Deficit and Alterations in Glutamatergic and Cholinergic Neurotransmitter Systems.
Alzheimer's disease (AD) is one of the most serious human, medical, and socioeconomic burdens. Here we tested the hypothesis that a rat model of AD (Samaritan; Taconic Pharmaceuticals, USA) based on the application of amyloid beta42 (Abeta42) and the pro-oxidative substances ferrous sulfate heptahydrate and L-buthionine-(S, R)-sulfoximine, will exhibit cognitive deficits and disruption of the glutamatergic and cholinergic systems in the brain. Behavioral methods included the Morris water maze (MWM; long-term memory version) and the active allothetic place avoidance (AAPA) task (acquisition and reversal), testing spatial memory and different aspects of hippocampal function. Neurochemical methods included testing of the NR1/NR2A/NR2B subunits of NMDA receptors in the frontal cortex and CHT1 transporters in the hippocampus, in both cases in the right and left hemisphere separately. Our results show that Samaritan rats(™) exhibit marked impairment in both the MWM and active place avoidance tasks, suggesting a deficit of spatial learning and memory. Moreover, Samaritan rats exhibited significant changes in NR2A expression and CHT1 activity compared to controls rats, mimicking the situation in patients with early stage AD. Taken together, our results corroborate the hypothesis that Samaritan rats are a promising model of AD in its early stages.

Neonatal immune activation by lipopolysaccharide causes inadequate emotional responses to novel situations but no changes in anxiety or cognitive behavior in Wistar rats.
Infection during the prenatal or neonatal stages of life is considered one of the major risk factors for the development of mental diseases such as schizophrenia or autism. However, the impacts of such an immune challenge on adult behavior are still not clear. In our study, we used a model of early postnatal immune activation by the application of bacterial endotoxin lipopolysaccharide (LPS) to rat pups at a dose of 2 mg/kg from postnatal day (PD) 5 to PD 9. In adulthood, the rats were tested in a battery of tasks probing various aspects of behavior: spontaneous activity (open field test), social behavior (social interactions and female bedding exploration), anxiety (elevated plus maze), cognition (active place avoidance in Carousel) and emotional response (ultrasonic vocalization recording). Moreover, we tested sensitivity to acute challenge with MK-801, a psychotomimetic drug. Our results show that the application of LPS led to increased self-grooming in the female bedding

exploration test and inadequate emotional reactions in Carousel maze displayed by ultrasonic vocalizations. However, it did not have serious consequences on exploration, locomotion, social behavior or cognition. Furthermore, exposition to MK-801 did not trigger social or cognitive deficits in the LPS-treated rats. We conclude that the emotional domain is the most sensitive to the changes induced by neonatal immune activation in rats, including a disrupted response to novel and stressful situations in early adulthood (similar to that observed in human patients suffering from schizophrenia or autism), while other aspects of tested behavior remain unaffected.

OPTICAL INFERENCE OF FUNCTIONAL CONNECTIVITY IN THE AWAKE MOUSE CORTEX

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

He Zheng[1], Karim Oweiss[2]
[1]University of Florida, Ece, Gainesville, United States of America, [2]University of Florida, Electrical Engineering, Gainesville, United States of America

Mapping functional connectivity among many simultaneously observed neurons is critical to understanding the neural basis of behavior. Ideally, each putative pre-synaptic cell is stimulated and the evoked membrane voltage in post-synaptic cells is measured using whole-cell patch clamp recording. While this approach is standard in vitro, its invasiveness and low-yield make it extremely challenging in vivo, particularly in awake behaving animals. We aim to develop an all-optical approach to infer connectivity between many simultaneously observed neurons in awake, behaving mice. We have previously developed an algorithm that utilizes parallel, multi neuron photostimulation, subthreshold voltage recording and compressive sensing to fully reconstruct synaptic connectivity with drastically fewer measurements. This approach, however, requires imaging/recording voltage which remains limited to few neurons. Here, we rely on measuring suprathreshold voltage dynamics (Ca^{2+} fluorescence) during optical stimulation of each presynaptic cell while stabilizing its suprathreshold output via an 'optical clamp'. Mice are injected with viral-encoded calcium indicator GCamp8 and opsins (soma-targeted Chrome or ChRMine) in the primary visual cortex and installed a cranial window and headplate. Awake mice are head-fixed and a cell expressing opsins is photo-stimulated, while the calcium signal in individual cells imaged with a two-photon system. The clamped cell is stimulated when its output falls below a threshold. We show that different clamp levels produce different spatiotemporal activation patterns in the neuronal ensemble within the field of view. Our method allows timely mapping of connectivity in a behaving animal, which would be a critical tool in decoding the neural basis of behavior.

Environmental Enrichment Sharpens Sensory Acuity by Enhancing Information Coding in Barrel Cortex and Premotor Cortex.
Environmental enrichment (EE) is beneficial to sensory functions. Thus, elucidating the neural mechanism underlying improvement of sensory stimulus discrimination is important for developing therapeutic strategies. We aim to advance the understanding of such neural mechanism. We found that tactile enrichment improved tactile stimulus feature discrimination. The neural correlate of such improvement was revealed by analyzing single-cell information coding in both the primary somatosensory cortex and the premotor cortex of awake behaving animals. Our results show that EE enhances the decision-information coding capacity of cells that are tuned to adjacent whiskers, and of premotor cortical cells.

State-aware detection of sensory stimuli in the cortex of the awake mouse.
Cortical responses to sensory inputs vary across repeated presentations of identical stimuli, but how this trial-to-trial variability impacts detection of sensory inputs is not fully understood. Using multi-channel local field potential (LFP) recordings in primary somatosensory cortex (S1) of the awake mouse, we optimized a data-driven cortical state classifier to predict single-trial sensory-evoked responses, based on features of the spontaneous, ongoing LFP recorded across cortical layers. Our findings show that, by utilizing an ongoing prediction of the sensory response generated by this state classifier, an ideal observer improves overall detection accuracy and generates robust detection of sensory inputs across various states of ongoing cortical activity in the awake brain, which could have implications for variability in the performance of detection tasks across brain states.

Adaptive shaping of cortical response selectivity in the vibrissa pathway.
One embodiment of context-dependent sensory processing is bottom-up adaptation, where persistent stimuli decrease neuronal firing rate over hundreds of milliseconds. Adaptation is not, however, simply the fatigue of the sensory pathway, but shapes the information flow and selectivity to stimulus features. Adaptation enhances spatial discriminability (distinguishing stimulus location) while degrading detectability (reporting presence of the stimulus), for both the ideal observer of the cortex and awake, behaving animals. However, how the dynamics of the adaptation shape the cortical response and this detection and discrimination tradeoff is unknown, as is to what degree this phenomenon occurs on a continuum as opposed to a switching of processing modes. Using voltage-sensitive dye imaging in anesthetized rats to capture the temporal and spatial characteristics of the cortical response to tactile inputs, we showed that the suppression of the cortical response, in both magnitude and spatial spread, is continuously modulated by the increasing amount of energy in the adapting stimulus, which is nonuniquely determined by its frequency and velocity. Single-trial ideal observer analysis demonstrated a tradeoff between

detectability and spatial discriminability up to a moderate amount of adaptation, which corresponds to the frequency range in natural whisking. This was accompanied by a decrease in both detectability and discriminability with high-energy adaptation, which indicates a more complex coupling between detection and discrimination than a simple switching of modes. Taken together, the results suggest that adaptation operates on a continuum and modulates the tradeoff between detectability and discriminability that has implications for information processing in ethological contexts.

24607233: Ollerenshaw DR, Zheng HJV, Millard DC, Wang Q, Stanley GB
The adaptive trade-off between detection and discrimination in cortical representations and behavior.
It has long been posited that detectability of sensory inputs can be sacrificed in favor of improved discriminability and that sensory adaptation may mediate this trade-off. The extent to which this trade-off exists behaviorally and the complete picture of the underlying neural representations that likely subserve the phenomenon remain unclear. In the rodent vibrissa system, an ideal observer analysis of cortical activity measured using voltage-sensitive dye imaging in anesthetized animals was combined with behavioral detection and discrimination tasks, thalamic recordings from awake animals, and computational modeling to show that spatial discrimination performance was improved following adaptation, but at the expense of the ability to detect weak stimuli. Together, these results provide direct behavioral evidence for the trade-off between detectability and discriminability, that this trade-off can be modulated through bottom-up sensory adaptation, and that these effects correspond to important changes in thalamocortical coding properties.
Neuron, 2014; 81

22327024: Wang Q, Millard DC, Zheng HJ, Stanley GB
Voltage-sensitive dye imaging reveals improved topographic activation of cortex in response to manipulation of thalamic microstimulation parameters.
Voltage-sensitive dye imaging was used to quantify in vivo, network level spatiotemporal cortical activation in response to electrical microstimulation of the thalamus in the rat vibrissa pathway. Thalamic microstimulation evoked a distinctly different cortical response than natural sensory stimulation, with response to microstimulation spreading over a larger area of cortex and being topographically misaligned with the cortical column to which the stimulated thalamic region projects. Electrical stimulation with cathode-leading asymmetric waveforms reduced this topographic misalignment while simultaneously increasing the spatial specificity of the cortical activation. Systematically increasing the asymmetry of the microstimulation pulses revealed a continuum between symmetric and asymmetric stimulation that gradually reduced the topographic bias. These data strongly support the hypothesis that manipulation of the electrical stimulation waveform can be used to selectively activate specific neural elements. Specifically, our results are consistent with the prediction that cathode-leading asymmetric waveforms preferentially stimulate cell bodies over axons, while symmetric waveforms preferentially activate axons over cell bodies. The findings here provide some initial steps toward the design and optimization of microstimulation of neural circuitry, and open the door to more sophisticated engineering tools, such as nonlinear system identification techniques, to develop technologies for more effective control of activity in the nervous system.

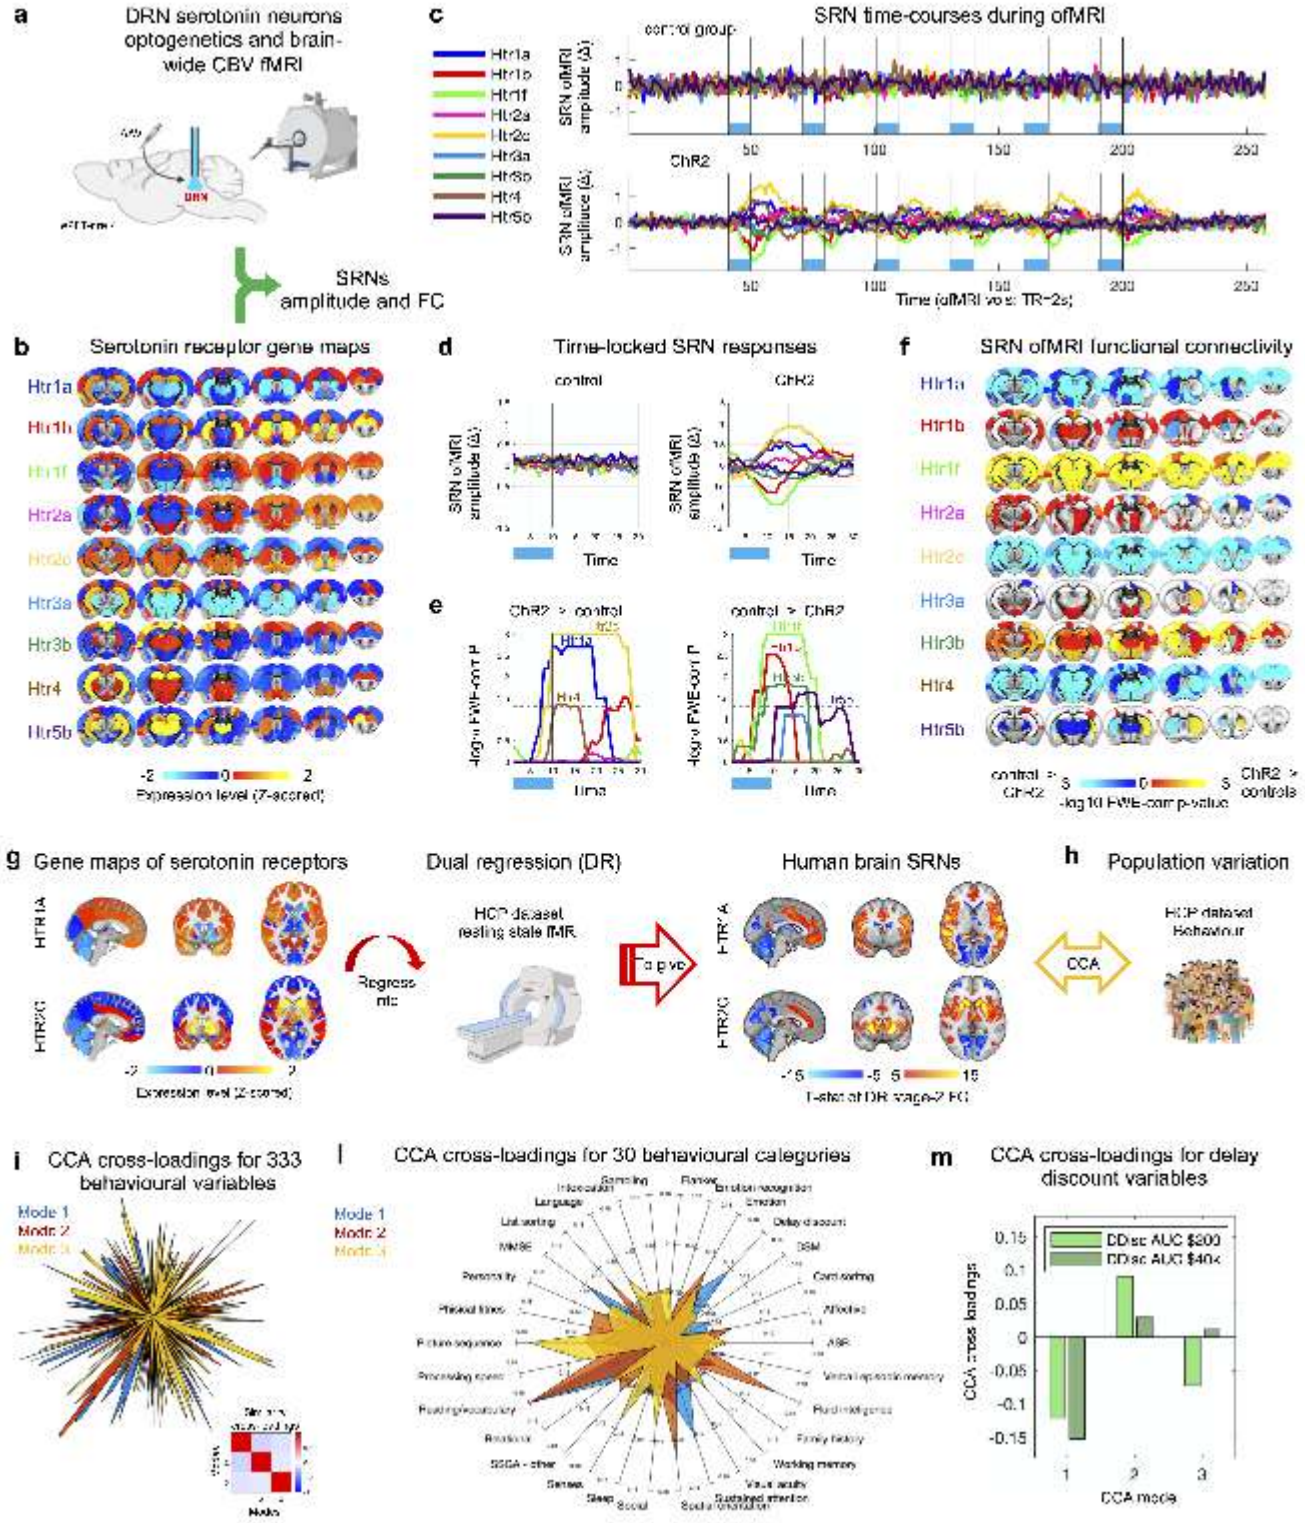
SEROTONIN REGULATION OF BEHAVIOUR VIA LARGE-SCALE NEUROMODULATION OF SEROTONIN RECEPTOR NETWORKS

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Piergiorgio Salvan[1], Madalena Fonseca[1], Anderson Winkler[2], Antoine Beauchamp[3], Jason Lerch[1], Heidi Johansen-Berg[1]
[1]University of Oxford, Clinical Neurosciences, Oxford, United Kingdom, [2]National Institute of Mental Health, National Institutes Of Health, Bethesda, United States of America, [3]Hospital for Sick Children, Mouse Imaging Centre, Toronto, Canada

Although we understand how serotonin receptors function at the single-cell level, what role different serotonin receptors play in regulating brain-wide activity and, in turn, human behaviour, remains unknown. Here, we developed transcriptomic-neuroimaging mapping to characterise brain-wide functional signatures associated with specific serotonin receptors: serotonin receptor networks (SRNs). Probing SRNs with optogenetics-fMRI and pharmacology in mice, we show that activation of dorsal raphe serotonin neurons differentially modulates the amplitude and functional connectivity of different SRNs, showing that receptors' spatial distributions can confer specificity not only at the local, but also at the brain-wide, network-level (fig.a-f). In humans, using resting state fMRI, different sets of SRNs are linked to different behavioural phenotypes (fig.g-m). These results provide compelling evidence that heterogeneous brain-wide distributions of different serotonin receptor types may underpin behaviourally-distinct modes of serotonin regulation. This suggests that dorsal raphe

serotonin neurons may regulate multiple aspects of human behaviour via modulation of large-scale receptor



networks.

Reassessing associations between white matter and behaviour with multimodal microstructural imaging.
Several studies have established specific relationships between White Matter (WM) and behaviour. However, these studies have typically focussed on fractional anisotropy (FA), a neuroimaging metric that is sensitive to multiple tissue properties, making it difficult to identify what biological aspects of WM may drive such relationships. Here, we carry out a pre-registered assessment of WM-behaviour relationships in 50 healthy individuals across multiple behavioural and anatomical domains, and complementing FA with myelin-sensitive quantitative MR modalities (MT, R1, R2∗). Surprisingly, we only find support for predicted relationships between FA and behaviour in one of three pre-registered tests. For one behavioural domain, where we failed to detect an FA-behaviour correlation, we instead find evidence for a correlation between behaviour and R1. This hints that multimodal approaches are able to identify a wider range of WM-behaviour relationships than focusing on FA alone. To test whether a common biological substrate such as myelin underlies WM-behaviour relationships, we then ran joint multimodal analyses, combining across all MRI parameters considered. No significant multimodal signatures were found and power analyses suggested that sample sizes of 40-200 may be required to detect such joint multimodal effects, depending on the task being considered. These results demonstrate that FA-behaviour relationships from the literature can be replicated, but may not be easily generalisable across domains. Instead, multimodal microstructural imaging may be best placed to detect a wider range of WM-behaviour relationships, as different MRI modalities provide distinct biological sensitivities. Our findings highlight a broad heterogeneity in WM's relationship with behaviour, suggesting that variable biological effects may be shaping their interaction.

Frequency modulation of entorhinal cortex neuronal activity drives distinct frequency-dependent states of brain-wide dynamics.
Human neuroimaging studies have shown that, during cognitive processing, the brain undergoes dynamic transitions between multiple, frequency-tuned states of activity. Although different states may emerge from distinct sources of neural activity, it remains unclear whether single-area neuronal spiking can also drive multiple dynamic states. In mice, we ask whether frequency modulation of the entorhinal cortex activity causes dynamic states to emerge and whether these states respond to distinct stimulation frequencies. Using hidden Markov modeling, we perform unsupervised detection of transient states in mouse brain-wide fMRI fluctuations induced via optogenetic frequency modulation of excitatory neurons. We unveil the existence of multiple, frequency-dependent dynamic states, invisible through standard static fMRI analyses. These states are linked to different anatomical circuits and disrupted in a frequency-dependent fashion in a transgenic model of cognitive disease directly related to entorhinal cortex dysfunction. These findings provide cross-scale insight into basic neuronal mechanisms that may underpin flexibility in brain-wide dynamics.

A triple-network organization for the mouse brain.
The triple-network model of psychopathology is a framework to explain the functional and structural neuroimaging phenotypes of psychiatric and neurological disorders. It describes the interactions within and between three distributed networks: the salience, default-mode, and central executive networks. These have been associated with brain disorder traits in patients. Homologous networks have been proposed in animal models, but their integration into a triple-network organization has not yet been determined. Using resting-state datasets, we demonstrate conserved spatio-temporal properties between triple-network elements in human, macaque, and mouse. The model predictions were also shown to apply in a mouse model for depression. To validate spatial homologies, we developed a data-driven approach to convert mouse brain maps into human standard coordinates. Finally, using high-resolution viral tracers in the mouse, we refined an anatomical model for these networks and validated this using optogenetics in mice and tractography in humans. Unexpectedly, we find serotonin involvement within the salience rather than the default-mode network. Our results support the existence of a triple-network system in the mouse that shares properties with that of humans along several dimensions, including a disease condition. Finally, we demonstrate a method to humanize mouse brain networks that opens doors to fully

data-driven trans-species comparisons.

Multimodal Imaging Brain Markers in Early Adolescence Are Linked with a Physically Active Lifestyle.
The World Health Organization promotes physical exercise and a healthy lifestyle as means to improve youth development. However, relationships between physical lifestyle and human brain development are not fully understood. Here, we asked whether a human brain-physical latent mode of covariation underpins the relationship between physical activity, fitness, and physical health measures with multimodal neuroimaging markers. In 50 12-year old school pupils (26 females), we acquired multimodal whole-brain MRI, characterizing brain structure, microstructure, function, myelin content, and blood perfusion. We also acquired physical variables measuring objective fitness levels, 7 d physical activity, body mass index, heart rate, and blood pressure. Using canonical correlation analysis, we unravel a latent mode of brain-physical covariation, independent of demographics, school, or socioeconomic status. We show that MRI metrics with greater involvement in this mode also showed spatially extended patterns across the brain. Specifically, global patterns of greater gray matter perfusion, volume, cortical surface area, greater white matter extra-neurite density, and resting state networks activity covaried positively with measures reflecting a physically active phenotype (high fit, low sedentary individuals). Showing that a physically active lifestyle is linked with systems-level brain MRI metrics, these results suggest widespread associations relating to several biological processes. These results support the notion of close brain-body relationships and underline the importance of investigating modifiable lifestyle factors not only for physical health but also for brain health early in adolescence. An active lifestyle is key for healthy development. In this work, we answer the following question: How do brain neuroimaging markers relate with young adolescents' level of physical activity, fitness, and physical health? Combining advanced whole-brain multimodal MRI metrics with computational approaches, we show a robust relationship between physically active lifestyles and spatially extended, multimodal brain imaging-derived phenotypes. Suggesting a wider effect on brain neuroimaging metrics than previously thought, this work underlies the importance of studying physical lifestyle, as well as other brain-body relationships in an effort to foster brain health at this crucial stage in development.

Language ability in preterm children is associated with arcuate fasciculi microstructure at term.
In the mature human brain, the arcuate fasciculus mediates verbal working memory, word learning, and sublexical speech repetition. However, its contribution to early language acquisition remains unclear. In this work, we aimed to evaluate the role of the direct segments of the arcuate fasciculi in the early acquisition of linguistic function. We imaged a cohort of 43 preterm born infants (median age at birth of 30 gestational weeks; median age at scan of 42 postmenstrual weeks) using high b value high-angular resolution diffusion-weighted neuroimaging and assessed their linguistic performance at 2 years of age. Using constrained spherical deconvolution tractography, we virtually dissected the arcuate fasciculi and measured fractional anisotropy (FA) as a metric of white matter development. We found that term equivalent FA of the left and right arcuate fasciculi was significantly associated with individual differences in linguistic and cognitive abilities in early childhood, independent of the degree of prematurity. These findings suggest that differences in arcuate fasciculi microstructure at the time of normal birth have a significant impact on language development and modulate the first stages of language learning. Road work on memory lane--functional and structural alterations to the learning and memory circuit in adults born very preterm.

Very preterm (VPT) birth is considered a risk factor not only for neurological impairment, but also for reduced function in several cognitive domains in childhood and later in life. Individuals who were born VPT are more likely to demonstrate learning and memory difficulties compared to term-born controls. These problems contribute to more VPT-born children repeating grades and underachieving in school. This, in turn, affects their prospects in adult life. Here we aimed to 1) study how the VPT-born adult brain functionally recruited specific areas during learning, i.e. encoding and recall across four repeated blocks of verbal stimuli, and to investigate how these patterns of activation differed from term-born subjects; and 2) probe the microstructural differences of white-matter tracts connecting these areas to other parts of the learning and memory network. To investigate these functional-structural relationships we analyzed functional and diffusion-weighted MRI. Functional-MRI and a verbal paired associate learning (VPAL) task were used to extract Blood Oxygenation Level Dependent (BOLD) activity in 21 VPT-born adults (<33 weeks of gestation) (mean age: 19.68 years ± 0.85; IQ: 99.86 ± 11.20) and 10 term-born controls (mean age: 19.87 years ± 2.04; IQ: 108.9 ± 13.18). Areas in which differences in functional activation were observed between groups were used as seed regions for tractography. Fractional anisotropy (FA) of the tract-skeleton was then compared between groups on a voxel-wise basis. Results of functional MRI analysis showed a significantly different pattern of activation between groups during encoding in right anterior cingulate-caudate body, and during retrieval in left thalamus, hippocampus and parts of left posterior parahippocampal gyrus. The number of correctly recalled word pairs did not statistically differ between individuals who were born VPT and controls. The VPT-born group was found to have reduced FA in tracts passing through the thalamic/hippocampal region that was differently activated during the recall condition, with the hippocampal fornix, inferior longitudinal fasciculus and inferior fronto-occipital fasciculus particularly affected. Young adults who were born very preterm display a strikingly different pattern of activation during the process of learning in key structures of the learning and memory network, including anterior cingulate and caudate body during encoding and thalamus/parahippocampal gyrus during cued recall. Altered activation in thalamus/parahippocampal gyrus may be explained by reduced connections between these areas and the hippocampus, which may be a direct consequence of neonatal hypoxic/ischemic injury. These results could reflect the effect of adaptive plastic processes associated with high-order cognitive functions, at least when the cognitive load remains relatively low, as ex-preterm young adults displayed unimpaired performance in completing the verbal paired associate learning task.

HOW SPATIAL EMBEDDING SHAPES FEEDBACK CORTICAL PROJECTIONS TO VISUAL CORTEX IN MACAQUE

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Henry Kennedy[1,2], Yujie Hou[1], Mingli Wang[2], Loïc Magrou[1], Kenneth Knoblauch[1], David Van Essen[3], Takuya Hayashi[4], Zhiming Shen[2]
[1]Inserm U1208, Stem Cell And Brain Research Institute, Bron, France, [2]Institute of Neuroscience, Chinese Academy of Sciences, Key Laboratory Of Primate Neurobiology, Shanghai, China, [3]Washington University Medical School, Department Of Neuroscience, St. Louis, MO, United States of America, [4]RIKEN Center for Biosystems Dynamics Research, Laboratory For Brain Connectomics Imaging, Kobe, Japan

Projections from area V1 target higher-order cortical areas, and these ascending, feedforward pathways are reciprocated by feedback projections. Within the cortical connectome there are two functional streams: an occipital-parietal dorsal stream ensuring visuo-spatial motor information processing and an occipital-temporal stream ensuring visual object recognition. Elsewhere we have proposed that the exponential decline of connection weight with distance constitutes an important rule-based principle (EDR **E**xponential **D**istance **R**ule) of brain connectivity explaining numerous observed features of the cortex (Ercsey-Ravasz et al., Neuron 2013). Representation of the retina in V1 ensures that the far periphery lower field is located in dorsal cortex and the far periphery upper field in ventral cortex. To test the role of the EDR in shaping the functional streams we made tracer injections at different retinotopic locations and quantified the weight distribution in extrastriate cortical areas. The results show: (i) 5-8 areas project uniquely to peripheral retinotopic locations and could subserve specific functions ranging from multimodal integration to regulation of body posture; (ii) Injections in the far periphery lower-field label preferentially areas in the dorsal stream while injections in the fovea and upper-field representation label neurons preferentially in the ventral stream. Analysis of the distances between injected regions and preferentially labeling confirmed that the results obeyed the EDR. They suggest that the cortical connectome of the macaque is anchored in the visual cortex and propose that future large-scale models of the cortex embrace the ecological theory of vision (Previc, Behav Brain Sci 1990).

IN-VIVO INVESTIGATION OF CEREBELLO-PREFRONTAL CORTEX CONNECTIONS IN ANESTHETIZED MICE

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Danila Di Domenico[1], Ileana Montagna[1], Letizia Moscato[1], Simona Tritto[1], Lisa Mapelli[1], Egidio D'Angelo[1,2]
[1]University of Pavia, Dept. Of Brain And Behavioral Sciences, Pavia, Italy, [2]IRCCS Mondino Foundation, Brain Connectivity Center, Pavia, Italy

Alterations in cerebello-prefrontal cortex (mPFC) connections characterize several cognitive dysfunctions (such as schizophrenia), suggesting that the cerebellum has a crucial impact on mPFC functioning. Cerebellar activity might regulate mPFC neuronal activity through a dopaminergic pathway relayed by the ventral tegmental area (VTA), and a glutamatergic pathway relayed by the mediodorsal and ventrolateral nuclei of the thalamus. At present, the mechanisms of cerebellar regulation of mPFC are unknown. To get insight into the process of cerebellum-mPFC communication, we used single-unit recordings *in vivo* in the prelimbic area (PrL) of mPFC in anesthetized mice. Electrical stimulation of the contralateral cerebellar dentate nucleus elicited a pause in PrL neurons firing, sometimes followed by an excitation rebound. To investigate the nature of PrL responses, we co-applied D1-like and D2-like dopamine receptor antagonists (SCH23390 and sulpiride, respectively), a GABAA receptor antagonist (gabazine), and NMDA and AMPA glutamate receptors antagonists (NBQX, D-APV and 7Cl-kynurenate). The blockade of dopaminergic transmission modulated PrL neurons spontaneous firing rate without abolishing pause responses, which were suppressed by gabazine perfusion. Perfusion of glutamate receptor antagonists almost completely abolished the basal discharge of PrL neurons along with any response to dentate nucleus stimulation. Our data show that cerebellar activation transiently silences PrL activity engaging local inhibitory circuits (probably activated by thalamic projections), while dopaminergic receptors regulate PrL basal discharge. Thus, the combined effect of the two pathways tuned the PrL signal-to-noise ratio through pauses in neuronal discharge. Overall, these findings provide evidence for a complex cerebellar functional control over the PrL.

GENE-ENVIRONMENT CAUSAL PATHWAY TO IMPOVERISHED COGNITIVE DEVELOPMENT CONTRIBUTES TO PSYCHOTIC-LIKE EXPERIENCE IN CHILDREN

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Junghoon Park[1], Eunji Lee[2], Gyeongcheol Cho[3], Heungsun Hwang[3], Yoonie Joo[4], Jiook Cha[2]
[1]Seoul National University, Graduate School Of Artificial Intelligence, Seoul, Korea, Republic of, [2]Seoul National University, Department Of Psychology, Seoul, Korea, Republic of, [3]Mcgill University, Psychology, Montréal, Canada, [4]Korea University, Institute Of Data Science, Seoul, Korea, Republic of

Identifying the social and biological mechanisms of cognitive and psychological development of children is essential for optimizing preventive and educational efforts. However, the causal pathways by which genetic and environmental factors affect cognitive and psychiatric outcomes remain unknown, especially in early childhood. We examined the causal relationships among genes, the environment, intelligence, and psychotic-like experiences in 7,632 multiethnic (5,905 with European ancestry) children aged 9-10 years old from the Adolescent Brain Cognitive Development (ABCD) Study. Using up-to-date computational causal analysis and robust path modeling, we found a significant causal influence of residential, family, and school environments and genome-wide polygenic scores of cognitive capacities on preadolescents' psychotic-like experiences mediated by intelligence. Mitigation of good parenting behavior and positive school environments on psychotic-like experiences dominated the pernicious effects of genetic and residential adversities. Our findings support that intelligence may be a biological resilience factor for psychosis. To the best of our knowledge, this is the first study to identify casual trajectories of neurocognitive development in early childhood and the first to provide empirical evidence that positive parenting behavior and school environment can impose a considerable degree of causal impact on children's cognitive and psychiatric outcomes. We suggest the implementation of socioeconomic policies to improve family and school environments and promote local economic development to enhance children's cognitive ability and mental health.

MACHINE LEARNING TO PERSONALIZE COGNITIVE TRAINING

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Melina Vladisauskas[1], Laouen Belloli[2], Diego Fernández Slezak[2], Andrea Goldin[1]
[1]Universidad Torcuato di Tella, Laboratorio De Neurociencia, Buenos Aires, Argentina, [2]Laboratorio de Inteligencia Artificial Aplicada - Universidad de Buenos Aires, Departamento De Computación, CABA, Argentina

Introduction Executive functions are a class of processes critical for purposeful goal-directed behavior. Cognitive training is the adequate stimulation of executive functions and has been extensively studied and applied. However, there is still a lack of solid consensus about its potential to elicit consistent improvements in untrained domains. Individual differences are considered one of the most important factors of inconsistent reports on cognitive training benefits, as differences in cognitive functioning are both genetic and context-dependent, and might be affected by age and socioeconomic status. **Aims and Methods** We aimed to predict if a child would benefit or not from a certain training, based on some of his/her baseline individual qualities. We explored supervised machine learning techniques to predict improvements, using baseline performance in previous cognitive tasks as features to every model. We used a dataset from an investigation in which 73 6-year-olds tested and challenged their executive functions using an online software with a fixed protocol. **Results and conclusions** We trained multiple algorithms, and the best one in the task was a support vector classifier that successfully predicted (average accuracy = .67, AUC=.707) improvements after the cognitive stimulation, using baseline individual differences as features. We also performed permutation feature importance analysis that suggested that features contribute equally to the model's performance. Our study is meant as a proof of concept showing that Machine Learning tools can be implemented to personalize cognitive training interventions. In the long term, these algorithms might allow us to personalize training protocols to maximize the stimulation.

EVIDENCE FOR FUNCTIONAL CONNECTIVITY CHANGES IN THE AMYGDALA ACROSS THE MENSTRUAL CYCLE - A RESTING-STATE FMRI STUDY.

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Camila Servin-Barthet[1,2], Óscar Vilarroya[1,2], Susanna Carmona[3,4], Clara Pretus[1,2]
[1]Universitat Autònoma de Barcelona, Departament De Psiquiatria I Medicina Legal, Barcelona, Spain, [2]Institut Hospital del Mar d'Investigaciones Mèdiques, Departament De Recerca En Neurociències, Barcelona, Spain, [3]Instituto de Investigación Sanitario Gregorio Marañón, Unidad De Medicina Y Cirugía Experimental, Madrid, Spain, [4]Centro de Investigación Biomédica en Red de Salud Mental, Cb/07/09/0031, Madrid, Spain

Over the last decade, neuroimaging research has pointed out changes in brain structure and function over the menstrual cycle, particularly in emotion-processing centers such as the amygdala. However, results are sparse, and the amygdala modulation during the menstrual cycle is still poorly understood. In the present study, we used resting-state fMRI (rs-fMRI) to identify menstrual cycle-related connectivity changes in the amygdala-based network. We scanned 126 naturally cycling women either in their early follicular (N=42; days 1-7), late follicular (N=51; days 8-14), or mid-luteal phase (N=33; days 17-26) and performed a separate seed-based connectivity analysis for each amygdala. We found that functional connectivity between the right amygdala and the left lateral prefrontal cortex (LFPC) was more negative during the late follicular and mid-luteal phases compared to the early follicular phase. These results are aligned with research that points to a negative correlation between the amygdala and the LPFC during cognitive reappraisal tasks. Thus, our findings suggest that phase-dependent differences in functional connectivity between these two regions could be related to shifts in cognitive reappraisal mechanisms throughout the menstrual cycle. The present research contributes to understanding the impact of the menstrual cycle on affective and cognitive processes in menstruating people.

STRUCTURES IN SPACE AND TIME – HIERARCHICAL NETWORK DYNAMICS IN THE AMYGDALA

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Yael Bitterman, Julien Courtin, Alejandro Tsai, Andreas Lüthi
Friedrich Miescher Institute for Biomedical Research, Neuroscience, Basel, Switzerland

In addition to its role in the learning and expression of conditioned behavior, the amygdala has long been implicated in the regulation of persistent states, such as anxiety and drive. Yet, it is not evident what features of the neuronal activity capture the functional role of the network across such different timescales, specifically when behavior and neuronal spaces are complex and high-dimensional. We applied a dynamical approach for the analysis of calcium imaging data from the basolateral amygdala, collected while mice performed complex, self-paced behavior, including goal directed actions. The seemingly complex network dynamics could be effectively described by a hierarchical, modular structure, with robust correspondence to behavior on multiple timescales. We describe the remapping of the network dynamics in response to perturbations along different dimensions and the interplay between slow, state-like representation and the fast processing of specific events and actions. The emergent spatio-temporal symmetries between nested dynamics, provide specific hypotheses regarding the principles and mechanisms that support the updating and maintenance of abstract task representations. We suggest hierarchical dynamical models offer a unified framework to capture amygdala involvement in such different functions as associative learning, action selection and emotional processing.

DYNAMIC FUNCTIONAL CONNECTIVITY ASSOCIATED WITH PROSPECTIVE MEMORY SUCCESS IN CHILDREN

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Teruo Hashimoto, Ryuta Kawashima
Tohoku University, Developmental Cognitive Neuroscience, Sendai, Japan

Prospective memory (PM) requires multiple process including memory and higher cognitive function. To remember the intention successfully, back-and-forth between background task and intention or dynamics of process can be critical. Executive function is associated with PM success in children but neural mechanism of PM in children has not been investigated. The purpose of this study in revealing dynamic functional connectivity underlying PM success in children. Healthy 108 children aged 7 to 15 were participated. This study was approved by the local ethics committee, and written informed consent was obtained from the parents of each participant based on the Declaration of Helsinki. PM task was a single trial with 30 min delay that children were given a post-it, then they were asked to return it to the experimenter when they come back to the initial room. Background task was watching animation in the room next-door to answer questions. The resting-state fMRI scan was done before or after PM task. About 70% of children successfully remembered the intention. No significant success/failure group differences in age, male/female ratio, and background task performance. Dynamics in connectivity between the right dorsolateral prefrontal cortex (DLPFC) and intraparietal sulcus, and between the right DLPFC and insula showed significant differences between children with PM success and failure. Attention and monitoring for background task in right fronto-parietal network and internal-state monitoring for prospective intention in insula network and those dynamics might be associated with PM success in children.

PHOTOBIOMODULATION DOES NOT LEAD TO VISIBLE EFFECTS ON MALE NOR FEMALE RAT BRAIN DEVELOPMENT

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Alba Gutiérrez Menéndez[1,2,3], Marta Méndez[1,2,3], Jorge Arias[1,2,3]
[1]Instituto de Neurociencias del Principado de Asturias, Ineuropa, Oviedo, Asturias, Spain, [2]Instituto Biosanitario del Principado de Asturias, Ispa, Oviedo, Spain, [3]University of Oviedo, Psychology, Oviedo, Asturias, Spain

The role of light in our biological processes and systems is extensively known and the use of light devices has been introduced in the health field as an opportunity to administer light. Photobiomodulation (PBM) is a non-invasive technique that uses red to infrared light to stimulate, heal, regenerate and protect tissue. Numerous studies have documented several brain positive effects in adult subjects (improve metabolic function, anti-apoptotic proteins upregulation, stimulation of neurogenesis, synaptogenesis, migration, secretion of neurotrophins…), due to the light absorption by the cytochrome c-oxidase (CCO), terminal enzyme in the mitochondrial electron transport chain. This study aims to examine the effects of PBM in the developing brain (prefrontal cortex, striatum, thalamus, amygdala, hippocampus) of healthy 23 days-old male (n=31) and female (n=30) Wistar rats. Three groups of each sex were used: photobiomodulation group received five days of light therapy, a device group submitted to the same conditions but without light radiation and a control basal group. Brain metabolic activity and immediate early genes activation were analysed by CCO histochemistry and c-Fos immunostaining, respectively. Results displayed no metabolic differences between the three groups in both sexes. Same results were found in the analysis of c-Fos positive cells, reporting no differences between groups. This research, in contrast to the PBM consequences reported in adult healthy subjects, showed the lack of PBM effects in young healthy rat brain. Further studies should be necessary to deeply examine the effects of PBM in the developing brain. Funding: MINECO PID2020-117259RB-I00, FICYT AYUD/2021/51378 and MCIU-19-PRE2018-086220 to A.G.M

BRAIN-HEART INTERACTIONS DURING MOTOR RESPONSES IN REACTIVE AND PROACTIVE CONTEXTS

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Elena Mussini[1], Mauro Gianni Perrucci[2], Andrea Zaccaro[1], Marcello Costantini[3], Francesca Ferri[2]
[1]G. d'Annunzio" University of Chieti-Pescara, Chieti, Italy, Department Of Neuroscience, Imaging And Clinical Sciences, Chieti, Italy, [2]G. d'Annunzio" University of Chieti-Pescara, Chieti, Italy, Institute For Advanced Biomedical Technologies - Itab, Chieti, Italy, [3]G. d'Annunzio" University of Chieti-Pescara, Chieti, Italy, Department Of Psychological, Health And Territorial Sciences, Chieti, Italy

Aims The brain and the heart continuously interact to optimize adaptive responses to the environment, including motor preparation, stop/go signal processing and motor execution. However, such interactions have not been systematically studied so far. Here we investigated Heartbeat Evoked Potential (HEP) modulations during different phases of motor responses and their relationships with co-occurring motor event-related potentials: the Bereitschaftspotential (BP) occurring during motor preparation, and the prefrontal Positive1 (pP1) associated to sensorimotor processing of go signals. We hypothesized that brain-heart interactions might adapt to the context, that could be either reactive (inhibitory) or proactive. ***Methods*** We used electroencephalography to measure HEP, BP and pP1 components. Participants performed two Go/No-Go tasks in which the different percentages of go and no-go trials created either a proactive or a reactive context. ***Results*** Results showed that HEP increases the closer we get to the motor responses. Moreover, HEP differently modulates according to the context. Specifically, the modulation is stronger in the reactive (inhibitory) than in the proactive context. Lastly, only in the proactive context, HEPs falling during motor preparation and sensorimotor processing of go signals correlate with the co-occurring BP and pP1 components, respectively. ***Conclusion*** Our findings are the first to empirically demonstrate context-dependent modulations of HEPs directly linked to different phases of motor responses.

MIRROR INVARIANCE FOR OBJECTS AND BRAILLE LETTERS IN CONGENITALLY BLIND PEOPLE; A BEHAVIORAL AND FMRI STUDY.

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Maksymilian Korczyk[1], Katarzyna Rączy[2], Marcin Szwed[1]
[1]Jagiellonian University, Psychology, Kraków, Poland, [2]Hamburg University, Biological Psychology And Neuropsychology, Hamburg, Germany

Mirror images of objects are recognized as the same object, but letters are not (“d” is not “b”). Unlearning this mirror invariance for letters is achieved when learning to read. Its neuronal correlate can be observed in sighted individuals for objects, words, and letters (Pegado et al., 2011). Previous studies have shown that the fusiform cortex is important formirror discrimination. De Heering and colleagues (2018) showed that the congenitally blind humans can break mirror invariance for Braille letters like the sighted with the visual alphabet. Here, we investigated which neural mechanisms underlie this process. Nineteen congenitally blind adults participated in behavioural and fMRI experiments. First, they performed two behavioural same-different tactile comparisons tasks. Stimuli were pairs of Braille letters, geometric shapes, and everyday objects (e.g., toothbrush) wich were presented in same (“p” and “p”), mirror orientation (“p” and “q”) and different (“p” and “z”) pairs. In the fMRI part, Braille letters and everyday objects in the above-mentioned formats were presented in a priming paradigm. Participants had shorter response-times and higher accuracy for Braille letters and objects than for shapes. fMRI results showed mirror priming for objects in the fusiform cortex. Moreover, left lingual gyrus seems to distinguish between left-right orientation of Braille letters. Our results demonstrate that the fusiform cortex of blind individuals exhibits mirror invariance for tactile objects similar to the one observed for visual objects in the sighted. Moreover, language area (lingual) is involved in Braille letters’ mirror discrimination.

IMPLICIT READING IN TACTILE DOMAIN - A LONGITUDINAL FMRI STUDY OF SIGHTED PARTICIPANTS LEARNING BRAILLE ALPHABET

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Agnieszka Kulesza[1], Maciej Gaca[1], Alicja Olszewska[1], Dawid Droździel[1], Małgorzata Paplińska[2], Jacek Matuszewski[1], Katarzyna Jednoróg[3], Aleksandra Herman[1], Artur Marchewka[1]
[1]Nencki Institute of Experimental Biology of the Polish Academy of Sciences, Laboratory Of Brain Imaging, Warsaw, Poland, [2]Maria Grzegorzewska University, Institute Of Special Education, Warsaw, Poland, [3]Nencki Institute of Experimental Biology of the Polish Academy of Sciences, Laboratory Of Language Neurobiology, Warsaw, Poland

In skilled readers, reading occurs implicitly, even without explicit instruction to read. After intensive training, sighted participants can also read in the tactile domain, though it is not clear whether such reading could be implicit. In the current study, 18 Braille-naïve sighted participants took part in an extensive 7 month-long tactile Braille reading course. 19 age and gender-matched participants were recruited as a passive control group. We employed longitudinal functional magnetic resonance imaging with 5 time-points (TP) and a non-linguistic target detection task for both groups. We tested for a group-by-time interaction to answer the questions about if and when participants start to process Braille implicitly. After the course, participants in the experimental group could read by touch on average up to 17 letters and nearly 7 words per minute. At the neuronal level, we found significant interaction in the lingual gyrus, the superior parietal lobule and the lateral occipital cortex. Additional analyses showed that the neuronal responses to implicit reading were stronger in the experimental group at the last TP when participants were most proficient in Braille reading. Since the above-mentioned brain regions are crucial to letter recognition and spatial processing, our results suggest that learning to read the Braille alphabet in sighted participants could lead to implicit processing in the tactile domain. Nevertheless, this phenomenon is strongly modulated by reading proficiency.

INCREASING CORTICO-SUBCORTICAL CONNECTIVITY PREDICTS A BURSTING EVENT DURING SEVOFLURANE-INDUCED BURST SUPPRESSION STATE IN HUMANS

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Juliana Zimmermann[1], Fabian Hirsch[1], Rachel Nuttall[2], Daniel Golkowski[3], Gerhard Schneider[2], Andreas Ranft[2], Rüdiger Ilg[4], Christian Sorg[1], Afra Wohlschläger[1]
[1]Klinikum Rechts der Isar Technical University of Munich, Neuroradiology, Munich, Germany, [2]Klinikum rechts der Isar Technical University of Munich, Anesthesiology, Munich, Germany, [3]University of Heidelberg, Neurology, Heidelberg, Germany, [4]Asklepios Stadtklinik Bad Tölz, Neurology, Bad Tölz, Germany

Burst suppression is a global electroencephalogram (EEG) pattern characterized by an alternating high-voltage activity (bursts) and isoelectric quiescence (flat line or suppression). This pattern has been identified as a global state of profound brain inactivation, physiologically seen during comatose states but also artificially induced by deep anesthesia. Evidence from animal and human data suggest the participation of the cortex, thalamus, and the ascending arousal system (ARAS) in the dynamics of a burst, however the driving mechanism of this process is still unclear. Using simultaneous EEG-fMRI previously published data of 19 male subjects during anesthesia-induced burst suppression state, we have studied functional connectivity of fMRI BOLD fluctuations from cortical, thalamus and ARAS regions ~10seconds before a bursting event. Events where labelled using EEG. To analyze time-resolved inter-regional connectivity prior to burst, we have applied a jackknife correlation approach, consisting of a repetitive re-estimation of the pair-wise correlation value between two regions after the removal of a single observation. The characteristic strong signal amplitude variations were accounted for by using global signal regression. Finally, using a principal component analysis (PCA) of the correlation results averaged per parcel (cortex, thalamus, ARAS), we calculated the amount of variance explained per parcel per time-point before the burst, enabling a reconstruction of the connectivity trajectory before an event. Our results indicate that just before an event, the cortical-ARAS and cortical-thalamic connectivity increase while cortico-cortical connectivity decreases ($p=0.03$). This supports the idea that subcortical areas are causal in the generation of individual bursts in sevoflurane anesthesia.

CHALLENGING THE ROLE OF THE THALAMUS IN COGNITION: THE NEUROPSYCHOLOGICAL IMPACT OF CHRONIC THALAMIC STROKE

POSTER SESSION 03 - SECTION: FUNCTIONAL CONNECTIVITY AND COGNITION

Julie Vidal[1,2], Lola Danet[2,3], Germain Arribarat[2], Jérémie Pariente[2,3], Patrice Péran[2], Emmanuel J. Barbeau[1]
[1]CNRS, Cerco (brain And Cognition Research Center) - Université Paul Sabatier, Toulouse, France, [2]INSERM, Tonic (toulouse Neuroimaging Center) - Université Paul Sabatier, Toulouse, France, [3]Hôpital Purpan, Centre Hospitalier Universitaire de Toulouse, Département De Neurologie, Toulouse, France

Aims: The thalamus is a deep structure of the diencephalon. Until the 20th century, case studies revealed major cognitive deficits following thalamic lesions, ranging from visual blindness to amnesia. However, the recent literature, which relies on neuroimaging and group studies, seems to highlight the opposite pattern, with rather moderate cognitive deficits. This implies that we don't fully understand the neuropsychological consequences of thalamic lesions. Methods: We collected data from 40 patients with ischemic thalamic lesions (27 left, 6 right, 7 bilateral) and 45 matched healthy subjects. Patients underwent a detailed neuropsychological assessment and a high-resolution MRI scan at the chronic phase (>3 months after the stroke). Lesions were localized using Morel's atlas and were correlated to cognitive functions using AnaCOM2. Results: Group analyses revealed impaired verbal memory, and moderate deficits in executive functions, attention and naming. A cluster analysis revealed that the majority of patients (60%) did not show major impairment. However, a subgroup of patients (37%) showed more severe verbal memory impairment (median Z-score = -6), related to lesions of the left or bilateral thalamus. Lesion of the MTT was not a predictor of the subgroup of the patient. Only one young patient with large isolated left thalamic lesions showed a major impairment in several cognitive domains. The majority of lesions were located in the dorsomedian and ventrolateral regions. Conclusion: The majority of thalamic strokes only moderately alter the patients' cognitive status. It highlights a misunderstanding of the role of the thalamus in cognition that needs to be resolved.

QUANTIFYING SOCIAL BEHAVIORS IN JUVENILE SHANK3 MICE USING ANIMAL POSE ESTIMATION TOOLS

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Rosalba Proce, Hanna Hörnberg
Max Delbruck Center, Molecular And Cellular Basis Of Behavior, Berlin, Germany

Social interaction is a core aspect of mammalian behavior, and alterations in social behaviors are found across many neurodevelopmental and psychiatric conditions. Mice display a range of socioemotional behaviors and are commonly used as models to investigate the neuronal circuits and molecular mechanisms underlying differences in social behaviors. Analyzing social interactions in mice is often done by manual quantification of videos. Although multiple methods for automated tracking have been developed in recent years, reliable tracking and automated behavioral classification of multiple freely-moving unmarked animals have remained challenging. The use of an unbiased classification system in a more naturalistic environment could help obtain a translatable way to study social behaviors, in particular in mouse models for neuropsychiatric conditions. Here, we use open-source toolkits including DeepLabCut and SimBA to track and quantify reciprocal self-selected social interactions in freely-moving sex-and age-matched animals in a home cage. To study differences in social interaction we use juvenile female and male mice that lack the autism-associated gene Shank3. We show that DeepLabCut can track the movement of two size-matched juvenile mice freely interacting in a home-cage, and behavioral classification using supervised and unsupervised methods can detect differences in social interaction between Shank3 knockout and control mice. Quantifying behavior in an unbiased way remains a challenge in animal research. We confirm that freely-available open-source toolkits can be used to track and classify social interactions in freely-moving mice in a home cage, thereby providing a simple, low-cost solution to analyze social behaviors in age and sex-matched mice.

Social interactions and communication are key behaviors in the life of mice. Mice interact socially to regulate reproduction, inter-individual coordination and protection from predators. Despite their broad use as models for neuropsychiatric disorders, the knowledge on their social communication system is still fragmented. Our goal is to decipher the functions of ultrasonic vocalizations (USV) in mice during spontaneous social interactions. We automaticaly synchronize the behavioural annotation of live mouse tracker https://livemousetracker.org and automatic USV detections https://usv.pasteur.cloud over three days in freely behaving same-sex pairs of familiar C57BL/6J mice. We compute correlation between USVs and behaviors. We also provide specific software to explore and label USVs and behaviors that are not yet labeled automatically. We highlight significant variations between sexes in the spontaneous usage and structure of ultrasonic vocalizations, with females emitting more USVs in longer sequences and with longer duration and more frequency modulations compared to males. Also, females emit most of their calls in social contacts while males emit USVs when isolated. In females, the acoustic features of USVs vary according to the behavioral context. We also extend the study to manual deep exploration of the data to point out specific acoustic traits correlated with very specific behavioral situations. These results suggest USVs do not have the same functions in both sexes. Further investigations on other mouse strains should help understand the functions of these communicative signals, and better integrate them in the behavioral phenotyping of mouse models of communicative disorders.

Fragile X syndrome (FXS) is the most prevalent form of inheritable cognitive disability, and also the most frequent monogenic cause of autism. Individuals with FXS are suffering from a range of symptoms including impaired cognition, communication, and social behavior. Similar deficits have been reported in the FXS mouse model (*Fmr1*-KO mouse). Alterations in vocal communication have been shown even in early postnatal development, however, mostly focusing on a narrow age range. In this study, mouse pup isolation calls from both male and female *Fmr1*-KO and sighted FVB (FVB.129P2-Pde6b^{+}Tyr$^{c\text{-}ch}$/AntJ; wt) control mice are examined in a developmental range from before hearing onset until shortly after (P2 – P12). We noticed alterations in the temporal domain of mouse pup isolation calls mainly in female *Fmr1*-KO pups. These alterations encompassed changes in the number of calls emitted and an on-average constant call duration. Most strikingly however, throughout their developmental trajectory female *Fmr1*-KO mice displayed an altered temporal organization of the calls they emitted, which was expressed by longer breaks between single calls. The in-depth analysis of the impact of the lack of the *Fmr1*-gene on the spectral call parameters is currently still ongoing. Our results will provide further insights into the alterations during early development of vocal communication in the *Fmr1*-KO mouse that might be beneficial for our understanding of the impaired communication in FXS.

Objectives Autism Spectrum Disorder (ASD) is a group of neurodevelopmental conditions which affect approximately 1.5% of the population worldwide. Individuals with ASD exhibit communication and socialization impairments, hyperactivity, repetitive behaviors, and restricted interests. Several genetic mutations have been tightly linked to ASD, including mutations in the *FMR1* (fragile X mental retardation 1) gene that leads to the Fragile X syndrome, a monogenic cause of ASD. Rodent models of ASD recapitulate behavior abnormalities observed in humans and serve as valuable tools to validate pharmacological compounds alleviating ASD behaviors. Thi study aimed to behaviorally characterize the *Fmr1*-Knockout (KO) mouse model compared with C57BL/6JRj animals. Additionally, the effects of the widely used GABAergic drug R-Baclofen on behavior were investigated. **Methods** Male B6.129P2-*Fmr1*^{tm1Cgr}/J (*Fmr1*-KO) mice were allocated to two different groups and intraperitoneally treated once with R-Baclofen or vehicle. Additionally, C57BL/6JRj mice received vehicle. Open field, grooming, three-chamber-social-interaction test, and ultrasonic vocalization (USV) emission recording test were conducted at the age of 7-10 weeks. **Results** *Fmr1*-KO vehicle-treated mice showed significantly higher activity, hyperactivity, grooming duration/episodes, as well as impaired social interaction and interest compared to C57BL/6JRj mice. USV recordings revealed a significant reduction in the number of calls in *Fmr1*-KO vehicle-treated mice compared to C57BL/6JRj animals. Acute R-Baclofen treatment alleviated repetitive grooming behavior in *Fmr1*-KO mice. **Conclusions** From our data, we concluded that the *Fmr1*-KO mouse model can serve as a valuable tool to investigate some core and secondary symptoms of ASD. Intriguingly, R-Baclofen treatment alleviated repetitive behavior of grooming in *Fmr1*-KO mice.

Pathogenetic Impact of Bacterial-Fungal Interactions.
Polymicrobial infections are of paramount importance because of the potential severity of clinical manifestations, often associated with increased resistance to antimicrobial treatment. The intricate interplay with the host and the immune system, and the impact on microbiome imbalance, are of importance in this context. The equilibrium of microbiota in the human host is critical for preventing potential dysbiosis and the ensuing development of disease. Bacteria and fungi can communicate via signaling molecules, and produce metabolites and toxins capable of modulating the immune response or altering the efficacy of treatment. Most of the bacterial-fungal interactions described to date focus on the human fungal pathogen and different bacteria. In this review, we discuss more than twenty different bacterial-fungal interactions involving several clinically important human pathogens. The interactions, which can be synergistic or antagonistic, both and , are addressed with a focus on the quorum-sensing molecules produced, the response of the immune system, and the impact on clinical outcome.

Affective touch is necessary for proper neurodevelopment and sociability. However, it is still unclear how the neurons innervating the skin detect affective and social behaviours. The C-low threshold mechanoreceptors (C-LTMRs), a specific population of somatosensory neurons in mice, appears particularly well suited, physiologically and anatomically, to perceive affective and social touch. However, their contribution to sociability has not been resolved yet. Our observations revealed that C-LTMRs functional deficiency from birth induced social isolation and reduced tactile interactions in adulthood. Conversely, transient increase in C-LTMRs excitability in adults, using chemogenetics, was rewarding, promoted touch-seeking behaviours and had pro-social influences on group dynamics. This work provides the first empirical evidence that specific peripheral inputs alone can drive complex social behaviours. It demonstrates the existence of a specialised neuronal circuit, originating in the skin, wired to promote interactions with other individuals.

SOCIAL BEHAVIOR DEFICITS FOLLOWING SEROTONIN 2A RECEPTOR CONSTITUTIVE DELETION

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Agostina Sacson[1], Juan Morici[2], Marcelo Giachero[1], Pedro Bekinschtein[1], Noelia Weisstaub[1]
[1]Institute of Translational and Cognitive Neuroscience (INCYT) CONICET (National Council of Science and Technology) - Favaloro University - INECO Foundation., Laboratory Of Molecular Cognition, Ciudad Autónoma de Buenos Aires, Argentina, [2]Institut du Fer-à-Moulin, Inserm U1270, Paris, France

Social behavior (SB) is defined as interactions among individuals that offer mutual benefits and comprise different actions. Deficits in SB are a hallmark of different psychiatric disorders, including autism spectrum disorders. Changes in 5-HT levels, as well as some activity of key molecules within the system have been associated with deficits in SB. Serotonin 2A receptors (5-HT2aR) are one of the main excitatory serotonergic receptors. Social deficits in humans were associated with 5-HT2aR hypofunction. Interestingly, 5-HT2aR agonists increase social interaction (SI) in humans and animal models suggesting that 5-HT2aR might modulate SB. We used genetically modified male and female mice (htr2a-/-) and their littermates' controls (htr2a+/+) to study the specific role of the receptor in SB. P90 or older animals were exposed to different behavioral paradigms. In the three-chambers SI test *htr2a-/-* male and female mice show decreased discrimination indexes compared with same sex *htr2+/+* mice. Moreover, this deficit was rescued by the genetic restoration of the 5-HT2aR expression in the cortex suggesting a specific role of the receptor in this area. However, pharmacological manipulations in *htr2+/+* adult mice before the SI test showed no effect suggesting that 5-HT2aR is not acutely recruited for SB. Taken together, these results suggest that 5-HT2aR has a role in SB and its involvement appears to be due to a developmental or chronic action.

Dentate Gyrus Somatostatin Cells are Required for Contextual Discrimination During Episodic Memory Encoding.
Memory systems ought to store and discriminate representations of similar experiences in order to efficiently guide future decisions. This problem is solved by pattern separation, implemented in the dentate gyrus (DG) by granule cells to support episodic memory formation. Pattern separation is enabled by tonic inhibitory bombardment generated by multiple GABAergic cell populations that strictly maintain low activity levels in granule cells. Somatostatin-expressing cells are one of those interneuron populations, selectively targeting the distal dendrites of granule cells, where cortical multimodal information reaches the DG. Nonetheless, somatostatin cells have very low connection probability and synaptic efficacy with both granule cells and other interneuron types. Hence, the role of somatostatin cells in DG circuitry, particularly in the context of pattern separation, remains uncertain. Here, by using optogenetic stimulation and behavioral tasks in mice, we demonstrate that somatostatin cells are required for the acquisition of both contextual and spatial overlapping memories.

STUDY OF MITOCHONDRIAL FUNCTION AND SOCIAL BEHAVIORS UNDER PSYCHOGENIC STRESS

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Eva Ramos Fernandez, Carmen Sandi
EPFL, Bmi, Lausanne, Switzerland

Aims: Stress conditions threaten the organism's homeostasis, triggering adaptative responses. For instance, during stress, the brain adapts to cope with the increased energy demand by augmenting metabolism, glucose oxidation and oxygen consumption. We aim to unveil the molecular mechanisms triggered during stress and mediated by corticosterone, that if maladaptive, can lead to neuropsychiatric disorders. Considering that mitochondria and bioenergetics are emerging as important key players in psychopathologies, our goal is to study mitochondrial structure and function in Nucleus Accumbens (NAc). This brain region is implicated in stress-related pathologies and can be altered after stress exposure affecting social behavior. Here we study the effect of stress on mitochondrial-endoplasmic reticulum interactions, key for mitochondrial activity and ATP production in NAc. **Methods:** To this end, we evaluated the effect of the corticosterone and stress on mouse behavior, inter-organelle contacts using protein ligation assay, mitochondrial respiration assessed by high-resolution respirometry and ATP production. **Results:** Interestingly, our data show that in a situational dominance tube test confrontation against non-stressed animals, acutely stressed mice had a social advantage. The acutely stressed mice won almost all trials immediately after acute stress. Corticosterone levels correlated with success rate and ATP levels in NAc. In vitro studies showed that corticosterone can induce mito-ER contacts, modifying mitochondrial respiration and ATP levels, and our results indicate that this effect could be cell-specific. **Conclusions:** Corticosterone -through modulatory actions on mitochondrial inter-organelle interactions- seem to modulate mitochondrial activity to fulfil the energy demand that occurs during behavioral adaptation to stress.

Wnt5a promotes hippocampal postsynaptic development and GluN2B-induced expression via the eIF2α HRI kinase.
Wnt signaling plays a key role in neurodevelopment and neuronal maturation. Specifically, Wnt5a stimulates postsynaptic assemblies, increases glutamatergic neurotransmission and, through calcium signaling, generates nitric oxide (NO). Trying to unveil the molecular pathway triggering these postsynaptic effects, we found that Wnt5a treatment induces a time-dependent increases in the length of the postsynaptic density (PSD), elicits novel synaptic contacts and facilitates F-actin flow both in in vitro and ex vivo models. These effects were partially abolished by the inhibition of the Heme-regulated eukaryotic initiation factor 2α (HRI) kinase, a kinase which phosphorylates the initiation translational factor eIF2α. When phosphorylated, eIF2α normally avoids the translation of proteins not needed during stress conditions, in order to avoid unnecessary energetic expenses. However, phosphorylated eIF2α promotes the translation of some proteins with more than one open reading frame in its 5' untranslated region. One of these proteins targeted by Wnt-HRI-eIF2α mediated translation is the GluN2B subunit of the NMDA receptor. The identified increase in GluN2B expression correlated with increased NMDA receptor function. Considering that NMDA receptors are crucial for excitatory synaptic transmission, the molecular pathway described here contributes to the understanding of the fast and plastic translational mechanisms activated during learning and memory processes.

Astrocytic release of ATP through type 2 inositol 1,4,5-trisphosphate receptor calcium signaling and social dominance behavior in mice.
Brain mitochondrial function is critical for numerous neuronal processes. We recently identified a link between brain energy and social dominance, where higher levels of mitochondrial function resulted in increased social competitive ability. The underlying mechanism of this link, however, remains unclear. Here, we investigated the contribution of astrocytic release of adenosine triphosphate (ATP) through the type 2 inositol 1,4,5-triphosphate receptor to social dominance behavior. Mice lacking the type 2 inositol 1,4,5-triphosphate receptor were characterized for their social dominance behavior, as well as their performance on a nonsocial task, the Morris Water Maze. In parallel, we also examined mitochondrial function in the medial

prefrontal cortex, nucleus accumbens, and hippocampus to investigate how deficiencies in astrocytic ATP could modulate overall mitochondrial function. While knockout mice showed similar competitive ability compared with their wild-type littermates, dominant knockout mice exhibited a significant delay in exerting their dominance during the initial encounter. Otherwise, there were no differences in anxiety and exploratory traits, spatial learning and memory, or brain mitochondrial function in either light or dark circadian phases. Our findings point to a marginal role of astrocytic ATP through IP R2 in social competition, suggesting that, under basal conditions, the neuronal compartment is predominant for social dominance exertion.

Therapeutic potential of glutathione-enhancers in stress-related psychopathologies.
The mammalian brain has high energy demands, which may become higher in response to environmental challenges such as psychogenic stress exposure. Therefore, efficient neutralization of reactive oxygen species that are produced as a by-product of ATP synthesis is crucial for preventing oxidative damage and ensuring normal energy supply and brain function. Glutathione (GSH) is arguably the most important endogenous antioxidant in the brain. In recent years, aberrant GSH levels have been implicated in different psychiatric disorders, including stress-related psychopathologies. In this review, we examine the available data supporting a role for GSH levels and antioxidant function in the brain in relation to anxiety and stress-related psychopathologies. Additionally, we identify several promising compounds that could raise GSH levels in the brain by either increasing the availability of its precursors or the expression of GSH-regulating enzymes through activation of Nuclear factor erythroid-2-related factor 2 (Nrf2). Given the high tolerability and safety profile of these compounds, they may represent attractive new opportunities to complement existing therapeutic manipulations against stress-related psychopathologies.

Non-canonical function of IRE1α determines mitochondria-associated endoplasmic reticulum composition to control calcium transfer and bioenergetics.
Mitochondria-associated membranes (MAMs) are central microdomains that fine-tune bioenergetics by the local transfer of calcium from the endoplasmic reticulum to the mitochondrial matrix. Here, we report an unexpected function of the endoplasmic reticulum stress transducer IRE1α as a structural determinant of MAMs that controls mitochondrial calcium uptake. IRE1α deficiency resulted in marked alterations in mitochondrial physiology and energy metabolism under resting conditions. IRE1α determined the distribution of inositol-1,4,5-trisphosphate receptors at MAMs by operating as a scaffold. Using mutagenesis analysis, we separated the housekeeping activity of IRE1α at MAMs from its canonical role in the unfolded protein response. These observations were validated in vivo in the liver of IRE1α conditional knockout mice, revealing broad implications for cellular metabolism. Our results support an alternative function of IRE1α in orchestrating the communication between the endoplasmic reticulum and mitochondria to sustain bioenergetics.

Wnt-7a Stimulates Dendritic Spine Morphogenesis and PSD-95 Expression Through Canonical Signaling.
Wnt signaling regulates brain development and synapse maturation; however, the precise molecular mechanism remains elusive. Here, we report that Wnt-7a stimulates dendritic spine morphogenesis in the hippocampus via glycogen synthase kinase-3 β (GSK-3β) inhibition, triggering β-catenin/T cell factor/lymphoid enhancer factor (TCF/LEF)-dependent gene transcription and promoting postsynaptic density-95 (PSD-95) protein expression. In addition, wild-type mice treated with an inhibitor of β-catenin/TCF/LEF-mediated transcription showed a reduction in spatial memory acquisition accompanied by a reduction in PSD-95 and decreases in spine density measured by Golgi staining, suggesting that PSD-95 is a novel Wnt target gene. Together, our data strongly demonstrate that Wnt-dependent target gene transcription is essential to hippocampal synaptic plasticity.

Wnt Signaling Prevents the Aβ Oligomer-Induced Mitochondrial Permeability Transition Pore Opening Preserving Mitochondrial Structure in Hippocampal Neurons.
Alzheimer's disease (AD) is a neurodegenerative disorder mainly known for synaptic impairment and neuronal cell loss, affecting memory processes. Beside these damages, mitochondria have been implicated in the pathogenesis of AD through the induction of the mitochondrial permeability transition pore (mPTP). The mPTP is a non-selective pore that is formed under apoptotic conditions, disturbing mitochondrial structure and thus, neuronal viability. In AD, Aβ oligomers (Aβos) favor the

opening of the pore, activating mitochondria-dependent neuronal cell death cascades. The Wnt signaling activated through the ligand Wnt3a has been described as a neuroprotective signaling pathway against amyloid-β (Aβ) peptide toxicity in AD. However, the mechanisms by which Wnt signaling prevents Aβos-induced neuronal cell death are unclear. We proposed here to study whether Wnt signaling protects neurons earlier than the late damages in the progression of the disease, through the preservation of the mitochondrial structure by the mPTP inhibition. To study specific events related to mitochondrial permeabilization we performed live-cell imaging from primary rat hippocampal neurons, and electron microscopy to analyze the mitochondrial morphology and structure. We report here that Wnt3a prevents an Aβos-induced cascade of mitochondrial events that leads to neuronal cell death. This cascade involves (a) mPTP opening, (b) mitochondrial swelling, (c) mitochondrial membrane potential loss and (d) cytochrome c release, thus leading to neuronal cell death. Furthermore, our results suggest that the activation of the Wnt signaling prevents mPTP opening by two possible mechanisms, which involve the inhibition of mitochondrial GSK-3β and/or the modulation of mitochondrial hexokinase II levels and activity. This study suggests a possible new approach for the treatment of AD from a mitochondrial perspective, and will also open new lines of study in the field of Wnt signaling in neuroprotection.

Glutamatergic stimulation induces GluN2B translation by the nitric oxide-Heme-Regulated eIF2α kinase in cortical neurons.
The activation of N-Methyl D-Aspartate Receptor (NMDAR) by glutamate is crucial in the nervous system function, particularly in memory and learning. NMDAR is composed by two GluN1 and two GluN2 subunits. GluN2B has been reported to participate in the prevalent NMDAR subtype at synapses, the GluN1/2A/2B. Here we studied the regulation of GluN2B expression in cortical neurons finding that glutamate up-regulates GluN2B translation through the action of nitric oxide (NO), which induces the phosphorylation of the eukaryotic translation initiation factor 2 α (eIF2α). It is a process mediated by the NO-heme-regulated eIF2α kinase (HRI), as the effect was avoided when a specific HRI inhibitor or a HRI small interfering RNA (siHRI) were used. We found that the expressed GluN2B co-localizes with PSD-95 at the postsynaptic ending, which strengthen the physiological relevance of the proposed mechanism. Moreover the receptors bearing GluN2B subunits upon NO stimulation are functional as high Ca2+ entry was measured and increases the co-localization between GluN2B and GluN1 subunits. In addition, the injection of the specific HRI inhibitor in mice produces a decrease in memory retrieval as tested by the Novel Object Recognition performance. Summarizing our data suggests that glutamatergic stimulation induces HRI activation by NO to trigger GluN2B expression and this process would be relevant to maintain postsynaptic activity in cortical neurons.

Wnt-5a/Frizzled9 Receptor Signaling through the Gαo-Gβγ Complex Regulates Dendritic Spine Formation.
Wnt ligands play crucial roles in the development and regulation of synapse structure and function. Specifically, Wnt-5a acts as a secreted growth factor that regulates dendritic spine formation in rodent hippocampal neurons, resulting in postsynaptic development that promotes the clustering of the PSD-95 (postsynaptic density protein 95). Here, we focused on the early events occurring after the interaction between Wnt-5a and its Frizzled receptor at the neuronal cell surface. Additionally, we studied the role of heterotrimeric G proteins in Wnt-5a-dependent synaptic development. We report that FZD9 (Frizzled9), a Wnt receptor related to Williams syndrome, is localized in the postsynaptic region, where it interacts with Wnt-5a. Functionally, FZD9 is required for the Wnt-5a-mediated increase in dendritic spine density. FZD9 forms a precoupled complex with Gαo under basal conditions that dissociates after Wnt-5a stimulation. Accordingly, we found that G protein inhibition abrogates the Wnt-5a-dependent pathway in hippocampal neurons. In particular, the activation of Gαo appears to be a key factor controlling the Wnt-5a-induced dendritic spine density. In addition, we found that Gβγ is required for the Wnt-5a-mediated increase in cytosolic calcium levels and spinogenesis. Our findings reveal that FZD9 and heterotrimeric G proteins regulate Wnt-5a signaling and dendritic spines in cultured hippocampal neurons.

Posttranslational nitro-glycative modifications of albumin in Alzheimer's disease: implications in cytotoxicity and amyloid-β peptide aggregation.
Glycation and nitrotyrosination are pathological posttranslational modifications that make proteins prone to losing their physiological properties. Since both modifications are increased in Alzheimer's disease (AD) due to amyloid-β peptide (Aβ) accumulation, we have studied their effect on albumin, the most abundant protein in cerebrospinal fluid and blood. Brain and

plasmatic levels of glycated and nitrated albumin were significantly higher in AD patients than in controls. In vitro turbidometry and electron microscopy analyses demonstrated that glycation and nitrotyrosination promote changes in albumin structure and biochemical properties. Glycated albumin was more resistant to proteolysis and less uptake by hepatoma cells occurred. Glycated albumin also reduced the osmolarity expected for a solution containing native albumin. Both glycation and nitrotyrosination turned albumin cytotoxic in a cell type-dependent manner for cerebral and vascular cells. Finally, of particular relevance to AD, these modified albumins were significantly less effective in avoiding Aβ aggregation than native albumin. In summary, nitrotyrosination and especially glycation alter albumin structural and biochemical properties, and these modifications might contribute for the progression of AD.

Modification of γ-secretase by nitrosative stress links neuronal ageing to sporadic Alzheimer's disease.
Inherited familial Alzheimer's disease (AD) is characterized by small increases in the ratio of Aβ42 versus Aβ40 peptide which is thought to drive the amyloid plaque formation in the brain of these patients. Little is known however whether ageing, the major risk factor for sporadic AD, affects amyloid beta-peptide (Aβ) generation as well. Here we demonstrate that the secretion of Aβ is enhanced in an in vitro model of neuronal ageing, correlating with an increase in γ-secretase complex formation. Moreover we found that peroxynitrite (ONOO(-)), produced by the reaction of superoxide anion with nitric oxide, promoted the nitrotyrosination of presenilin 1 (PS1), the catalytic subunit of γ-secretase. This was associated with an increased association of the two PS1 fragments, PS1-CTF and PS1-NTF, which constitute the active catalytic centre. Furthermore, we found that peroxynitrite shifted the production of Aβ towards Aβ(42) and increased the Aβ(42) /Aβ(40) ratio. Our work identifies nitrosative stress as a potential mechanistic link between ageing and AD.

UNDERSTANDING THE COMMUNICATIVE VALUE OF ULTRASONIC CALLS IN MALE AND FEMALE LABORATORY MICE: LESSONS FROM MOUSE MODELS OF NEURODEVELOPMENTAL DISORDERS

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Susanna Pietropaolo, Silvia Giannoccaro, Valeria Petroni, Celeste Ferraguto, Marion Piquemal-Lagoueillat
Bordeaux University CNRS, Incia, Pessac, France

Ultrasonic vocalizations (USVs) are a major tool for assessing social communication in laboratory mice during their entire lifespan. At adulthood, male mice preferentially emit USVs towards a female conspecific, while females mostly produce ultrasonic calls when facing an adult intruder of the same sex. Recent studies have largely developed several sophisticated tools to analyze pup and adult mouse USVs, especially in males, because of the relevance of communication abnormalities in the behavioral phenotyping of mouse models of autism spectrum disorder (ASD). Nonetheless, little is still known about the communicative value of the different types of ultrasonic calls emitted by male and female mice. Little attention has been indeed devoted to the impact of these calls on the behavior of the receiver, a crucial issue to understand the significance of certain call characteristics in the communication context. Here we have performed playback studies in adult male and female mice, in order to assess the behavioral impact of sex differences both on the emitting and the receiving subject. Moreover, we have combined these findings with data obtained from an extensive qualitative analysis of the ultrasonic calls emitted by adult male and female transgenic mice modelling major neurodevelopmental disorders (NDDs). Our results show that male- and female-specific calls have different attractive/aversive properties for male and female adult mice and their perception is clearly altered in mouse models of NDDs.

Social and asocial learning are required to cope with the complexity of the environment. They are behaviourally distinct. However, whether they use a single (general-purpose) or distinct (special-purpose) cognitive mechanisms remains elusive. A general-purpose mechanism should comprise a single set of genes, while a special-purpose mechanism should comprise two sets of genes, possibly regulating different biochemical pathways and/or neural circuits. This study aims to disentangle the genetic architecture of social and asocial learning in *Drosophila melanogaster*. We firstly tested social and asocial learning abilities in 40 lines of the DGRP, a panel constituted of hundreds of isogenic sequenced lines that together represent the genetic variation of a natural *Drosophila* population. We used aversive conditioning paradigms for oviposition sites. We obtained significant learning performance variation across the tested lines. Secondly, we performed a Genome-Wide Association Study – a statistical correlation between the genetic variants in the DGRP and each learning phenotype. We obtained two completely different sets of candidate genes for social and asocial learning, ranging from genes with unknown biological activity to genes already known to be related to learning. Thirdly, to functionally validate the role of each candidate gene on each learning phenotype, we used GAL4/RNAi-UAS lines, with knockdown induced by the pan-neuronal *nsyb-GAL4* driver. We found genes with no effect, genes with similar or opposite (trade-off) effects, and genes with social learning specialization. This study is the first experimental evidence supporting the special-purpose cognitive mechanism hypothesis. Future work will address this specialization at the neural circuitry level.

Microglia cytoarchitecture in the brain of adenosine A receptor knockout mice: Brain region and sex specificities.
Microglia cells exert a critical role in brain development, mainly supported by their immune functions, which predicts an impact on the genesis of psychiatric disorders. In fact, microglia stress during gestation is, for instance, associated with chronic anxiety and cognitive deficits accompanied by long-lasting, region- and sex-specific changes in microglia morphology. We recently reported that the pattern of microglia morphologic plasticity, which is sex-determined, impacts on anxious-like behaviour and cognition. We also reported that the pharmacologic blockade of adenosine A receptors (A R) is able to reshape microglia morphology, in a sex-specific manner and with behavioural sequelae. In order to better understand the role of A R in the sex differentiation of microglia, we now compared their morphology in wild-type and A R knockout male and female C57BL/6 mice in two cardinal brain regions implicated in anxiety-like behaviour and cognition, the prefrontal cortex (PFC) and the dorsal hippocampus (dHIP). We report interregional differences between PFC and dHIP in a sex-specific manner: while males presented more complex microglia in the dHIP, microglia from females had a more complex morphology in the PFC. Surprisingly, the genetic deletion of A R did not alter these sex differences, but promoted the exclusive remodelling (increase in complexity) in PFC microglia from females. These findings further support the existence of a heterogeneous microglial network, distinct between sexes and brain regions, and help characterizing the role of A R in the sex- and brain region-specific morphologic differentiation of microglia.

EMERGENCE OF INDIVIDUAL PERSONALITY TRAITS IN MICE LIVING IN SAME SEX COLONIES FROM WEANING: SOCIAL BEHAVIORS, ACOUSTIC COMMUNICATION AND MOTIVATION PROFILES

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Nastasia Mirofle, Sylvie Granon, Alexis Faure
Paris-Saclay Institute of Neurosciences (NeuroPSI), Cognitive & Network Neuroscience Departement (cnn), Saclay, France

Origin of individual variability has not yet been fully defined in pathological or in healthy states despite its impact on cognition. We expect variability to be promoted by early life social interaction and, therefore, that an environment offering more stimulations will favor the emergence of individual profiles. **Aim:** Our aim was to study individual behavioral variability regarding social behaviors. In a group of healthy adolescent mice living in a small stable colony, we assessed the range of behavioral individual variation over time, and differences between individuals. Some behaviors -within the social repertoire- might change throughout development, whereas some others might be stable, thus reflecting individual profile. **Methods:** We focused on housing conditions that would allow animals to develop a large behavioral repertoire and maximize behavioral variability detection. We expect to evaluate the influence of an enriched environment compared to standard housing conditions on mice behavior from adolescence to adulthood. **Results:** For that, we evaluated how an enriched environment influences individual differences in reward preference, social interactions, ultrasonic vocalizations or social motivation. We further investigated gender effects. **Conclusions:** We expect this work to increase our knowledge about the development of social profiles in mice. We shall also get information about the influence of a naturalistic environment and of gender on social and communication behaviors, and eventually on the development of social profiles.

PREGNANCY-INDUCED INDUCTION OF PARENTAL BEHAVIOUR

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Francesco Monaca
The Francis Crick Institute, The Francis Crick Institute, London, United Kingdom

Understanding how physiological states shape information processing in neural circuits is a fundamental question in neuroscience. Parenting is an instinctive behaviour that is crucial for survival and wellbeing of the offspring in many species. While considerable progress has been made in dissecting parental behaviour in rodents and other species, very little is known about the modulation of this behaviour and its underlying circuits by the females' reproductive state. Specifically, while the onset of parental behaviour is assumed to be linked to parturition and motherhood, whether, and when, pregnancy affects parental behaviour remains unexplored. Here we characterise pup-directed interactions in female mice throughout pregnancy. We find that parental interactions significantly increase during pregnancy, with the most pronounced changes occurring in the last trimester. By also tracking parental interactions in (1) ovariectomised females and (2) pregnant females not repeatedly exposed to pups, we identify aspects of parenting that are affected by pregnancy hormones, rather than by sensitisation due to frequent pup exposure. Moreover, we find that in addition to individual parenting parameters, entire pup-directed behavioural sequences are affected by pregnancy. Intriguingly, hormonally mediated increases in parental behaviour persist until at least one month after parturition, suggesting that they result from (semi)permanent remodelling of the brain by pregnancy hormones. We are currently investigating the neuronal and circuit-level changes underlying these behavioural adaptations. Uncovering the behavioural and neural effects of pregnancy hormone action will provide insights into how physiological states modulate brain function to instruct adaptive behavioural changes.

CHRONIC MATERNAL SSRI EXPOSURE DURING THE PRENATAL AND/OR POSTNATAL PERIOD INDUCED VOCAL BEHAVIOR DEFICITS AND AFFECTED SEROTONERGIC NEUROGENESIS IN THE MOUSE OFFSPRING

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Ziguo Lan[1,2], Noriko Osumi[2], Kouta Kanno[1]

The mechanism of autism spectrum disorders (ASD) remains unclear, even though more than a thousand of genes have been identified as genetic factors. Regarding environmental factors, maternal infection and drug exposure are paid attention as increased risks. Clinical reports suggest that maternal intake of Fluoxetine (FLX), a selective serotonin reuptake inhibitor (SSRI), during pregnancy may cause an increased risk of ASD in their offspring. To investigate how maternal SSRI exposure impacts on behavior of the offspring, we used wild type (C57BL/6J) mice as a model. We recorded maternal separation-induced ultrasonic vocalizations (USVs), an important indicator of vocal communication, previously reported as an ASD-related behavior. The tested mouse pups were divided into four groups according to the period of maternal FLX administration; pups raised with mothers that were orally administrated with FLX during both pregnancy and lactation periods (FLX), during the pregnancy (F-Sa), during the lactation (Sa-F), and with those administrated with vehicle water (with saccharin) during both pregnancy and lactation periods (Sa). We observed impaired production of USVs in FLX and Sa-F groups, suggesting that FLX exposure in lactation periods could be risky for deficits of vocal communication. Additionally, we performed immunohistochemistry using the same cohorts, in which the number of serotonergic neurons was reduced in all three groups treated with FLX maternally. This result indicated that persistent FLX exposure during pregnancy and/or lactation may inhibit serotonergic neurogenesis. Overall, our results provide potential insights for ASD mouse model research and clues associated with maternal SSRI intake during pregnancy and/or lactation.

CORTICOTROPIN-RELEASING HORMONE FROM THE PREFRONTAL CORTEX REGULATES SOCIAL PREFERENCE

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Noelia Sofia De León Reyes, Paula Sierra, Antonia Ruiz, Yuki Nomura, Felix Leroy
Instituto de Neurociencias de Alicante, Cognition And Social Interactions, Alicante, Spain

Social preference is a key feature of optimizing social interactions. In mice, social preference is based on anxiety, sex, strain and kinship but also on social memory. For example, adult rodents prefer to interact with novel versus familiar individuals (social novelty preference) whereas young pups prefer to interact with familiar littermates. Despite social novelty preference being used routinely to assess social memory, it is still unclear which neuronal circuits guide social preference and whether such circuits promote social interactions with the preferred individuals or prevent interactions with the non-preferred ones. The infra-limbic area of the pre-frontal cortex (ILA) - involved in social decision-making - and the lateral septum (LS) - involved in the inhibition of motivated behaviors, including social interactions - are necessary for social novelty preference but the neuronal circuits and molecular mechanisms allowing them to regulate social interactions are still unknown. Here, we show how the release of corticotropin-releasing hormone (CRH, a 41 amino acid neuropeptide) from ILA into the rostro-dorsal region of LS (rdLS) inhibits social interaction with familiar mice. This circuit therefore participates in the process of familiarization (decrease in interaction as a novel mouse becomes familiar) and contributes to social novelty preference in adult mice. We also demonstrate how the maturation of CRH expression during the first two post-natal weeks enables a shift of social preference from familiar to novel mice.

Transient callosal projections of L4 neurons are eliminated for the acquisition of local connectivity.
Interhemispheric axons of the corpus callosum (CC) facilitate the higher order functions of the cerebral cortex. According to current views, callosal and non-callosal fates are determined early after a neuron's birth, and certain populations, such as cortical layer (L) 4 excitatory neurons of the primary somatosensory (S1) barrel, project only ipsilaterally. Using a novel axonal-retrotracing strategy and GFP-targeted visualization of Rorb neurons, we instead demonstrate that L4 neurons develop transient interhemispheric axons. Locally restricted L4 connectivity emerges when exuberant contralateral axons are refined in an area- and layer-specific manner during postnatal development. Surgical and genetic interventions of sensory circuits demonstrate that refinement rates depend on distinct inputs from sensory-specific thalamic nuclei. Reductions in input-dependent refinement result in mature functional interhemispheric hyperconnectivity, demonstrating the plasticity and bona fide callosal potential of L4 neurons. Thus, L4 neurons discard alternative interhemispheric circuits as instructed by thalamic input. This may ensure optimal wiring.

Development and plasticity of the corpus callosum.
The corpus callosum (CC) connects the cerebral hemispheres and is the major mammalian commissural tract. It facilitates bilateral sensory integration and higher cognitive functions, and is often affected in neurodevelopmental diseases. Here, we review the mechanisms that contribute to the development of CC circuits in animal models and humans. These species comparisons reveal several commonalities. First, there is an early period of massive axonal projection. Second, there is a postnatal temporal window, varying between species, in which early callosal projections are selectively refined. Third, sensory-derived activity influences axonal refinement. We also discuss how defects in CC formation can lead to mild or severe CC congenital malformations.

Excitotoxic inactivation of constitutive oxidative stress detoxification pathway in neurons can be rescued by PKD1.
Excitotoxicity, a critical process in neurodegeneration, induces oxidative stress and neuronal death through mechanisms

largely unknown. Since oxidative stress activates protein kinase D1 (PKD1) in tumor cells, we investigated the effect of excitotoxicity on neuronal PKD1 activity. Unexpectedly, we find that excitotoxicity provokes an early inactivation of PKD1 through a dephosphorylation-dependent mechanism mediated by protein phosphatase-1 (PP1) and dual specificity phosphatase-1 (DUSP1). This step turns off the IKK/NF-κB/SOD2 antioxidant pathway. Neuronal PKD1 inactivation by pharmacological inhibition or lentiviral silencing in vitro, or by genetic inactivation in neurons in vivo, strongly enhances excitotoxic neuronal death. In contrast, expression of an active dephosphorylation-resistant PKD1 mutant potentiates the IKK/NF-κB/SOD2 oxidative stress detoxification pathway and confers neuroprotection from in vitro and in vivo excitotoxicity. Our results indicate that PKD1 inactivation underlies excitotoxicity-induced neuronal death and suggest that PKD1 inactivation may be critical for the accumulation of oxidation-induced neuronal damage during aging and in neurodegenerative disorders.
Nat Commun, 2017; 8
34030948: Bragg-Gonzalo L, De León Reyes NS, Nieto M
Genetic and activity dependent-mechanisms wiring the cortex: Two sides of the same coin.
The cerebral cortex is responsible for the higher-order functions of the brain such as planning, cognition, or social behaviour. It provides us with the capacity to interact with and transform our world. The substrates of cortical functions are complex neural circuits that arise during development from the dynamic remodelling and progressive specialization of immature undefined networks. Here, we review the genetic and activity-dependent mechanisms of cortical wiring focussing on the importance of their interaction. Cortical circuits emerge from an initial set of neuronal types that engage in sequential forms of embryonic and postnatal activity. Such activities further complement the cells' genetic programs, increasing neuronal diversity and modifying the electrical properties while promoting selective connectivity. After a temporal window of enhanced plasticity, the main features of mature circuits are established. Failures in these processes can lead to neurodevelopmental disorders whose treatment remains elusive. However, a deeper dissection of cortical wiring will pave the way for innovative therapies.

AUTOMATICALLY ANNOTATED MOTION TRACKING IDENTIFIES A DISTINCT SOCIAL BEHAVIORAL PROFILE FOLLOWING CHRONIC SOCIAL DEFEAT STRESS

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Joeri Bordes[1], Lucas Miranda[2], Maya Reinhardt[1], Lea Brix[1], Lotte Van Doeselaar[1], Clara Engelhardt[1], Benno Pütz[2], Felix Agakov[2], Bertram Müller-Myhsok[2], Mathias Schmidt[1]

Severe stress exposure is a global problem with long-lasting negative behavioral and physiological consequences, which can increase the risk for stress-related disorders such as major depressive disorder (MDD). Studying the role of social behavior in relation to the development of MDD is crucial, as poor social networks have been linked to lowered mental and physical health. An important animal model for the research in MDD is chronic social defeat stress (CSDS), which induces a cascade of stress-related physiological and behavioral responses. Here, we introduce the open-source tool “DeepOF”, to specifically investigate the social behavioral profile in mice by providing supervised and unsupervised behavioral profiling of DeepLabCut annotated pose-estimation data. The supervised pipeline relies on pretrained classifiers to automatically detect already defined traits for both single and dyadic animal behavior. Subsequently, the unsupervised pipeline aims to explore the behavioral repertoire of the animals without label priming. A distinct social behavioral profile is observed following CSDS using the DeepOF social behavioral classifiers and unsupervised profiling. In both cases, the observed social behavioral pattern was exclusively observed in the first 2.5 minutes of the interaction with a novel conspecific, which coincides with a state of social arousal, that disappears after 2.5 minutes due to habituation. Moreover, the classical social avoidance task does identify the social behavioral profile induced by CSDS, but both DeepOF behavioral pipelines provide a stronger profile. This study shows that the DeepOF module can contribute to further unravel the role of social behavior in stress-related disorders, such as MDD.

VGLUT3 AS A MARKER OF VULNERABILITY TO STRESS AND ASSOCIATED PSYCHIATRIC DISORDERS

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Marine Pujol, Véronique Fabre, Stephanie Daumas
Sorbonne Université, Neurosciences Paris Seine - Institut De Biologie Paris Seine, Paris, France

Aims: Stress is a major risk factor that can lead to psychiatric and sleep disorders. Emotional responses to stress are characterized by an inter-individual variability which is influenced by environmental and genetic factors. The glutamatergic transmission, mediated by vesicular glutamate transporters, type 1-3 (VGLUT1-3), is involved in mood disorders. In humans, the p.T8I-VGLUT3 variant is linked to addictive behaviors. The aim of this study was to understand the role of this mutation in stress-related behaviors and its consequences on sleep patterns. **Methods:** VGLUT3$^{T8I/T8I}$ and VGLUT3$^{+/+}$ adult mice (male and female) were subjected to the chronic social defeat stress paradigm (CSDS). Social, anxiety- and depressive-like behaviors were assessed before and after stress exposure. Polysomnographic sleep recordings were done before, during and after CSDS. **Results:** Social behavior was differently impacted in control and mutant male mice. VGLUT3$^{T8I/T8I}$ male mice showed a higher susceptibility to stress characterized by a stronger social avoidance after CSDS. These mice also showed greater levels of anxiety-like behaviors, suggesting that the p.T8I variant plays a role in susceptibility to stress. In female mice, social and anxiety-like behaviors were similarly impacted after CSDS between control and mutant mice, suggesting sex differences in the role of the mutation in stress-related behaviors. CSDS also impaired sleep in both groups, with a long term increased wake time suggesting an insomniac-like phenotype. A stress-anticipatory arousal was found in control mice but not in mutant mice after CSDS. **Conclusion:** Our results revealed the role of the p.T8I mutation in susceptibility to stress.

DISSECTING THE NEURAL BASES UNDERLYING OBSERVATIONAL LEARNING OF PROSOCIAL AND SELFISH BEHAVIORS

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Filippo La Greca, Elisa Zianni, Jennifer Stanic, Fabrizio Gardoni, Monica Di Luca, Diego Scheggia
Università degli Studi di Milano (UNIMI), Department Of Pharmacological And Biomolecular Sciences (disfeb), Milan, Italy

Background: Humans constantly observe and learn from others (ie, observational learning). Through observation, humans model another's individual behavior, skills, emotions, and may replicate complex social outcomes such as prosocial or selfish acts. Rodent studies have helped defining the neural circuitry underlying spatial and fear learning by observation of their conspecifics. However, whether rodents can learn refined social behaviors through observation is unknown. The hippocampus is crucial for learning and has a key role (ie, dorsal CA1) in the representation of self-others location and action in the space. Given this evidence, neurodegenerative diseases affecting hippocampal activity might compromise observational learning ability. **Aims:** The major goal was dissecting the neural bases underlying observational learning. We studied observational learning in mice specifically focusing on the role of dorsal CA1. We also analyzed observational learning in a model of Alzheimer's dementia (ie, AD mice) characterized by hippocampal dysfunction. **Methods:** We used an operant social decision-making task where mice observe their conspecifics and learn to make prosocial or selfish choices. We investigated the role of dorsal CA1 by inhibitory chemogenetics. Then, we tested AD mice in our task. **Results:** Our results show that mice, after observation, display faster learning compared to mice not observing the task. Chemogenetic silencing of dorsal CA1 and AD mice showed impairments in observational learning. **Conclusions:** Our study starts addressing the role of dorsal CA1 in observational learning of complex social behaviors. Besides, our results with AD mice highlight how hippocampal dysfunction might compromise observational learning potentially disrupting social interactions.

GluA3 autoantibodies induce alterations in dendritic spine and behavior in mice.
Autoantibodies targeting the GluA3 subunit of AMPA receptors (AMPARs) have been found in patients with Rasmussen's encephalitis and different types of epilepsy and were associated with the presence of learning and attention deficits. Our group recently identified the presence of anti-GluA3 immunoglobulin G (IgG) in about 25% of patients with frontotemporal dementia (FTD), thus suggesting a novel pathogenetic role also in chronic neurodegenerative diseases. However, the in vivo behavioral, molecular and morphological effects induced these antibodies are still unexplored. We injected anti-GluA3 IgG purified from the serum of FTD patients, or control IgG, in mice by intracerebroventricular infusion. Biochemical analyses showed a reduction of synaptic levels of GluA3-containing AMPARs in the prefrontal cortex (PFC), and not in the hippocampus. Accordingly, animals injected with anti-GluA3 IgG showed significant changes in recognition memory and impairments in social behavior and in social cognitive functions. As visualized by confocal imaging, functional outcomes were paralleled by profound alterations of dendritic spine morphology in the PFC. All observed behavioral, molecular and morphological alterations were transient and not detected 10-14 days from anti-GluA3 IgG injection. Overall, our in vivo preclinical data provide novel insights into autoimmune encephalitis associated with anti-GluA3 IgG and indicate an additional pathological mechanism affecting the excitatory synapses in FTD patients carrying anti-GluA3 IgG that could contribute to clinical symptoms.

DOES PATERNAL METHAMPHETAMINE EXPOSURE CAUSE SUCH A SERIOUS IMPACT TO RAT OFFSPRING DURING DEVELOPMENT AND IN ADULTHOOD AS MATERNAL DRUG EXPOSURE?

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Lydia Mihalcikova, Anna Bednarikova, Romana Slamberova
Charles University, Depatment Of Physiology, Praha, Czech Republic

Drug addiction and its influence on behavior and development of offspring has become a serious problem in our society. Methamphetamine (MA) is one of the most abused psychostimulants in the Czech Republic and worldwide. Previous studies have demonstrated the adverse effects of maternal drug abuse. However, the father's contribution is unclear. The present study aimed to examine the effect of MA exposure on male sexual behavior and the paternal MA exposure on development and locomotor activity in rat offspring. MA was administrated for 30 days in dose of 5mg/kg s.c. to adult male rats. First, the effect of MA on sexual behavior and locomotor activity of adult male rats was examined. Second, the impact of paternal MA exposure on rat pups was investigated using behavioral tests during development and locomotor activity tests in adulthood. Prior to testing, adult offspring were exposed to an acute challenge dose of MA (1 mg/kg) to examine the possible sensitizing effect of the paternal treatment. Our results demonstrated that MA exposure does not affect sexual behavior. The data from Laboras test showed that MA administration has significant effect on locomotor activity only in case of acute MA application. As a matter of paternal administration effect on offspring, there were no significant differences in development or locomotor activity in adulthood. In conclusion, in contrast to the maternal MA administration, our results demonstrated that paternal MA administration does not affect behavior during development and in adult offspring as it was shown after maternal administration. EFFECTS OF SEX AND FAMILIARITY ON HELPING BEHAVIOR WITH AND WITHOUT SOCIAL REWARD IN RATS

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Keren Ruzal[1], Estherina Trachtenberg[1], Einat Bigelman[2], Inbal Ben-Ami Bartal[1,2]
[1]Tel Aviv Univerity, Sagol School Of Neuroscience, Tel Aviv, Israel, [2]Tel Aviv University, School Of Psychological Sciences, Tel Aviv, Israel

Introduction: Prosocial behavior, like helping others in distress, relies on empathic responding. To investigate the neurobiological mechanisms underlying this behavior rats were tested in the Helping Behavior Test (HBT), where they help a trapped conspecific by opening the door to a restrainer. To dissociate the contribution of social reward, rats were physically separated and could not interact after helping. We found that helping selectively occurs for ingroup members even in the lack of social reward across strain and sex. **Methods**: Experiments were conducted in adult rats (8-13 pairs per group), with different sex, strain (Sprague Dawley/Long Evans/Fischer344, or SD/LE/F344), and familiarity (cagemate/stranger). Social reward was manipulated by using a single arena where rats could interact (non-separated) or a split arena where rats enter when released (separated). **Results**: In the non-separated HBT, SD males released cagemates more than LE strangers, reproducing previous results. Female F344 also released cagemates, as opposed to male F344. In the separated HBT, LE males typically released an LE. Movement analysis show differing social motivations across conditions, and point to anxiety as detrimental for helping. **Conclusions**: Social reward is not required for helping behavior in rats, who continue to release a trapped conspecific without contact. Social context is the main predictor of helping, whereas variations in anxiety, cognitive and motor abilities explain strain differences in door-opening. Follow-up experiments study the effects of co-housing across strains on the neural mechanisms involved in helping in the absence of social reward.

SOCIAL ISOLATION DURING ADOLESCENCE TRIGGERS EMOTIONAL DYSFUNCTION IN BOTH FEMALE AND MALE MICE

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Caterina Barezzi
Istituto superiore di sanità, Centro Di Neuroscienze Comportamentali, Roma, Italy

Aims: Depressive disorder in adolescents constitutes a huge socio-economic issue, represents the second leading cause of death among teenagers, and is more than twice as likely among girls than boys. Since social deprivation during adolescence triggers adolescent depression, we aimed to investigate in a preclinical model how adolescent social isolation leads to emotional dysfunction in both sexes. **Methods:** C57BL/6 male and female mice were exposed from weaning to adulthood either to standard housing conditions or to a social isolation protocol: in the latter, control mice were housed four per cage, while in the former, mice were singly housed. The behavioral phenotype was assessed during this period through saccharin preference, open field, and elevated plus-maze tests. **Results:** Following adolescent isolation, both male and female mice displayed increased anhedonic and anxiety-like profiles. Isolated mice showed a significantly decreased saccharin preference, compared to control mice. In the elevated plus-maze, isolated mice spent less time in the open arms performing longer rearing behavior, an index of increased fear. Moreover, isolated mice spent less time in the center of the open field arena displaying a longer stretch attend posture duration, a risk-assessment defensive mouse behavior. **Conclusion:** Our findings show that social isolation during adolescence leads to the onset of emotional dysfunction concerning depressive- and anxiety-like domains in both males and females mice. Translationally, the similar vulnerability in the two sexes suggests that the gender differences in adolescent depression might be ascribed not only to social deprivation but also to the interaction of several factors.

Although mice are social animals, studies that explore the simultaneously recorded neural activities of multiple mice, especially in a naturalistic social setting, are still lacking. This study used a minimized head-mounted wireless edge-computing solution to record electrophysiological signals from multiple awake, freely-moving mice simultaneously. Four mice were allowed to interact freely with each other or were individually separated, while their behaviors and electrophysiological signals were recorded for three hours. Power spectral density (PSD) estimates of local field potential (LFP) recordings in the dorsomedial prefrontal cortex (dmPFC) showed differential patterns of powers at low- and high- frequencies when the mice were in a group and when they were separated. High- and Low-power ratio (HLR) was low when the mice were inactive, and it was high when they were active—whether or not they were moving—, and the mice in the group showed higher HLR in any behavioral states. However, the group/single HLR disparity disappeared when the mice were huddling (gathering together), suggesting the importance of active gathering or affiliative touch. The mice in the 'group' condition showed correlated patterns of HLR in the time domain, while the mice in the 'single' condition showed no correlation of HLR, suggesting the existence of the interbrain synchrony. Granger causality analysis indicated there is unilateral temporal precedence of the HLR among the mice, implying a dominant directed influence exists in the group of mice. Overall, this study shows that the neural activities of the multiple mice can be co-modulated by social context and locomotive status.

Differential Inhibitory Configurations Segregate Frequency Selectivity in the Mouse Inferior Colliculus.
Receptive fields and tuning curves of sensory neurons represent the neural substrates that allow animals to efficiently detect and distinguish external stimuli. They are progressively refined to create diverse sensitivity and selectivity for neurons along ascending central pathways. However, the neural circuitry mechanisms have not been directly determined for such fundamental qualities in relation to sensory neurons' functional organizations, because of the technical difficulty of correlating neurons' input and output. Here, we obtained spike outputs and synaptic inputs from the same neurons within characteristically defined neural ensembles, to determine the synaptic mechanisms driving their diverse frequency selectivity in the mouse inferior colliculus. We find that the synaptic strength and timing of excitatory and inhibitory inputs are configured differently and independently within individual neurons' receptive fields, which segregate sensitive and selective neurons and endow neural populations with broad receptive fields and sharp frequency tuning. By computationally modeling spike outputs from integrating synaptic inputs and comparing them with real spike responses of the same neurons, we show that space-clamping errors did not qualitatively affect the estimation of spike responses derived from synaptic currents in voltage-clamp recordings. These data suggest that heterogeneous inhibitory circuits coexist locally for a parallel but differentiated representation of incoming signals. Sensitivity and selectivity are functional qualities of sensory systems to facilitate animals' survival. There is little direct evidence for the synaptic basis of neurons' functional variance within neural ensembles. Here we adopted a novel framework to fill such a long-standing gap by uniting population activities with single cells' spike outputs and their synaptic inputs. Furthermore, the effects of space-clamping errors on subcortical synaptic currents were evaluated , by comparing recorded spike responses and simulated spike outputs from computationally integrating synaptic inputs. Our study illustrated that the synaptic strength and timing of inhibition relative to excitation can be configured differently for neurons within a defined neural ensemble, to segregate their selectivity. It provides new insights into coexisting heterogeneous local circuits.

COGNITIVE AND EMOTIONAL FUNCTIONS OF MICE LACKING THE MINERALOCORTICOID RECEPTOR IN GLUTAMATERGIC OR GABAERGIC NEURONS

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Huanqing Yang[1], Juan Pablo Lopez[2], Carlo De Donno[2], Lotte Van Doeselaar[1], Joeri Bordes[1], Lea Brix[1], Sowmya Narayan[1], Margherita Springer[1], Clara Engelhardt[1], Shiladitya Mitra[1], Mattias Eder[1], Jan Deussing[3], Mathias Schmidt[1]

Aims: To examine whether deletion of Mineralocorticoid receptor (MR) in glutamatergic pyramidal cells and GABA-ergic cells has differential effects on behavior and cognition. Methods: We generated mice lacking the MR in glutamatergic neurons (MRlox/lox-Nex-Cre) or GABAergic neurons (MRlox/lox-Dlx-Cre). First, we performed basal phenotyping of knockout or wild-type littermates on anxiety-related behaviour and cognition. We then tested how their behaviour changes after exposure to chronic social defeat stress (CSDS). In addition, electrophysiological experiments and Golgi staining were used to observe the changes of function and structure in MRlox/lox-Nex-Cre mice. Blood corticosterone and the adrenal weights of the animals were measured to test the reactivity of the hypothalamic-pituitary-adrenal axis following the stress and harvested the brains for further analysis of gene expression. Results: Under baseline conditions, only MRlox/lox-Nex-Cre mice displayed increased anxiety in the open field and elevated plus-maze test, the learning and memory ability of MRlox/lox-Dlx-Cre mice was improved under stressful test conditions. Following CSDS, there were few genotype x chronic stress interactions in either male MRlox/lox-Nex-Cre or MRlox/lox-Dlx-Cre mice and CSDS showed mostly genotype-independent effects. Electrophysiological recordings indicate that MRlox/lox-Nex-Cre mice release less glutamate neurotransmitters in CA3 presynaptic vesicles and have less receptors in the CA1 postsynaptic membrane. The preliminary structural analysis found that the number of dendritic branches of MRlox/lox-Nex-Cre mice is significantly decreased compared to wild-type. Conclusions: MR plays a specific role in regulating anxiety-related behaviour in glutamatergic neurons, while it affects memory function in GABAergic neurons.

FKBP51 in the Oval Bed Nucleus of the Stria Terminalis Regulates Anxiety-Like Behavior.
The cochaperone FKBP51, encoded by the gene, has been identified as central risk factor for anxiety-related disorders and stress system dysregulation. In the brain, the oval bed nucleus of the stria terminalis (ovBNST) has been implicated in stress-induced anxiety. However, the role of in the ovBNST and its impact on anxiety-like behavior have remained unknown. Here, we show in mice that in the ovBNST is reactive to acute stress and coexpressed with the stress-regulated neuropeptides and Subsequently, results obtained from viral-mediated manipulation indicate that overexpression (OE) in the ovBNST results in an anxiolytic-like tendency regarding behavior and endocrinology, whereas a knock-out (KO) exposed a clear anxiogenic phenotype, indicating that native ovBNST expression and regulation is necessary for normal anxiety-related behavior. Notably, our data suggests that a stress-induced increase of in the ovBNST may in fact have a protective role, leading to a transient decrease in anxiety and suppression of a future stress-induced hypothalamic-pituitary-adrenal (HPA) axis activation. Together, our findings provide a first insight into the previously unknown relationship and effects of and the ovBNST on anxiety-like behavior and HPA axis functioning.

Chronic social defeat stress in female mice leads to sex-specific behavioral and neuroendocrine effects.
Over the years, it has become increasingly clear that males and females respond differently towards environmental stressors, highlighting the importance of including both sexes when studying the effects of stress. This study aims to provide further insight into the detailed consequences of exposing female mice to 21 days of chronic social defeat stress (CSDS). We used a protocol that relies on the ability of odorants and pheromones in male urine to trigger male mouse aggressive behavior. Collected male C57Bl/6n urine was applied to female C57Bl/6n mice who were then attacked by a novel male CD1 mouse each day according to the CDSD protocol. Control females were pair-housed and handled daily. Physiological, neuroendocrine and behavioral changes were evaluated during the experiment. CSDS exposure resulted in number of physiological changes, such as body weight gain, enlarged adrenals and reduced thymus weight, exaggerated HPA-axis negative feedback and increased anxiety-like behavior. However, no generalized social avoidance behavior was observed. This study provides important insights in the physiological, neuroendocrine and behavioral responses of female mice to CSDS, which are partially dependent on estrous cycle stage. This protocol will allow direct comparison of male and female responses to CSDS and enable sex-specific study of mechanisms underlying individual stress resilience.Lay summaryIn this study we found that there are differences in the way that female and male mice respond towards chronic social stress conditions when it comes to behavior and hormonal changes.

Study of brain morphology change in Alzheimer's disease and amnestic mild cognitive impairment compared with normal controls.
With an aggravated social ageing level, the number of patients with Alzheimer's disease (AD) is gradually increasing, and mild cognitive impairment (MCI) is considered to be an early form of Alzheimer's disease. How to distinguish diseases in the early stage for the purposes of early diagnosis and treatment is an important topic.

THE ROLE OF ENDGONOUS OPOID SIGNALING IN SOCIAL RECOGNITION

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Here we investigate how endogenous opioid signaling controls social recognition mice. We have used two strains of genetically modified mice with deletion of the genes encoding the two main precursors of endogenous opioid peptides prodynorphin (*Pdyn*) and preproenkephalin (*Penk*). Male and female mice of both strains had no apparent impairments, showed normal activity in the open field test and no change in anxiety-like behaviors. Interestingly, both strains showed normal preference of saccharine-sweetened water, and did not differ in the volume of liquids consumed. The mutations had no appreciable effects on the amount of time spent in interaction in the open field with a novel partner, thus indicating normal social anxiety and/or sociability. However, in the test for social memory, animals lacking the *Penk* gene showed significantly increased social interaction time with a previously encountered partner. Conversely, social memory appeared intact in mice with the *Pdyn* mutation. Taken together, these data replicate some of the previously reported phenotypes in *Penk* and *Pdyn* KO mice, though we would like to note that, contrary to previous findings, no evidence was found for altered-anxiety like behaviors or preference for sweet taste. The potential change in social memory could be in line with the proposed role of opioid signaling in social behaviors, though this requires further validation.

Loss of mu and delta opioid receptors on neurons expressing dopamine receptor D1 has no effect on reward sensitivity. Opioid signaling controls the activity of the brain's reward system. It is involved in signaling the hedonic effects of rewards and has essential roles in reinforcement and motivational processes. Here, we focused on opioid signaling through mu and delta receptors on dopaminoceptive neurons and evaluated the role these receptors play in reward-driven behaviors. We generated a genetically modified mouse with selective double knockdown of mu and delta opioid receptors in neurons expressing dopamine receptor D1. Selective expression of the transgene was confirmed using immunostaining. Knockdown was validated by measuring the effects of selective opioid receptor agonists on neuronal membrane currents using whole-cell patch clamp recordings. We found that in the nucleus accumbens of control mice, the majority of dopamine receptor D1-expressing neurons were sensitive to a mu or delta opioid agonist. In mutant mice, the response to the delta receptor agonist was blocked, while the effects of the mu agonist were strongly attenuated. Behaviorally, the mice had no obvious impairments. The mutation did not affect the sensitivity to the rewarding effects of morphine injections or social contact and had no effect on preference for sweet taste. Knockdown had a moderate effect on motor activity in some of the tests performed, but this effect did not reach statistical significance. Thus, we found that knocking down mu and delta receptors on dopamine receptor D1-expressing cells does not appreciably affect some of the reward-driven behaviors previously attributed to opioid signaling.

Social isolation is classified as a chronic mild stressor, which can lead to the development of neuropsychiatric disorders, including anxiety and depression. Chronic stress can induce activation of neuroinflammatory mediators, being this molecular response also linked with depressive disorders. NLRP3 inflammasome (NLRP3) activation integrates the stress-associated signals and the consequent release of Interleukin-1β. Currently, there is a knowledge gap regarding glial cells and neuroinflammatory alterations induced by social isolation. **Aim:** This work uses a rodent model of isolation to unveil its impact over the neuroinflammatory context, focusing on the NLRP3 pathway. **Methods:** Young and Aged C57BL7/J male mice were divided into 2 groups: group housed (GH) and socially isolated (SI) for 3 weeks. Depression and anxiety were evaluated through Force Swim (FST) and Open Field (OFT) tests, respectively. Morris Water Maze (MWM) was performed to assess spatial memory. In the hippocampus, glial cell reactivity and components of NLRP3 pathway were evaluated by western blotting, while proinflammatory cytokines were quantified by ELISA. **Results:** Aged-SI mice showed a depressive and anxiety-like behaviour during FST and OFT, respectively. Moreover, social isolation induced spatial memory impairment in Aged mice. Microglia activation analyses demonstrated an increase of Iba-1 expression in Aged-SI group and a decrease of anti-inflammatory microglia marker (Ym1) in Young-SI. Also, SI groups had a higher NLRP3 protein expression. Pro-inflammatory cytokines levels were higher in Aged groups. **Conclusions:** Depressive- and anxiety-like behaviour and cognitive impairment were promoted, together with a neuroinflammatory response, by social isolation in Aged mice.

Ex vivo model of epilepsy in organotypic slices-a new tool for drug screening.
Epilepsy is a prevalent neurological disorder worldwide. It is characterized by an enduring predisposition to generate seizures and its development is accompanied by alterations in many cellular processes. Organotypic slice cultures represent a multicellular environment with the potential to assess biological mechanisms, and they are used as a starting point for refining molecules for in vivo studies. Here, we investigated organotypic slice cultures as a model of epilepsy.

HYBRIDIZATION-BASED IN SITU SEQUENCING IN THE NUCLEUS ACCUMBENS REVEALS PERIPUBERTAL STRESS-INDUCED CHANGES IN SEVERAL CELL TYPES

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Laia Morato[1], Dogukan Ulgen[2], Carmen Sandi[3]

Exposure to stress in early life constitutes a crucial risk factor for the development of psychopathologies in adult stages. A peripubertal stress (PPS) paradigm has been established as a mouse model for such stress-induced psychopathologies. To investigate the effect of peripubertal stress on the cells that constitute the nucleus accumbens (NAc) and dorsal striatum (DS), we utilized hybridization-based in situ sequencing (HybISS), a state-of-the-art spatial transcriptomics technique. High resolution of HybISS allowed to check the expression levels of 65 genes in a cell-type specific manner. Stress resulted in a downregulation of several genes involved in NAD^+ metabolism and circadian clock. D2 medium spiny neurons of the NAc showed most of the significant gene expression changes, while transcript levels in cells of the DS remained largely unchanged. Interestingly, overexpression of nicotinamide phosphoribosyltransferase (Nampt), which is reduced by PPS, in the adipose tissue was sufficient to revert some of the stress-associated changes in the NAc. Hence, this study identifies PPS-associated changes in the cells of the NAc and unveils a link between the adipose tissue regulation and stress.

THE ROLE OF PTH2 NEUROPEPTIDE IN THE CONTROL OF SOCIAL BEHAVIOUR – A STUDY USING PTH2 RECEPTOR KO MICE

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Nikolett Arrasz[1], Árpád Dobolyi[1,2]
[1]Eötvös Loránd Research Network and Eötvös Loránd University, Department Of Physiology And Neurobiology, Budapest, Hungary, [2]Eötvös Loránd University, Department Of Physiology And Neurobiology, Budapest, Hungary

Social behaviour is important to reproduce and survive in rodents as well as human. The role of parathormon 2 neuropeptide (PTH2) in the recognition of conspecifics was recently proven in zebrafish (Anneser et al., 2020, Nature). Here, we aim to demonstrate the role of the TIP39-PTH2R neuromodulator system in rodent social behaviour. Therefore, we compared PTH2R knock-out (KO) mice and wild type (WT) littermates in different tests of sociability. We found significant differences in social novelty preference test. WT mice spent more time with an unfamiliar mouse than their cagemates. This expected behaviour disappeared in KO mice. Furthermore, KO mice has an increased latency of sniffing in social environment, an introductory behaviour between mice. In turn, there was no detectable difference between WT and KO mice in the elevated plus maze test. Using c-Fos immunohistochemistry, we found a reduced number of activated cells in KO compared to WT mice in medial prefrontal cortex, in the ventral part of the lateral septum and in the medial preoptic area, which regions are known to be connected to social behaviour. These data suggest that TIP39 contribute to the neuronal activation in these brain regions via the PTH2R. In conclusion, TIP39 may be involved in the control of some aspects of social behaviours. The brain regions with reduced social activation in the absence of PTH2R are likely to be involved in the social brain network affected by TIP39. Developmental exposure to pesticides such as chlorpyrifos (CPF), has been shown to cause adverse effects. Although, the EU has banned the use of CPF since 2020, it is still in use in several developing countries. The massive use of CPF in the lasts years had been linked to the increased prevalence of Autism Spectrum Disorder (ASD). A growing body of literature, hypothesizes that excitatory and inhibitory (E/I) neurotransmitters imbalance are present in autism patients. For this reason, the aims of this study are to assess autistic-like behaviors and to identify associations between autism, apoE genotype and CPF exposure, in both sexes. C57BL/6 and humanized apoE3 and apoE4 homozygous mice were exposed to 0 or 1 mg/kg/day of CPF through the diet, between gestational day (GD) 12 and 18. Moreover, as a positive control of autism, C57BL/6 were exposed to 300 mg/kg/day of valproic acid (VPA) on GD 12 and 13 by a subcutaneous injection. During adolescence, social behaviors were assessed by a Three-chamber test. Then, at postnatal day (PND) 46 mice were sacrificed and hippocampal samples were collected to study gene expression related to GABA and glutamate signaling. Results showed a general preference for the social stimulus, even thought, social memory was altered in treated C57BL/6 male mice, as well as apoE3 and apoE4 CPF-treated females. Regarding molecular pathway, CPF increase GABA expression in females, whereas in males, pesticide increase glutamate expression, generating an E/I imbalance. Thus, our finding suggests that CPF could modulate social behaviors according to genotype and sex.

The core symptoms of many neurological disorders have traditionally been thought to be caused by genetic variants affecting brain development and function. However, the gut microbiome, another important source of variation, can also influence specific behaviors. Thus, it is critical to unravel the contributions of host genetic variation, the microbiome, and their interactions to complex behaviors. Unexpectedly, we discovered that different maladaptive behaviors are interdependently regulated by the microbiome and host genes in the *Cntnap2*$^{-/-}$ model for neurodevelopmental disorders. The hyperactivity phenotype of *Cntnap2*$^{-/-}$ mice is caused by host genetics, whereas the social behavior phenotype is mediated by the gut microbiome. Interestingly, specific microbial intervention with *Lactobacillus (L.) reuteri* selectively rescued the social deficits in *Cntnap2*$^{-/-}$mice through upregulation of metabolites in the tetrahydrobiopterin synthesis pathway. Our findings that behavioral abnormalities could have distinct origins (host genetic vs microbial) may change the way we think about neurological disorders and how to treat them.

Activation of the ISR mediates the behavioral and neurophysiological abnormalities in Down syndrome.
Down syndrome (DS) is the most common genetic cause of intellectual disability. Protein homeostasis is essential for normal brain function, but little is known about its role in DS pathophysiology. In this study, we found that the integrated stress response (ISR)-a signaling network that maintains proteostasis-was activated in the brains of DS mice and individuals with DS, reprogramming translation. Genetic and pharmacological suppression of the ISR, by inhibiting the ISR-inducing double-stranded RNA-activated protein kinase or boosting the function of the eukaryotic translation initiation factor eIF2-eIF2B complex, reversed the changes in translation and inhibitory synaptic transmission and rescued the synaptic plasticity and long-term memory deficits in DS mice. Thus, the ISR plays a crucial role in DS, which suggests that tuning of the ISR may provide a promising therapeutic intervention.

Mechanisms Underlying Microbial-Mediated Changes in Social Behavior in Mouse Models of Autism Spectrum Disorder.
Currently, there are no medications that effectively treat the core symptoms of Autism Spectrum Disorder (ASD). We recently

found that the bacterial species Lactobacillus (L.) reuteri reverses social deficits in maternal high-fat-diet offspring. However, whether the effect of L. reuteri on social behavior is generalizable to other ASD models and its mechanism(s) of action remains unknown. Here, we found that treatment with L. reuteri selectively rescues social deficits in genetic, environmental, and idiopathic ASD models. Interestingly, the effects of L. reuteri on social behavior are not mediated by restoring the composition of the host's gut microbiome, which is altered in all of these ASD models. Instead, L. reuteri acts in a vagus nerve-dependent manner and rescues social interaction-induced synaptic plasticity in the ventral tegmental area of ASD mice, but not in oxytocin receptor-deficient mice. Collectively, treatment with L. reuteri emerges as promising non-invasive microbial-based avenue to combat ASD-related social dysfunction.

Gut Bacteria Seize Control of the Brain to Prevent Epilepsy.
Why ketogenic diet (KD) effectively controls seizures in some people with epilepsy is unclear. In a recent issue of Cell, Olson et al. (2018) showed that KD prevents seizures by upregulating key bacterial species (Akkermansia muciniphila and Parabacteroides merdae). These bacteria synergize to decrease gammaglutamylation of amino acids, increase hippocampal GABA/Glutamate ratios, and, ultimately, prevent seizures.

In humans, adolescence is characterized by complex changes is social behaviors, among them a decrease in affect experienced when interacting with family members. Here, we test whether similar phenotypic changes occur in mice. To model the behavior we have used the social conditioned place preference task, where interaction with siblings causes an increase in the time spent in a previously neutral context. We found that pre-adolescent male C57BL/6 mice (i.e., 33 to 34 days) acquired a robust preference for the context paired with the social contact, however, the preference was significantly decreased in adolescent animals (35-40 days), and then again rose upon reaching sexual maturity (41-42 days). To test if the decrease in preference was specific to social reward, mice of corresponding age were tested for cocaine-induced place preference and opposite effects were observed, with highest mean preference observed in mice aged 35 to 37 days. Next, we tested the hypothesis that endogenous opioids are essential in signaling social reward in adolescence. We found that cyprodime, a selective mu opioid receptor antagonist, administered 1h before the post-test (1 mg/kg i.p.), restored the preference for socially conditioned context during the early-adolescent drop in rewarding effects of social interactions. Taken together, these data show an interesting parallel in the developmental changes of sensitivity to social reward in humans and mice during adolescence. Furthermore, the results reveal specific involvement of mu opioid receptors in the expression of social-conditioned behaviors during early adolescence.

DEVELOPMENT OF A NOVEL BEHAVIORAL FRAMEWORK TO STUDY SOCIAL MOTIVATION NEUROBIOLOGY IN MICE

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Bastien Redon, Benoît Girard, Camilla Bellone
Université de Genève, Département Des Neurosciences Fondamentales, Genève, Switzerland

Social behaviors are crucial for one's environmental fitness, and alterations of social interactions are observed in psychiatric disorders. Despite intense research in social neurosciences, the neurobiology underlying social interactions, and their pathological impairments are loosely described. Social motivation is a crucial component of conspecific interactions and refers to the need to interact with others. Recently, a growing body of evidence substantiated theories linking impairments in social motivation with psychiatric disorders such as autism. Research on the neurophysiological mechanisms underlying motivation in general has been a hot topic for decades, leading to the discovery of the major involvement of the mesolimbic dopaminergic system. However, *the neurobiological ground specifically underlying social motivation, namely which brain processes drive animals to engage socially, and its impairments in psychiatric disorders, remains elusive.* Several factors can explain this gap in knowledge among which (i) the absence of a unified framework to study social motivation, and (ii) therefore an incomplete description of its neurobiology. ***The main aim of our work was to address these shortcomings and pursue the characterization of the neurobiology underlying social motivation*** through (i) the development of a novel behavioral paradigm suitable to dissect social motivation feature allowing (ii) the characterization of the underlying neurocircuit using cutting-edge genetic and molecular tools, and also (iii) to evaluate the face validity of current animal models of neuropsychiatric disorders.

Subcellular specificity of cannabinoid effects in striatonigral circuits.
Recent advances in neuroscience have positioned brain circuits as key units in controlling behavior, implying that their positive or negative modulation necessarily leads to specific behavioral outcomes. However, emerging evidence suggests that the activation or inhibition of specific brain circuits can actually produce multimodal behavioral outcomes. This study shows that activation of a receptor at different subcellular locations in the same neuronal circuit can determine distinct behaviors. Pharmacological activation of type 1 cannabinoid (CB) receptors in the striatonigral circuit elicits both antinociception and catalepsy in mice. The decrease in nociception depends on the activation of plasma membrane-residing CB receptors (pmCB), leading to the inhibition of cytosolic PKA activity and substance P release. By contrast, mitochondrial-associated CB receptors (mtCB) located at the same terminals mediate cannabinoid-induced catalepsy through the decrease in intra-mitochondrial PKA-dependent cellular respiration and synaptic transmission. Thus, subcellular-specific CB receptor signaling within striatonigral circuits determines multimodal control of behavior.

Exercise craving potentiates excitatory inputs to ventral tegmental area dopaminergic neurons.
Physical exercise, which can be addictogenic on its own, is considered a therapeutic alternative for drug craving. Exercise might thus share with drugs the ability to strengthen excitatory synapses onto ventral tegmental area (VTA) dopaminergic neurones, as assessed by the ratio of AMPA receptor (AMPAR)-mediated excitatory postsynaptic currents (EPSCs) to NMDA receptor (NMDAR)-mediated EPSCs. As did acute cocaine, amphetamine, or Δ -tetrahydrocannabinol (THC) pretreatments, an acute 1-h wheel-running session increased the AMPAR/NMDAR ratio in VTA dopaminergic neurones. To dissect the respective influences of wheel-running seeking and performance, mice went through an operant protocol wherein wheel-running was conditioned by nose poking under fixed ratio schedules of reinforcement. Conditioned wheel-running increased

the AMPAR/NMDAR ratio to a higher extent than free wheel-running, doing so although running performance was lower in the former paradigm than in the latter. Thus, the cue-reward association, rather than reward consumption, played a major role in this increase. The AMPAR/NMDAR ratio returned to baseline levels in mice that had extinguished the cued-running motivated task, but it increased after a cue-induced reinstatement session. The amplitude of this increase correlated with the intensity of exercise craving, as assessed by individual nose poke scores. Finally, cue-induced reinstatement of running seeking proved insensitive to acute cocaine or THC pretreatments. Our study reveals for the first time that the drive for exercise bears synaptic influences on VTA dopaminergic neurones which are reminiscent of drug actions. Whether these influences play a role in the therapeutic effects of exercise in human drug craving remains to be established.

Cannabis and exercise: Effects of Δ-tetrahydrocannabinol on preference and motivation for wheel-running in mice.
Recent surveys have revealed close links between cannabis and exercise. Specifically, cannabis usage before and/or after exercise is an increasingly common habit primarily aimed at boosting exercise pleasure, motivation, and performance whilst facilitating post-exercise recovery. However, whether these beliefs reflect the true impact of cannabis on these aspects of exercise is unknown. This study has thus examined the effects of cannabis' main psychoactive ingredient, namely Δ-tetrahydrocannabinol (THC), on (i) mouse wheel-running preference and performance and (ii) running motivation and seeking behaviour. Wheel-running preference and performance were investigated using a T-maze with free and locked wheels located at the extremity of either arm. Running motivation and seeking were assessed by a cued-running operant task wherein wheel-running was conditioned by nose poking. Moreover, because THC targets cannabinoid type 1 (CB) receptors, i.e. receptors previously documented to control running motivation, this study also assessed the role of these receptors in running preference, performance, and craving-like behaviour. Whilst acute blockade or genetic deletion of CB receptors decreased running preference and performance in the T-maze, THC proved ineffective on either variable. The failure of THC to affect running variables in the T-maze extended to running motivation, as assessed by cued-running under a progressive ratio (PR) reinforcement schedule. This ineffectiveness of THC was not related to the treatment protocol because it successfully increased motivation for palatable food. Although craving-like behaviour, as indexed by a cue-induced reinstatement of running seeking, was found to depend on CB receptors, THC again proved ineffective. Neither running motivation nor running seeking were affected when CB receptors were further stimulated by increasing the levels of the endocannabinoid 2-arachidonoylglycerol. These results, which suggest that the drive for running is insensitive to the acute stimulation of CB receptors, raise the hypothesis that cannabis is devoid of effect on exercise motivation. Future investigation using chronic administration of THC, with and without other cannabis ingredients (e.g. cannabidiol), is however required before conclusions can be drawn.

The ergogenic impact of the glucocorticoid prednisolone does not translate into increased running motivation in mice.
Glucocorticoids, such as prednisolone, are considered sport doping agents owing to their ergogenic properties. These are accounted for by peripheral mechanisms associated with energetic and anti-inflammatory processes. However, because glucocorticoids target brain tissues, it is likely that these ergogenic impacts are associated with central effects. One of these might be reward motivation, which relies on glucocorticoid receptor-expressing mesocorticolimbic dopaminergic neurons. In keeping with this possibility, this study has explored in mice whether repeated prednisolone administration (5 or 15 µg/ml of drinking water for 10 days) affected intrinsic motivation for running, a strong reinforcer in rodents. Running motivation was assessed by means of a cued-reward motivated instrumental task wherein wheel-running was conditioned by prior nose poke responses under fixed (FR), and then progressive (PR), ratio reinforcement schedules. Sub-chronic ingestion of prednisolone decreased the running distance covered during each rewarded sequence under FR schedules. This finding did not extend to wheel-running performances in mice provided free (i.e. unconditioned) wheel-running opportunities. Running motivation, as estimated under a PR reinforcement schedule, was found to be decreased (lowest concentration) or to remain unaffected (highest concentration) by prednisolone concentration. Lastly, an inter-individual analysis of the respective effects of prednisolone on muscular endurance (as assessed in the wire grid-hanging test) and on running motivation indicated that the former was not predictive of the latter. This observation suggests that prednisolone ergogenic impacts might occur without any concomitant increase in intrinsic exercise motivation.

An Operant Conditioning Task to Assess the Choice between Wheel Running and Palatable Food in Mice.
Wheel running, especially in the homecage, has been widely used to study the neurobiology of exercise because animal tends to use it voluntarily. However, as for each reward, its consumption (in the present case, running performance) does not specifically provide information on its incentive value, , the extent to which animals are motivated to run independently from

their consumption of that reward. This is a major drawback, especially when focusing on the neurobiology governing the pathological imbalances between exercise and , feeding (obesity, anorexia nervosa). Yet, few studies have shown that operant conditioning wherein wheel-running is used as a reinforcer that can be "consumed" after nose-poking or lever-pressing allows to distinguish motivation from consumption. Thus, nose-poking or lever-pressing under a progressive ratio schedule of reinforcement in animals trained under fixed ratio reinforcement schedules provides, through the so-called breakpoint, an index of running motivation. As compared to wheel-running, numerous studies have used food as a reinforcer, which helped to uncover the neurobiology of feeding. However, to our knowledge, there is no paradigm allowing the assessment of the choice between running and feeding when presented in concurrence, with the possibility to measure the motivation for each reward. Herein, we describe a protocol that first permits to measure the drive for each of these two rewards before it allows to measure the preference for one over the other in a reward choice setting. This paradigm could help to better characterize the neurobiology underlying pathological imbalances between physical activity and feeding, which is the core feature of eating disorders.

Beyond the Activity-Based Anorexia Model: Reinforcing Values of Exercise and Feeding Examined in Stressed Adolescent Male and Female Mice.
Anorexia nervosa (AN), mostly observed in female adolescents, is the most fatal mental illness. Its core is a motivational imbalance between exercise and feeding in favor of the former. The most privileged animal model of AN is the "activity-based anorexia" (ABA) model wherein partly starved rodents housed with running wheels exercise at the expense of feeding. However, the ABA model bears face and construct validity limits, including its inability to specifically assess running motivation and feeding motivation. As infant/adolescent trauma is a precipitating factor in AN, this study first analyzed post-weaning isolation rearing (PWIR) impacts on body weights and wheel-running performances in female mice exposed to an ABA protocol. Next, we studied through operant conditioning protocols i) whether food restriction affects in a sex-dependent manner running motivation before ii) investigating how PWIR and sex affect running and feeding drives under fed conditions and food restriction. Besides amplifying ABA-elicited body weight reductions, PWIR stimulated wheel-running activities in anticipation of feeding in female mice, suggesting increased running motivation. To confirm this hypothesis, we used a cued-reward motivated instrumental task wherein wheel-running was conditioned by prior nose poke responses. It was first observed that food restriction increased running motivation in male, but not female, mice. When fed grouped and PWIR mice were tested for their running and palatable feeding drives, all mice, excepted PWIR males, displayed increased nose poke responses for running over feeding. This was true when rewards were proposed alone or within a concurrent test. The increased preference for running over feeding in fed females did not extend to running performances (time, distance) during each rewarded sequence, confirming that motivation for, and performance during, running are independent entities. With food restriction, mice displayed a sex-independent increase in their preference for feeding over running in both group-housed and PWIR conditions. This study shows that the ABA model does not specifically capture running and feeding drives, i.e. components known to be affected in AN.

The motivation for exercise over palatable food is dictated by cannabinoid type-1 receptors.
The lack of intrinsic motivation to engage in, and adhere to, physical exercise has major health consequences. However, the neurobiological bases of exercise motivation are still unknown. This study aimed at examining whether the endocannabinoid system (ECS) is involved in this process. To do so, we developed an operant conditioning paradigm wherein mice unlocked a running wheel with nose pokes. Using pharmacological tools and conditional mutants for cannabinoid type-1 (CB1) receptors, we provide evidence that CB1 receptors located on GABAergic neurons are both necessary and sufficient to positively control running motivation. Conversely, this receptor population proved dispensable for the modulation of running duration per rewarded sequence. Although the ECS mediated the motivation for another reward, namely palatable food, such a regulation was independent from CB1 receptors on GABAergic neurons. In addition, we report that the lack of CB1 receptors on GABAergic neurons decreases the preference for running over palatable food when mice were proposed an exclusive choice between the two rewards. Beyond providing a paradigm that enables motivation processes for exercise to be dissected either singly or in concurrence, this study is the first to our knowledge to identify a neurobiological mechanism that might contribute to sedentary behavior.

Hippocampal CB Receptors Control Incidental Associations.

By priming brain circuits, associations between low-salience stimuli often guide future behavioral choices through a process known as mediated or inferred learning. However, the precise neurobiological mechanisms of these incidental associations are largely unknown. Using sensory preconditioning procedures, we show that type 1 cannabinoid receptors (CBR) in hippocampal GABAergic neurons are necessary and sufficient for mediated but not direct learning. Deletion and re-expression of CBR in hippocampal GABAergic neurons abolishes and rescues mediated learning, respectively. Interestingly, paired presentations of low-salience sensory cues induce a specific protein synthesis-dependent enhancement of hippocampal CBR expression and facilitate long-term synaptic plasticity at inhibitory synapses. CBR blockade or chemogenetic manipulations of hippocampal GABAergic neurons upon preconditioning affect incidental associations, as revealed by impaired mediated learning. Thus, CBR-dependent control of inhibitory hippocampal neurotransmission mediates incidental associations, allowing future associative inference, a fundamental process for everyday life, which is altered in major neuropsychiatric diseases. VIDEO ABSTRACT.

Pregnenolone blocks cannabinoid-induced acute psychotic-like states in mice.

Cannabis-induced acute psychotic-like states (CIAPS) represent a growing health issue, but their underlying neurobiological mechanisms are poorly understood. The use of antipsychotics and benzodiazepines against CIAPS is limited by side effects and/or by their ability to tackle only certain aspects of psychosis. Thus, safer wide-spectrum treatments are currently needed. Although the blockade of cannabinoid type-1 receptor (CB1) had been suggested as a therapeutical means against CIAPS, the use of orthosteric CB1 receptor full antagonists is strongly limited by undesired side effects and low efficacy. The neurosteroid pregnenolone has been recently shown to act as a potent endogenous allosteric signal-specific inhibitor of CB1 receptors. Thus, we tested in mice the potential therapeutic use of pregnenolone against acute psychotic-like effects of Δ-tetrahydrocannabinol (THC), the main psychoactive component of cannabis. We found that pregnenolone blocks a wide spectrum of THC-induced endophenotypes typically associated with psychotic-like states, including impairments in cognitive functions, somatosensory gating and social interaction. In order to capture THC-induced positive psychotic-like symptoms (e.g. perceptual delusions), we adapted a behavioral paradigm based on associations between different sensory modalities and selective devaluation, allowing the measurement of mental sensory representations in mice. Acting at hippocampal CB1 receptors, THC impaired the correct processing of mental sensory representations (reality testing) in an antipsychotic- and pregnenolone-sensitive manner. Overall, this work reveals that signal-specific inhibitors mimicking pregnenolone effects can be considered as promising new therapeutic tools to treat CIAPS.

SOCIAL INTERACTION MODULATES NOXIOUS THRESHOLDS IN ZEBRAFISH

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Alizee Kastler, Elena Dreosti
University College London, Wolfson Institute For Biomedical Research, London, United Kingdom

We cope better when we are not alone. Supportive social environments are known to have an analgesic effect, significantly reducing our perception of pain. Functional and anatomical studies in humans have indicated that the nociceptive and social circuits share overlapping areas of activity in the brain. However, the underlying circuitry as well as its molecular mechanisms are poorly understood. To better understand how pain and social circuits can modulate one another, we study juvenile zebrafish. An ideal model for this study, zebrafish are highly social, show stereotyped responses to noxious stimuli, and allow whole brain imaging with single cell resolution. We developed a new behavioural assay where fish are exposed to both social and noxious heat stimuli simultaneously. This assay has provided evidence that the mere sight of other, conspecific zebrafish is enough to increase heat tolerance, strongly suggesting the presence of a descending pain modulatory pathway that is activated by social context, similar to humans. Several genes of the descending pathway have already been identified in humans and other animal models. However, they have only been characterised individually, limiting our understanding of their functional role. Zebrafish offer the unique advantage of studying the system as a whole. By using a combination of anatomical, functional and pharmacological tools, we aim to identify key brain areas and genes involved in modulating pain responses.

CHARACTERIZATION OF PARENTAL CAREGIVING OF SICK OFFSPRING IN MICE

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Asha Caslin[1], Kioni Marshall[2], Luisa Schuster[1], Robert Froemke[3,4]
[1]NYU School of Medicine, Neuroscience & Physiology, NEW YORK, United States of America, [2]Wesleyan University, Neuroscience, Middletown, United States of America, [3]NYU Grossman School of Medicine, Skirball/Neuroscience Institutes, Departments Of Otolaryngology/neuroscience And Physiology, New York, United States of America, [4]New York University School of Medicine, Skirball Institute, New York, United States of America

Most organisms respond to infection and injury with physiological changes and an array of recovery-focused 'sickness behaviors' which include fatigue, appetite loss, and altered social behavior. These behaviors may thus act as social signals allowing for detection and response to sickness. While most investigations of inflammatory-induced sickness focus on social withdrawal and avoidance behaviors, there is evidence that sickness can instead promote familiarity-dependent prosociality. **Aims**
Here we identify how a mouse dam responds with directed caregiving and maternal behaviors toward sick juvenile offspring. We further test whether dams display a preference for sick vs. healthy offspring. **Methods**
Using a multi-camera longitudinal behavioral monitoring system coupled with semi-automated analysis of spontaneous behaviors, we characterized and compared maternal and caregiving behaviors of a mouse dam toward juvenile offspring injected with lipopolysaccharides (LPS) vs. saline controls over the course of 48-hours. Behaviors of interest included pup retrieval, nursing, grooming, nestbuilding, sniffing, huddling, and allo-grooming. Dams were also tested in a social preference assay and time spent in a chamber with LPS- vs. saline-injected offspring and non-offspring was measured. **Results**
Our results show that dams display increased approach and huddling behavior toward LPS-injected offspring vs. saline controls over the course of 48 hours. Dams also spend more time in the chamber with LPS-injected offspring than saline-injected offspring in the social preference test. We do not see this effect with non-offspring. **Conclusion**
These data indicate that dams exhibit increased caregiving behavior toward sick vs. healthy offspring and display a familiarity-dependent preference toward sick juveniles.

DL-3-n-butylphthalide induced neuroprotection, regenerative repair, functional recovery and psychological benefits following traumatic brain injury in mice.
Previous investigations suggest that DL-3-n-butylphthalide (NBP) is a promising multifaceted drug for the treatment of stroke. It is not clear whether NBP can treat traumatic brain injury (TBI) and what could be the mechanisms of therapeutic benefits. To address these issues, TBI was induced by a controlled cortical impact in adult male mice. NBP (100 mg/kg) or saline was intraperitoneally administered within 5 min after TBI. One day after TBI, apoptotic events including caspase-3/9 activation, cytochrome c release from the mitochondria, and apoptosis-inducing factor (AIF) translocation into the nucleus in the pericontusion region were attenuated in NBP-treated mice compared to TBI-saline controls. In the assessment of the nuclear factor kappa-light-chain-enhancer of activated B (NF-κB) pathway, NBP ameliorated the p65 expression and the p-IκB-α/IκB-α ratio, indicating reduced NF-κB activation. Consistently, NBP reduced the upregulation of proinflammatory cytokines such as tumor necrotizing factor-alpha (TNF-α) and interleukin-1beta (IL-1β) after TBI. In sub-acute treatment experiments, NBP was intranasally delivered once daily for 3 days. At 3 days after TBI, this repeated NBP treatment significantly reduced the contusion volume and cell death in the pericontusion region. In chronic experiments up to 21 days after TBI, continues daily intranasal NBP treatment increased neurogenesis, angiogenesis, and arteriogenesis in the post-TBI brain, accompanied with upregulations of regenerative genes including brain-derived neurotrophic factor (BDNF), vascular endothelial growth factor (VEGF), endothelial-derived nitric oxide synthase (eNOS), and matrix metallopeptidase 9 (MMP-9). The NBP treatment significantly improved sensorimotor functional recovery and reduced post-TBP depressive behavior. These new findings demonstrate that NBP shows multiple therapeutic benefits after TBI.

EXPOSURE TO AIR POLLUTION NANOPARTICLES: DEPRESSIVE-LIKE BEHAVIORS, LEARNING AND MEMORY IMPAIRMENT AND ALTERS OF HIPPOCAMPAL CYTOKINES EXPRESSION

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Mojtaba Ehsanifar
Kashan University of Medical Science, Anatomical Science Research Center, Kashan, Iran

Air pollution particulate matter (PM) is a world risk factor that the effects of long-term exposure to these factors in terms of damage to cardiovascular and pulmonary function are well known, but little is known comparatively about the effects of PM on emotional and cognitive processes. Exposure to ultrafine particulate matter (UFPs<100 nm (PM0.1)), can be adversely impacted the central nervous system (CNS) by the activation of proinflammatory pathways and reactive oxygen species associated with air pollution particulate matter. Therefore, we investigated whether prolonged exposure to diesel exhaust particles (DEPs) affects hippocampal inflammatory cytokines, emotional responses, learning and memory, cognition, and neuronal morphology. Male mice were DEPs exposed for 6 and 14 weeks. Mice exposed to DEPs showed more disorders in spatial memory and learning and depressive-like responses than control mice. Expression of hippocampal pro-inflammatory cytokine was increased among DEPs exposure mice. The density of neurons in hippocampus CA1, CA3, and dentate gyrus (DG) regions decreased in DEPs mice, respectively. Overall, these findings show that prolonged exposure to DEPs in the world's major cities can alter behavior and impair cognition. **Keywords:** Depression; Air pollution Nano-particles; Learning and Memory Neuroinflammation; Hippocampal morphology

Airborne aerosols particles and COVID-19 transition.
With the outbreak of Coronavirus (2019) (COVID-19), as of late March 2020, understanding how the cause of Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) transmitted is one of the most important questions that researchers are seeking to answer; because this effort helps to reduce the spread of disease. The COVID-19 is highly transmissible and deadly. Despite "tracking the call" and carefully examining patient contact, it is not yet clear how the virus is transmitted from one sick person to another. Why it is so transmissible? Can viruses be transmitted through speech and exhalation aerosols? How far can these aerosols go? How long can an aerosol containing a virus stay in the air? Is the virus amount in these aerosols enough to lead to an infection? There is no consensus on aerosols' role in the transmission of SARS-CoV-2. Findings show that SARS-CoV-2 aerosol transmission is possible. Therefore, to effectively reduce SARS-CoV-2, precautionary control strategies for aerosol transfer should be considered. Our aim is to review the evidence of the aerosol transmission containing SARS-CoV-2.

Investigation of metabolic kinetics in different brain regions of awake rats using the [H-C]-NMR technique.
Energy metabolism and neurotransmission are necessary for sustaining normal life activities. Hence, neurological or psychiatric disorders are always associated with changes in neurotransmitters and energy metabolic states in the brain. Most studies have only focused on the most important neurotransmitters, particularly GABA and Glu, however, other metabolites such as NAA and aspartate which are also very important for cerebral function are rarely investigated. In this study, most of the metabolic kinetics information of different brain regions was investigated in awake rats using the [H-C]-NMR technique. Briefly, rats (n = 8) were infused [1-C] glucose through the tail vein for two minutes. After 20 min of glucose metabolism, the animals were sacrificed and the brain tissue was extracted and treated. Utilizing the H observed/C-edited nuclear magnetic resonance (POCE-NMR), the enrichment of neurochemicals was detected which reflected the metabolic changes in different brain regions and the metabolic connections between neurons and glial cells in the brain. The results suggest that the distribution of every metabolite differed from every brain region and the metabolic rate of NAA was relatively low at 8.64 ± 2.37 μmol/g/h. In addition, there were some correlations between several C enriched metabolites, such as Glu-Gln ($p = 0.062$), Glu-GABA ($p < 0.01$), Glx-Glx ($p < 0.001$), Asp-NAA ($p < 0.001$). This correlativity reflects the signal transmission

between astrocytes and neurons, as well as the potential interaction between energy metabolism and neurotransmission. In conclusion, the current study systematically demonstrated the metabolic kinetics in the brain which shed light on brain functions and the mechanisms of various pathophysiological states.

Learning and memory disorders related to hippocampal inflammation following exposure to air pollution.
It has been demonstrated that sub-chronic exposure to air pollution containing nanoscale (<100 nm) diesel exhaust particles (DEPs) may lead to excessive oxidative stress and neuro-inflammation in adult male mice. Hereby, we investigated the effects of DEPs on hippocampus-dependent spatial learning and neuro-inflammation and memory-related gene expression in male mice. In this study, we divided 48 adult NMRI male mice into control group VS. three exposure groups. Mice were exposed to 300-350 μg/m DEPs for 2, 5, and 7 h daily for 12 weeks. The Morris Water Maze (MWM) and Elevated Plus Maze device were used to examine anxiety, spatial memory and learning, respectively. The mRNAs expression of pro-inflammatory cytokines, N-methyl-D-aspartate (NMDA) receptor subunits, and glutaminase were studied in hippocampus (HI) by real-time RT-PCR. Besides, malondialdehyde (MDA) tests were used to determine the state of oxidative stress. After 5 and 7 h. of DEPs exposure, mRNA expression of NR2A and NR3B IL1α, IL1β, TNFα, NMDA receptor subunits and MDA levels increased significantly (< 0.05). Also, DEPs exposed mice for 2, 5, and 7 h. showed diminished entrance into open arms with short time spent there. Indeed, 5 and 7 h/day exposed mice required a longer time to reach the hidden platform. Sub-chronic exposure to DEPs increased oxidative stress markers, neuroinflammation, anxiety, impaired spatial learning and memory.

Hippocampal inflammation and oxidative stress following exposure to diesel exhaust nanoparticles in male and female mice.
Air pollution exposure is among the most prevalent reasons for environmentally-induced oxidative stress and inflammation, both of which are involved in the development and progression of central nervous system (CNS) diseases. Ultrafine particles (UFPs) plays an important role in global air pollution and the diesel exhaust particles (DEPs) are the most important component in this regard. There are more than 40 toxic air pollutants in diesel exhaust (DE), which is one of the main constituents of an environmental pollutant and including particulate matter (PM) especially UFPs. Thus, in this study, adult female and male NMRI mice were exposed to DEPs (350-400 μg/m) for 14 weeks (6 h per day and 5 days per week). After 14 weeks of exposure, expression of pro-inflammatory cytokines (IL-1α, IL-1β, IL-6, TNF-α), nNOS, HO1, NR2A, and NR2B and malondialdehyde (MDA) level were analyzed in various brain regions such as the hippocampus (HI) and olfactory bulb (OB). Exposure to DEPs caused neuroinflammation and oxidative stress in female and male mice. That these effects observed in females were less pronounced than in male mice. The male mice emerged to be more susceptible significantly than the female mice to induced neuroinflammation following DEPs exposure. Also, our findings indicate that long term exposure to DEPs results in altered expression of hippocampal NMDA receptor subunits, and suggests that gender can play important role in the modulating susceptibility to neurotoxicity induced by DEPs exposure.

Prenatal exposure to diesel exhaust particles causes anxiety, spatial memory disorders with alters expression of hippocampal pro-inflammatory cytokines and NMDA receptor subunits in adult male mice offspring.
Air pollution by Diesel exhaust (DE) consists of gaseous compounds and diesel exhaust particles (DEPs). Previous studies show associations between prenatal exposure to diesel exhaust affects the central nervous system (CNS). However, there was not reported that these effects were caused by gaseous compounds, diesel exhaust particles, or both. A limited number of studies in rodent models have shown that exposure to DEPs can result in CNS. Here, we explored the effects of prenatal exposure to DEPs on anxiety and learning and memory in NMRI mice male offspring. Three groups of pregnant mice were exposed to 350-400 μg DEPs/m for 2, 4 and 6 h daily in a closed system room. We examined anxiety and learning and memory in 8-to-9-week-old male offspring using the Elevated plus maze and Morris water maze (MWM) test. Hippocampi were isolated after the behavioral tests and measured pro-inflammatory cytokines and N-methyl-D-aspartate (NMDA) receptor expression by quantitative RT-PCR analysis. Mice exposed to DEPs in utero showed deficits in the Elevated plus maze and Morris water maze test. In addition, DEPs exposed mice exhibited decreased hippocampal NR2A and NR3B expression. Taken together, our data suggest that maternal DEP exposure is associated with anxiety, disrupts learning and memory and reduction hippocampal NR2A and NR3B expression in male offspring.

Exposure to nanoscale diesel exhaust particles: Oxidative stress, neuroinflammation, anxiety and depression on adult male mice.
Exposure to nanoscale diesel engines exhausted particles (DEPs) is a well-recognized risk factor for respiratory and

cardiovascular diseases. Rodents as commonly used models for urban air pollution in health effect studies demonstrate constant stimulation of inflammatory responses in the main areas of the brain. Nevertheless, the primary effect of diesel exhaust particulate matter on some of the brain regions and relation by behavioral alterations still remains untouched. We evaluated the brain regional inflammatory responses to a nanosized subfraction of diesel engines exhaust particulate matter (DEPs < 200 nm) in an adult male mice brain. Adult male mice were exposed to DEPs for 3, 6, and 8 h per day, 12 weeks and five days per week. Degree of anxiety and the depression by elevated plus maze and Forced Swimming Test respectively (FST) did measurement. After behavior tests, the plasma and some of the brain regions such as olfactory bulb (OB) and hippocampus (HI) were analyzed for oxidative stress and inflammatory responses. The inflammation and oxidative stress changes in OB and HI, markedly coincides with the results of behavioral alterations. These responses corresponded with rapid induction of MDA and nitrite oxide (NO) in brain regions and neuronal nitric oxide synthase (nNOS) mRNA followed by IL6, IL1α, and TNFα in OB and HI. The different times of DEPs exposure, leads to oxidative stress and inflammatory in plasma and brain regions. That this cumulative transport of inhaled nanoscale DEPs into the brain and creating to inflammation responses of brain regions may cause problems of brain function and anxiety and depression.

EARLY LIFE ADOPTION SHOWS REARING ENVIRONMENT SUPERSEDES TRANSGENERATIONAL EFFECTS OF PATERNAL STRESS ON AGGRESSIVE TEMPERAMENT IN THE OFFSPRING.

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Ipshita Zutshi[1], Sonakshi Gupta[2], Olivia Zanoletti[3], Carmen Sandi[3], Guillaume Poirier[3]
[1]Langone Medical Center, New York University, Neuroscience Institute And Department Of Neurology, New York, United States of America, [2]École normale supérieure (ENS), Paris, Biology Department, Paris, France, [3]Ecole Polytechnique Federale de Lausanne, Brain Mind Institute, Lausanne, Switzerland

Prenatal experience and transgenerational influences are increasingly recognized as critical for defining the socio-emotional system, through the development of social competences and of their underlying neural circuitries. Here, we used an established rat model of social stress resulting from male partner aggression induced by peripubertal (P28-42) exposure to unpredictable fearful experiences. Using this model, we aimed to first, characterize adult emotionality in terms of the breadth of the socio-emotional symptoms and second, to determine the relative impact of prenatal vs postnatal influences. For this purpose, male offspring of pairs comprising a control or a peripubertally stressed male were cross-fostered at birth and tested at adulthood on a series of socio-emotional tests. In the offspring of peripubertally stressed males, the expected antisocial phenotype was observed, as manifested by increased aggression towards a female partner and a threatening intruder, accompanied by lower sociability. This negative outcome was yet accompanied by better social memory as well as enhanced active coping, based on more swimming and longer latency to immobility in the forced swim test, and less immobility in the shock probe test. Furthermore, the cross-fostering manipulation revealed that these adult behaviors were largely influenced by the post- but not the prenatal environment, an observation contrasting with both pre- and postnatal effects on attacks during juvenile play behavior. Adult aggression, other active coping behaviors, and social memory were determined by the predominance at this developmental stage of postnatal over prenatal influences. Together, our data highlight the relative persistence of early life influences.

MITOCHONDRIAL ASTROCYTIC CB1 ARE NECESSARY FOR THE AMNESIC EFFECTS OF SOCIALLY TRANSMITTED STRESS

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Paula Gomez-Sotres[1], Urszula Skupio[2], Astrid Cannich[2], Francisca Julio-Kalajzic[2], Doriane Gisquet[1], Jaideep Bains[3], Giovanni Marsicano[2]
[1]INSERM U1215, Universite de Bordeaux, Neurocentre Magendie, Bordeaux Cedex, France, [2]Inserm U1215, Universite de Bordeaux, Neurocentre Magendie, Bordeaux Cedex, France, [3]University of Calgary, Physiology & Pharmacology, Calgary, Canada

AIMS: Stress impacts cognitive processes like memory. Stress is also transmitted to others, but whether transmitted stress affects memory is not known. Here we explored mechanisms responsible for the detection of stress and then used this information to ask whether transmitted stress affects memory. We focused on olfactory signaling, and specifically, the role of type-1 cannabinoid receptors (CB1R) in astrocytes of the olfactory bulb in these processes. METHODS: We investigated social interactions between a naive observer mouse (OBS) and a stressed demonstrator (DEM) and then assessed memory performance in a novel object recognition (NOR) long-term memory test. We used several conditional mutant lines and viral approaches to understand the contribution of CB1 receptors to this behavior. RESULTS: Here we show that socially-transmitted stress impairs NOR in the OBS mouse, an effect that phenocopies the deficit observed in the stressed DEM. Interestingly, genetic deletion of CB1R in astrocytes decreased time OBS spent exploring the anogenital region of the stressed DEM and did not show any impairment of memory. An identical phenotype was observed in mice expressing a mutated form of the CB1R, which excludes localization in mitochondria. Finally, loss of mtCB1R specifically in olfactory bulb astrocytes produced deficits in anogenital investigation and abolished amnesia in OBS mice. CONCLUSION: These findings indicate that mtCB1Rs in astrocytes of the olfactory bulb are a critical hub for guiding behaviors related to detection of negative affective states and for linking the consequent emotional reciprocity to memory alterations.

RFAMIDE-RELATED PEPTIDE (RFRP) NEURONS DRIVE ANXIETY-LIKE AND DEPRESSION-LIKE BEHAVIOURS IN MALE MICE

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

India Sawyer, Greg Anderson
University of Otago, Centre For Neuroendocrinology And Department Of Anatomy, Dunedin, New Zealand

Activation of RFRP neurons using designer receptors increases corticosterone and central infusion of the peptide RFRP-3 increases anxiety-like behaviours in female mice[1,2]. Additionally, RFRP neurons express glucocorticoid receptors and are activated by stressor exposure and corticosterone[3]. This suggests RFRP neurons are involved in driving various stress responses, and amplifying them following glucocorticoid feedback. This research aimed to elucidate the role of RFRP neurons in anxiety-like and depression-like behaviours in mice. Mice expressing the stimulatory hM3Dq-DREADD receptor in RFRP-Cre neurons, through breeding or viral transfection, were treated with clozapine-n-oxide (CNO; 1-2 mg/kg) before testing in an elevated-plus maze followed by a forced-swim test and one week later before testing in a light-dark box followed by a tail-suspension test. There was a significant ~40% increase in immobility in depressive-like behavioural tests in bred RFRP-Cre-hM3Dq male mice vs control mice ($p<0.05$), whereas in AAV-hM3Dq transfected male mice there was a significant two-fold reduction in open space exploration in the elevated plus maze, showing increased anxiety-like behaviours, vs control mice ($p<0.05$). RFRP neuronal activation did not markedly alter female behaviours. Acute activation of RFRP neurons increases anxiety-like and depressive-like behaviours in male mice, and elicits a corticosterone response, indicating RFRP neurons are involved in the relay of stressor information to both the neuroendocrine and behavioural stress responses. This implicates RFRP neurons as potential therapeutic targets for treating HPA axis dysfunction and mental health disorders. 1 Mamgain et al., 2020, JNeurosci.

RFamide-Related Peptide Neurons Modulate Reproductive Function and Stress Responses.
RF-amide related peptide 3 (RFRP-3) is a neuropeptide thought to inhibit central regulation of fertility. We investigated whether alterations in RFRP neuronal activity led to changes in puberty onset, fertility, and stress responses, including stress and glucocorticoid-induced suppression of pulsatile luteinizing hormone secretion. We first validated a novel RFRP-Cre mouse line, which we then used in combination with Cre-dependent neuronal ablation and DREADD technology to selectively ablate, stimulate, and inhibit RFRP neurons to interrogate their physiological roles in the regulation of fertility and stress responses. Chronic RFRP neuronal activation delayed male puberty onset and female reproductive cycle progression, but RFRP-activated and ablated mice exhibited apparently normal fertility. When subjected to either restraint- or glucocorticoid-induced stress paradigms. However, we observed a critical sex-specific role for RFRP neurons in mediating acute and chronic stress-induced reproductive suppression. Female mice exhibiting RFRP neuron ablation or silencing did not exhibit the stress-induced suppression in pulsatile luteinizing hormone secretion observed in control mice. Furthermore, RFRP neuronal activation markedly stimulated glucocorticoid secretion, demonstrating a feedback loop whereby stressful stimuli activate RFRP neurons, which in turn further activate the stress axis. These data provide evidence for a neuronal link between the stress and reproductive axes.

Aims Autophagy is a catabolic process that degrades damaged macromolecules and organelles to preserve cellular homeostasis. Neuronal autophagy is also crucial during the development of the CNS and its refinement through synaptic pruning. Autophagy is a highly conserved process involving more than thirty autophagy-related (ATG) genes. In humans, ATG mutations and dysregulations of autophagy pathways have been reported in neurodegenerative and neuropsychiatric disorders. Our project aims to explore the role of the IRGM1 protein - involved in autophagy and related to innate immunity - during brain development and function. We thus initiate the study of neurodevelopmental impacts of *Irgm1* invalidation during preweaning stage (see also poster “Ultrasonic vocalization (USV) and social interaction from preweaning up to adult *Irgm1*-ko mice”). **Methods** The study is performed in C57BL/6NCrl *Irgm1*-ko mice (gift from Taylor, Duke University, USA). Sensorimotor battery of tests (surface righting, negative geotaxis, grasping, front-limb suspension, acoustic startle and eyelid opening) are performed between PND4 and PND17. USV are recorded in a maternal separation context at PND9 and analyzed with Avisoft software. **Results** To date, 4 litters of 4 to 9 pups were obtained from HzxHz mattings. Preliminary results indicate no premature death since pups of all genotypes and both sexes survived up two months. Experiments and data analysis are in progress. **Conclusions** Together, these behavioral studies with neurodevelopmental, -histological, -molecular and biochemical studies will be detrimental to evaluate the potential role of Irgm autophagic pathway in brain disorders. The model will subsequently be used for gene x environment interaction studies.

MOTHERHOOD CHANGES THE PROCESSING AND RESPONSE TO SOCIAL CUES OF FEMALE MICE.

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Sandra Sanahuja Irene, Rafael Goterris-Cerisuelo, María De La Cinta Navarro-Moreno, María José Sánchez Catalán, Fernando Martínez-García
Universitat Jaume I, Unitat Predepartamental De Biomedicina, Castelló de la Plana, Spain

Motherhood entails changes in how females detect, process and react to social stimuli. After parturition, the social life of the dam is restricted to maternal care of the offspring and maternal aggression, e.g. furious attacks to adults approaching the nest. Therefore, male-derived pheromones change their significance during motherhood, from attractive to aggression-eliciting. The aim of this work is to understand the neural basis of this change. To do so, we performed two different experiments. First, we exposed virgin and late-pregnant female mice to pups or buttons (control). Second, virgin and postpartum females were exposed to clean or male soiled-bedding. Ninety minutes afterwards, females' brains were processed for immunohistochemistry of cFos, a proxy of neural activity. We quantitatively analysed the pattern of activity in three functional systems in the brain of females: a) nasal chemosensory systems (olfactory and vomeronasal); b) sociosexual brain network; c) brain circuit for motivation. The results indicate important changes in the processing of social cues in all three systems, with sharp differences relative to the activity of the motivation circuitry, which likely reflect hormone-induced changes in salience of the different social cues. Our results reinforce the view that a single neural network governs the expression of different social behaviours, instead of individual linear pathways controlling specific behaviours (maternal, aggressive, sexual, etc). Our data also stress the importance of motivation in the expression of social behaviours, which are also modulated by motherhood hormones. STRAIN AND SEX DIFFERENCES IN ANXIETY AND DEPRESSION-LIKE BEHAVIOR FOLLOWING EXPOSITION TO CHRONIC MILD STRESS IN MICE

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Anzu G. Zevallos-Arias, Carlos Medina-Saldivar, Sergio R. Cruz-Visalaya, Grace E. Pardo, Luis F. Pacheco-Otalora
Universidad Andina del Cusco, Laboratorio De Investigacion En Neurociencias., Cusco, Peru

Stress-related mood disorders such as anxiety and depression are highly prevalent in the population and affect the ability of individuals to function and live a rewarding life. Anxiety and depressive disorders are higher in women, and susceptibility is affected by multiple genetic, environmental stressors, and psychological factors. Research using inbreed mouse strain provides a relatively stable and narrow range of genetic and environmental variability that is valuable for unraveling interactions between genetic and environmental stressors factors. Here, we assess the effects of chronic mild stress (CMS) on anxiety and depressive-like behaviors of males and females of two inbred mice (C57BL/6NCrl and BALB/c) that differ in their sensitivity to stress. While exposure to CMS resulted in a consistent reduction of weight gain of males but not females in C57BL/6NCrl, BALB/c mice of both sexes were little affected at the end of CMS protocol. CMS increased anxiety-like behavior in female but not male BALB/c strain mice with no effect on C57 BL/6NCrl mice of both sexes. Exposure to CMS increased depressive-like behaviors in males but not females of C57BL/6NCrl strain mice. On the contrary, males but not females of the BALB/c strain reduced depressive-like behaviors phenotypes. These findings suggest that C57/6NCrl mice strains are more vulnerable to CMS than BALB/c mice, being male mice more susceptible to CMS than females in terms of the severity of depressive behaviors.

MATERNAL HIGH-FAT DIET-INDUCED MICROBIAL CHANGES ARE ASSOCIATED WITH ALTERED FOETAL BRAIN METABOLOME AND ADOLESCENT BEHAVIOUR

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Anna Ratsika[1,2], Martin Codagnone[1,2], Thomaz Bastiaanssen[1,2], Caoimhe Lynch[1,2], Ana Paula Ventura Silva[1,2], Valentina Caputi[1,2], Christine Fülling[1,2], John Cryan[1,2]
[1]APC Microbiome Ireland, University College Cork, Cork, Ireland, [2]University College Cork, Anatomy And Neuroscience, Cork, Ireland

Maternal overweight and obesity perinatally has been linked to changes in neurodevelopment, plasticity and affective disorders in the offspring, with implications for microbial input from maternal intestines. Here, we investigate how maternal microbial signals imprint foetal brain metabolomics and adolescent behaviour. Adult female C57/Bl6 mice were fed either a control diet (CD: 10% fat) or a high-fat diet (HFD: 60% fat) from 8 weeks prior to mating throughout lactation. Whole brain metabolomic analysis in embryos and maternal caecal microbiota composition were assessed at embryonic day 18 (E18). Locomotor activity and anxiety-like behaviour were assessed in the adolescent offspring. HFD induced weight gain (p=0.0098 HFDvsCD) and altered caecal microbial composition (p=0.0022 HFDvsCD) in dams at E18. Maternal HFD led to upregulation of microbial genes linked to quinolinic acid synthesis (p=0.005 HFDvsCD), a neuroplasticity mediator linked to glutamate metabolism. Metabolomic analysis of embryo brains detected molecules linked to glutamate-glutamine cycle mediated by diet, such as alanine (p=0.0011 HFDvsCD), glutamate (p=0.0029 HFDvsCD) and glutathione disulphide (p=0.0001 HFDvsCD). Pathway enrichment analysis of the differentially abundant metabolites revealed 35 times higher glutamine and glutamate metabolism in the foetal brains than expected (p= 0.00115 HFDvsCD). Female adolescent offspring from HFD-fed dams led to increased locomotor activity (total distance travelled p=0.004 HFDvsCD in open field) and anxiety-like behaviour (p=0.017 HFDvsLFD number of transitions in closed arms of the elevated plus maze). Our results suggest that maternal microbiota-mediated behavioural imprinting in the offspring is sex-specific, and might be linked to altered brain metabolites during critical developmental windows perinatally.

Priming for Life: Early Life Nutrition and the Microbiota-Gut-Brain Axis.
Microbes colonize the human body during the first moments of life and coexist with the host throughout the lifespan. Intestinal microbiota and their metabolites aid in the programming of important bodily systems such as the immune and the central nervous system during critical temporal windows of development, with possible structural and functional implications throughout the lifespan. These critical developmental windows perinatally (during the first 1000 days) are susceptible timepoints for insults that can endure long lasting effects on the microbiota-gut-brain axis. Environmental and parental factors like host genetics, mental health, nutrition, delivery and feeding mode, exposure to antibiotics, immune activation and microbiota composition antenatally, are all factors that are able to modulate the microbiota composition of mother and infant and may thus regulate important bodily functions. Among all these factors, early life nutrition plays a pivotal role in perinatal programming and in the modulation of offspring microbiota from birth throughout lifespan. This review aims to present current data on the impact of early life nutrition and microbiota priming of important bodily systems and all the factors influencing the microbial coexistence with the host during early life development.

Animal models for assessing impact of C-section delivery on biological systems.
There has been a significant increase in Caesarean section (C-section) births worldwide over the past two decades and although it can be a life-saving procedure, the enduring effects on host physiology are now undergoing further scrutiny. Indeed, epidemiological data have linked C-section birth with multiple immune, metabolic and neuropsychiatric diseases. Birth by C-section is known to alter the colonisation of the neonatal gut microbiota (with C-section delivered infants lacking vaginal microbiota associated with passing along the birth canal), which in turn can impact the development and maintenance of many important biological systems. Appropriate animal models are key to disentangling the role of missing microbes in

brain health and disease in C-section births. In this review of preclinical studies, we interrogate the effects of C-section birth on the development (and maintenance) of several biological systems and we discuss the involvement of the gut microbiome on C-section-related alterations.

We previously identified the posterior intralaminar thalamic nucleus (PIL) as a relay station of socially relevant sensory information innervating and activating oxytocin-secreting neurons upon social encounter. Here, we addressed to characterize the exact role of the PIL neurons and their projections to the preoptic area of the hypothalamus in the control of the social behavior. First, we determined the effect of chemogenetic stimulation of PIL neurons on social interactions between familiar adult female rats. The projections of PIL neurons were analyzed using anterograde tract-tracing. The selective chemogenetic stimulation of the preoptic area-projecting PIL neurons was performed using double viral injections and also by CNO administration directly into the preoptic area. PIL projects to several socially implicated brain regions, such as the medial amygdala, the medial preoptic area and the infralimbic cortex. Chemogenetic stimulation of the PIL resulted in the activation of previously anatomically identified target areas and increased the duration of social grooming. Direct contact during social interaction caused the largest increase in the activity in the medial preoptic area. Specific chemogenetic stimulation of the PIL-preoptic pathway led to elevated direct social contact. The results suggest that posterior thalamic PIL neurons convey socially relevant information to a variety of different forebrain centers, among which the preoptic area is involved in the processing of physical contact. Transcriptome Sequencing in the Preoptic Region of Rat Dams Reveals a Role of Androgen Receptor in the Control of Maternal Behavior.
(1) Background: Preoptic region of hypothalamus is responsible to control maternal behavior, which was hypothesized to be associated with gene expressional changes. (2) Methods: Transcriptome sequencing was first applied in the preoptic region of rat dams in comparison to a control group of mothers whose pups were taken away immediately after parturition and did not exhibit caring behavior 10 days later. (3) Results: Differentially expressed genes were found and validated by quantitative RT-PCR, among them NACHT and WD repeat domain containing 1 (Nwd1) is known to control androgen receptor (AR) protein levels. The distribution of Nwd1 mRNA and AR was similar in the preoptic area. Therefore, we focused on this steroid hormone receptor and found its reduced protein level in rat dams. To establish the function of AR in maternal behavior, its antagonist was administered intracerebroventricularly into mother rats and increased pup-directed behavior of the animals. (4) Conclusions: AR levels are suppressed in the preoptic area of mothers possibly mediated by altered Nwd1 expression in order to allow sustained high-level care for the pups. Thus, our study first implicated the AR in the control of maternal behaviors.

Secretion and Function of Pituitary Prolactin in Evolutionary Perspective.
The hypothalamo-pituitary system developed in early vertebrates. Prolactin is an ancient vertebrate hormone released from the pituitary that exerts particularly diverse functions. The purpose of the review is to take a comparative approach in the description of prolactin, its secretion from pituitary lactotrophs, and hormonal functions. Since the reproductive and osmoregulatory roles of prolactin are best established in a variety of species, these functions are the primary subjects of discussion. Different types of prolactin and prolactin receptors developed during vertebrate evolution, which will be described in this review. The signal transduction of prolactin receptors is well conserved among vertebrates enabling us to describe the whole subphylum. Then, the review focuses on the regulation of prolactin release in mammals as we have the most knowledge on this class of vertebrates. Prolactin secretion in response to different reproductive stimuli, such as estrogen-induced release, mating, pregnancy and suckling is detailed. Reproduction in birds is different from that in mammals in several aspects. Prolactin is released during incubation in avian species whose regulation and functional significance are discussed. Little information is available on prolactin in reptiles and amphibians; therefore, they are mentioned only in specific cases to explain certain evolutionary aspects. In turn, the osmoregulatory function of prolactin is well established in fish. The different types of pituitary prolactin in fish play particularly important roles in the adaptation of eutherian species to fresh water environments. To achieve this function, prolactin is released from lactotrophs in hyposmolarity, as they are directly osmosensitive in fish. In turn, the released prolactin acts on branchial epithelia, especially ionocytes of the gill to retain salt and excrete water. This review will highlight the points where comparative data give new ideas or suggest new approaches for investigation in other taxa.

Prolactin-induced and neuronal activation in the brain of mother mice.
Nursing has important consequences on mothers. To separate the prolactin-mediated and the neuronally-mediated actions of nursing, neurons directly affected by prolactin were visualized using pSTAT5 immunohistochemistry in relation to Fos-expressing neurons in suckled mother mice. In response to pup exposure following 22-h pup deprivation, we found a markedly elevated number of pSTAT5-containing neurons in several brain regions, including the lateral septum, medial amygdaloid nucleus, subparafascicular area, caudal periaqueductal gray, dorsal raphe, lateral parabrachial nucleus, nucleus of the solitary tract, and the periventricular, medial preoptic, paraventricular, arcuate and ventromedial nuclei of the hypothalamus. Pup exposure also induced Fos expression in all of these brain regions except the arcuate and ventromedial hypothalamic nuclei. Bromocriptine treatment known to reduce prolactin levels eliminated pSTAT5 from most brain regions while it did not affect Fos activation following suckling. The degree of colocalization for pSTAT5 and Fos ranged from 8 to 80% in the different brain regions suggesting that most neurons responding to pup exposure in mother mice are driven either by prolactin or direct neuronal input from the pups, while the number of neurons affected by both types of inputs depends on the examined brain area. In addition, both pSTAT5 and Fos were also double-labeled with estrogen receptor alpha (ERα) in mother mice, which revealed a very high degree of colocalization between pSTAT5 and ERα with much less potential interaction between Fos- and ERα-containing neurons suggesting that estrogen-sensitive neurons are more likely to be affected by prolactin than by direct neuronal activation.

A Thalamo-Hypothalamic Pathway That Activates Oxytocin Neurons in Social Contexts in Female Rats.
Oxytocin is released from neurons in the paraventricular hypothalamic nucleus (PVN) in mothers upon suckling and during adult social interactions. However, neuronal pathways that activate oxytocin neurons in social contexts are not yet established. Neurons in the posterior intralaminar complex of the thalamus (PIL), which contain tuberoinfundibular peptide 39 (TIP39) and are activated by pup exposure in lactating mothers, provide a candidate projection. Innervation of oxytocin neurons by TIP39 neurons was examined by double labeling in combination with electron microscopy and retrograde tract-tracing. Potential classic neurotransmitters in TIP39 neurons were investigated by in situ hybridization histochemistry. Neurons activated after encounter with a familiar conspecific female in a familiar environment were mapped with the c-Fos technique. PVN and the supraoptic nucleus oxytocin neurons were closely apposed by an average of 2.0 and 0.4 TIP39 terminals, respectively. Asymmetric (presumed excitatory) synapses were found between TIP39 terminals and cell bodies of oxytocin neurons. In lactating rats, PIL TIP39 neurons were retrogradely labeled from the PVN. TIP39 neurons expressed vesicular glutamate transporter 2 but not glutamic acid decarboxylase 67. PIL contained a markedly increased number of c-Fos-positive neurons in response to social encounter with a familiar conspecific female. Furthermore, the PIL received ascending input from the spinal cord and the inferior colliculus. Thus, TIP39 neurons in the PIL may receive sensory input in

response to social interactions and project to the PVN to innervate and excite oxytocin neurons, suggesting that the PIL-PVN projection contributes to the activation of oxytocin neurons in social contexts.

Maternally involved galanin neurons in the preoptic area of the rat.
Recent selective stimulation and ablation of galanin neurons in the preoptic area of the hypothalamus established their critical role in control of maternal behaviors. Here, we identified a group of galanin neurons in the anterior commissural nucleus (ACN), and a distinct group in the medial preoptic area (MPA). Galanin neurons in ACN but not the MPA co-expressed oxytocin. We used immunodetection of phosphorylated STAT5 (pSTAT5), involved in prolactin receptor signal transduction, to evaluate the effects of suckling-induced prolactin release and found that 76 % of galanin cells in ACN, but only 12 % in MPA were prolactin responsive. Nerve terminals containing tuberoinfundibular peptide 39 (TIP39), a neuropeptide that mediates effects of suckling on maternal motivation, were abundant around galanin neurons in both preoptic regions. In the ACN and MPA, 89 and 82 % of galanin neurons received close somatic appositions, with an average of 2.9 and 2.6 per cell, respectively. We observed perisomatic innervation of galanin neurons using correlated light and electron microscopy. The connection was excitatory based on the glutamate content of TIP39 terminals demonstrated by post-embedding immunogold electron microscopy. Injection of the anterograde tracer biotinylated dextran amine into the TIP39-expressing posterior intralaminar complex of the thalamus (PIL) demonstrated that preoptic TIP39 fibers originate in the PIL, which is activated by suckling. Thus, galanin neurons in the preoptic area of mother rats are innervated by an excitatory neuronal pathway that conveys suckling-related information. In turn, they can be topographically and neurochemically divided into two distinct cell groups, of which only one is affected by prolactin.

A RANDOMIZED CONTROLLED TRIAL ON THE EFFECT OF PARENTING INTERVENTION THROUGH "CARE FOR CHILD DEVELOPMENT GUIDELINE" ON EARLY CHILD DEVELOPMENT AND BEHAVIORS

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Roya Kelishadi, Omid Yaghini, Shahrbanou Daniali, Maryam Bemanalizadeh
Research Institute for Primordial Prevention of Non-Communicable Disease, Isfahan University of Medical Sciences, Child Growth And Development Research Center, Isfahan, Iran

Background It is suggested that parenting intervention programs can play a core component in early child development. Given the limited healthcare resources in developing countries, a group design intervention might be cost-effective. **Methods** This randomized controlled trial was conducted in a public Pediatrics clinic in Isfahan, Iran. We included 210 pregnant women in their third trimester, and then followed their children for 18 months. The intervention group underwent 5 educational group sessions. The main outcomes were the children's development and behaviors based on Bayley Scales of Infant and Toddler Development-III (BSCID-III) at 12 months and Children Behavior Checklist (CBCL) at 18-month of age. **Results** Data of 181 children were analyzed (80 in the intervention group and 101 controls. The adjusted median differences were significantly lower in the intervention group than in controls for attention problems (-3.38; SE=1.59; P=0.035), anxiety problems (-2.28; SE=1.03; P=0.007) and pervasive developmental problems (-5; SE= 1.16; P<0.001) based on CBCL results. However, the difference of proportions was not significant in none of the BSCID-III domains in the intervention and control groups. **Conclusion** We found that parenting interventions through CCD group sessions were significantly effective on several child's behavior domains, but not on children's development. Future longitudinal studies are necessary in this field.

IN VIVO FIBRE PHOTOMETRY REVEALS INCREASED NEURAL ACTIVITY IN THE LATERAL SEPTUM IS ASSOCIATED WITH FLEEING SOCIAL CONTACT IN MICE

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Mia Langguth[1,2], Erin Lynch[1,2], Nicholas Everett[1,2], Karly Turner[3], Michael Bowen[1,2]

AIMS Social avoidance is a core feature of numerous disorders. The lateral septum (LS) modulates social avoidance in mice. However, the specific behaviours affected by the LS in this context are not yet characterised. Our aim, therefore, was to examine the relationship between LS dynamics and specific social approach and avoidance behaviours with high temporal precision using fibre photometry and social fear conditioning (SFC). **METHOD** C57BL/6 mice underwent surgery to infuse a fluorescent calcium sensor and implant a fibre optic cannula within the LS. Three weeks post-surgery mice were socially isolated for one week, then presented with a series of social stimuli (caged novel mice) for 3 min each with a 3 min ITI (SFC-). One week later, mice underwent SFC, and the next day were again presented with a series of social stimuli (SFC+). Using fibre photometry and frame-locked video recordings, LS dynamics during exposure to SFC- and SFC+ social stimuli were correlated with specific behaviours. **RESULTS** Peaks in LS activity immediately preceded instances of the mouse rapidly fleeing the social stimulus. These peaks were observed when mice were unconditioned and when they were socially fear conditioned. However, peaks were most pronounced during the first social stimulus exposure during the SFC+ testing, and showed a reduction over successive social stimulus exposures, alongside the extinction of social fear. No other clear associations between LS activity and specific behaviours were identified. **CONCLUSION** These findings suggest that neuronal firing in the LS may promote social avoidance by driving social fleeing behaviour.

STUDY OF BOTTLENOSE DOLPHIN (TURSIOPS TRUNCATUS) ACOUSTIC COMMUNICATION DURING HUMAN-DOLPHIN INTERACTION USING AI METHODS

POSTER SESSION 03 - SECTION: THE SOCIAL BRAIN: FROM GENES TO BEHAVIOR

Paparelli Anita
IBENS, Sumbre Lab, Neural Circuit And Behaviour, Paris, France

Bottlenose dolphins (*Tursiops truncatus*) are known for their highly social complexity and associated cognitive abilities such as communication. The animal's acoustic repertoire is manifold, spanning from echolocation clicks for navigation to burst pulsed sounds and -signature and non-signature- whistles for social interaction. As gregarious animals, voluntary interactions with other species such as humans is not innocuous and vocal interaction may often result. However, this complex exchange remains understudied due to the strenuous experimental conditions that are faced when studying marine mammals in the wild. Our project proposes to overcome this challenge by investigating dolphin acoustic communication in a semi-captive environment through the growing use of novel computational methods such as automated clustering of sounds. At Eilat reef in Israel, an habituated group of cetaceans freely comes and leaves the pod while spontaneously interacting with the local care-takers. Daily activity is recorded with underwater hydrophones and video cameras, therefore providing us with unprecedented data. To elicit human-dolphin interaction, specific bells are rang at random times during the day to which dolphins respond, or not, by approaching and interacting with the "ringers". Recurrence of dolphin sounds are then clustered, classified and assessed with AI. Preliminary results have found that dolphins sometimes display vocal mimicry during inter-species interaction. Hence, we formulate the double hypothesis that these sounds produced by dolphins are non-random and that this repertoire may vary when interacting with humans. We hope with this unique approach that this study will contribute and disclose new queries in the field of animal social communication.

FUNCTIONAL CHARACTERIZATION OF AFFERENT INPUTS FROM THE VENTRAL MIDBRAIN TO THE ZONA INCERTA

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Ping-Chen Ho, Hau-Jie Yau
Graduate Institute of Brain and Mind Sciences, National Taiwan University, Taipei, Taiwan

In nature, animals are constantly exposed to variable environmental stimuli relevant to their survival, such as food or threat-related stimuli. When animals perceive reward-related or dangerous stimuli, they show appropriate responses to retrieve the reward or avoid the threat. Recent studies have shown that the ventral tegmental area (VTA) and substantia nigra (SN) in the ventral midbrain can regulate defensive behaviors. Although both regions send projections to the ZI, which is an integrative node for global modulation of a variety of behaviors, such as feeding, defensive or investigating behavior, the functional roles of midbrain-to-ZI connections remain elusive. As the first step to investigate their functions, we combined dual viral retrograde targteting approach with *in situ* RNAscope technique to study the neurochemical phenotypes of midbrain cells projecting to the ZI. We found that ZI-projecting VTA neurons consisted mostly of glutamatergic and a small population of GABAergic neurons, whereas ZI-projecting SN neurons consisted mostly of GABAergic and some dopaminergic neurons. To characterize the behavioral function of ZI-projecting midbrain neurons, we adapted a mouse model of stress and performed neural activity-dependent marker c-Fos immunostaining. We found that ZI-projecting midbrain neurons were significantly involved in restraint stress. Further causal manipulation experiments are ongoing to further examine the function roles of the midbrain-to-ZI connections.

SILENCING OF ASCENDING PAIN PATHWAYS WITH BOTULINUM-SUBSTANCE P PERSISTS FOR OVER 100DAYS AND CAN BE RESTORED WITH A SECOND INJECTION OF BOTULINUM CONJUGATE.

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Silvia Silva Hucha[1], Sofia Fontana-Guisti[2], Charlotte Leese[3], Bazbek Davletov[3], Stephen Hunt[1], María Maiaru[2]

Aims. We have shown that a single intrathecal injection of substance P conjugated to the light chain of botulinum toxin (SP-BOT) silenced neurons in the dorsal horn of the spinal cord and alleviated persistent pain states in mice (Maiáru et al., 2018). The SP-BOT construct selectively silenced neurokinin 1 receptor positive (NK1R+) neurons in the superficial dorsal horn. A subset of these NK1R+ neurons are nociceptive projection neurons that convey pain-related information to the brainstem. Here we investigated how long botulinum-based neuronal silencing persisted in the dorsal horn following a single injection of conjugate. **Methods.** a) Peripheral spared nerve injury (SNI) was carried out at 30d, 60d, 90d and 120d after injection of SP-BOT or b) ankle injection of CFA complete Freund's adjuvant (CFA), a model of inflammatory pain, was followed by intrathecal injection of SP-BOT. Affective (attending behaviour, response to cold, elevated plus maze) and reflex (von Frey hairs) measures of pain behaviour were measured. **Results.** By monitoring both affective and reflex pain behaviours after SNI or CFA we established that NK1R+ spinal neurons in the superficial lamina of the dorsal horn were silenced for 100days following a single intrathecal injection of the botulinum construct without toxicity. We also show that behavioural alleviation of neuropathic pain symptoms could be reinstated by a second injection of SP-BOT at 128d. **Conclusions.** Botulinum toxin conjugates provide a powerful new way of providing long term pain relief following a single injection of the conjugate with the potential for repeated dosing when pain returns.

Extraocular motoneurons of the adult rat show higher levels of vascular endothelial growth factor and its receptor Flk-1 than other cranial motoneurons.
Recent studies show a relationship between the deficit of vascular endothelial growth factor (VEGF) and motoneuronal degeneration, such as that occurring in amyotrophic lateral sclerosis (ALS). VEGF delivery protects motoneurons from cell death and delayed neurodegeneration in animal models of ALS. Strikingly, extraocular motoneurons show lesser vulnerability to neurodegeneration in ALS compared to other cranial or spinal motoneurons. Therefore, the present study investigates possible differences in VEGF and its main receptor VEGFR-2 or Flk-1 between extraocular and non-extraocular brainstem motoneurons. We performed immunohistochemistry and Western blot to determine the presence of VEGF and Flk-1 in rat motoneurons located in the three extraocular motor nuclei (abducens, trochlear and oculomotor) and to compare it to that observed in two other brainstem nuclei (hypoglossal and facial) that are vulnerable to degeneration. Extraocular motoneurons presented higher amounts of VEGF and its receptor Flk-1 than other brainstem motoneurons, and thus these molecules could be participating in their higher resistance to neurodegeneration. In conclusion, we hypothesize that differences in VEGF availability and signaling could be a contributing factor to the different susceptibility of extraocular motoneurons, when compared with other motoneurons, in neurodegenerative diseases.

Extraocular Motor System Exhibits a Higher Expression of Neurotrophins When Compared with Other Brainstem Motor Systems.
Extraocular motoneurons resist degeneration in diseases such as amyotrophic lateral sclerosis. The main objective of the present work was to characterize the presence of neurotrophins in extraocular motoneurons and muscles of the adult rat. We also compared these results with those obtained from other cranial motor systems, such as facial and hypoglossal, which indeed suffer neurodegeneration. Immunocytochemical analysis was used to describe the expression of nerve growth factor, brain-derived neurotrophic factor and neurotrophin-3 in oculomotor, trochlear, abducens, facial, and hypoglossal nuclei of

adult rats, and Western blots were used to describe the presence of neurotrophins in extraocular, facial (buccinator), and tongue muscles, which are innervated by the above-mentioned motoneurons. In brainstem samples, brain-derived neurotrophic factor was present both in extraocular and facial motoneuron somata, and to a lesser degree, in hypoglossal motoneurons. Neurotrophin-3 was present in extraocular motor nuclei, while facial and hypoglossal motoneurons were almost devoid of this protein. Finally, nerve growth factor was not present in the soma of any group of motoneurons, although it was present in dendrites of motoneurons located in the neuropil. Neuropil optical density levels were higher in extraocular motoneuron nuclei when compared with facial and hypoglossal nuclei. Neurotrophins could be originated in target muscles, since Western blot analyses revealed the presence of the three molecules in all sampled muscles, to a larger extent in extraocular muscles when compared with facial and tongue muscles. We suggest that the different neurotrophin availability could be related to the particular resistance of extraocular motoneurons to neurodegeneration.

Vascular Endothelial Growth Factor (VEGF) Prevents the Downregulation of the Cholinergic Phenotype in Axotomized Motoneurons of the Adult Rat.
Vascular endothelial growth factor (VEGF) was initially characterized by its activity on the vascular system. However, there is growing evidence indicating that VEGF also acts as a neuroprotective factor, and that its administration to neurons suffering from trauma or disease is able to rescue them from cell death. We questioned whether VEGF could also maintain damaged neurons in a neurotransmissive mode by evaluating the synthesis of their neurotransmitter, and whether its action would be direct or through its well-known angiogenic activity. Adult rat extraocular motoneurons were chosen as the experimental model. Lesion was performed by monocular enucleation and immediately a gelatine sponge soaked in VEGF was implanted intraorbitally. After 7 days, abducens, trochlear, and oculomotor nuclei were examined by immunohistochemistry against choline acetyltransferase (ChAT), the biosynthetic enzyme of the motoneuronal neurotransmitter acetylcholine. Lesioned motoneurons exhibited a noticeable ChAT downregulation which was prevented by VEGF administration. To explore whether this action was mediated via an increase in blood vessels or in their permeability, we performed immunohistochemistry against laminin, glucose transporter-1 and the plasmatic protein albumin. The quantification of the immunolabeling intensity against these three proteins showed no significant differences between VEGF-treated, axotomized and control animals. Therefore, the present data indicate that VEGF is able to sustain the cholinergic phenotype in damaged motoneurons, which is a first step for adequate neuromuscular neurotransmission, and that this action seems to be mediated directly on neurons since no sign of angiogenic activity was evident. These data reinforces the therapeutical potential of VEGF in motoneuronal diseases.

Sources and lesion-induced changes of VEGF expression in brainstem motoneurons.
Motoneurons of the oculomotor system show lesser vulnerability to neurodegeneration compared to other cranial motoneurons, as seen in amyotrophic lateral sclerosis (ALS). The overexpression of vascular endothelial growth factor (VEGF) is involved in motoneuronal protection. As previously shown, motoneurons innervating extraocular muscles present a higher amount of VEGF and its receptor Flk-1 compared to facial or hypoglossal motoneurons. Therefore, we aimed to study the possible sources of VEGF to brainstem motoneurons, such as glial cells and target muscles. We also studied the regulation of VEGF in response to axotomy in ocular, facial, and hypoglossal motor nuclei. Basal VEGF expression in astrocytes and microglial cells of the cranial motor nuclei was low. Although the presence of VEGF in the different target muscles for brainstem motoneurons was similar, the presynaptic element of the ocular neuromuscular junction showed higher amounts of Flk-1, which could result in greater efficiency in the capture of the factor by oculomotor neurons. Seven days after axotomy, a clear glial reaction was observed in all the brainstem nuclei, but the levels of the neurotrophic factor remained low in glial cells. Only the injured motoneurons of the oculomotor system showed an increase in VEGF and Flk-1, but such an increase was not detected in axotomized facial or hypoglossal motoneurons. Taken together, our findings suggest that the ocular motoneurons themselves upregulate VEGF expression in response to lesion. In conclusion, the low VEGF expression observed in glial cells suggests that these cells are not the main source of VEGF for brainstem motoneurons. Therefore, the higher VEGF expression observed in motoneurons innervating extraocular muscles is likely due either to the fact that this factor is more avidly taken up from the target muscles, in basal conditions, or is produced by these motoneurons themselves, and acts in an autocrine manner after axotomy.
Brain Struct Funct, 2020; 225
33467517: Silva-Hucha S, Pastor AM, Morcuende S
Neuroprotective Effect of Vascular Endothelial Growth Factor on Motoneurons of the Oculomotor System.
Vascular endothelial growth factor (VEGF) was initially characterized as a potent angiogenic factor based on its activity on the

vascular system. However, it is now well established that VEGF also plays a crucial role as a neuroprotective factor in the nervous system. A deficit of VEGF has been related to motoneuronal degeneration, such as that occurring in amyotrophic lateral sclerosis (ALS). Strikingly, motoneurons of the oculomotor system show lesser vulnerability to neurodegeneration in ALS compared to other motoneurons. These motoneurons presented higher amounts of VEGF and its receptor Flk-1 than other brainstem pools. That higher VEGF level could be due to an enhanced retrograde input from their target muscles, but it can also be produced by the motoneurons themselves and act in an autocrine way. By contrast, VEGF's paracrine supply from the vicinity cells, such as glial cells, seems to represent a minor source of VEGF for brainstem motoneurons. In addition, ocular motoneurons experiment an increase in VEGF and Flk-1 level in response to axotomy, not observed in facial or hypoglossal motoneurons. Therefore, in this review, we summarize the differences in VEGF availability that could contribute to the higher resistance of extraocular motoneurons to injury and neurodegenerative diseases.

TARGETING CHOLINERGIC BASAL FOREBRAIN NEURONS TO MODULATE INFLAMMATORY PAIN IN MICE

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Manfred Oswald[1], Yechao Han[1], Samuel Marashli[2], Han Li[1], Zheng Gan[1], Bhavya Ojha[1], Deniz Oglou[1], Paul Naser[1], Rohini Kuner[1]
[1]Heidelberg University, Institute Of Pharmacology, Heidelberg, Germany, [2]IZN Heidelberg, Izn Heidelberg, Basel, Switzerland

Cholinergic neurons in the basal forebrain (BFB) project widely to the cerebral cortex and influence attention, arousal and cognition via cholinergic modulation of cortical network activity. As attention is diminished in chronic pain patients our aim was to examine the role of the BFB cholinergic activity in mouse models of inflammatory pain. Using the expression of cFos as a surrogate marker of neuronal activity we found that cholinergic neurons in BFB nuclei that project to the cerebral cortex are activated in excess by mechanical stimuli when applied to the inflamed paw compared to the naïve state. Using *in vivo* electrical recordings in behaving mice we found that beta and gamma local field potential activity is evoked in the BFB by noxious stimuli in naïve mice and by otherwise non-noxious stimuli in mice with an inflamed paw. On enhancing the activity of cholinergic neurons in the BFB, and more specifically BFB cholinergic terminals in the medial PFC (mPFC) with optogenetic techniques, we found that paw withdrawals to mechanical and thermal stimuli in inflamed conditions were reduced. Attentional performance in the 5-CSRT task was enhanced in mice when activating BFB cholinergic neurons with a chemogenetic technique. Optogenetic stimulation of the cholinergic terminals in the mPFC enhanced neuronal cFos expression but did not alter attentional performance in the 5-CSRT task. These findings suggest that the concept of enhancing prefrontal attention networks in brain regions that are linked to descending pain control may facilitate the development of therapeutic strategies.

LOCOMOTOR CONTROL BY THETA-RANGE ACTIVATION OF GLUTAMATERGIC MSDB TO VTA PROJECTIONS

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Petra Mocellin[1], Kevin Luxem[1], Sanja Mikulovic[2], Stefan Remy[1,3]
[1]Leibniz Institute for Neurobiology, Cellular Neuroscience, Magdeburg, Germany, [2]Leibniz Institute for Neurobiology, Cognition And Emotion Laboratory, Magdeburg, Germany, [3]German Center for Neurodegenerative Diseases, Neuronal Networks Group, Bonn, Germany

Subcortical circuits modulate and select the appropriate locomotor responses based on the external demands and the internal state of the animal. However, how subcortical circuitry regulates the onset and vigor of locomotion is still unresolved. Here, we show that a glutamatergic pathway from the Medial Septum and Diagonal Band of Broca (MSDB) to neurons in the Ventral Tegmental Area (VTA) controls locomotor behavior. When stimulated in the theta frequency range mice invariably increased speed and locomotor activity in a frequency-dependent manner. Moreover, using a self-supervised machine learning approach we observed a specific change in their behavioral repertoire, leading to an overrepresentation of the walking and rearing motifs upon activation of the circuit. Finally, we mapped the VTA output cells of this glutamatergic MSDB projection and discovered that it monosynaptically targets both glutamatergic and dopaminergic VTA neurons. Taken together, we identify a previously unknown glutamatergic basal forebrain to midbrain pathway that initiates and modulates locomotor activity and contributes to the selection of locomotion-associated motifs.

Pubmed:
34366795: Mocellin P, Mikulovic S
The Role of the Medial Septum-Associated Networks in Controlling Locomotion and Motivation to Move.
The Medial Septum and diagonal Band of Broca (MSDB) was initially studied for its role in locomotion. However, the last several decades were focussed on its intriguing function in theta rhythm generation. Early studies relied on electrical stimulation, lesions and pharmacological manipulation, and reported an inconclusive picture regarding the role of the MSDB circuits. Recent studies using more specific methodologies have started to elucidate the differential role of the MSDB's specific cell populations in controlling both theta rhythm and behaviour. In particular, a novel theory is emerging showing that different MSDB's cell populations project to different brain regions and control distinct aspects of behaviour. While the majority of these behaviours involve movement, increasing evidence suggests that MSDB-related networks govern the motivational aspect of actions, rather than locomotion . Here, we review the literature that links MSDB, theta activity, and locomotion and propose open questions, future directions, and methods that could be employed to elucidate the diverse roles of the MSDB-associated networks.

Acquisition of negative experience is essential for the survival. Negative stimuli immediately and simultaneously activate the main aversive centers, the lateral habenula (LHb) and medial ventral tegmental area (mVTA) and the memory processing septo-hippocampal system. However, it is still unknown, which neurons coordinate these processes during negative experience. Here, we found that the brainstem median raphe region (MRR) harbors a new type of excitatory population of neurons that expresses vesicular glutamate transporter 2 (vGluT2). With anatomical tracing experiments, we found that these neurons innervate LHb, mVTA and the septo-hippocampal system and they receive inputs from negative experience-related brain centers. With in vivo optical tagging method, we found that MRR vGluT2 neurons are rapidly and selectively activated during aversive, but not rewarding events. Optogenetic stimulation of MRR vGluT2 neurons induced acute and conditioned place aversion, suppressed reward seeking behavior and created memory acquisition-promoting hippocampal theta-oscillations. By contrast, optogenetic inhibition of MRR vGluT2-neurons during an aversive foot-shock impaired both contextual and cued fear memory-formation and prevented fear generalization. Our results suggest that MRR vGluT2-neurons are both necessary and sufficient to acquire negative experience and they may play an important role in several types of mood disorders. **Conflict of interest:** The authors have no conflict of interest. **Funding:** This project was supported by the ÚNKP-18-2-I-SE-22 and ÚNKP-21-3-SE-9 New National Excellence Program of the Ministry of Innovation and by the EFOP-3.6.3-VEKOP-16-2017-00009 Semmelweis 250+ Excellence PhD Fellowship.

Median raphe controls acquisition of negative experience in the mouse.
Adverse events need to be quickly evaluated and memorized, yet how these processes are coordinated is poorly understood. We discovered a large population of excitatory neurons in mouse median raphe region (MRR) expressing vesicular glutamate transporter 2 (vGluT2) that received inputs from several negative experience-related brain centers, projected to the main aversion centers, and activated the septohippocampal system pivotal for learning of adverse events. These neurons were selectively activated by aversive but not rewarding stimuli. Their stimulation induced place aversion, aggression, depression-related anhedonia, and suppression of reward-seeking behavior and memory acquisition-promoting hippocampal theta oscillations. By contrast, their suppression impaired both contextual and cued fear memory formation. These results suggest that MRR vGluT2 neurons are crucial for the acquisition of negative experiences and may play a central role in depression-related mood disorders.

MGLU5 RECEPTORS MODULATE SOMATOSTATIN INTERNEURON CONTROL OF EMOTIONAL BEHAVIORS

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Arnau Ramos Prats[1], Pawel Matulewicz[1], Marie-Luise Edenhofer[2], Kay-Yi Wang[3], Chia-Wei Yeh[3], Michaela Kress[2], Kai Kummer[2], Chen-Chang Lien[3], Francesco Ferraguti[1]

Aims: Metabotropic glutamate receptors subtype 5 (mGlu5 receptors) are known to play an important role in regulating functioning of cognitive, social and negative valence system domains. However, it remains largely unknown at which neuronal circuits and neuronal subtypes do mGlu5 receptors act to influence behavioral phenotypes relevant for neuropsychiatric disorders. Methods: Here, we examined the contribution of these receptors in somatostatin (SST+) interneuron activity function, plasticity, brain synchrony modulation and behavior. Results: Loss of mGlu5 receptors in SST+ neurons elicited excitatory synaptic dysfunction in a region and sex-specific manner and a range of emotional imbalances, which included diminished social novelty preference, anxiety and fear responses. A key finding of our study comes from the observation that mGlu5 receptors in SST+ neurons modulate the facilitation of theta oscillations during negative valence processing in both mPFC and vHPC. Conclusions: Deficits in SSTCre-mGlu5-/- mice did not arise from inability to generate theta frequency or a shift in dominant frequency, but rather as a weakened signal power, suggesting a lower engagement of neuronal ensembles encompassing an internal fearful state in those animals. Similarly, our study also points towards a necessity of mGlu5 receptors in SST+ neurons to enable cooperative neuronal spiking dynamics between the mPFC and vHPC. Altogether, our findings reveal a critical role of mGlu5 receptors in regulating SST+ neurons excitability necessary for emotional behavior homeostasis.

Loss of mGluR5 in D1 Receptor-Expressing Neurons Improves Stress Coping.
The metabotropic glutamate receptor type 5 (mGluR5) has been proposed to play a crucial role in the selection and regulation of cognitive, affective, and emotional behaviors. However, the mechanisms by which these receptors mediate these effects remain largely unexplored. Here, we studied the role of mGluR5 located in D1 receptor-expressing (D1) neurons in the manifestation of different behavioral expressions. Mice with conditional knockout (cKO) of mGluR5 in D1 neurons (mGluR5 cKO) and littermate controls displayed similar phenotypical profiles in relation to memory expression, anxiety, and social behaviors. However, mGluR5 cKO mice presented different coping mechanisms in response to acute escapable or inescapable stress. mGluR5 cKO mice adopted an enhanced active stress coping strategy upon exposure to escapable stress in the two-way active avoidance (TWA) task and a greater passive strategy upon exposure to inescapable stress in the forced swim test (FST). In summary, this work provides evidence for a functional integration of the dopaminergic and glutamatergic system to mediate control over internal states upon stress exposure and directly implicates D1 neurons and mGluR5 as crucial mediators of behavioral stress responses.

Inter-individual and inter-strain differences in cognitive and social abilities of Dark Agouti and Wistar Han rats.
Healthy animals displaying extreme behaviours that resemble human psychiatric symptoms are relevant models to study the natural psychobiological processes of maladapted behaviours. Using a Rat Gambling Task, healthy individuals spontaneously making poor decisions (PDMs) were found to co-express a combination of other cognitive and reward-based characteristics similar to symptoms observed in human patients with impulse-control disorders. The main goals of this study were to 1) confirm the existence of PDMs and their unique behavioural phenotypes in Dark Agouti (DA) and Wistar Han (WH) rats, 2) to extend the behavioural profile of the PDMs to probability-based decision-making and social behaviours and 3) to extract key discriminative traits between DA and WH strains, relevant for biomedical research. We have compared cognitive abilities, natural behaviours and physiological responses in DA and WH rats at the strain and at the individual level. Here we found that the naturally occurring PDM's profile was consistent between both rat lines. Then, although the PDM individuals

did not take more risks in probability discounting task, they seemed to be of higher social ranks. Finally and despite their similarities in performance, WH and DA lines differed in degree of reward sensitivity, impulsivity, locomotor activity and open space-occupation. The reproducibility and conservation of the complex phenotypes of PDMs and GDMs (good decision makers) in these two genetically different strains support their translational potential. Both strains, present large phenotypic variation in behaviours pertinent for the study of the underlying mechanisms of poor decision making and associated disorders.

An Appraisal of the Influence of the Metabotropic Glutamate 5 (mGlu5) Receptor on Sociability and Anxiety.
Amongst the many neurotransmitter systems causally linked to the expression of social behavior, glutamate appears to play a pivotal role. In particular, metabotropic glutamate 5 (mGlu5) receptors have received much attention as its altered function has been reported in several mouse models of autism spectrum disorders and mental retardation. Inhibition of the activity of mGlu5 receptors by means of genetic or pharmacological manipulations improved social deficits in some of these animal models. However, in normal wild-type (WT) mice, pharmacological blockade of mGlu5 receptors yielded inconsistent results. The aim of our study was to investigate the actual contribution of decreased or absent mGlu5 receptor function in sociability and anxiety-like behavior as well as to explore the impact of mGlu5 receptor ablation on the pattern of brain activation upon social exposure. Here we show that -/- mice display higher social preference indexes compared to age-matched WT mice in the three-chambered social task. However, this effect was accompanied by a decreased exploratory activity during the test and increased anxiety-like behavior. Contrary to mGlu5 receptor ablation, the mGlu5 receptor negative allosteric modulator 3-((2-methyl-1,4-thiazolyl)ethynyl)pyridine (MTEP) induced anxiolytic effects without affecting social preference in WT mice. By mapping c-Fos expression in 21 different brain regions known to be involved in social interaction, we detected a specific activation of the prefrontal cortex and dorsolateral septum in -/- mice following social interaction. C-Fos expression correlation-based network and graph theoretical analyses further suggested dysfunctional connectivity and disruption of the functional brain network generated during social interaction in -/- mice. The lack of mGlu5 receptors resulted in profound rearrangements of the functional impact of prefrontal and hippocampal regions in the social interaction network. In conclusion, this work reveals a complex contribution of mGlu5 receptors in sociability and anxiety and points to the importance of these receptors in regulating brain functional connectivity during social interaction.

Controllability affects endocrine response of adolescent male rats to stress as well as impulsivity and behavioral flexibility during adulthood.
Exposure to stress during adolescence exerts a long-term impact on behavior and might contribute to the development of several neuropsychiatric disorders. In adults, control over stress has been found to protect from the negative consequences of stress, but the influence of controllability at early ages has not been extensively studied. Here, we evaluated in a rodent model the effects of repeated exposure in adolescent male rats to controllable versus uncontrollable foot-shock stress (CST or UST, respectively). Rats were assigned to three groups: non-stress (stress-naïve), CST (exposed to 8 sessions of a two-way shuttle active avoidance task over a period of 22 days) and UST (receiving the same amount of shocks as CST, regardless of their actual behavior). During adulthood, different cohorts were tested in several tasks evaluating inhibitory control and cognitive flexibility: 5-choice serial reaction time, delay-discounting, gambling test and probabilistic reversal learning. Results showed that the hypothalamic-pituitary-adrenal response to the first shock session was similar in CST and UST animals, but the response to the 8 session was lower in CST animals. In adulthood, the UST animals presented impaired motor (but not cognitive) impulsivity and more perseverative behavior. The behavioral effects of UST were associated with increased number of D2 dopamine receptors in dorsomedial striatum, but not in other striatal regions. In summary, UST exposure during adolescence induced long-term impairments in impulsivity and compulsivity, whereas CST had only minor effects. These data support a critical role of stress uncontrollability on the long-lasting consequences of stress, as a risk factor for mental illnesses.

GAT1-SAPORIN-INDUCED GABAERGIC LESION IN THE VENTRAL PALLIDUM/SUBSTANTIA INNOMINATA REDUCES BEHAVIORAL DESPAIR AND PROMOTES ACTIVE COPING STRATEGIES

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Cemal Akmese, Cem Sevinc, Sahar Halim, Gunes Unal
Bogazici University, Psychology, Istanbul, Turkey

Aim: The ventral pallidum (VP) and substantia innominata (SI) send substantial GABAergic projections to the amygdala and the bed nucleus of the stria terminalis (BNST), two limbic structures that respectively orchestrate acute and chronic fear response. We did two set of experiments to reveal the functional connectivity between the amygdaloid complex and VP/SI (anatomy), and elucidate the role of VP/SI GABAergic neurons in various cognitive and affective processes (behavior). Methods: We made bilateral retrograde tracer (RetroBeads, Lumafluor) injections into the VP/SI of adult male Wistar rats to reveal and characterize its limbic afferents by means of immunohistochemistry. For behavioral testing, we used bilateral GAT1-saporin (or PBS) injections to silence GABAergic neurons of the VP/SI, and assessed the animals in the forced swim test (FST), open field test (OFT), elevated plus maze (EPM), Morris water maze (MWM) and Pavlovian fear conditioning. Results: We observed several amygdaloid neuronal groups that target the VP/SI, with distinct types of projections originating from the central and lateral nuclei (anatomy). GAT1-saporin lesions in the VP/SI reduced behavioral despair without altering general locomotor activity. These animals also showed reduced freezing and increased darting behavior during the acquisition day of fear conditioning (behavior). Conclusions: Silencing the VP/SI GABAergic neurons produce an antidepressant effect while promoting active coping strategies. Long-range basal forebrain GABAergic neurons that target different nuclei of the amygdala and the BNST may constitute therapeutic targets for treating clinical depression as well as anxiety and fear-related disorders.

Neuronal circuits located in the midbrain play a critical role in controlling defensive behavior. However, it is still elusive how different neuron types contribute to distinct behavioral outcomes during the presence of threat. In this study, we investigated a group of neurons in the ventral periaqueductal gray and dorsal raphe nucleus that express vasoactive intestinal polypeptide (VIP). Using viral tracing conducted in Vip-Cre mice, we observed that these VIP neurons innervated exclusively the bed nucleus of stria terminalis (BNST) and central amygdala (CeA), the two main regions of the extended amygdala. Interestingly, neurons in these two brain regions contributed to the innervation of midbrain VIP neurons to a large extent revealed by monosynaptic rabies tracing. In vitro electrophysiological recordings combined with optogenetics revealed that light stimulation of VIP afferents activated ionotropic glutamate receptors on their postsynaptic partners in the extended amygdala. Electron microscopy determined that spines were the major targets of VIP immunoreactive boutons both in the BNST and CeA. To clarify the role of the midbrain VIP neurons in defensive behavior, we inhibited their activity using chemogenetics and observed that inhibition of these midbrain neurons during fear conditioning impaired the contextual, but not cued fear memory tested on subsequent days. In addition, inhibiting the VIP neuronal activity reduced avoidance behavior in a predator odor avoidance test. These results collectively show that the excitatory midbrain-extended amygdala pathway expressing VIP plays a critical role in the regulation of a set of defensive behaviors.

Synaptic Organization of Perisomatic GABAergic Inputs onto the Principal Cells of the Mouse Basolateral Amygdala.
Spike generation is most effectively controlled by inhibitory inputs that target the perisomatic region of neurons. Despite the critical importance of this functional domain, very little is known about the organization of the GABAergic inputs contacting the perisomatic region of principal cells (PCs) in the basolateral amygdala. Using immunocytochemistry combined with in vitro single-cell labeling we determined the number and sources of GABAergic inputs of PCs at light and electron microscopic levels in mice. We found that the soma and proximal dendrites of PCs were innervated primarily by two neurochemically distinct basket cell types expressing parvalbumin (PVBC) or cholecystokinin and CB1 cannabinoid receptors (CCK/CB1BC). The innervation of the initial segment of PC axons was found to be parceled out by PVBCs and axo-axonic cells (AAC), as the majority of GABAergic inputs onto the region nearest to the soma (between 0 and 10 μm) originated from PVBCs, while the largest portion of the axon initial segment was innervated by AACs. Detailed morphological investigations revealed that the three perisomatic region-targeting interneuron types significantly differed in dendritic and axonal arborization properties. We found that, although individual PVBCs targeted PCs via more terminals than CCK/CB1BCs, similar numbers (15-17) of the two BC types converge onto single PCs, whereas fewer (6-7) AACs innervate the axon initial segment of single PCs. Furthermore, we estimated that a PVBC and a CCK/CB1BC may target 800-900 and 700-800 PCs, respectively, while an AAC can innervate 600-650 PCs. Thus, BCs and AACs innervate ~10 and 20% of PC population, respectively, within their axonal cloud. Our results collectively suggest, that these interneuron types may be differently affiliated within the local amygdalar microcircuits in order to fulfill specific functions in network operation during various brain states.

Excitation of Diverse Classes of Cholecystokinin Interneurons in the Basal Amygdala Facilitates Fear Extinction.
There is growing evidence that interneurons (INs) orchestrate neural activity and plasticity in corticoamygdala circuits to regulate fear behaviors. However, defining the precise role of cholecystokinin-expressing INs (CCK INs) remains elusive due to the technical challenge of parsing this population from CCK-expressing principal neurons (CCK PNs). Here, we used an intersectional genetic strategy in CCK-Cre;Dlx5/6-Flpe double-transgenic mice to study the anatomical, molecular and electrophysiological properties of CCK INs in the basal amygdala (BA) and optogenetically manipulate these cells during fear extinction. Electrophysiological recordings confirmed that this strategy targeted GABAergic cells and that a significant proportion expressed functional cannabinoid CB1 receptors; a defining characteristic of CCK-expressing basket cells. However, immunostaining showed that subsets of the genetically-targeted cells expressed either neuropeptide Y (NPY; 29%) or parvalbumin (PV; 17%), but not somatostatin (SOM) or Ca/calmodulin-dependent protein kinase II (CaMKII)-α. Further morphological and electrophysiological analyses showed that four IN types could be identified among the EYFP-expressing cells: CCK/cannabinoid receptor type 1 (CB1R)-expressing basket cells, neurogliaform cells, PV+ basket cells, and PV+ axo-axonic cells. At the behavioral level, optogenetic photostimulation of the targeted population during extinction acquisition led to reduced freezing on a light-free extinction retrieval test, indicating extinction memory facilitation; whereas photosilencing was without effect. Conversely, non-selective (i.e., inclusive of INs and PNs) photostimulation or photosilencing of CCK-targeted cells, using CCK-Cre single-transgenic mice, impaired extinction. These data reveal an unexpectedly high degree of phenotypic complexity in a unique population of extinction-modulating BA INs.

Total Number and Ratio of GABAergic Neuron Types in the Mouse Lateral and Basal Amygdala.
GABAergic neurons are key circuit elements in cortical networks. Despite growing evidence showing that inhibitory cells play a critical role in the lateral (LA) and basal (BA) amygdala functions, neither the number of GABAergic neurons nor the ratio of their distinct types has been determined in these amygdalar nuclei. Using unbiased stereology, we found that the ratio of GABAergic neurons in the BA (22%) is significantly higher than in the LA (16%) in both male and female mice. No difference was observed between the right and left hemispheres in either sex. In addition, we assessed the ratio of the major inhibitory cell types in both amygdalar nuclei. Using transgenic mice and a viral strategy for visualizing inhibitory cells combined with immunocytochemistry, we estimated that the following cell types together compose the vast majority of GABAergic cells in the LA and BA: axo-axonic cells (5.5%-6%), basket cells expressing parvalbumin (17%-20%) or cholecystokinin (7%-9%), dendrite-targeting inhibitory cells expressing somatostatin (10%-16%), NPY-containing neurogliaform cells (14%-15%), VIP and/or calretinin-expressing interneuron-selective interneurons (29%-38%), and GABAergic projection neurons expressing somatostatin and neuronal nitric oxide synthase (5.5%-8%). Our results show that these amygdalar nuclei contain all major GABAergic neuron types as found in other cortical regions. Furthermore, our data offer an essential reference for future studies aiming to reveal changes in GABAergic cell number and in inhibitory cell types typically observed under different pathologic conditions, and to model functioning amygdalar networks in health and disease. GABAergic cells in cortical structures, as in the lateral and basal nucleus of the amygdala, have a determinant role in controlling circuit operation. In this study, we provide the first estimate for the total number of inhibitory cells in these two amygdalar nuclei. In addition, our study is the first to define the ratio of the major GABAergic cell types present in these cortical networks. Taking into account that hyperexcitability in the amygdala, arising from the imbalance between excitation and inhibition typifies many altered brain functions, including anxiety, post-traumatic stress disorder, schizophrenia, and autism, uncovering the number and ratio of distinct amygdalar inhibitory cell types offers a solid base for comparing the changes in inhibition in pathologic brain states.

In face of a threat, animals must select a response among a range of defensive behaviors, and the selection of a response suitable to each situation is essential for their survival. This response selection relies not only on the characteristics of the threat itself, but also on its multimodal integration with environmental features that constrain the repertoire of strategies that can be used to cope with the threatening encounter. The dorsomedial prefrontal cortex (dmPFC) is a key structure in the regulation of defensive behaviors, but how its excitatory and inhibitory neuronal populations differentially contribute to the selection of the most adaptive defensive response in each threatening condition remains unexplored. To investigate the contribution of the main dmPFC neuronal types - namely pyramidal, parvalbumin- (PV+) and somatostatin-expressing (SST+) neurons –, to threat evaluation and defensive response selection, *in vivo* calcium imaging is coupled to a novel behavioral paradigm that allows the execution of different defensive behaviors in response to distinct threatening situations. This approach allows us to identify the encoding of threat-related information in distinct neuronal populations and to investigate the role of the activity of dmPFC interneurons in the population representation of threats and in the mice selection of defensive behaviors.

The lateral hypothalamic area (LHA) controls negative valence through glutamatergic projections to lateral habenula (LHb). The complex nature of negative emotional signaling suggest a specialized functional organization able to carry distinct negative values signals present in complex behavioral responses. However, basic knowledge exploring the diversity of glutamatergic LHA-LHb neurons is lacking, precluding detailed functional investigations using genetic strategies. To elucidate the organization of the LHA-LHb pathway we here characterized by Patch-seq the electrophysiological, neuroanatomical, and molecular diversity of Vglut2+ LHA-LHb neurons. While the glutamatergic LHA-LHb neurons have been considered a homogeneous population, we find that this projection is instead composed of several discrete neuron types characterized by their respective intrinsic properties, molecular markers, and spatial projection patterns. To reveal the functional relevance of such diversity, we further combined genetic targeting of identified neuron types with high-density electrophysiological recordings and optogenetic manipulations during a set of emotion-related behavior tasks. Cell-type specific optogenetic manipulations, guided by classification of LHA-LHb subtypes using Patch-seq, revealed cell-type specific negative signals, distinct immediate aversive behaviors as well as region-specific negative neural state in the prefrontal cortex (PFC) upon LHA-LHb pathways manipulation. Interestingly, we could detail a cell-type specific LHA-LHb persistent shift in the intrinsic properties upon stress. Altogether, through multimodal classification we detailed an unexpected molecular heterogeneity reflected by functional organization of parallel LHA-LHb circuits.

NEUROANATOMY OF PATHWAYS FOR INTEGRATION OF CARDIO-BEHAVIOURAL DEFENSIVE REPONSES

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Orlando Cortés Campo[1], César Redondo Alanon[1], Jérémy Signoret-Genest[1,2], Philip Tovote[1]
[1]Institute of Clinical Neurobiology, Defense Circuits Lab, Würzburg, Germany, [2]University Hospital Würzburg, Institute Of Clinical Neurobiology, Wuerzburg, Germany

In the face of threat, higher organisms exhibit various defensive responses, of which the behavioral component has extensively been investigated. However, the defense reaction also comprises diverse physiological responses such as cardiac and endocrine adjustments, as well as analgesia. The individual defensive responses have been used to define specific defensive states, and much research was dedicated to exploration of the neuroanatomical substrates of defensive behavioral responses in a neuronal type-specific manner. However, the circuit mechanisms underlying integration of individual defensive responses to orchestrate the overall defensive state remain elusive. We used intersectional viral approaches to better understand neuroarchitecture of forebrain-to-brainstem pathways involved in behavioral as well as cardiac defensive responses. Tracing of inputs to the dorsal vagal complex (DVC), a central regulator of cardiovascular functions revealed glutamatergic projections from the ventrolateral column of the periaqueductal gray (vlPAG) as well as GABAergic, non-somatostatin (SOM-) inputs from neurons of the medial subdivision of the central amygdala (CeM). Interestingly, projections from both vlPAG and the CeM, send collaterals to common hypothalamic nuclei. Furthermore, the identified glutamatergic pathway innervates the freezing-related magnocellular nucleus of the medulla (Mc), while vlPAG and the bed nucleus of the stria terminalis (BNST), both implicated in anxiety-related defensive states, receive GABAergic collaterals from SOM- neurons in the CeM. Optogenetic interference with the GABAergic projection from the CeM to the DVC and the vlPAG suggests a modulatory function of this pathway during threat conditioning. Our results add to our understanding of the circuit basis mediating a multi-modal, integrated defense reaction.

RESPONSES OF LATERAL HABENULA NEURONS TO AN AVERSIVE STIMULUS ACROSS ALTERNATING BRAIN STATES OF URETHANE ANAESTHETISED RAT.

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Martyna Marzec, Gabriela Izowit, Tomasz Błasiak
Institute of Zoology and Biomedical Research, Jagiellonian University in Cracow, Department Of Neurophysiology And Chronobiology, Cracow, Poland

The lateral habenula (LHb), a glutamatergic structure of the epithalamus, is known to signal negative value of events to the dopaminergic neurons, playing a pivotal role in processes related to learning and motivation. LHb indirectly inhibits dopaminergic neurons in the ventral tegmental area (VTA) via excitation of local GABAergic neurons or via rostromedial tegmental nucleus. Two subpopulations of LHb neurons were distinguished based on their opposite responses (excitation or inhibition) to aversive stimuli (AS). Additionally, differences in the response of LHb neurons to AS are correlated with the pattern and level of their basal activity as well as their spatial location. Our previous study described a subpopulation of VTA dopaminergic neurons that responds to AS in brain state-dependent manner under urethane anaesthesia. It is not known, however, whether LHb neurons may also undergo such changes and potentially account for the variability of VTA responses to AS. To address this question, we recorded LHb neurons' activity *in vivo*, using multi electrode arrays, and observed their responses to the AS in urethane anesthetized rats. In agreement with literature, we observed AS-excited and AS-inhibited LHb neurons. However, we also encountered a subpopulation of LHb neurons that changes the type of response to AS and the basal level of activity between REM-like and non-REM-like brain states. This study extends the knowledge about LHb neurons' responses to the aversive stimuli, and may shed new light on the relationship between the general state of brain and neuronal processing of aversion.

INSULIN-LIKE GROWTH FACTOR I MITIGATES POST-TRAUMATIC STRESS BY INHIBITING AMP-KINASE IN OREXIN NEURONS

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

M Estrella Fernandez De Sevilla[1,2], Jaime Pignatelli[1,2], Jonathan A Zegarra-Valdivia[1,3], Pablo Mendéz[2], Angel Nuñez[4], Ignacio Torres Aleman[1,2,3]
[1]Ciberned, Ciberned, Madrid, Spain, [2]Cajal Institute, Functional And Systems Neurobiology, Madrid, Spain, [3]Achucarro Basque Neuroscience Center, Laboratory Of Neurobiology Of Insulin Peptides, Leioa, Spain, [4]University Autonoma of Madrid, Madrid, Spain, Anatomy, Histology And Neuroscience, Madrid, Spain

Maladaptive coping behaviors are probably involved in post-traumatic stress disorders (PTSD), but underlying mechanisms are incompletely understood. We documented that insulin-like growth factor I (IGF-I) is associated to vulnerability to stress in mice and humans. Since orexin neurons express IGF-I receptors and are involved in stress responses, we analyzed their role in modulatory actions of IGF-I on stress. Anxiolytic actions of IGF-I were measured after predator exposure using osmotic minipumps in mice lacking IGF-I receptors in orexin neurons (Firoc). Firoc mice were submitted to fear conditioning and thereafter c-Fos immunostaining in orexin and locus coeruleus nucleus was performed. Similar experiments were carried out with optogenetic activation in orexin neurons. Chemogenetic inhibition of orexin neurons was performed in fear conditioning, context recall and anhedonia tests. PTSD-related molecular changes were qPCR determined. Excitatory/inhibitory (E/I) balance in orexin neurons was analyzed. We found that Firoc mice are unresponsive to the anxiolytic actions of IGF-I and develop PTSD-like behavior that is ameliorated by inhibition of orexin neurons. Further, systemic IGF-I treatment ameliorated PTSD-like behavior in a wild type mouse model of PTSD. In addition, systemic IGF-I increased the E/I ratio in orexin neurons of wild type mice by increasing the dephosphorylation of GABA(B) receptor subunit through inhibition of AMP-kinase (AMPK). Significantly, pharmacological inhibition of AMPK mimicked IGF-I, normalizing fear in PTSD mice. Collectively, these results suggest that IGF-I enables coping behaviors by balancing E/I input onto orexin neurons in a context-dependent manner. This provides a novel therapeutic approach to PTSD through modulation of AMPK.

Reduced Insulin-Like Growth Factor-I Effects in the Basal Forebrain of Aging Mouse.
It is known that aging is frequently accompanied by a decline in cognition. Furthermore, aging is associated with lower serum IGF-I levels that may contribute to this deterioration. We studied the effect of IGF-I in neurons of the horizontal diagonal band of Broca (HDB) of young (≤6 months old) and old (≥20-month-old) mice to determine if changes in the response of these neurons to IGF-I occur along with aging. Local injection of IGF-I in the HDB nucleus increased their neuronal activity and induced fast oscillatory activity in the electrocorticogram (ECoG). Furthermore, IGF-I facilitated tactile responses in the primary somatosensory cortex elicited by air-puffs delivered in the whiskers. These excitatory effects decreased in old mice. Immunohistochemistry showed that cholinergic HDB neurons express IGF-I receptors and that IGF-I injection increased the expression of c-fos in young, but not in old animals. IGF-I increased the activity of optogenetically-identified cholinergic neurons in young animals, suggesting that most of the IGF-I-induced excitatory effects were mediated by activation of these neurons. Effects of aging were partially ameliorated by chronic IGF-I treatment in old mice. The present findings suggest that reduced IGF-I activity in old animals participates in age-associated changes in cortical activity.

Circulating Insulin-Like Growth Factor I is Involved in the Effect of High Fat Diet on Peripheral Amyloid β Clearance.
Obesity is a risk factor for Alzheimer's disease (AD), but underlying mechanisms are not clear. We analyzed peripheral clearance of amyloid β (Aβ) in overweight mice because its systemic elimination may impact brain Aβ load, a major landmark of AD pathology. We also analyzed whether circulating insulin-like growth factor I (IGF-I) intervenes in the effects of overweight as this growth factor modulates brain Aβ clearance and is increased in the serum of overweight mice. Overweight

mice showed increased Aβ accumulation by the liver, the major site of elimination of systemic Aβ, but unaltered brain Aβ levels. We also found that Aβ accumulation by hepatocytes is stimulated by IGF-I, and that mice with low serum IGF-I levels show reduced liver Aβ accumulation-ameliorated by IGF-I administration, and unchanged brain Aβ levels. In the brain, IGF-I favored the association of its receptor (IGF-IR) with the Aβ precursor protein (APP), and at the same time, stimulated non-amyloidogenic processing of APP in astrocytes, as indicated by an increased sAPPα/sAPPβ ratio after IGF-I treatment. Since serum IGF-I enters into the brain in an activity-dependent manner, we analyzed in overweight mice the effect of brain activation by environmental enrichment (EE) on brain IGF-IR phosphorylation and its association to APP, as a readout of IGF-I activity. After EE, significantly reduced brain IGF-IR phosphorylation and APP/IGF-IR association were found in overweight mice as compared to lean controls. Collectively, these results indicate that a high-fat diet influences peripheral clearance of Aβ without affecting brain Aβ load. Increased serum IGF-I likely contributes to enhanced peripheral Aβ clearance in overweight mice, without affecting brain Aβ load probably because its brain entrance is reduced.

Insulin-like growth factor I modulates sleep through hypothalamic orexin neurons.
Although sleep disturbances are common co-morbidities of metabolic diseases, the underlying processes linking both are not yet fully defined. Changes in the duration of sleep are paralleled by changes in the levels of insulin-like growth factor-I (IGF-I), an anabolic hormone that shows a circadian pattern in the circulation and activity-dependent entrance in the brain. However, the specific role, if any, of IGF-I in this universal homeostatic process remains poorly understood. We now report that the activity of orexin neurons, a discrete cell population in the lateral hypothalamus that is involved in the circadian sleep/wake cycle and arousal, is modulated by IGF-I. Furthermore, mice with blunted IGF-I receptor activity in orexin neurons have lower levels of orexin in the hypothalamus, show altered electro-corticographic patterns with predominant slow wave activity, and reduced onset-sleep latency. Collectively, these results extend the role in the brain of this pleiotropic growth factor to shaping sleep architecture through the regulation of orexin neurons. We speculate that poor sleep quality associated to diverse conditions may be related to disturbed brain IGF-I input to orexin neurons.

Sources and lesion-induced changes of VEGF expression in brainstem motoneurons.
Motoneurons of the oculomotor system show lesser vulnerability to neurodegeneration compared to other cranial motoneurons, as seen in amyotrophic lateral sclerosis (ALS). The overexpression of vascular endothelial growth factor (VEGF) is involved in motoneuronal protection. As previously shown, motoneurons innervating extraocular muscles present a higher amount of VEGF and its receptor Flk-1 compared to facial or hypoglossal motoneurons. Therefore, we aimed to study the possible sources of VEGF to brainstem motoneurons, such as glial cells and target muscles. We also studied the regulation of VEGF in response to axotomy in ocular, facial, and hypoglossal motor nuclei. Basal VEGF expression in astrocytes and microglial cells of the cranial motor nuclei was low. Although the presence of VEGF in the different target muscles for brainstem motoneurons was similar, the presynaptic element of the ocular neuromuscular junction showed higher amounts of Flk-1, which could result in greater efficiency in the capture of the factor by oculomotor neurons. Seven days after axotomy, a clear glial reaction was observed in all the brainstem nuclei, but the levels of the neurotrophic factor remained low in glial cells. Only the injured motoneurons of the oculomotor system showed an increase in VEGF and Flk-1, but such an increase was not detected in axotomized facial or hypoglossal motoneurons. Taken together, our findings suggest that the ocular motoneurons themselves upregulate VEGF expression in response to lesion. In conclusion, the low VEGF expression observed in glial cells suggests that these cells are not the main source of VEGF for brainstem motoneurons. Therefore, the higher VEGF expression observed in motoneurons innervating extraocular muscles is likely due either to the fact that this factor is more avidly taken up from the target muscles, in basal conditions, or is produced by these motoneurons themselves, and acts in an autocrine manner after axotomy.

Serum Insulin-Like Growth Factor I Deficiency Associates to Alzheimer's Disease Co-Morbidities.
Increasing evidence supports the notion that Alzheimer's disease (AD), a condition that presents heterogeneous pathological disturbances, is also associated to perturbed metabolic function affecting insulin and insulin-like growth factor I (IGF-I). While impaired insulin activity leading to insulin resistance has been associated to AD, whether altered IGF-I function affects the disease is not entirely clear. Despite the limitations of mouse models to mimic AD pathology, we took advantage that serum IGF-I deficient mice (LID mice) present many functional perturbations present in AD, most prominently cognitive loss, which is reversed by treatment with systemic IGF-I. We analyzed whether these mice display other pathological traits that are usual

co-morbidities of AD. We found that LID mice not only display cognitive disturbances, but also show altered mood and sociability, increased susceptibility to epileptiform activity, and a disturbed sleep/wake cycle. Collectively, these data suggest that reduced IGF-I activity contributes to heterogeneous deficits commonly associated to AD. We suggest that impaired IGF-I activity needs to be taken into consideration when modeling this condition.

Insulin-like growth factor I mitigates post-traumatic stress by inhibiting AMP-kinase in orexin neurons.
Maladaptive coping behaviors are probably involved in post-traumatic stress disorders (PTSD), but underlying mechanisms are incompletely understood. We now report that mice lacking functional insulin-like growth factor I (IGF-I) receptors in orexin neurons of the lateral hypothalamus (Firoc mice) are unresponsive to the anxiolytic actions of IGF-I and develop PTSD-like behavior that is ameliorated by inhibition of orexin neurons. Conversely, systemic IGF-I treatment ameliorated PTSD-like behavior in a wild-type mouse model of PTSD (PTSD mice). Further, systemic IGF-I modified the GABA/Glutamate synaptic structure in orexin neurons of naïve wild-type mice by increasing the dephosphorylation of GABA(B) receptor subunit through inhibition of AMP-kinase (AMPK). Significantly, pharmacological inhibition of AMPK mimicked IGF-I, normalizing fear behavior in PTSD mice. Thus, we suggest that IGF-I enables coping behaviors by balancing E/I input onto orexin neurons in a context-dependent manner. These observations provide a novel therapeutic approach to PTSD through modulation of AMPK.

Midbrain dopaminergic neurons, located in the ventral tegmental area (VTA) and substantia nigra pars compacta (SNc), control animals' motivation, experience-based learning and motor functions. Our preliminary observations suggested that one of the inputs controlling the dopaminergic system may arise from the brainstem nucleus incertus (NI) involved in aversive stimuli processing and stress response generation. Therefore, our study was aimed to further investigate the hitherto unknown neuronal pathway connecting NI and the dopaminergic system in the Sprague Dawley rats. For this purpose, anatomical, electrophysiological and behavioural experiments were performed. Before electrophysiological and behavioural experiments, two viral vectors, one retrograde, carrying Cre recombinase gene and the other carrying Cre-dependent genes for the red light-sensitive cationic channel and fluorescent protein, were injected into animal's VTA/SNc and NI respectively. To visualise the anatomy of the studied pathway retrogradely transported viral vector carrying genes for fluorescent protein was injected to VTA/SNc. Our anatomical data confirmed the existence of a monosynaptic input from NI to VTA/SNc neurons. Furthermore, electrophysiological observations showed a subpopulation of VTA/SNc neurons that respond to NI optogenetic activation with fast, short duration inhibition. Juxtacellular recording-labelling combined with immunostaining proved that those inhibited neurons are DA. Finally, behavioural data revealed the aversive nature of NI to VTA input. Overall, our study shows that NI-originating innervation of the midbrain DA neurons is inhibitory and that its activation is sufficient to induce conditioned aversion. Superior Colliculus Controls the Activity of the Rostromedial Tegmental Nuclei in an Asymmetrical Manner.
Dopaminergic (DA) neurons of the midbrain are involved in controlling orienting and approach of animals toward relevant external stimuli. The firing of DA neurons is regulated by many brain structures; however, the sensory input is provided predominantly by the ipsilateral superior colliculus (SC). It is suggested that SC also innervates the contralateral rostromedial tegmental nucleus (RMTg)-the main inhibitory input to DA neurons. Therefore, this study aimed to describe the physiology and anatomy of the SC-RMTg pathway. To investigate the anatomic connections within the circuit of interest, anterograde, retrograde, and transsynaptic tract-tracing studies were performed on male Sprague Dawley rats. We have observed that RMTg is monosynaptically innervated predominantly by the lateral parts of the intermediate layer of the contralateral SC. To study the physiology of this neuronal pathway, we conducted electrophysiological experiments combined with optogenetics; the activity of RMTg neurons was recorded using silicon probes, while either contralateral or ipsilateral SC was optogenetically stimulated. Obtained results revealed that activation of the contralateral SC excites the majority of RMTg neurons, while stimulation of the ipsilateral SC evokes similar proportions of excitatory or inhibitory responses. Consequently, single-unit recordings showed that the activation of RMTg neurons innervated by the contralateral SC, or stimulation of contralateral SC-originating axon terminals within the RMTg, inhibits midbrain DA neurons. Together, the anatomy and physiology of the discovered brain circuit suggest its involvement in the orienting and motivation-driven locomotion of animals based on the direction of external sensory stimuli. Dopaminergic neurons are the target of predominantly ipsilateral, excitatory innervation originating from the superior colliculus. However, we demonstrate in our study that SC inhibits the activity of dopaminergic neurons on the contralateral side of the brain via the rostromedial tegmental nucleus. In this way, sensory information received by the animal from one hemifield could induce opposite effects on both sides of the dopaminergic system. It was shown that the side to which an animal directs its behavior is a manifestation of asymmetry in dopamine

release between left and right striatum. Animals tend to move oppositely to the hemisphere with higher striatal dopamine concentration. This explains how the above-described circuit might guide the behavior of animals according to the direction of incoming sensory stimuli.

Effects of brief inhibition of the ventral tegmental area dopamine neurons on the cocaine seeking during abstinence.
Preclinical studies strongly suggest that cocaine seeking depends on the neuronal activity of the ventral tegmental area (VTA) and phasic dopaminergic (DA) signaling. Notably, VTA pharmacological inactivation or dopamine receptor blockade in the forebrain may induce behavioral inhibition in general and acute aversive states in particular, thus reducing cocaine seeking indirectly. Such artifacts hinder successful translation of these findings in clinical studies and practice. Here, we aimed to evaluate if dynamic VTA manipulations effectively reduce cocaine seeking. We used male tyrosine hydroxylase (TH) IRES-Cre rats along with optogenetic tools to inhibit directly and briefly VTA DA neurons during conditioned stimulus (CS)-induced cocaine seeking under extinction conditions. The behavioral effects of optogenetic inhibition were also assessed in the real-time dynamic place aversion, conditioned place aversion, and CS-induced food-seeking tests. We found that brief and nondysphoric/nonsedative pulses of VTA photo-inhibition (1 s every 9 s, ie, for 10% of time) attenuated CS-induced cocaine seeking under extinction conditions in rats expressing archaerhodopsin selectively on the TH neurons. Furthermore, direct inhibition of the VTA DA activity reduced CS-induced cocaine seeking 24 hours after photo-modulation. Importantly, such effect appears to be selective for cocaine seeking as similar inhibition of the VTA DA activity had no effect on CS-induced food seeking. Thus, briefly inhibiting VTA DA activity during CS-induced cocaine seeking drastically and selectively reduces seeking without behavioral artifacts such as sedation or dysphoria. Our results point to the therapeutic possibilities of coupling nonpharmacologic treatments with extinction training in reducing cocaine addiction.

NEUROKININ B NEURONS OF THE BED NUCLEUS OF THE STRIA TERMINALIS IN EMOTION AND FEEDING BEHAVIOR

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Pradeepa Mohan Bethuraj, Heide Hörtnagl, Ramon Tasan
Medical University Innsbruck, Department Of Pharmacology, Innsbruck, Austria

Objective: The bed nucleus of stria terminalis (BNST) is a limbic fore brain structure involved in stress-regulation and related to human psychiatric diseases. Studies suggest that neurons within the BNST are capable of modulating both, aversive and appetitive behaviors. Neurokinin B (NKB) is an abundantly expressed yet little explored neuropeptide in the BNST. Our aim is to investigate whether NKB supports the integrative function of BNST neurons. **Methods:** Histochemistry and viral vector mediated neuronal tract tracing were used to identify, characterize and map the elaborated network of BNST NKB neurons. The modulatory role of NKB neurons on anxiety, fear and feeding behavior was studied using chemogenetic activation and inactivation followed by behavioral testing in transgenic Tac2cre mice. **Results:** NKB was abundantly expressed in calretinin positive neurons of the BNST and dominant projections were found in amygdala, hypothalamus and periaqueductal grey. Chemogenetic stimulation of BNST NKB neurons increased anxiety-related behavior and sustained fear expression but reduced food intake, while inhibition of these neuronal population did not alter these behaviors. Furthermore, activation of BNST NKB neurons in the BNST did not result in altered pain sensation nor promote an aversive phenotype. **Conclusion:** Our results suggest that NKB neurons of the BNST play a substantial role in coordinating sustained fear and feeding-related behaviors, probably by interacting with distinct amygdala, hypothalamic and brainstem nuclei.

NPY Released From GABA Neurons of the Dentate Gyrus Specially Reduces Contextual Fear Without Affecting Cued or Trace Fear.
Disproportionate, maladapted, and generalized fear are essential hallmarks of posttraumatic stress disorder (PTSD), which develops upon severe trauma in a subset of exposed individuals. Among the brain areas that are processing fear memories, the hippocampal formation exerts a central role linking emotional-affective with cognitive aspects. In the hippocampus, neuronal excitability is constrained by multiple GABAergic interneurons with highly specialized functions and an extensive repertoire of co-released neuromodulators. Neuropeptide Y (NPY) is one of these co-transmitters that significantly affects hippocampal signaling, with ample evidence supporting its fundamental role in emotional, cognitive, and metabolic circuitries. Here we investigated the role of NPY in relation to GABA, both released from the same interneurons of the dorsal dentate gyrus (DG), in different aspects of fear conditioning. We demonstrated that activation of dentate GABA neurons specifically during fear recall reduced cue-related as well as trace-related freezing behavior, whereas inhibition of the same neurons had no significant effects. Interestingly, concomitant overexpression of NPY in these neurons did not further modify fear recall, neither under baseline conditions nor upon chemogenetic stimulation. However, potentially increased co-release of NPY substantially reduced contextual fear, promoted extinction learning, and long-term suppression of fear in a foreground context-conditioning paradigm. Importantly, NPY in the dorsal DG was not only expressed in somatostatin neurons, but also in parvalbumin-positive basket cells and axoaxonic cells, indicating intense feedback and feedforward modulation of hippocampal signaling and precise curtailing of neuronal engrams. Thus, these findings suggest that co-release of NPY from specific interneuron populations of the dorsal DG modifies dedicated aspects of hippocampal processing by sharpening the activation of neural engrams and the consecutive fear response. Since inappropriate and generalized fear is the major impediment in the treatment of PTSD patients, the dentate NPY system may be a suitable access point to ameliorate PTSD symptoms and improve the inherent disease course.

CORTICO-THALAMIC PRINCIPLES DEFINE THE COMPLEXITY OF THE INTRA-AMYGDALAR CONNECTIVITY

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Ákos Babiczky[1,2,3], Kinga Kocsis[2,4], Ferenc Mátyás[2,5,6]
[1]Institute of Experimental Medicine, Neuronal Network And Behavior Research Group, Budapest, Hungary, [2]Research Centre for Natural Sciences, Cognitive Neuroscience And Psychology, Budapest, Hungary, [3]Budapest University of Technology and Economics, Department Of Cognitive Science, Faculty Of Natural Sciences, Budapest, Hungary, [4]Pázmány Péter Catholic University, Roska Tamás Doctoral School Of Sciences And Technology, Budapest, Hungary, [5]Institute of Experimental Medicine, -, Budapest, Hungary, [6]University of Veterinary Medicine, Dept. Of Anatomy And Histology, Budapest, Hungary

The amygdala and the neurocircuitry it is embedded in have long been implicated in a wide range of emotional processes. During associative learning - according to the well-accepted model -, conditioned and unconditioned stimuli reach the basolateral complex of the amygdala (BLA) from various cortical and thalamic sources, which then, conveyed to the central amygdala (CeA). Finally, CeA outputs directly control behavioral responses via its subcortical targets. However, numerous anatomical and functional inconsistencies in the amygdala literature question this model. Therefore, our main goal was to provide a comprehensive anatomical map with connectivity principles of the amygdalar subregions. First, we delineated the different amygdala subnuclei using several molecular markers. Then, we performed antero- and retrograde tracer microinjections to selectively label all major amygdala subnuclei in mice. We mapped the intra-amygdalar connections between these territories and discovered the existence of several, rather non-overlapping pathways. This intra-amygdalar connectivity pattern showed remarkable overlap with the selectivity of the main cortical and thalamic innervations. These results were further supported by in-vivo electrophysiological data showing that stimulation of different thalamic inputs elicits distinct intra-amygdalar activation patterns. Taken together, our findings highlight the existence of parallel (rather than serial) information flow within the amygdala defined by their intra-amygdalar and cortical/thalamic innervation that could provide a framework for future studies on understanding amygdalar function.

Associative and plastic thalamic signaling to the lateral amygdala controls fear behavior.
Decades of research support the idea that associations between a conditioned stimulus (CS) and an unconditioned stimulus (US) are encoded in the lateral amygdala (LA) during fear learning. However, direct proof for the sources of CS and US information is lacking. Definitive evidence of the LA as the primary site for cue association is also missing. Here, we show that calretinin (Calr)-expressing neurons of the lateral thalamus (CalrLT neurons) convey the association of fast CS (tone) and US (foot shock) signals upstream from the LA in mice. CalrLT input shapes a short-latency sensory-evoked activation pattern of the amygdala via both feedforward excitation and inhibition. Optogenetic silencing of CalrLT input to the LA prevents auditory fear conditioning. Notably, fear conditioning drives plasticity in CalrLT neurons, which is required for appropriate cue and contextual fear memory retrieval. Collectively, our results demonstrate that CalrLT neurons provide integrated CS-US representations to the LA that support the formation of aversive memories.

A highly collateralized thalamic cell type with arousal-predicting activity serves as a key hub for graded state transitions in the forebrain.
Sleep cycles consist of rapid alterations between arousal states, including transient perturbation of sleep rhythms, microarousals, and full-blown awake states. Here we demonstrate that the calretinin (CR)-containing neurons in the dorsal medial thalamus (DMT) constitute a key diencephalic node that mediates distinct levels of forebrain arousal. Cell-type-specific activation of DMT/CR cells elicited active locomotion lasting for minutes, stereotyped microarousals, or transient disruption of sleep rhythms, depending on the parameters of the stimulation. State transitions could be induced in both slow-wave and rapid eye-movement sleep. The DMT/CR cells displayed elevated activity before arousal, received selective subcortical inputs, and innervated several forebrain sites via highly branched axons. Together, these features enable DMT/CR cells to

summate subcortical arousal information and effectively transfer it as a rapid, synchronous signal to several forebrain regions to modulate the level of arousal.

Beneficial Effects of Rosmarinic Acid on IPEC-J2 Cells Exposed to the Combination of Deoxynivalenol and T-2 Toxin.
Mycotoxin contamination in feedstuffs is a worldwide problem that causes serious health issues both in humans and animals, and it contributes to serious economic losses. Deoxynivalenol (DON) and T-2 toxin (T-2) are major trichothecene mycotoxins and are known to challenge mainly intestinal barrier functions. Polyphenolic rosmarinic acid (RA) appeared to have antioxidant and anti-inflammatory properties . The aim of this study was to investigate protective effects of RA against DON and T-2 or combined mycotoxin-induced intestinal damage in nontumorigenic porcine cell line, IPEC-J2. It was ascertained that simultaneous treatment of DON and T-2 (DT2: 1 mol/L DON + 5 nmol/L T - 2) for 48 h and 72 h reduced transepithelial electrical resistance of cell monolayer, which was restored by 50 mol/L RA application. It was also found that DT2 for 48 h and 72 h could induce oxidative stress and elevate interleukin-6 (IL-6) and interleukin-8 (IL-8) levels significantly, which were alleviated by the administration of RA. DT2 administration contributed to the redistribution of claudin-1; however, occludin membranous localization was not altered by combined mycotoxin treatment. In conclusion, beneficial effect of RA was exerted on DT2-deteriorated cell monolayer integrity and on the perturbated redox status of IPEC-J2 cells.

Investigation of the inflammatory and oxidative stress-inducing effects of deoxynivalenol and T-2 toxin exposure in non-tumorigenic human intestinal cell model.
Fungi in the Fusarium genus produce trichothecene mycotoxins including deoxynivalenol (DON) and T-2 toxin which may elicit their damaging effects on the gastrointestinal tract following the consumption of contaminated cereal-based foods. The aim of our study was to evaluate the effects of these commonly occurring fusarotoxins alone and in combination using the human, non-cancerous intestinal epithelial cell line HIEC-6. Based on our experimental data, 24 h after treatment with fusarotoxins, hydrogen peroxide levels, intracellular oxidative stress and the amounts of inflammatory interleukins IL-6 and IL-8 significantly increased. Cell membrane localization of the tight junction protein claudin-1 decreased, whereas distribution of occludin remained unchanged. Taken together, the HIEC-6 cell line appears to be a suitable experimental model for monitoring the combined effects of mycotoxins at the cellular level including changes in the redox states of cells.

Novel Lysine-Rich Delivery Peptides of Plant Origin ERD and Human S100: The Effect of Carboxyfluorescein Conjugation, Influence of Aromatic and Proline Residues, Cellular Internalization, and Penetration Ability.
The need for novel drug delivery peptides is an important issue of the modern pharmaceutical research. Here, we test K-rich peptides from plant dehydrin ERD14 (ERD-A, ERD-B, and ERD-C) and the C-terminal CPP-resembling region of S100A4 (S100) using the 5(6)-carboxyfluorescein (Cf) tag at the N-terminus. Via a combined pH-dependent NMR and fluorescence study, we analyze the effect of the Cf conjugation/modification on the structural behavior, separately investigating the (5)-Cf and (6)-Cf forms. Flow cytometry results show that all peptides internalize; however, there is a slight difference between the cellular internalization of (5)- and (6)-Cf-peptides. We indicate the possible importance of residues with an aromatic sidechain and proline. We prove that ERD-A localizes mostly in the cytosol, ERD-B and S100 have partial colocalization with lysosomal staining, and ERD-C mainly localizes within vesicle-like compartments, while the uptake mechanism mainly occurs through energy-dependent paths.

A FUNCTIONAL CHARACTERIZATION OF SOMATOSTATIN EXPRESSING NEURONS IN THE BED NUCLEUS OF THE STRIA TERMINALIS

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Quentin Denis, Ramon Tasan
Medical University Innsbruck, Department Of Pharmacology, Innsbruck, Austria

Aims: The Bed Nucleus of the Stria Terminalis (BNST) is a sexually dimorphic forebrain structure and part of the extended amygdala. Widely acknowledged for its involvement in anxiety, a growing body of evidence also suggest for a role in fear-related behaviors. The diversity of the roles that it presents calls for a better understanding of the subpopulations that compose the BNST and their specific roles. Indeed, the BNST is divided in distinct subnuclei and composed of various, mostly GABAergic neuronal populations. Among these subpopulations, inhibitory somatostatin neurons ($BNST^{SOM}$) remain elusive in their role and projection targets. We therefore aim to better characterize these neurons and their actions. **Methods :** In our study, we used a Somatostatin-IRES-Cre mouse line to selectively transfect $BNST^{SOM}$ neurons with chemogenetic activating Designer Receptors Exclusively Activated by Designer Drug (DREADD) or neuronal tracers. Mice were tested for feeding and anxiety-like behavior as well as phasic and sustained fear expression upon activation of these neurons. **Results :** We identified projections notably to the Periaqueductal Grey, a region linked to both anxiety and fear-like disorders. Chemogenetic activation of the $BNST^{SOM}$ neurons led to enhanced states of sustained fear in male mice. Interestingly, similar activation had an anxiogenic effect in female mice, and enhanced both phasic and sustained states of fear. **Conclusion :** Together, our findings point towards a potential role of $BNST^{SOM}$ neurons in the modulation of anxious states and fear expression.

Pridopidine Induces Functional Neurorestoration Via the Sigma-1 Receptor in a Mouse Model of Parkinson's Disease. Pridopidine is a small molecule in clinical development for the treatment of Huntington's disease. It was recently found to have high binding affinity to the sigma-1 receptor, a chaperone protein involved in cellular defense mechanisms and neuroplasticity. Here, we have evaluated the neuroprotective and neurorestorative effects of pridopidine in a unilateral 6-hydroxydopamine (6-OHDA) lesion model of parkinsonism in mice. By 5 weeks of daily administration, a low dose of pridopidine (0.3 mg/kg) had significantly improved deficits in forelimb use (cylinder test, stepping test) and abolished the ipsilateral rotational bias typical of hemiparkinsonian animals. A higher dose of pridopidine (1 mg/kg) significantly improved only the rotational bias, with a trend towards improvement in forelimb use. The behavioral recovery induced by pridopidine 0.3 mg/kg was accompanied by a significant protection of nigral dopamine cell bodies, an increased dopaminergic fiber density in the striatum, and striatal upregulation of GDNF, BDNF, and phosphorylated ERK1/2. The beneficial effects of pridopidine 0.3 mg/kg were absent in 6-OHDA-lesioned mice lacking the sigma-1 receptor. Pharmacokinetic data confirmed that the effective dose of pridopidine reached brain concentrations sufficient to bind S1R. Our results are the first to show that pridopidine promotes functional neurorestoration in the damaged nigrostriatal system acting via the sigma-1 receptor. Neurotherapeutics, 2019; 16

Dopaminergic neurons of the ventral tegmental area (VTA) and substantia nigra pars compacta (SNc) form the core of reward and motivation system in the mammalian brain. Midbrain dopaminergic neurons have long been known to code information about either value or salience of aversive stimuli by responding with decrease or increase of their activity, respectively. Given that both level and pattern of VTA and SNc dopaminergic neurons' activity depend on alternating brain states under urethane anaesthesia, we hypothesized that midbrain dopaminergic neurons' responses to the aversive stimuli are also brain state-dependent.
We carried out in vivo recordings of dopaminergic neurons' responses to the electrical footshocks in urethane anaesthetized rats. Dopaminergic nature of recorded neurons was confirmed using juxtacellular labelling, combined with immunohistochemical staining against TH, or optotagging (TH-Cre rats). Consistently with previous studies, we observed two subpopulations of VTA and SNc dopaminergic neurons – one excited and one inhibited by the footshocks. However, we also discovered a third, previously undescribed, population of dopaminergic neurons that is characterized by dynamic, brain state-dependent changes in the type of response to electrical footshocks. Most of these dopaminergic neurons are inhibited by an aversive stimulus in a low theta-frequency brain state, but after the brain goes into slow wave state these neurons begin be excited by footshock. By describing a new population of midbrain dopaminergic neurons that likely encode both stimulus value and salience, our results broaden the current understanding of aversive event coding and processing in the brain.

SIMULTANEOUS INVESTIGATION OF NEUROMODULATORY SYSTEMS DURING OPERANT CONDITIONING BY FIBER PHOTOMETRY AND ELECTROPHYSIOLOGY

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Vivien Pillár, Bálint Király, Balazs Hangya
Institute of Experimental Medicine, Lendület Laboratory, Budapest, Hungary

The key role of different neuromodulatory systems in learning and memory has long been known. However, the relationship between different neuromodulatory systems and possible synergistic or antagonistic effects are almost completely unknown. In addition, the known association of the degeneration of cholinergic and dopaminergic neurons with neurodegenerative diseases such as Alzheimer's and Parkinson's lends special importance to studying these systems. According to recent findings, reward prediction error previously known only in the dopaminergic system may also be encoded by the cholinergic system. It is not yet clear what similarities and differences the information represented by the two systems show. In this work, we investigated the two systems simultaneously in an auditory operant psychometric learning task using fiber photometry and electrophysiological methods. We found that dopaminergic neurons responded earlier than cholinergic cells after reward-predicting tones, while neither of them responded to punishment-predicting tones. We observed more activity after the delivery of unexpected than expected reward in both cell-types. Cholinergic neurons responded earlier than dopaminergic neurons to both expected and unexpected reward. Dopaminergic neurons were heterogeneous in their responses to punishment, being either suppressed or activated. A group of cholinergic neurons responded to punishment with an extremely precise and fast activation, while some neurons did not respond. Our results point to the similarities and differences between the two systems and how they work simultaneously. Crosscorrelation analysis revealed fast within system and slow across system temporal correlations, which suggest a complex relationship between the two neuromodulatory systems.

IN VIVO EXAMINATION OF AGE-DEPENDENT CHANGES IN THE ACTIVITY OF BASAL FOREBRAIN CHOLINERGIC NEURONS DURING A PAVLOVIAN CONDITIONING TASK

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Anna Velencei[1], Sergio Martínez-Bellver[1,2], Bálint Király[3], Hegedüs Panna[1], Balazs Hangya[3]

By releasing acetylcholine, the basal forebrain cholinergic neurons and their widespread projections to the cortical mantle play a key role in the control of cognitive functions, like sensory processing, attention, arousal and reinforcement expectation. Several age-related changes were observed in these neurons, such as degeneration of dendrites, axons and synapsis; nonetheless the connection between cholinergic activity during learning and the age-related neurodegeneration is still not completely clear. To address this, we combined fluorescent in vivo recording techniques and optogenetic manipulations in headfixed mice during an auditory cued Pavlovian conditioning task. By using fiber photometry, we measured acetylcholine release in the basolateral nucleus of the amygdala (BLA) using a newly developed acetylcholine sensor. As another approach, we optogenetically inhibited the cholinergic neurons of the horizontal diagonal band of Broca (HDB) during the presentation of conditioned stimuli (CS). Our results suggest that cholinergic cells respond to the reward-predicting CS and also to the unconditioned stimuli with an increase of activity and acetylcholine release. It seems that acetylcholine release in the BLA occurs only during the reward-predicting but not the punishment-predicting sensory stimuli. In old mice, acetylcholine levels in the BLA showed no response to the CS. In the optogenetic manipulation experiments, we found that the animals which received the inhibitory virus in their HDB had difficulties learning the task compared to the animals which received the control virus. According to our results acetylcholine release from basal forebrain neurons is required during the acquisition of the CS-US association during Pavlovian conditioning.

Training protocol for probabilistic Pavlovian conditioning in mice using an open-source head-fixed setup.
High throughput, temporally controlled, reproducible quantitative behavioral assays are important for understanding the neural mechanisms underlying behavior. Here, we provide a step-by-step training protocol for a probabilistic Pavlovian conditioning task, where two auditory cues predict probabilistic outcomes with different contingencies. This protocol allows us to study the differential behavioral and neuronal correlates of expected and surprising outcomes. It has been tested in combination with chronic electrophysiological recordings and optogenetic manipulations in ChAT-Cre and PV-Cre mouse lines. For complete details on the use and execution of this protocol, please refer to Hegedüs et al. (2021).

Maternal care is a special form of social behaviour regulated by both hormones and neuronal inputs. Our research group previously described a thalamo-hypothalamic pathway containing the maternally induced neuropeptide, parathyroid hormone-2 (PTH2) expressed by neurons of the posterior intralaminar thalamic nucleus (PIL). Additional to the hypothalamic medial preoptic area (MPOA), the central regulator of maternal behaviour, PIL neurons also project to the lateral septum (LS). The LS is known to show pup-induced activation in rodent mothers and to have reciprocal connection with the MPOA. Therefore, we hypothesize that LS participates in the PIL-MPOA circuit controlling maternal care. Here, we demonstrate that LS receives input from maternally-activated PIL neurons and fibres arising from the PIL are PTH2+. Furthermore, we found elevated number of pup-induced activated calbindin LS neurons closely apposed by PTH2-terminals. We also revealed, all calbindin and maternally-activated LS neurons are GABAergic. Synaptic connection of GABAergic LS neurons with PTH2-terminals was confirmed by electron microscopy. We showed that LS GABAergic and calbindin neurons send prominent input to the MPOA. Since MPOA also receives dense PTH2+ projection from PIL neurons, we provided evidence that LS-projecting PIL neurons send axon collaterals to the MPOA by identifying double labelled PIL neurons following injection of different retrograde neuronal tracers into the LS and MPOA simultaneously. We conclude that pup directed information is conveyed to the LS and the MPOA via the PTH2+ input from the PIL. PTH2-innervated calbindin LS neurons may regulate maternal-related neurons of the MPOA via inhibitory signal. Support: NKFIH-4300-1/2017-NKP_17-0002, OTKA K134221, TKP2020-IKA-05

Habenula is an evolutionary conserved brain region that was shown to play important roles in adaptive and defensive behavior. Notably, it receives both, excitation and inhibitory inputs from the forebrain and relays this information to monoaminergic brain nuclei. We observed that several members of group III metabotropic glutamate receptors (mGluRs) are expressed in the zebrafish habenula. Targeting those group III mGluRs pharmacologically, alters the membrane potential and the connectivity of habenular neurons. In addition, perturbing group III mGluRs with both, genetic and pharmacological methods directly modulates the ongoing and sensory driven activity in habenula and the forebrain of juvenile zebrafish. Our preliminary results suggest that perturbing group III mGluRs also alters defensive and adaptive behaviors. Altogether, these findings propose an important role for group III mGluRs for regulating habenular circuits and animal behavior.

Ongoing habenular activity is driven by forebrain networks and modulated by olfactory stimuli.
Ongoing neural activity, which represents internal brain states, is constantly modulated by the sensory information that is generated by the environment. In this study, we show that the habenular circuits act as a major brain hub integrating the structured ongoing activity of the limbic forebrain circuitry and the olfactory information. We demonstrate that ancestral homologs of amygdala and hippocampus in zebrafish forebrain are the major drivers of ongoing habenular activity. We also reveal that odor stimuli can modulate the activity of specific habenular neurons that are driven by this forebrain circuitry. Our results highlight a major role for the olfactory system in regulating the ongoing activity of the habenula and the forebrain, thereby altering brain's internal states.

RXFP3-INDUCED MODULATION OF AMYGDALA NEURONAL NETWORK ACTIVITY.

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Etienne Clauss--Creusot, Alexandre Charlet
CNRS, Inci, Strasbourg, France

The relaxin-3 (rln3) is a neuropeptide that has been shown to be involved in several physiological functions. It is synthetized in GABAergic neurons of the *nucleus incertus*. Relaxin-3 mainly acts through RXFP3, a G-protein coupled receptor that once activated, lead to a neuronal inhibition. Both RXFP3-expressing neurons and rln3 positive projections are found throughout many brain structures. Among them, the basal and central amygdala which are known to be involved in emotions processing, including pain and its comorbidities. Preliminary experiments have shown that amygdala RXFP3 activation triggers mechanical analgesia in a mice model of pain-induced inflammatory sensitization. Hence, our project aims to decipher the effect of RXFP3 activation on the amygdala neuronal network activity. To do so, we will take advantage of newly developed specific agonists of RXFP3 to characterize the RXFP3 effects using *ex vivo* patch clamp recording of both GABAergic interneurons and projection neurons. Finally, we will assess the contribution of *nucleus incertus* Rln3 neurons to the modulation of the amygdala using an optogenetic-based circuit deciphering approach.

BIOPHYSICAL PROPERTIES AND GENE EXPRESSION PROFILE OF SINGLE PERIAQUEDUCTAL GRAY NEURONS

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Oriol Pavon Arocas, Sarah Olesen, Tiago Branco
University College London, Sainsbury Wellcome Centre For Neural Circuits And Behaviour, London, United Kingdom

The midbrain periaqueductal gray (PAG) is a longitudinal columnar structure where instinctive behaviours as diverse as escaping from predators, vocalising, and pup grooming segregate onto distinct anatomical subdivisions. This parallel between behaviour and brain circuit anatomy provides a unique opportunity for investigating how neural mechanisms support the computation of different adaptive actions. Here, we characterised the biophysical properties and gene expression profile of single neurons across PAG subdivisions. First, we measured the intrinsic firing properties of PAG neurons using loose-seal cell-attached recordings in acute midbrain slices of transgenic mice. We found that, even in the absence of synaptic inputs, inhibitory ($VGAT^+$) neurons fire action potentials spontaneously, whereas excitatory ($VGluT2^+$) neurons do not. Next, to link the expression of ion channels, receptors, and molecular effectors to specific PAG subdivisions, we performed cell-type specific single-cell RNA-sequencing while preserving the anatomical origin of each neuron. We individually isolated fluorescently labelled neurons from acute midbrain slices of transgenic mice and processed them with Smart-seq2 and a sequencing depth of 4 million reads per sample. Graph-based clustering of the resulting data revealed putative subtypes of neurons that map onto different PAG subdivisions, whereas differential expression analysis of these data identified candidate ion channel subunit and neuromodulator genes for setting and regulating key biophysical properties of PAG neurons. By leveraging the unique relationship between PAG circuit anatomy and behavioural output, our work uses anatomical location as an anchor to provide a framework for studying how molecularly defined biophysical properties might underpin behavioural control by the PAG.

In humans and animals, changes in emotional states are known to modify posture, fine motor control, and/or coordination, inducing either beneficial or detrimental effects on motor performance. This suggests an overlap between neural circuits underlying emotions (limbic system) and motor control (basal ganglia). We thus performed an extensive review of the anatomical limbic-to-basal ganglia direct connections and chose to focus on the amygdala to caudate-putamen (CPu) projections in mice. The CPu is the gate of entry of the basal ganglia and is involved in action selection and movement. The amygdala, comprised of different subnuclei, is a key limbic structure involved in emotional processing such as valence-related signals, fear- and anxiety-related behavior. We hypothesize that amygdala-CPu neurons can modulate motor behavior during emotional states. Anatomical tracing tools, combined with *in vivo* and *ex-vivo* electrophysiology, show that the basolateral amygdala (BLA) complex is the main amygdala input to the CPu, with the densest projections to the medial CPu. These excitatory projections preferentially target medium-spiny neurons and parvalbumin interneurons. To define this neuronal sub-population, we mapped the inputs and outputs of the BLA-CPu neurons and determined the sources of their neuromodulators. Calcium imaging *in vivo* in anesthetized mice further confirms the functional connectivity of the main inputs to BLA-CPu neurons and shows that they respond to different sensory challenges, such as footshocks and air puffs. Our study shows that the BLA-CPu pathway connects limbic structures to the basal ganglia and can also relay sensory, cognitive and interoceptive to the motor system.

DOPAMINERGIC MODULATION OF NUCLEUS INCERTUS TO INTERPEDUNCULAR NUCLEUS INPUT – A POSSIBLE NEURONAL MECHANISM FOR STRESS-INDUCED NOVELTY PREFERENCE DEFICIENCIES

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Appropriate novelty/familiarity discrimination and adequate responses to novelty are crucial for proper functioning and behaviour. Many neuropsychiatric disorders manifest in atypical reactions to novelty, and stress plays a key role in the development of this deficiency. Here we investigated the nucleus incertus (NI) to interpeduncular nucleus (IPN) innervation. NI is a stress-sensitive brainstem nucleus, and directly innervates the IPN, a neuroanatomical substrate for familiarity signalling. Concomitantly, dopamine (DA) has an established role in motivation-related processes and novelty preference. Aim: Investigate the functional NI to IPN connectivity, along with possible interactions of this innervation and DA/D1R signalling at the level of IPN neurons. Methods: Whole-cell patch-clamp recordings of IPN neuron activity were combined with optogenetic-stimulation of NI-originating fibres and D1R agonist application. Viral vector-based retrograde tract-tracing was combined with immunofluorescent staining. Results: Upon stimulation of NI-originating fibres, mostly light-evoked inhibitory postsynaptic currents (Ie iPSCs) were observed in the IPN. Among the neurons sensitive to optogenetic stimulation, 61.5% was excited by D1R activation, revealing that the same neurons are sensitive to novelty-related dopamine signalling and stress-related signals from the brainstem. Notably, analysis of Ie iPSC shape revealed that D1R agonist application decreased their amplitude. Neural tract-tracing revealed that the ventral tegmental area (VTA) is the main source of DA terminals in the IPN. Conclusions: These electrophysiological and anatomical data suggest a role for an NI–IPN–VTA pathway in the control of novelty preference and attentional processes, with DA/D1R signalling diminishing the negative influence of brainstem-originating stress signals on novelty preference. Bidirectional Communication between the Pontine Nucleus Incertus and the Medial Septum Is Carried Out by Electrophysiologically-Distinct Neuronal Populations.
Theta oscillations are key brain rhythm involved in memory formation, sensorimotor integration, and control of locomotion and behavioral states. Generation and spatiotemporal synchronization of theta oscillations rely on interactions between brain nuclei forming a large neural network, which includes pontine nucleus incertus (NI). Here we identified distinct populations of NI neurons, based on the relationship of their firing to hippocampal waves, with a special focus on theta oscillations, and the direction and type of interaction with the medial septum (MS) in male, urethane-anesthetized rats. By recording NI neuronal firing and hippocampal LFP, we described NI neurons that fire action potentials in a theta phase-independent or theta phase-locked and delta wave-independent or delta wave-locked manner. Among hippocampal activity-independent NI neurons, irregular, slow-firing, and regular, fast-firing cells were observed, while hippocampal oscillation-/wave-locked NI neurons were of a bursting or nonbursting type. By projection-specific optotagging, we revealed that only fast-firing theta phase-independent NI neurons innervate the MS, rarely receiving feedback information. In contrast, the majority of theta-bursting NI neurons were inhibited by MS stimulation, and this effect was mediated by direct GABAergic input. Described NI neuronal populations differ in reciprocal connections with the septohippocampal system, plausibly forming separate neuronal loops. Our results suggest that theta phase-independent NI neurons participate in theta rhythm generation through direct innervation of the MS, while theta-bursting NI neurons further transmit the rhythmic signal received from the MS to stabilize and/or strengthen rhythmic activity in other structures. The generation and spatiotemporal synchronization of theta oscillations rely on interactions between nuclei forming a large neural network, part of which is the pontine nucleus incertus (NI). Here we describe that within NI there are populations of neurons that can be distinguished based on the relationship of their firing to hippocampal theta oscillations and delta waves. We show that these neuronal populations largely do not have reciprocal connections with the septohippocampal system, but form separate neuronal loops. Our results suggest that medial septum (MS)-projecting, fast-firing, theta phase-independent NI neurons may participate in theta rhythm generation through direct

innervation of the MS, while theta-bursting NI neurons may further transmit the rhythmic signal received from the MS to other structures.

Altered vitamin D metabolism in the ovary and periovarian adipose tissue of rats with letrozole-induced PCOS.
Vitamin D (VD) plays an important role in the ovary and its deficiency is associated with ovarian pathologies, including polycystic ovary syndrome (PCOS). However, there is no data related to VD metabolism in the ovary during PCOS. Herein, we investigated differences in the expression of VD receptor (VDR) and key VD metabolic enzymes, 1α-hydroxylase (CYP27B1) and 24-hydroxylase (CYP24A1), in the ovary and periovarian adipose tissue (POAT) of control (proestrus and diestrus) and PCOS induced by letrozole rats. Vdr, Cyp27b1 and Cyp24a1 mRNA expression was determined, their protein abundance was examined and immunolocalized. Furthermore, VD metabolite concentrations in plasma (25OHD) and tissues (ovary and POAT; 1,25(OH)D), and plasma calcium level were determined. 25OHD concentration decreased markedly in letrozole-treated rats in comparison with controls, whereas calcium concentration did not vary among the examined groups. The amount of 1,25(OH)D decreased in both ovary and POAT of PCOS rats. In the ovary, we found decreased Cyp27b1 and increased Vdr mRNA expression in letrozole-treated and diestrus control group. Corresponding protein abundances were down-regulated and up-regulated, respectively but only following letrozole treatment. In POAT, only Cyp27b1 transcript level and CYP27B1 protein abundance were decreased in letrozole-treated rats. VDR was immunolocalized in healthy and cystic follicles, while CYP27B1 and CYP24A1 were found exclusively in healthy ones. Concluding, our results provide the first evidence of disrupted VD metabolism in the ovary and POAT of PCOS rats. The reduced 1,25(OH)D concentration in those tissues suggests their contribution to VD deficiency observed in PCOS and might implicate in PCOS pathogenesis.

RLN3/RXFP3 Signaling in the PVN Inhibits Magnocellular Neurons via M-like Current Activation and Contributes to Binge Eating Behavior.
Binge-eating disorder is the most common eating disorder. Various neuropeptides play important roles in the regulation of feeding behavior, including relaxin-3 (RLN3), which stimulates food intake in rats through the activation of the relaxin-family peptide-3 receptor (RXFP3). Here we demonstrate that a likely mechanism underlying the orexigenic action of RLN3 is RXFP3-mediated inhibition of oxytocin- and arginine-vasopressin-synthesizing paraventricular nucleus (PVN) magnocellular neurosecretory cells. Moreover, we reveal that, in male and female rats, this action depends on M-like potassium conductance. Notably, higher intra- and peri-PVN RLN3 fiber densities were observed in females, which may constitute an anatomic substrate for observed sex differences in binge-eating disorder. Finally, in a model of binge-eating in female rats, RXFP3 blockade within the PVN prevented binge-eating behavior. These data demonstrate a direct RLN3/RXFP3 action in the PVN of male and female rats, identify the associated ionic mechanisms, and reveal that hypothalamic RLN3/RXFP3 signaling regulates binge-eating behavior. Binge-eating disorder is the most common eating disorder worldwide, affecting women twice as frequently as men. Various neuropeptides play important roles in the regulation of feeding behavior, including relaxin-3, which acts via the relaxin-family peptide-3 receptor (RXFP3). Using a model of binge-eating, we demonstrated that relaxin-3/RXFP3 signaling in the hypothalamic paraventricular nucleus (PVN) is necessary for the expression of binge-eating behavior in female rats. Moreover, we elucidated the neuronal mechanism of RLN3/RXFP3 signaling in PVN in male and female rats and characterized sex differences in the RLN3 innervation of the PVN. These findings increase our understanding of the brain circuits and neurotransmitters involved in binge-eating disorder pathology and identify RXFP3 as a therapeutic target for binge-like eating disorders.

Levels of the neuropeptide phoenixin-14 and its receptor GRP173 in the hypothalamus, ovary and periovarian adipose tissue in rat model of polycystic ovary syndrome.
Phoenixin (PNX) is a newly discovered peptide produced by proteolytic cleavage of a small integral membrane protein 20 (Smim20), which acts as an important regulator of energy homeostasis and reproduction. Since dysfunction of reproduction is characteristic in polycystic ovarian syndrome (PCOS), the role of PNX in pathogenesis of PCOS needs further investigation. The objective of this study was to determine expression of Smim20, PNX-14 and its receptor GRP173 in the hypothalamus, ovary and periovarian adipose tissue (PAT) of letrozole induced PCOS rats. Phosphorylation of extracellular signal-regulated kinase (ERK1/2), protein kinases A (PKA) and B (Akt) were also estimated. We observed that PCOS rats had high weight gain and a number of ovarian cyst, high levels of testosterone, luteinizing hormone and PNX-14, while low estradiol. Smim20 mRNA expression was higher in the ovary and PAT, while PNX-14 peptide production was higher only in the ovary of PCOS

rat. Moreover, in PCOS rats Gpr173 level was lower in PAT but at the protein level increased only in the ovary. Depending on the tissues, kinases phosphorylation were significantly differ in PCOS rats. Our results showed higher levels of PNX-14 in PCOS rats and indicated some novel findings regarding the mechanisms of PCOS pathophysiology.

Electrophysiology and distribution of oxytocin and vasopressin neurons in the hypothalamic paraventricular nucleus: a study in male and female rats.
Magnocellular neurosecretory cells (MNCs) clustered in the hypothalamic paraventricular nucleus (PVN) and supraoptic nucleus constitute a major source of oxytocin (OXT) and arginine vasopressin (AVP) peptides, and are among the best described peptidergic neurons in the brain. OXT and AVP are involved in a range of homeostatic processes, social behaviours, emotional processes, and learning. Notably, their actions can be sex-specific, and several sex differences in the anatomies of the OXT and AVP systems have been reported. Nonetheless, possible sex differences in the detailed distributions of MNCs and in their intrinsic electrical properties ex vivo have not been extensively examined. We addressed these issues utilizing immunostaining and patch-clamp ex vivo recordings. Here, we showed that Sprague-Dawley rat PVN AVP neurons are more numerous than OXT cells and that more neurons of both types are present in males. Furthermore, we identified several previously unreported differences between putative OXT and AVP MNC electrophysiology contributing to their partially unique profiles. Notably, elucidation of the highly specific action potential (AP) shapes, with AVP MNCs having a narrower AP and faster hyperpolarizing after-potential (HAP) kinetics than OXT MNCs, allowed unambiguous discrimination between OXT and AVP MNCs ex vivo for the first time. Moreover, the examined electrophysiological properties of male and female MNCs generally overlapped with the following exceptions: higher membrane resistance in male MNCs and HAP kinetics in putative OXT MNCs, which was slower in males. These reported observations constitute a thorough addition to the knowledge of MNC properties shaping their diverse physiological actions in both sexes.

NOXIOUS STIMULUS-RESPONSIVE NEURONS IN THE VENTRAL-VENTROLATERAL PERIAQUEDUCTAL GRAY AND DORSAL RAPHE NUCLEUS

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Péter Földi[1], Kinga Müller[1,2], Gergő Nagy[1,2], Norbert Hájos[1]
[1]ELRN - Institute of Experimental Medicine, 'lendület' Laboratory Of Network Neurophysiology, Budapest, Hungary, [2]Semmelweis University, János Szentágothai Doctoral School Of Neurosciences, Budapest, Hungary

The ventral-ventrolateral periaqueductal gray (v/vlPAG) and dorsal raphe nucleus (DRN) play a critical role in controlling anxiety, fear memory formation and most particularly, it is largely involved in descending modulation of pain perception. It has been shown that different neuron types, such as dopaminergic and serotonergic cells are part of this circuitry, however their exact functions remained unclear. Using *in vivo* juxtacellular recording technique in urethane-anesthetized mice, we successfully recorded from more than 40 neurons. After monitoring the baseline activity of blindly targeted neurons in the v/vlPAG and DRN, we applied mild electrical shocks to both paws, sequentially. After the recordings we filled the neurons with Neurobiotin and perfused the animals. We performed post hoc immunostaining on the brain sections (n=18), visualizing tyrosine-hydroxylase (TH)- and serotonin-expressing neurons in addition to the Neurobiotin-content of the recorded neurons. Based on the spiking response upon noxious stimulation, we found neurons that showed excitation (34%), excitation followed by inhibition (14%), inhibition (18%), inhibition followed by excitation (7%). The remaining neurons did not show any significant change in their activity. All the identified TH+ neurons showed excitation. Our current results show that the firing of neurons in the v/vlPAG and DRN circuitries is distinctly modified by noxious stimuli, and support the previous observations, showing that dopaminergic neurons convey pain-related information to their downstream regions. The various responsiveness of neurons in the dorsal tegmentum upon noxious stimulation may have an important role in salient information processing.

PATTERNS OF COLLATERALIZATION OF MIDLINE BRAINSTEM RAPHE AND INCERTUS NUCLEI TO THE SEPTOHIPPOCAMPAL SYSTEM.

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Mónica Navarro Sánchez[1], Isis Gil-Miravet[1], Daniel Montero Caballero[1], Chaimaa Laassili[2], Aroa Mañas-Ojeda[1], Clara García Mompó[1], Francisco Olucha-Bordonau[1]

The relaxin 3 (RLN3) rich nucleus incertus (NI) and the serotonergic (5HT) raphe nuclei are midline brain stem units that modulates contextual related behaviours through the septo-hippocampal system. This work aims to characterize the pattern of collateralization from the NI to the 5HT groups and the supramammillary (SuM) nucleus. To this end, retrograde tracers fluorogold and cholera toxin B subunit (CTB) were injected into the medial septum (MS) and hippocampus, combined with 5HT, RLN3 and CTB immunofluorescence. Our results showed a higher density of RLN3 fibers in both median and dorsal raphe regions. In this area, RLN3 boutons were seen in close proximity from the 5HT somata and some of them contain synaptic markers. Few 5HT neurons from the MS were observed in the raphe nuclei, and a consistent density of relaxin3 boutons was observed around those neurons. Lastly, a population of SuM's neurons send collateral projections to the entorhinal/hippocampal system and the MS. Furthermore, this same population is innervated by RLN3 fibers. These findings revealed mapping of the modulator circuitry between the NI's RLN3 and Raphe's 5HT, and the interactions with the septo-hippocampus, which receives projections from the SuM. Based on this core of evidence, we can postulate that the SuM is a key component of the ascending NI's projections to the entorhinal-hippocampal circuit that is involved in the generation, coding and recall of spatial memories. LINKING EMOTIONAL VALENCE AND ANXIETY IN A MOUSE INSULA-AMYGDALA CIRCUIT

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Céline Nicolas
INSERM U1215, Neurocentre Magendie, BORDEAUX, France

The response of the insular cortex (IC) and amygdala to stimuli of positive and negative valence were found to be altered in patients with anxiety disorders. However, the coding properties of neurons controlling anxiety and valence remain unknown. Combining photometry recordings and chemogenetics in mice, we uncover the anxiogenic control of projection neurons in the anterior IC (aIC), independently of their projection target. Using viral tracing and *ex vivo* electrophysiology, we characterize the monosynaptic aIC to the basolateral amygdala (BLA) connection, and employed projection-specific optogenetics, to reveal anxiogenic properties of aIC-BLA neurons in anxiety-related behaviors. Finally, using photometry recordings, we identified that aIC-BLA neurons are active in anxiogenic spaces, and in response to aversive stimuli. Together, these findings show that negative valence, as well as anxiety-related information and behaviors, are encoded by aIC-BLA glutamatergic neurons, providing a starting point to understand how alterations of this pathway contribute to psychiatric disorders.

Sex Differences in Opioid and Psychostimulant Craving and Relapse: A Critical Review.
A widely held dogma in the preclinical addiction field is that females are more vulnerable than males to drug craving and relapse. Here, we first review clinical studies on sex differences in psychostimulant and opioid craving and relapse. Next, we review preclinical studies on sex differences in psychostimulant and opioid reinstatement of drug seeking after extinction of drug self-administration, and incubation of drug craving (time-dependent increase in drug seeking during abstinence). We also discuss ovarian hormones' role in relapse and craving in humans and animal models and speculate on brain mechanisms underlying their role in cocaine craving and relapse in rodent models. Finally, we discuss imaging studies on brain responses to cocaine cues and stress in men and women.The results of the clinical studies reviewed do not appear to support the notion that women are more vulnerable to psychostimulant and opioid craving and relapse. However, this conclusion is tentative because most of the studies reviewed were correlational, not sufficiently powered, and not a priori designed to detect sex differences. Additionally, imaging studies suggest sex differences in brain responses to cocaine cues and stress. The results of the preclinical studies reviewed provide evidence for sex differences in stress-induced reinstatement and incubation of cocaine craving but not cue- or cocaine-induced reinstatement of cocaine seeking. These sex differences are modulated in part by ovarian hormones. In contrast, the available data do not support the notion of sex differences in craving and relapse/reinstatement for methamphetamine or opioids in rodent models. SIGNIFICANCE STATEMENT: This systematic review summarizes clinical and preclinical studies on sex differences in psychostimulant and opioid craving and relapse. Results of the clinical studies reviewed do not appear to support the notion that women are more vulnerable to psychostimulant and opioid craving and relapse. Results of preclinical studies reviewed provide evidence for sex differences in reinstatement and incubation of cocaine seeking but not for reinstatement or incubation of methamphetamine or opioid seeking.

Incubation of Cocaine Craving After Intermittent-Access Self-administration: Sex Differences and Estrous Cycle.
Studies using continuous-access drug self-administration showed that cocaine seeking increases during abstinence (incubation of cocaine craving). Recently, studies using intermittent-access self-administration showed increased motivation to self-administer and seek cocaine. We examined whether intermittent cocaine self-administration would potentiate incubation of craving in male and female rats and examined the estrous cycle's role in this incubation.

Generalization of effects of environmental enrichment on seeking for different classes of drugs of abuse.
Addiction is a chronic disease characterized by persistent vulnerability to relapse during abstinence. In animal models of addiction, accumulating evidence suggests that exposure to environmental enrichment (EE) during periods of abstinence can have curative effects on addiction and reduce the risks of relapse. However, until present most studies have mainly focused on cocaine. In this study, we investigated whether EE could have beneficial effects on cue-induced seeking for several psychoactive drugs belonging to different pharmacological classes such as methamphetamine (METH), heroin (HER) and nicotine (NIC).

Longitudinal Changes in Brain Metabolic Activity after Withdrawal from Escalation of Cocaine Self-Administration.
The chronic and relapsing nature of addiction suggests that drugs produce persistent adaptations in the brain that make individuals with drug addiction particularly sensitive to drug-related cues and stress and incapable of controlling drug-seeking and drug-taking behavior. In animal models, several long-lasting neuroadaptations have been described. However, few studies have used brain-imaging techniques to provide a complete picture of brain functioning in the course of withdrawal from cocaine. In this study, we allowed rats to self-administer cocaine under short-access (1-h/day) or long-access (6-h/day) conditions and used 2-deoxy-2-(F)fluoro-d-glucose (FDG) positron emission tomography scanning to investigate the longitudinal changes in metabolic activity 1 and 4 weeks after discontinuation of cocaine self-administration. We found that compared to naive rats, both long-access and short-access rats showed significant disruptions in basal brain metabolic activity. However, compared to short-access, long-access rats showed more intense, and long-lasting neuroadaptations in a network of brain areas. In particular, abstinence from extended access to cocaine was associated with decreased metabolic activity in the anterior cingulate cortex, the insular cortex, and the dorsolateral striatum, and increased metabolic activity in the mesencephalon, amygdala, and hippocampus. This pattern is strikingly similar to that described in humans that has led to the proposal of the Impaired Response Inhibition and Salience Attribution model of addiction. These results demonstrate that extended access to cocaine leads to persistent neuroadaptations in brain regions involved in motivation, salience attribution, memory, stress, and inhibitory control that may underlie increased risks of relapse.

Exposure to sucrose during periods of withdrawal does not reduce cocaine-seeking behavior in rats.
Concomitant access to drugs of abuse and alternative rewards such as sucrose has been shown to decrease addiction-related behaviors in animals. Here we investigated whether access to sucrose during abstinence in contexts that are temporally and physically distinct from drug-related contexts could reduce subsequent drug seeking. In addition, we investigated whether a history of cocaine self-administration would alter the rewarding effects of sucrose. Rats self-administered cocaine for ten sessions, while yoked-saline rats received only saline injections, and then we subjected them to a 30-day withdrawal period during which they had access to water and sucrose continuously or intermittently according to a schedule that induces binge-drinking behavior. At the end of the withdrawal period, rats were tested for cocaine seeking behavior during a single 6 h session. We found that exposure to cocaine increased sucrose consumption only when rats had intermittent access to sucrose, but exposure to sucrose did not alter drug seeking regardless of the schedule of access. These results suggest that exposure to cocaine cross-sensitizes to the rewarding effects of sucrose, but exposure to sucrose during abstinence, temporally and physically distinct from drug-related environments, does not to reduce drug seeking.

Statins Reduce the Risks of Relapse to Addiction in Rats.
Statins are drugs that have been used for decades in humans for the treatment of hypercholesterolemia. More recently, several lines of evidence demonstrate that statins, in addition to their peripheral effects, produce a wide variety of effects in the brain and may be beneficial in neurological and psychiatric conditions. In this study, we allowed rats to self-administer cocaine for several weeks and, at the end of self-administration training, we treated them with low doses of statins daily for a 21-day period of abstinence. Chronic administration of brain-penetrating statins, simvastatin (1 mg/kg) and atorvastatin (1 mg/kg), reduced cocaine seeking compared with vehicle, whereas administration of pravastatin (2 mg/kg), a statin with low brain penetrability, did not. Importantly, the effects of brain-penetrating statins persisted even after discontinuation of the treatment and were specific for drug seeking because drug taking was not altered by simvastatin treatment. Finally, the effects of simvastatin were found to generalize to another drug of abuse such as nicotine, but not to food reward, and to reinstatement of cocaine seeking induced by stress. These results demonstrate that brain-penetrating statins can reduce risks of relapse to addiction. Given their well-known safety profile in humans, statins could be a novel effective treatment for relapse to cocaine and nicotine addiction and their use could be implemented in clinical settings without major health risks.

In modern society, stress has become a common trigger for inappropriate eating behaviors, yet the mechanism behind is not well established. The central melanocortin system is known to be the key regulator of energy homeostasis, it is mediated through a family of five related G protein–coupled melanocortin receptors, MC1R through MC5R, whereas only MC3R and MC4R are expressed in the brain. Mice lacking MC3R have been shown to have abnormal responses to fasting, shown by inappropriate refeeding behavior and altered corticosterone levels. However, where these MC3R neurons are acting to mediate effects of nutritional stresses such as fasting is unknown. In addition, recent work shows a role for MC3R in social behaviors as well. Therefore, we studied the role of MC3R modulation in two different stress paradigms (nutritional and non-nutritional). Further, we identified innervation of MC3R neurons to target sites using the MC3R-Cre; ROSA26-LSL-Synaptophysin-TdTomato mouse model. One site identified as a target of MC3R neurons was the amygdala. Interestingly, we found out a distinct pattern of MC3R projections to the central Amygdala and completely absent of projection to the basolateral amygdala (BLA). The amygdala is responsible for fear response, reward mechanisms and promoting anxiety-like behavior. We hypothesize, MC3R regulates neuronal circuits projecting to the AMY to mediate food intake under stress situations.

The hypothalamic neuropeptide oxytocin (OXT) and vasopressin (AVP) are two hormones known to modulate body homeostasis and social behavior. Studies have shown the action of oxytocin in enhancing complex social activities such as pair bonding, affiliative preferences, and parental behaviors. OXT is known to impact the activity of mesolimbic regions such as the ventral tegmental area (VTA) and nucleus accumbens (NAc) which play a crucial role not only in reward and motivation, but also in the expression of affiliative behaviors. The precise way in which oxytocin and vasopressin neural pathways interact with the reward system remains underinvestigated. We examined the anatomical and functional connectivity between the reward circuit regions, namely the VTA and NAc, and the ALPO, an area rich in oxytocin neurons and subdivided in different nuclei namely the striohypothamic (StHY), the Septohypothamic (SHy) and the Dopaminergic 14

(DA14). Next, we characterized the neurochemical identity of these networks by coupling rabies virus tracing method with RNAscope fluorescent in situ hybridization and immunohistoflourescence. Preliminary findings showed a direct projection between StHY and VTA and between SHy and DA14 towards NAc in addition to OXT neurons in StHY, SHy and DA14 sending an indirect path to VTA and NAc. Interestingly, two populations of OXT neurons in StHY and SHy nuclei co-express OXT and AVP in the pathways innervating VTA and NAc whereas another population expresses only OXT projected to NAc. We will discuss the role of these circuits from ALPO region and their potential role in coloring social contexts as rewarding

Understanding the neural circuits underlying defensive behaviors is crucial in elucidating survival mechanisms. Defensive behaviors can be triggered by learned and innately aversive threats. In a learning paradigm, a neutral stimulus (CS) triggers a defensive response only after being paired with an unconditioned aversive stimulus (US). On the other hand, an innately aversive threat induces defensive responses from the first presentation. The amygdala has been studied extensively and it is known to be essential in emotional behavioral responses. Among other functions, it is well known that the amygdala is required to elicit defensive responses in a wide range of threats. However, it remains unclear whether the learned and innate defensive responses share a common node in the amygdala. Combining circuit mapping, chemogenetics, and fiberphotometry, we tested our hypothesis that the basolateral amygdala (BLA) processes learned and innately aversive threats. With a loss-of-function approach, we show that bilateral silencing of the lateral amygdala suppresses the defensive responses induced by the looming stimulus as well as aversive conditioning. Fiber photometry of the BLA pyramidal neurons reveals an increase in the calcium signal linked to the defensive behaviors induced by the looming stimulus. Repeated exposure to the stimulus, reduces the defensive response as well as the calcium signal activity. Together, these findings support the hypothesis that the amygdala is a shared node in the neural circuit that regulates the defensive responses to an innately and learned aversive threat.

TRACE: An Unbiased Method to Permanently Tag Transiently Activated Inputs.
A fundamental interest in circuit analysis is to parse out the synaptic inputs underlying a behavioral experience. Toward this aim, we have devised an unbiased strategy that specifically labels the afferent inputs that are activated by a defined stimulus in an activity-dependent manner. We validated this strategy in four brain circuits receiving known sensory inputs. This strategy, as demonstrated here, accurately identifies these inputs.

Offline ventral subiculum-ventral striatum serial communication is required for spatial memory consolidation.
The hippocampal formation is considered essential for spatial navigation. In particular, subicular projections have been suggested to carry spatial information from the hippocampus to the ventral striatum. However, possible cross-structural communication between these two brain regions in memory formation has thus far been unknown. By selectively silencing the subiculum-ventral striatum pathway we found that its activity after learning is crucial for spatial memory consolidation and learning-induced plasticity. These results provide new insight into the neural circuits underlying memory consolidation and establish a critical role for off-line cross-regional communication between hippocampus and ventral striatum to promote the storage of complex information.

The serotonergic system of mammals innervates virtually all the central nervous system and regulates a broad spectrum of behavioral and physiological functions. In mammals, serotonergic neurons located in the rostral raphe nuclei encompass diverse sub-systems characterized by specific circuitry and functional features. Substantial evidence suggest that functional diversity of serotonergic circuits has a molecular and connectivity basis. However, the landscape of intrinsic developmental mechanisms guiding the formation of serotonergic sub-systems is unclear. Here, we employed developmental disruption of gene expression specific to serotonergic subsets to probe the contribution of the tyrosine kinase receptor ErbB4 to serotonergic circuit formation and function. Through an *in vivo* loss-of-function approach, we found that ErbB4 expression occurring in a subset of serotonergic neurons, is necessary for axonal arborization of defined long-range projections to the forebrain but is dispensable for the innervation of other targets of the serotonergic system. We also found that *Erbb4*-deletion does not change the global excitability or the number of neurons with serotonin content in the dorsal raphe nuclei. In addition, ErbB4-deficiency in serotonergic neurons leads to specific behavioral deficits in memory processing that involve aversive or social components. Altogether, our work unveils a developmental mechanism intrinsically acting through ErbB4 in subsets of serotonergic neurons to orchestrate a precise long-range circuit and ultimately involved in the formation of emotional and social memories.

Aims Oxytocin (OT)/oxytocin receptor (OTR) signalling exerts pleiotropic physiological and behavioural effects, including the modulation of food and water intake, reproduction, memory, emotional processing, and social interaction. A possible effector of these actions are the OTR-expressing neurons in the *nucleus incertus* (NI) that modulate arousal and other processes that overlap with known OT functions. Therefore, our aim was to characterise the anatomy, neuronal and behavioural effects of OT/OTR signalling in the rat NI. Methods In these studies, we employed single-cell-resolution, fluorescent *in situ* hybridisation, immunostaining, viral tract-tracing tools, and extracellular multielectrode and whole cell patch-clamp recordings *ex vivo*. Finally, using a newly generated OTR-IRES-Cre knock-in rat, we chemogenetically activated NI OTR-expressing neurons and examined the effects on behaviour. Results A majority (88%) of OTR mRNA-positive NI neurons are GABAergic (expressing vGAT mRNA). Exogenous OT dose- and OTR-dependently excited 70% of NI neurons, via a postsynaptic action. The NI lacks a substantial OT innervation, but the juxtaposition of the NI to the fourth ventricle suggests endogenous OT may reach the NI via the cerebrospinal fluid. Chemogenetic activation of OTR NI neurons promoted locomotor activity, reduced anxiety, altered social interaction, and improved social recognition. Conclusions These studies identify the brainstem *nucleus incertus* as a site of action of OT/OTR signalling. Notably, our reasults reveal a possible neuronal mechanism underlying OT-mediated modulation of arousal, and provide evidence for a key role of extrahypothalamic OT actions in governing behaviour. *Funding:* Alexander von Humboldt Foundation, Germany: Humboldt Research Fellowship; NSC, Poland: UMO-2018/30/E/NZ4/00687.

Role of Heme-Oxygenase-1 in Biology of Cardiomyocytes Derived from Human Induced Pluripotent Stem Cells.
Heme oxygenase-1 (HO-1, encoded by) is a cytoprotective enzyme degrading heme into CO, Fe, and biliverdin. HO-1 was demonstrated to affect cardiac differentiation of murine pluripotent stem cells (PSCs), regulate the metabolism of murine adult cardiomyocytes, and influence regeneration of infarcted myocardium in mice. However, the enzyme's effect on human cardiogenesis and human cardiomyocytes' electromechanical properties has not been described so far. Thus, this study aimed to investigate the role of HO-1 in the differentiation of human induced pluripotent stem cells (hiPSCs) into hiPSC-derived cardiomyocytes (hiPSC-CMs). hiPSCs were generated from human fibroblasts and peripheral blood mononuclear cells using Sendai vectors and subjected to CRISPR/Cas9-mediated knock-out. After confirming lack of HO-1 expression on the protein level, isogenic control and HO-1-deficient hiPSCs were differentiated into hiPSC-CMs. No differences in differentiation efficiency and hiPSC-CMs metabolism were observed in both cell types. The global transcriptomic analysis revealed, on the other hand, alterations in electrophysiological pathways in hiPSC-CMs devoid of HO-1, which also demonstrated increased size. Functional consequences in changes in expression of ion channels genes were then confirmed by patch-clamp analysis. To the best of our knowledge, this is the first report demonstrating the link between HO-1 and electrophysiology in human cardiomyocytes.

Estrous Cycle Modulation of Feeding and Relaxin-3/Rxfp3 mRNA Expression: Implications for Estradiol Action.
Food intake varies during the ovarian hormone/estrous cycle in humans and rodents, an effect mediated mainly by estradiol. A potential mediator of the central anorectic effects of estradiol is the neuropeptide relaxin-3 (RLN3) synthetized in the nucleus incertus (NI) and acting via the relaxin family peptide-3 receptor (RXFP3).

RLN3/RXFP3 Signaling in the PVN Inhibits Magnocellular Neurons via M-like Current Activation and Contributes to Binge Eating Behavior.
Binge-eating disorder is the most common eating disorder. Various neuropeptides play important roles in the regulation of feeding behavior, including relaxin-3 (RLN3), which stimulates food intake in rats through the activation of the relaxin-family peptide-3 receptor (RXFP3). Here we demonstrate that a likely mechanism underlying the orexigenic action of RLN3 is RXFP3-mediated inhibition of oxytocin- and arginine-vasopressin-synthesizing paraventricular nucleus (PVN) magnocellular neurosecretory cells. Moreover, we reveal that, in male and female rats, this action depends on M-like potassium conductance. Notably, higher intra- and peri-PVN RLN3 fiber densities were observed in females, which may constitute an anatomic substrate for observed sex differences in binge-eating disorder. Finally, in a model of binge-eating in female rats, RXFP3 blockade within the PVN prevented binge-eating behavior. These data demonstrate a direct RLN3/RXFP3 action in the PVN of male and female rats, identify the associated ionic mechanisms, and reveal that hypothalamic RLN3/RXFP3 signaling regulates binge-eating behavior. Binge-eating disorder is the most common eating disorder worldwide, affecting women twice as frequently as men. Various neuropeptides play important roles in the regulation of feeding behavior, including relaxin-3, which acts via the relaxin-family peptide-3 receptor (RXFP3). Using a model of binge-eating, we demonstrated that relaxin-3/RXFP3 signaling in the hypothalamic paraventricular nucleus (PVN) is necessary for the expression of binge-eating behavior in female rats. Moreover, we elucidated the neuronal mechanism of RLN3/RXFP3 signaling in PVN in male and female rats and characterized sex differences in the RLN3 innervation of the PVN. These findings increase our understanding of the brain circuits and neurotransmitters involved in binge-eating disorder pathology and identify RXFP3 as a therapeutic target for binge-like eating disorders.

Electrophysiology and distribution of oxytocin and vasopressin neurons in the hypothalamic paraventricular nucleus: a study in male and female rats.
Magnocellular neurosecretory cells (MNCs) clustered in the hypothalamic paraventricular nucleus (PVN) and supraoptic nucleus constitute a major source of oxytocin (OXT) and arginine vasopressin (AVP) peptides, and are among the best described peptidergic neurons in the brain. OXT and AVP are involved in a range of homeostatic processes, social behaviours, emotional processes, and learning. Notably, their actions can be sex-specific, and several sex differences in the anatomies of the OXT and AVP systems have been reported. Nonetheless, possible sex differences in the detailed distributions of MNCs and in their intrinsic electrical properties ex vivo have not been extensively examined. We addressed these issues utilizing immunostaining and patch-clamp ex vivo recordings. Here, we showed that Sprague-Dawley rat PVN AVP neurons are more numerous than OXT cells and that more neurons of both types are present in males. Furthermore, we identified several previously unreported differences between putative OXT and AVP MNC electrophysiology contributing to their partially unique profiles. Notably, elucidation of the highly specific action potential (AP) shapes, with AVP MNCs having a narrower AP and faster hyperpolarizing after-potential (HAP) kinetics than OXT MNCs, allowed unambiguous discrimination between OXT and AVP MNCs ex vivo for the first time. Moreover, the examined electrophysiological properties of male and female MNCs generally overlapped with the following exceptions: higher membrane resistance in male MNCs and HAP kinetics in putative OXT MNCs, which was slower in males. These reported observations constitute a thorough addition to the knowledge of MNC properties shaping their diverse physiological actions in both sexes.

Melanin-concentrating hormone and orexin systems in rat nucleus incertus: Dual innervation, bidirectional effects on neuron activity, and differential influences on arousal and feeding.
The rat nucleus incertus (NI) contains GABA/peptide-projection neurons responsive to orexin (hypocretin)/orexin receptor-2 (OX) signalling. Melanin-concentrating hormone (MCH) and orexin neurons often innervate and influence common target areas. Therefore, we assessed the relationship between these hypothalamic peptidergic systems and rat NI, by investigating the presence of an MCH innervation and MCH receptor-1 (MCH) expression, and neurophysiological and behavioural effects of MCH c.f. orexin-A (OXA), within the NI. We identified lateral hypothalamus (LH), perifornical and sub-zona incerta MCH neurons that innervate NI, and characterised the rostrocaudal distribution of MCH-containing fibres in NI. Single-cell RT-PCR

detected MCH and OX mRNA in NI, and multiplex, fluorescent in situ hybridisation revealed distinct co-expression patterns of MCH and OX mRNA in NI neurons expressing vesicular GABA transporter (vGAT) mRNA. Patch-clamp recordings revealed 34% of NI neurons tested were hyperpolarised by MCH (1 μM), representing a distinct population from OXA-sensitive NI neurons (35%). Intra-NI OXA infusion (600 pmol) in satiated rats during the light/inactive phase produced increased locomotor activity and food (standard chow) intake, whereas intra-NI MCH infusion (600 pmol) produced only a trend for decreased locomotor activity and no effect on food intake. Furthermore, in satiated or pre-fasted rats tested during the dark/active phase, intra-NI infusion of MCH did not alter the elevated locomotor activity or higher food intake observed. However, quantification of neuropeptide-immunostaining revealed differential diurnal fluctuations in orexin and MCH trafficking to NI. Our findings identify MCH and orexin inputs onto divergent NI populations which may differentially influence arousal and motivated behaviours.

Diverse action of repeated corticosterone treatment on synaptic transmission, neuronal plasticity, and morphology in superficial and deep layers of the rat motor cortex.
One of the adverse effects of prolonged stress in rats is impaired performance of skilled reaching and walking tasks. The mechanisms that lead to these abnormalities are incompletely understood. Therefore, we compared the effects of twice daily repeated corticosterone injections for 7 days on miniature excitatory postsynaptic currents (mEPSCs), as well as on synaptic plasticity and morphology of layers II/III and V pyramidal neurons of the primary motor cortex (M1) of male Wistar rats. Corticosterone treatment resulted in increased frequency, but not amplitude, of mEPSCs in layer II/III neurons accompanied by increased complexity of the apical part of their dendritic tree, with no changes in the density of dendritic spines. The frequency and amplitude of mEPSCs as well as the parameters characterizing the complexity of the dendritic tree were not changed in layer V cells; however, their dendritic spine density was increased. While corticosterone treatment resulted in an increase in the amplitude of field potentials evoked in intralaminar connections within layer II/III, it did not influence field responses in layer V intralaminar connections, as well as the extent of chemically induced layer V long-term potentiation (chemLTP) by the application of tetraethylammonium (TEA, 25 mM). However, chemLTP induction in layer II/III was impaired in slices prepared from corticosterone-treated animals. These data indicate that repeated 7-day administration of exogenous corticosterone induces structural and functional plasticity in the M1, which occurs mainly in layer II/III pyramidal neurons. These findings shed light on potential sites of action and mechanisms underlying stress-induced impairment of motor functions.

Inhibition of oxytocin and vasopressin neuron activity in rat hypothalamic paraventricular nucleus by relaxin-3-RXFP3 signalling.
Relaxin-3 is a stress-responsive neuropeptide that acts at its cognate receptor, RXFP3, to alter behaviours including feeding. In this study, we have demonstrated a direct, RXFP3-dependent, inhibitory action of relaxin-3 on oxytocin and vasopressin paraventricular nucleus (PVN) neuron electrical activity, a putative cellular mechanism of orexigenic actions of relaxin-3. We observed a Gα -protein-dependent inhibitory influence of selective RXFP3 activation on PVN neuronal activity in vitro and demonstrated a direct action of RXFP3 activation on oxytocin and vasopressin PVN neurons, confirmed by their abundant expression of RXFP3 mRNA. Moreover, we demonstrated that RXFP3 activation induces a cadmium-sensitive outward current, which indicates the involvement of a characteristic magnocellular neuron outward potassium current. Furthermore, we identified an abundance of relaxin-3-immunoreactive axons/fibres originating from the nucleus incertus in close proximity to the PVN, but associated with sparse relaxin-3-containing fibres/terminals within the PVN.

Excitatory orexinergic innervation of rat nucleus incertus--Implications for ascending arousal, motivation and feeding control.
Orexin/hypocretin peptides play a central role in the integrated control of feeding/reward and behavioural activation, principally via interactions with other neural systems. A brainstem area involved in behavioural activation is the nucleus incertus (NI), located in the posterior ventromedial central grey. Several studies have implicated NI in control of arousal/stress and reward/feeding responses. Orexin receptor mRNA expression identifies NI as a putative target of orexin modulation. Therefore, in this study we performed neural tract-tracing and immunofluorescence staining to characterise the orexinergic innervation of NI. Our results indicate a convergent innervation of the NI area by different orexin neuron populations, with an abundance of orexin-A-containing axons making putative synaptic contacts with relaxin-3-positive NI neurons. The influence of orexin-A on NI neuron activity was investigated using patch-clamp recordings. Orexin-A depolarised the majority (64%) of

recorded neurons and this effect was maintained in the presence of tetrodotoxin and glutamate and GABA receptor antagonists, indicating a likely postsynaptic action. Voltage-clamp experiments revealed that in 'type I' NI neurons comprising relaxin-3-positive cells, orexin-A acted via L-type calcium channels, whereas in 'type II' relaxin-3-negative neurons, activation of a sodium/calcium exchanger was involved. A majority of the orexin-A sensitive neurons tested for the presence of orexin receptor mRNA, were OX2 mRNA-positive. Immunohistochemical staining for putative orexin receptors on NI neurons, confirmed stronger expression of OX2 than OX1 receptors. Our data demonstrate a strong influence of orexin-A on NI neurons, consistent with an important role for this hypothalamic/tegmental circuit in the regulation of arousal/vigilance and motivated behaviours.

Dietary acetylenic oxylipin falcarinol differentially modulates GABAA receptors.
The dietary oxylipins falcarinol (1a) and falcarindiol (1b) trap thiols by direct nucleophilic addition to their diyne system, but despite this, only falcarinol (1a) is a reversible agonist of cannabinoid receptors, providing a rationale for comparing their activity also on other neuronal targets. Because GABAA receptors (GABAARs) are exquisitely sensitive to polyacetylenic oxylipins in terms of either potentiation (falcarindiol, 1b) or inhibition (oenanthotoxin, 2a), the activity of 1a was investigated on synaptic (α1β2γ2L) and extrasynaptic (α1β2δ and α1β2) subtypes of GABAARs. Falcarinol (1a) significantly enhanced the amplitude of currents mediated by α1β2γ2L receptors, but this effect was associated with a use-dependent block. Conversely, α1β2 receptors were inhibited without any sign of use-dependent block for the entire range of concentrations tested (1-10 μM). Interestingly, responses mediated by α1β2δ receptors, showing no or very little macroscopic desensitization, were strongly potentiated by 1a, exhibiting a fading reminiscent of macroscopic desensitization. When compared to the activity of falcarindiol (1b), falcarinol (1a) showed a higher affinity for GABAARs and, overall, a substantially different profile of pharmacological action. Taken together, the present data support the view that modulation of GABAARs might underlie the insecticidal and sedative activity of falcarinol (1a).

[Relaxin-3 and relaxin family peptide receptors--from structure to functions of a newly discovered mammalian brain system].
Relaxin-3, a member of the relaxin peptide family, was discovered in 2001 as a homologue of relaxin--a well-known reproductive hormone. However, it is the brain which turned out to be a major expression site of this newly discovered peptide. Both its molecular structure and expression pattern were shown to be very conserved among vertebrates. Extensive research carried out since the discovery of relaxin-3 contributed to the significant progress in our knowledge regarding this neuropeptide. The endogenous relaxin-3 receptor (RXFP3) was identified and the anatomy of the yet uncharacterized mammalian brain system was described, with nucleus incertus as the main center of relaxin-3 expression. Not only its diffusive projections throughout the whole brain, which reach various brain structures such as the hippocampus, septum, intergeniculate leaflet or amygdala, but also functional studies of the relaxin-3/RXFP3 signaling system, allowed this brain network to be classified as one of the ascending nonspecific brain systems. Thus far, research depicts the connection of relaxin-3 with phenomena such as feeding behavior, spatial memory, sleep/wake cycle or modulation of pituitary gland hormone secretion. Responsiveness of relaxin-3 neurons to stress factors and the strong orexigenic effect exerted by this peptide suggest its participation in modulation of feeding by stress, in particular of the chronic type. The discovery of relaxin-3 opened a new research field which will contribute to our better understanding of the neurobiological basis of feeding disorders.

Psychedelics, since time immemorial, have been known to alter sensory perceptions, and have been thought to have positive effects on mood. Over the last few decades, experimental findings have shown that serotonergic psychedelics modulate the areas in the brain that are involved in mood regulation, and can be possibly used as therapeutics against mood disorders. However, it is not well known how these drugs influence different regions of the brain to drive positive effects on mood-behaviours. We found that acute administration of a serotonergic psychedelic DOI (2,5-dimethoxy-4-iodoamphetamine; a 5-HT_{2A} receptor agonist) exhibits anxiolytic response in rodents on the EPM, and this effect is driven via the CA1/subiculum field of the ventral hippocampus. Furthermore, we note that 5-HT_{2A} receptors on the Parvalbumin-positive interneurons in the CA1/subiculum region of the ventral hippocampus may be sufficient to drive the decreased anxiety-like response on DOI administration. This work not only explores the therapeutic potential of serotonergic psychedelics, but also tries to understand how information is relayed in the brain to harness their potential against anxiety-like behaviour.

Chronic hM4Di-DREADD-Mediated Chemogenetic Inhibition of Forebrain Excitatory Neurons in Postnatal or Juvenile Life Does Not Alter Adult Mood-Related Behavior.
G-protein-coupled receptors (GPCRs) coupled to G signaling, in particular downstream of monoaminergic neurotransmission, are posited to play a key role during developmental epochs (postnatal and juvenile) in shaping the emergence of adult anxiodepressive behaviors and sensorimotor gating. To address the role of G signaling in these developmental windows, we used a CaMKIIα-tTA::TRE hM4Di bigenic mouse line to express the hM4Di-DREADD (designer receptor exclusively activated by designer drugs) in forebrain excitatory neurons and enhanced G signaling via chronic administration of the DREADD agonist, clozapine--oxide (CNO) in the postnatal window (postnatal days 2-14) or the juvenile window (postnatal days 28-40). We confirmed that the expression of the HA-tagged hM4Di-DREADD was restricted to CaMKIIα-positive neurons in the forebrain, and that the administration of CNO in postnatal or juvenile windows evoked inhibition in forebrain circuits of the hippocampus and cortex, as indicated by a decline in expression of the neuronal activity marker c-Fos. hM4Di-DREADD-mediated inhibition of CaMKIIα-positive forebrain excitatory neurons in postnatal or juvenile life did not impact the weight profile of mouse pups, and also did not influence the normal ontogeny of sensory reflexes. Further, postnatal or juvenile hM4Di-DREADD-mediated inhibition of CaMKIIα-positive forebrain excitatory neurons did not alter anxiety- or despair-like behaviors in adulthood and did not impact sensorimotor gating. Collectively, these results indicate that chemogenetic induction of G signaling in CaMKIIα-positive forebrain excitatory neurons in postnatal and juvenile temporal windows does not appear to impinge on the programming of anxiodepressive behaviors in adulthood.

Postnatal Fluoxetine Treatment Alters Perineuronal Net Formation and Maintenance in the Hippocampus.
Elevation of serotonin via postnatal fluoxetine (PNFlx) treatment during critical temporal windows is hypothesized to perturb the development of limbic circuits thus establishing a substratum for persistent disruption of mood-related behavior. We examined the impact of PNFlx treatment on the formation and maintenance of perineuronal nets (PNNs), extracellular matrix (ECM) structures that deposit primarily around inhibitory interneurons, and mark the closure of critical period plasticity. PNFlx treatment evoked a significant decline in PNN number, with a robust reduction in PNNs deposited around parvalbumin (PV) interneurons, within the CA1 and CA3 hippocampal subfields at postnatal day (P)21 in Sprague Dawley rat pups. While the reduction in CA1 subfield PNN number was still observed in adulthood, we observed no change in colocalization of PV-

positive interneurons with PNNs in the hippocampi of adult PNFlx animals. PNFlx treatment did not alter hippocampal PV, calretinin (CalR), or Reelin-positive neuron numbers in PNFlx animals at P21 or in adulthood. We did observe a small, but significant increase in somatostatin (SST)-positive interneurons in the DG subfield of PNFlx-treated animals in adulthood. This was accompanied by altered GABA-A receptor subunit composition, increased dendritic complexity of apical dendrites of CA1 pyramidal neurons, and enhanced neuronal activation revealed by increased c-Fos-positive cell numbers within hippocampi of PNFlx-treated animals in adulthood. These results indicate that PNFlx treatment alters the formation of PNNs within the hippocampus, raising the possibility of a disruption of excitation-inhibition (E/I) balance within this key limbic brain region.

GPCR signaling: role in mediating the effects of early adversity in psychiatric disorders.
Early adversity is a key risk factor for the development of several psychiatric disorders, including anxiety and depression. During early life, neurocircuits that regulate emotionality undergo substantial structural remodeling and functional maturation, and are thus particularly susceptible to modification by environmental experience. Preclinical evidence indicates that early stress enhances adult anxio-depressive behaviors. A commonality noted across diverse early stress models is life-long alterations in neuroendocrine stress responses and monoaminergic neurotransmission in key limbic circuits. Dysregulation of G protein-coupled receptor (GPCR) signaling is noted across multiple early stress models and is hypothesized to be an important player in the programming of aberrant emotionality. This raises the possibility that disruption of GPCR signaling in key limbic regions during critical temporal windows could establish a substrate for enhanced risk of adult psychopathology. Here, we review literature, predominantly from preclinical models, which supports the building hypothesis that a disruption of GPCR signaling could play a central role in programming persistent molecular, cellular, functional, and behavioral changes as a consequence of early adversity.

Chronic postnatal chemogenetic activation of forebrain excitatory neurons evokes persistent changes in mood behavior.
Early adversity is a risk factor for the development of adult psychopathology. Common across multiple rodent models of early adversity is increased signaling via forebrain Gq-coupled neurotransmitter receptors. We addressed whether enhanced Gq-mediated signaling in forebrain excitatory neurons during postnatal life can evoke persistent mood-related behavioral changes. Excitatory hM3Dq DREADD-mediated chemogenetic activation of forebrain excitatory neurons during postnatal life (P2-14), but not in juvenile or adult windows, increased anxiety-, despair-, and schizophrenia-like behavior in adulthood. This was accompanied by an enhanced metabolic rate of cortical and hippocampal glutamatergic and GABAergic neurons. Furthermore, we observed reduced activity and plasticity-associated marker expression, and perturbed excitatory/inhibitory currents in the hippocampus. These results indicate that Gq-signaling-mediated activation of forebrain excitatory neurons during the critical postnatal window is sufficient to program altered mood-related behavior, as well as functional changes in forebrain glutamate and GABA systems, recapitulating aspects of the consequences of early adversity.

Acute Chemogenetic Activation of CamKIIα-Positive Forebrain Excitatory Neurons Regulates Anxiety-Like Behaviour in Mice.
Anxiety disorders are amongst the most prevalent mental health disorders. Several lines of evidence have implicated cortical regions such as the medial prefrontal cortex, orbitofrontal cortex, and insular cortex along with the hippocampus in the top-down modulation of anxiety-like behaviour in animal models. Both rodent models of anxiety, as well as treatment with anxiolytic drugs, result in the concomitant activation of multiple forebrain regions. Here, we sought to examine the effects of chemogenetic activation or inhibition of forebrain principal neurons on anxiety and despair-like behaviour. We acutely activated or inhibited Ca/calmodulin-dependent protein kinase II α (CamKIIα)-positive forebrain excitatory neurons using the hM3Dq or the hM4Di Designer Receptor Exclusively Activated by Designer Drug (DREADD) respectively. Circuit activation was confirmed via an increase in expression of the immediate early gene, c-Fos, within both the hippocampus and the neocortex. We then examined the influence of DREADD-mediated activation of forebrain excitatory neurons on behavioural tests for anxiety and despair-like behaviour. Our results indicate that acute hM3Dq DREADD activation of forebrain excitatory neurons resulted in a significant decline in anxiety-like behaviour on the open field, light-dark avoidance, and the elevated plus maze test. In contrast, hM3Dq DREADD activation of forebrain excitatory neurons did not alter despair-like behaviour on either the tail suspension or forced swim tests. Acute hM4Di DREADD inhibition of CamKIIα-positive forebrain excitatory neurons did not modify either anxiety or despair-like behaviour. Taken together, our results demonstrate that chemogenetic activation of excitatory neurons in the forebrain decreases anxiety-like behaviour in mice.

Serotonin regulates mitochondrial biogenesis and function in rodent cortical neurons via the 5-HT receptor and SIRT1-PGC-1α axis.
Mitochondria in neurons, in addition to their primary role in bioenergetics, also contribute to specialized functions, including regulation of synaptic transmission, Ca homeostasis, neuronal excitability, and stress adaptation. However, the factors that influence mitochondrial biogenesis and function in neurons remain poorly elucidated. Here, we identify an important role for serotonin (5-HT) as a regulator of mitochondrial biogenesis and function in rodent cortical neurons, via a 5-HT receptor-mediated recruitment of the SIRT1-PGC-1α axis, which is relevant to the neuroprotective action of 5-HT. We found that 5-HT increased mitochondrial biogenesis, reflected through enhanced mtDNA levels, mitotracker staining, and expression of mitochondrial components. This resulted in higher mitochondrial respiratory capacity, oxidative phosphorylation (OXPHOS) efficiency, and a consequential increase in cellular ATP levels. Mechanistically, the effects of 5-HT were mediated via the 5-HT receptor and master modulators of mitochondrial biogenesis, SIRT1 and PGC-1α. SIRT1 was required to mediate the effects of 5-HT on mitochondrial biogenesis and function in cortical neurons. In vivo studies revealed that 5-HT receptor stimulation increased cortical mtDNA and ATP levels in a SIRT1-dependent manner. Direct infusion of 5-HT into the neocortex and chemogenetic activation of 5-HT neurons also resulted in enhanced mitochondrial biogenesis and function in vivo. In cortical neurons, 5-HT enhanced expression of antioxidant enzymes, decreased cellular reactive oxygen species, and exhibited neuroprotection against excitotoxic and oxidative stress, an effect that required SIRT1. These findings identify 5-HT as an upstream regulator of mitochondrial biogenesis and function in cortical neurons and implicate the mitochondrial effects of 5-HT in its neuroprotective action.

NEURAL CORRELATES OF SERIAL DEPENDENCE ACROSS VISUAL HEMIFIELDS AND BILATERAL PREFRONTAL CORTEX

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Melanie Tschiersch[1], Joao Barbosa[2], Akash Umakantha[3], Matthew Smith[3], Albert Compte[1]
[1]IDIBAPS, Brain Circuits And Behavior Lab, Barcelona, Spain, [2]Ecole Normale Superieur, Group For Neural Theory, Paris, France, [3]Carnegie Mellon University, Smith Lab, Pittsburgh, United States of America

Previously perceived working memory (WM) items have been shown to attract current WM reports. This so-called serial dependence was shown to rely on the interaction of active neural representations and long-lasting activity-silent mechanisms in prefrontal cortex (PFC) [Barbosa, Stein et al., 2020]. Furthermore, WM representations have been shown to be more frequent for contralateral than ipsilateral memorized locations in PFC [Funahashi et al., 1989], and can transfer between hemispheres when midline-crossing saccades occur in the delay [Brincat et al., 2021]. This indicates the consistent specialization of each hemisphere for the corresponding visual hemifield in WM. However, serial dependence challenges this view as it is unclear how it can emerge when consecutive stimuli appear in different hemifields, which engage independent neural substrates. Here, we investigate the transfer of serial dependence between visual hemifields and the associated prefrontal correlates across hemispheres, in order to shed light on the mechanisms of integration of lateralized WM storage. We collected simultaneous multi-unit recordings in monkey bilateral PFC during an oculomotor visuospatial delayed response task. We analyzed behavioral responses, and population coding in neural data in relation to serial dependence. We found that serial dependence of stimuli presented across hemifields was diminished in comparison to trials within the same hemifield. Furthermore, the correlation of decoded neural traces between hemispheres reflected these differences. We conclude that serial dependence in WM is partly supported by lateralized mechanisms, showing an incomplete continuity of the effect, which is in line with the activity-silent theory for serial dependence.

FOCUS ON THE MOUSE INSULAR CORTEX: IN VIVO SINGLE-UNIT RECORDINGS DURING ANXIETY ASSAYS AND MAPPING OF THE DOPAMINERGIC SYSTEM

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Yoni Couderc
INSERM 1215, Neurocentre Magendie, Bordeaux Cedex, France

Aim. The insular cortex (insula) is over-activated in patients with anxiety disorders and preclinical observation showed that dysfunctions of dopamine (DA) transmission can alter anxiety level. DA receptors are widely expressed across the brain, but their role within the insula on anxiety remains unknown. ***Methods and results***. By performing extracellular recordings in freely-moving mice, we provide the first *in vivo* electrophysiological characterization of anterior insula neurons during anxiety assays. We found heterogeneity in single-unit firing profiles, depending on the location of the mice in safe or anxiogenic spaces, with a majority of units more active in anxiogenic spaces. Then, as an initial step to define the function of insula DA transmission in anxiety, we quantified dopamine 1 receptor expression in the insula using a transgenic D1:Ai14 mouse line. We found that **[1]** D1+ cells density is the highest in layer 2-3, **[2]** ~30% of inhibitory neurons are D1+, and **[3]** only 10% of excitatory neurons are D1+. Finally, by combining tyrosine hydroxylase immunohistochemistry and retrograde tracing, we mapped the source of dopaminergic inputs to the insula, and by using anterograde viral tracing in D1-cre mice, we mapped the outputs of the 10% of D1+ projection neurons. We evidenced that, as for the whole projection neurons of the insula, D1+ insula projection neurons mainly target the amygdala and controlateral insula. ***Conclusion***. Together, this preliminary study provides an electrophysiological and anatomical characterization of insula neurons as a starting point to identify the potential role of dopaminergic modulation of the insula in anxiety.

EARLY LIFE CHRONIC STRESS ALTERS ZEBRAFISH DORSAL RAPHE SEROTONERGIC NEURON RESPONSES TO SUBSEQUENT STRESSOR EXPOSURE

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Florence Kermen[1,2], Archana Golla[2], Paola Cappanna[2]
[1]University of Copenhagen, Department Of Neuroscience, Copenhagen, Denmark, [2]NTNU, Department Of Biology, Trondheim, Norway

Stress elicits variable systemic and neural changes in vertebrates, resulting in adaptive to pathological outcomes. Several studies have implicated the dorsal raphe nucleus (DRN), a brainstem nucleus containing a heterogeneous population of forebrain-projecting serotonergic neurons, in the adaptive stress response and the pathological changes resulting from chronic stress. However, it is not known whether early life chronic stress affects the developing DRN and its response to subsequent stressors, or whether the stress-induced changes affect subpopulations of serotonergic DRN neurons in a region- or phenotype-specific manner. To answer these questions, we used *in vivo* 2-photon calcium imaging of DRN neurons in two weeks old zebrafish exposed to early life chronic unpredictable stress, which subsequently displayed increased anxiety-like behaviors. We found that early life chronic stress blunted the normal serotonergic DRN response to an acute stressor. This was partly supported by a heterogeneous subpopulation of stress-inhibited neurons, which were preferentially located in the rostral DRN. Early life chronic stress also prevented the normal habituation of serotonergic DRN responses to a repeated acute stressor. Finally, repeated acute stress in control fish rapidly produced a response profile similar to that observed in chronically stressed fish, with an increased proportion of inhibitory responses preferentially in the rostral DRN. Together, our results indicate that early life chronic stress robustly alters DRN serotonergic neurons' functional responses to subsequent stressors and highlight the persistent effect of early life stress on DRN serotonergic neuron subpopulations.

The nucleus incertus (NI) has been described as a GABAergic structure and the main source of relaxin-3 (RLN3) projections to the forebrain. The NI is involved in arousal, stress responses and theta rhythm control, and is strongly linked to the septohippocampal pathway, mainly via direct connections with the medial septum (MS). However, the precise neurochemical nature of specific NI neuron populations remains elusive, and therefore, this study further explored the characteristics of NI neurons directly innervating the MS. Male, adult Sprague-Dawley rats were injected in the MS with an mCherry viral vector and RNAscope HiPlex *in situ* hybridization was subsequently performed on coronal NI sections. NI neurons innervating MS were counted, mapped and assigned to specific cell types, depending on their mRNA expression profile. Cell counting revealed that >50% of NI neurons expressed vGAT1 mRNA, ~40% was vGlut2-mRNA-positive and ~10% expressed both vGAT1 and vGlut2 mRNA. These populations expressed relaxin-3 or cholecystokinin mRNA. 38% of mCherry mRNA-expressing (i.e., MS innervating) neurons was vGlut2 mRNA-positive and ~20% was RLN3 mRNA-positive. Notably, 40% of RLN3 mRNA-positive cells expressed vGAT1/vGlut2 mRNA. Differences in neurochemical profile translated into differential localizations within the NI. Our results indicate that the rat NI should be considered as a neurochemically heterogeneous structure, comprising equivalent populations of GABAergic and glutamatergic neurons. As demonstrated for MS-innervating cells, these NI neurons are differentially located, and potentially linked to multiple connections and functions and diverse electrophysiological effects on target structures. NOVELTY RESPONSES AND SEROTONIN SIGNALING IN MICE

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Romain Ligneul, Solène Sautory, Zachary Mainen
Champalimaud Foundation, Champalimaud Research, Lisbon, Portugal

Novelty plays important roles for learning and decision-making. The exploration of novel stimuli is crucial to form efficient maps of one's environment. Yet, because novelty can also entail exposure to threats, novelty-seeking behaviors are dependent on a variety of affective and cognitive factors. Here, we combined optogenetics and calcium imaging with in-depth behavioral analysis to elucidate the involvement of serotonin (5-HT) signaling in novelty processing in several behavioral assays. We found that 5-HT neurons in the dorsal raphe nucleus (DRN) activate while animals approach novel stimuli and that short- and long-term manipulations of DRN 5-HT activity impact novelty-seeking behaviors in different ways. Going further, we compared serotonin and dopamine responses to novelty and we tested how novelty- and exploration-related 5-HT signals relate to behavioral plasticity and learning. Taken together, our findings reveal the unexpected role of DRN 5-HT activity in novelty detection and downstream neurobehavioral adaptations.

VTA DOPAMINE NEURONS ORTHOGONALLY ENCODE MOTIVATED BEHAVIOURS

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Hanna Van Den Munkhof[1,2], Vasyl Mykytiuk[1,2], Tatiana Korotkova[1,2]

Adaptive regulation of innate behaviours, such as feeding and locomotion, is crucial for survival. The ventral tegmental area (VTA) forms the core of the reward system driving these behaviours. Dopamine neurons not only encode reward, but multiplex non-reward variables. Also, individual dopamine neurons do not signal reward anticipation uniformly, but each encode a different possible reward outcome from a distribution. However, it remains unclear whether subpopulations of dopamine neurons distinguish between different reward types. Therefore, the aim of this study was to uncover the role of VTA dopamine neurons in driving the interaction with distinct rewards. We performed 1-photon calcium imaging in DAT-cre mice expressing GCaMP6m in the VTA, while they freely explored a paradigm with multiple rewards, including food, water, a conspecific, a running wheel and object. We recorded mice in sated state and after food deprivation. We found that VTA dopamine neurons do not respond uniformly to distinct rewards, but encode food proximity and locomotion in an orthogonal manner, with neurons excited by food proximity being inhibited in the running wheel and vice versa. Dopamine neuron activity selectively changed following food deprivation and increased wheel running. These results suggest that VTA dopamine neuron subpopulations distinguish between different rewards and can shift these responses according to changes in motivational state. OREXIN NEUROMODULATION OF THE DOPAMINERGIC SYSTEM: BEHAVIORAL CORRELATES AND MECHANISTIC INSIGHTS

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Stamatina Tzanoulinou, Richie Kalusivikako, Simran Rai, Mehdi Tafti, Anne Vassalli
University of Lausanne, Department Of Biomedical Sciences, Lausanne, Switzerland

Orexin neurons are located in the Lateral Hypothalamus (LH) and they have been established as critical modulators of sleep, wakefulness, and other motivated behaviors. There are two orexin peptides, A and B, that act at two different receptor subtypes, orexin receptor-1 (OX1R) and orexin receptor-2 (OX2R). Hypothalamic orexin neurons project to multiple brain areas including mesolimbic dopamine (DA) pathway regions, such as the ventral tegmental area (VTA) and the nucleus accumbens. In fact, the projection from the LH to the VTA is a major monosynaptic pathway among the basal forebrain and hypothalamic areas. Nevertheless, the functional consequences of DA neuron modulation by orexin inputs are not well understood. Using the Cre/lox technology and a *dopamine transporter* (*Dat*) Cre driver line, we generated two lines of mice harboring cell type-specific inactivation of the *Ox1R* or *Ox2R* genes in DA neurons. Assessing these mouse lines, along with their respective control littermates, we could show that orexin receptors in DA neurons play an important role in exploration/locomotion, reactivity to novelty and anxiety-like behavior. Moreover, our results indicate distinct contributions of OX1R and OX2R neuromodulation of the dopaminergic system to these different behavioral domains.

DIFFERENTIAL CODING OF EMOTIONAL EXPERIENCE IN VENTRAL AND DORSAL HIPPOCAMPUS

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Noé Hamou[1], Marco Pompili[2], Sidney Wiener[2]
[1]Collège de France, Centre Interdisciplinaire De Recherche En Biologie (cnrs Umr 7241, Inserm U1050), Paris, France, [2]College de France, Cirb, Paris, France

The dorsal (d) and ventral (v) parts of the hippocampus (HPC) are considered to support complementary cognitive functions: spatial and emotional processing, respectively. Here, we aimed to compare their responses to emotional changes with simultaneous recordings of multiple single units in four male rats during a fear conditioning protocol. We studied the evolution of dHPC and vHPC coding over the course of fear conditioning and control sessions. Both dHPC and vHPC population activity exhibited significant drifts relative to baseline in the PCA space following fear conditioning. Crucially, this drift was significantly greater for vHPC than dHPC, and was accompanied by stable changes in firing rate of individual neurons. Interestingly, dHPC activity decreased during freezing episodes, with transient peaks at the offset and onset of freezing, perhaps related to motor correlates. These preliminary results therefore suggest that fear conditioning induces stable firing rate changes specifically in vHPC which may therefore underpin emotional learning.

VICARIOUS REWARD SIGNALS IN THE VTA DRIVE PROSOCIAL CHOICES IN RATS

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Joan Esteve Agraz, Diana Costa, Kevin Caref, Cristina Marquez
Instituto de Neurociencias de Alicante, Neural Circuits Of Social Behaviour, San Juan de Alicante, Spain

Prosocial behaviours are those actions that benefit others. They are thought to be evolutionary conserved across different mammal species however, the neural mechanisms that explain this type of actions are yet poorly understood. In this work we first developed a new behavioural task to measure GCaMP6s activity using fiber-photometry on an observer rat, while being either rewarded or witnessing its cage-mate obtaining rewards. As expected, the reception of self-rewards induced activity in the ventral tegmental area (VTA). Furthermore, we observed increases in VTA GCaMP signals time-locked to the observation of a cage-mate receiving rewards, suggesting that observation of conspecifics in rewarding states is self-rewarding. Then, we assessed whether these reinforcing signals would guide social decisions. We tested pairs of rats in a social decision-making task, where we have previously demonstrated that rats display prosocial tendencies. In this task, a decision-maker could choose between the option that provided food to itself and its conspecific (prosocial choice) or the option that provided food only to itself (selfish choice). Using closed-loop wireless optogenetic tools, we silenced VTA activity specifically while the decision-maker was observing their partner being rewarded, after a prosocial choice. Silencing VTA activity during these specific moments blocked the emergence of prosocial choices over the testing sessions, remaining animals at chance levels. In conclusion, we found that witnessing the rewarding states from others induces vicarious reinforcing responses in rats, in the form of increased activity in VTA, being these the necessary signal that drives the motivation to help others.

KISSPEPTIN-8 SUPPRESSES LOCOMOTION AND MODULATES NUCLEUS ACCUMBENS ACTIVITY IN RATS

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Katalin Eszter Ibos[1], Éva Bodnár[1], Zsolt Bagosi[1], Zsolt Bozsó[2], Júlia Szakács[1], Krisztina Csabafi[1]
[1]University of Szeged, Department Of Pathophysiology, Szeged, Hungary, [2]University of Szeged, Department Of Medical Chemistry, Szeged, Hungary

Aims: Neuropeptide FF receptors are expressed in the ventral tegmental area (VTA)- nucleus accumbens (NAc) dopaminergic system and have been implicated in the regulation of locomotion. We aimed to investigate how an N-terminally truncated RF-amide octapeptide, kisspeptin-8 (Kp-8) affects locomotor activity and whether it modulates neurotransmitter release and gene expression in the NAc, a key structure in locomotion, motivation and addiction. **Methods:** Male Wistar rats were injected intracerebroventricularly with 0.1 or 1 µg of Kp-8, then computerized open field (OF) and marble burying tests (MB) were performed. Moreover, fractional GABA release was measured in the NAc using *ex vivo* superfusion and the expressions of *Fos*, *DRD1R, DRD2R* (dopamine receptor D1, D2), *GAD65* (glutamic acid decarboxylase 65kD*)*, and *NPFFR1, NPFFR2* genes were determined. **Results:** After 50 minutes in the OF arena, 1 µg of Kp-8 decreased locomotion and rearing activity. In MB, the 1 µg dose reduced the number and time of interactions with marbles. There was an increase in GABA release and a downregulation of *DRD1R* (1 µg Kp-8)*, DRD2R* (0.1 and 1 µg Kp-8) and *NPFF2R* (0.1 µg Kp-8) in the NAc*.* **Conclusions:** In our study, Kp-8 caused downregulation of D1 and D2 receptors. As these receptors are involved in locomotion and motivation, respectively, their downregulation might be in the background of hypolocomotion and decreased exploratory activity. Kp-8 possibly modulates the activity of the VTA-NAc system by acting on NPFF receptors expressed on GABAergic interneurons, thus it might also suppress the dopaminergic input from the VTA.

Kisspeptin-8 Induces Anxiety-Like Behavior and Hypolocomotion by Activating the HPA Axis and Increasing GABA Release in the Nucleus Accumbens in Rats.
Kisspeptins (Kp) are RF-amide neuropeptide regulators of the reproductive axis that also influence anxiety, locomotion, and metabolism. We aimed to investigate the effects of intracerebroventricular Kp-8 (an N-terminally truncated octapeptide) treatment in Wistar rats. Elevated plus maze (EPM), computerized open field (OF), and marble burying (MB) tests were performed for the assessment of behavior. Serum LH and corticosterone levels were determined to assess kisspeptin1 receptor (Kiss1r) activation and hypothalamic-pituitary-adrenal axis (HPA) stimulation, respectively. GABA release from the nucleus accumbens (NAc) and dopamine release from the ventral tegmental area (VTA) and NAc were measured via ex vivo superfusion. Kp-8 decreased open arm time and entries in EPM, and also raised corticosterone concentration, pointing to an anxiogenic effect. Moreover, the decrease in arm entries in EPM, the delayed increase in immobility accompanied by reduced ambulatory activity in OF, and the reduction in interactions with marbles show that Kp-8 suppressed exploratory and spontaneous locomotion. The increase in GABA release from the NAc might be in the background of hypolocomotion by inhibiting the VTA-NAc dopaminergic circuitry. As Kp-8 raised LH concentration, it could activate Kiss1r and stimulate the reproductive axis. As Kiss1r is associated with hyperlocomotion, it is more likely that neuropeptide FF receptor activation is involved in the suppression of locomotor activity.

BRAIN-BODY INTERACTIONS IN EMOTIONS: PERSPECTIVE MATTERS

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Tahnée Engelen, Anne Buot, Julie Grèzes, Catherine Tallon-Baudry
Ecole Normale Supérieure, Department Of Cognitive Science, Paris, France

Experiencing an emotion oneself and observing emotions in others share substantial physiological and neural similarities. Still, under normal circumstances we do not 'loose' our sense of self, and are able to distinguish our own emotions from someone else's. Neural monitoring of cardiac signals has recently been proposed as a mechanism for such self-other distinction and self-specification in the domains of perception and cognition. Here, we probe whether the same mechanism is at play for emotions – in other words, whether there is a domain-general mechanism of self-other distinction, valid across perception, cognition and emotion. We tackled this question in a paradigm where participants had to rate valence and arousal in response to affective social scenes. Before each trial, a cue indicated whether they would have to report the emotional experience they felt (Self condition), or the emotion expressed by people in the scene (Other condition). During cue, when participants prepared to adopt the Self or Other perspective, we found that Heartbeat Evoked Responses (HERs) distinguished between the Self and Other condition. During affective scene presentation, we found that in addition to expected covariations with valence and arousal, physiological measures (SCR and facial EMG) were sensitive to the perspective from which the image was being evaluated. Finally, we found that changes in bodily signals related to emotions significantly contributed to the ratings of valence and arousal of the participant irrespective of adopted perspective. The HER, however, specifically contributed to the experienced subjective valence when assessing self, but not someone else's emotions.

THE TEMPORAL STUDY OF TRAUMATIC STRESS RELATED FEAR MEMORY RETRIEVAL IN A RAT MODEL OF POST-TRAUMATIC STRESS DISORDER: BRAIN WAVE AND TRANSCRIPTOME-LEVEL GENE PROFILING

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Shao-Han Chang[1,2], Fu-Zen Shaw[1], Bai-Chuang Shyu[2]
[1]National Cheng Kung University, Department Of Psychology, Tainan City, Taiwan, [2]Academia Sinica, Institute Of Biomedical Sciences, Taipei, Taiwan

Post-traumatic stress disorder (PTSD) is a complex syndrome, which may occur after life-threatening event exposure. Fear memory abnormalities have been indicated as a key factor in the pathological course of PTSD. It was indicated that fear memories are not rigid; the retrieval of fear memory may change over time. Furthermore, previous studies have suggested that fear expression is strongly correlated with the theta (4Hz) activities. However, the relation between pathological fears and potential brain wave features after traumatic stress exposure still remains largely unknown. Here, we hypothesize after traumatic stress exposure, the longitudinal dynamic changes of abnormal fears in PTSD animal models could be reflected by local field potentials (LFPs) measurements and transcriptome-level gene profiling in the early and late phases. In our study, we use a well-established modified single prolonged stress (SPS&FS) PTSD rat model. Temporal brain wave activities were characterized in relation to fear expression after traumatic stress exposure. We found the SPS&FS rats showed sustained fear responses and heterogeneous PTSD phenotypes (significantly higher anxiety, depression and anhedonic levels). Time-dependent higher theta (5-8 Hz) and gamma (>30 Hz) activities were observed in early phases and started to shift to continuous lower delta (0.5-4Hz) from 2-4 hrs to day 1, 3 ,7 and 14 after SPS&FS. Besides, we also observed temporal differences in gene and protein levels. The longitudinal profiling of abnormal fears may help illustrate the time-dependent pathological fear memory retrieval in PTSD and may also help find better intervention strategies for this complex syndrome.

SOCIAL FEAR AFFECTS LIMBIC SYSTEM NEURONAL ACTIVITY AND GENE EXPRESSION

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Catharina Hamann[1], Julian Bankmann[1], Johannes Kornhuber[2], Klaus-Peter Lesch[1], Iulia Zoicas[2], Angelika Schmitt-Böhrer[1]
[1]University Clinic Würzburg, Department Of Psychiatry, Psychosomatics And Psychotherapy, Würzburg, Germany, [2]Universitätsklinikum Erlangen, Friedrich-Alexander University Erlangen-Nürnberg (FAU, Department Of Psychiatry And Psychotherapy, Erlangen, Germany

Among the spectrum of psychiatric disorders, social anxiety disorder (SAD) is a highly prevalent and comorbid anxiety disorder with rather unclear underlying mechanisms. We aimed to characterize neurobiological changes occurring in a mouse model of SAD to identify possible therapeutic targets. Social fear was induced via social fear conditioning (SFC), a validated animal model of SAD. We investigated expression levels of the immediate early genes (IEGs) cFos, Fosl2 and Arc as markers of neuronal activity and the expression levels of several genes of the GABAergic, serotoninergic, oxytocinergic, vasopressinergic and neuropeptide Y (NPY)-ergic systems. Target brain regions are involved in social- as well as fear-related behavior, the paraventricular nucleus of the hypothalamus, basolateral amygdala, septum, hippocampus and dorsal raphe nucleus. The setup investigated SFC+ and SFC- mice 2h after exposure to a conspecific. SFC+ mice showed a decreased number and density of cFos-positive cells and decreased expression levels of IEGs in the anterior hippocampus. SFC+ mice also showed alterations in the expression of NPY and serotonin system-related genes in all investigated brain regions except the hippocampus. Our results describe neuronal alterations occurring during the expression of social fear and identify the NPY and serotonergic system as possible targets in the treatment of SAD.

CONSTITUTIVE 5-HT2C RECEPTOR KNOCK-OUT FACILITATES FEAR EXTINCTION THROUGH ALTERED ACTIVITY OF A DORSAL RAPHE–BED NUCLEUS OF THE STRIA TERMINALIS PATHWAY

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Sandra Süß, Daniel Kremer, Linda Olbricht, Stefan Herlitze, Katharina Spoida
Ruhr-University Bochum, Department Of General Zoology And Neurobiology, Bochum, Germany

Serotonin 2C receptors (5-HT2CRs) are widely distributed throughout the brain and are strongly implicated in the pathophysiology of anxiety disorders such as post-traumatic stress disorder (PTSD). Although in recent years, a considerable amount of evidence supports 5-HT2CRs facilitating effect on anxiety behavior, the involvement in learned fear responses and fear extinction is rather unexplored. Here we used a 5-HT2CR knock-out mouse line (2CKO) to gain new insights into the involvement of 5-HT2CRs in the neuronal fear circuitry. Using a cued fear conditioning paradigm, our results revealed that global loss of 5-HT2CRs exclusively accelerates fear extinction, without affecting fear acquisition and fear expression. To investigate the neuronal substrates underlying the extinction enhancing effect, we mapped the immediate-early gene product cFos, a marker for neuronal activity, in the dorsal raphe nucleus (DRN), amygdala and bed nucleus of the stria terminalis (BNST). Surprisingly, besides extinction-associated changes, our results revealed alterations in neuronal activity even under basal home cage conditions in specific subregions of the DRN and the BNST in 2CKO mice. Neuronal activity in the dorsal BNST was shifted in an extinction-supporting direction due to 5-HT2CR knock-out. Finally, the assessment of DRN–BNST connectivity using antero- and retrograde tracing techniques uncovered a discrete serotonergic DRC–BNSTad pathway showing increased activity in 2CKO mice. Thus, our results provide new insights for the fear extinction network by revealing a specific serotonergic DRC–BNSTad pathway underlying a 5-HT2CR-sensitive mechanism with high significance in the treatment of PTSD.

THE BASAL FOREBRAIN AS A MEDIATOR OF INFRALIMBIC-AMYGDALA COMMUNICATION IN FEAR EXTINCTION

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Carolina Fernandes Henriques[1], Rebecca Zhang[2], Lyubov Yusufova[2], Yuval Guetta[3], Ekaterina Likhtik[1]
[1]Hunter College and Graduate Center, City University of New Yok, Biology Department, New York, United States of America, [2]Hunter College, City University of New York, Biology Department, New York, United States of America, [3]Hunter College, City University of New York, Psychology Department, New York, United States of America

Aims: Projections from the infralimbic region (IL) of the medial prefrontal cortex to the basolateral amygdala (BLA) are needed to suppress fear responses during extinction. However, which IL afferents serve as a teaching signal during extinction remains unknown. Given the importance of the basal forebrain (BF) in learning, we investigated whether BF-IL communication contributes to extinction and to IL-BLA physiology. **Methods:** We used multisite local field potential recordings in the IL, BF, and BLA during behavior to identify patterns of communication during extinction learning and recall. Retrograde neuroanatomical tracers were then used to study IL projections to the BLA and BF, and combined with functional immunohistochemistry to assess the activity of IL-BF versus IL-BLA projectors during fear and extinction recall. **Results:** During extinction learning and recall, cue-evoked IL theta power (4-8Hz) changes resembled the BF more than the BLA. Directionality analyses showed that IL-BF theta communication was bidirectional during extinction acquisition, but IL-to-BF directionality prevailed during extinction recall, whereas the IL-to-BLA directionality remained throughout. Furthermore, partial correlations showed that IL-BLA theta power correlations dropped dramatically when the BF signal was removed. Anatomical data showed IL-BLA projections arising from LII-III and IL-BF projections from LII-III and LIV-V. Immunohistochemical analyses showed that the IL-BLA projectors didn't exhibit preferred activation during fear vs extinction recall, whereas IL-BF projectors from LIV-V were more active during extinction recall. **Conclusions**: BF input to the IL is a teaching signal during extinction acquisition that influences IL-BLA communication, and IL-to-BF signaling during extinction recall.

COMPULSIVE SEXUAL BEHAVIOR DISORDER IMPACT ON STRIATUM AND AMYGDALA FUNCTIONAL RESPONSES DURING APPETITIVE CONDITIONING AND EXTINCTION

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Jakub Wojciechowski[1,2], Tomasz Wolak[1], Jan Szczypiński[3], Ewelina Kowalewska[4], Onno Kruse[5], Ewa Kublik[2], Mateusz Gola[6]
[1]Institute of Physiology and Pathology of Hearing, Bioimaging Research Center, Kajetany, Poland, [2]Nencki Institute of Experimental Biology, Laboratory Of Neurobiology Of Emotions, Warsaw, Poland, [3]Nencki Institute of Experimental Biology, Laboratory Of Brain Imaging, Warsaw, Poland, [4]Centre of Postgraduate Medical Education, Department Of Psychatry, Warsaw, Poland, [5]Justus-Liebig-University Giessen, Department For Psychotherapy And Systems Neuroscience, Giessen, Germany, [6]University of San Diego, Institute For Neural Computation, San Diego, United States of America

Compulsive Sexual Behavior Disorder (CSBD) was recently (2022) recognized in International Classification of Diseases (ICD-11). Its mechanisms are still unclear which compromises the development of effective therapies. In our study, we aimed to verify appetitive conditioning and extinction processes in CSBD using brain functional magnetic resonance imaging (fMRI). Age-matched CSBD patients and healthy control subjects (n=32 in each group) participated in the learning tasks with erotic and monetary rewards. We analyzed fMRI regions of interest (ROIs), reaction times (RT), and participants' subjective ratings of arousal and valence toward abstract cues paired with rewards before and after conditioning. Statistical analyzes were conducted using 3-way ANOVA: (2)Group x (2)Condition x (2)Task Phase. During conditioning, CSBD subjects showed increased value attribution (subjective) and motivation (RT) for both rewarding cues suggesting general alteration of action-reward learning in patients. During the conditioning phase, fMRI results suggest hypoactivity of the ventral striatum and amygdala in CSBD for both rewarding cues compared to healthy control. The extinction process in CSBD differentiated cue types in both brain structures - ventral striatum exhibited stronger deactivation from the early to the late phase of the task specifically for erotic cues, whereas amygdala showed a tendency for hypoactivity in the late phase for erotic cues compared to healthy control. Our results suggest that altered conditioning and extinction may underlay the development and persistence of Compulsive Sexual Behavior Disorder. (NCN-Grant-2016/21/N/HS6/02635)

EYE-TRACKING EVIDENCE FOR A MOOD CONGRUENCY BIAS IN DEPRESSION

POSTER SESSION 03 - SECTION: MIDBRAIN AND FOREBRAIN FUNCTION IN STRESS AND EMOTION

Rui Sun[1,2], Julia Fietz[1,3], Mira Erhart[1,3], Dorothee Poehlchen[1,3], Become Study Team[1], Michael Czisch[1], Philipp Saemann[1], Victor Spoormaker[1]
[1]Max Planck Institute of Psychiatry, Department Of Translational Research In Psychiatry, Munich, Germany, [2]Zhejiang University, Department Of Behavioral And Psychological Science, Hangzhou, China, [3]Max Planck Institute of Pschiatry, International Max Planck Research School For Translational Psychiatry (imprs-tp), Munich, Germany

In imaging genetics/psychiatry the emotional face recognition task by Hariri et al. (2002) is one of the most commonly employed tasks to examine amygdala activity. Scant work has employed eye-tracking to detect how various subjects are processing the stimuli. Here, we aim to explore fixation patterns and their neural correlates during this task to better understand emotional processing in depression. The analyses included patients with a depressive disorder (n=84) and healthy controls (n=114) from the BeCOME (the biological classification of mental disorders) study. They performed the task to match 6 types of emotion pairs in the MR-scanner while eye-tracking was recorded simultaneously. We split the 6s trials into two stages (before and after the behavioral response (i.e. free viewing stage)) and extracted dwelling times separately. Additionally, we examined amygdala activation to emotional faces by general linear models in SPM12 modeling in the face stimuli, the baseline geometric forms (control condition), and unspecific nuisance regressors. Depressive patients spent longer dwelling times on sad faces than other negative faces but only in the free viewing stage, while healthy controls did not show this differential pattern. In fMRI analyses, both groups showed significant whole-brain corrected activation clusters in the amygdala, whereas there were no significant differences between the groups at this significance level. Taken together, individuals with depression indicated a mood congruency bias manifest in eye-tracking patterns but not in other neurobehavioral readouts, indicating that eye-tracking is a sensitive readout for emotional processing in depression.

Interconnectivity between neocortical areas is critical for sensory integration and sensorimotor transformations. These functions are mediated by heterogeneous inter-areal cortical projection neurons (ICPN), which send axon branches across cortical areas as well as to subcortical targets. Although ICPN are anatomically diverse, they are molecularly homogeneous, and how the diversity of their anatomical and functional features emerge during development remains largely unknown. Here we address this question by linking the connectome and transcriptome in developing single ICPN of the mouse neocortex using a combination of multiplexed analysis of projections by sequencing (MAPseq, to identify single-neuron axonal projections) and single-cell RNA sequencing (to identify corresponding gene expression). Focusing on neurons of the primary somatosensory cortex (S1), we reveal a protracted unfolding of the molecular and functional diferentiation of motor cortex-projecting (M) ICPN compared with secondary somatosensory cortex-projecting (S2) ICPN. We identify SOX11 as a temporally diferentially expressed transcription factor in M versus S2 ICPN. Postnatal manipulation of SOX11 expression in S1 impaired sensorimotor connectivity and disrupted selective exploratory behaviours in mice. Together, our results reveal that within a single cortical area, diferent subtypes of ICPN have distinct postnatal paces of molecular diferentiation, which are subsequently refected in distinct circuit connectivities and functions. Dynamic diferences in the expression levels of a largely generic set of genes, rather than fundamental diferences in the identity of developmental genetic programs, may thus account for the emergence of intra-type diversity in cortical neurons.

The orbitofrontal cortex (OFC) encodes the subjective value of outcome-guided behaviour, through extensive communication with other brain areas, such as primary sensory cortices. However, the developmental dynamics of orbitofrontal-sensory coupling in relationship with the maturation of behavioural abilities remain largely unexplored. Here we combine *in vivo* multi-site extracellular recordings and optogenetic manipulation with projection tracing in neonatal mice (P1-12) to monitor the developmental profile of orbitofrontal-sensory communication. We show that already at neonatal age the OFC targets the primary sensory areas via monosynaptic projections. The density of these projections is higher for OFC-V1 and sparser for OFC-S1, yet the monosynaptic efferent connections from both primary sensory areas targeting OFC are almost entirely lacking. The patterns of neuronal and network activity are similar in all three brain areas; discontinuous events with sparse firing progressively transform into continuous activity and higher firing rates. In line with the monosynaptic projections, the functional coupling differs between OFC-S1 and OFC-V1, as directed and undirected communication is stronger between OFC-V1. These data reveal that during early development the OFC impacts the coordinated activity of primary sensory cortices.

INTERPLAY BETWEEN EXCITATORY AND GABAERGIC CORTEX-WIDE ACTIVITY PATTERNS ACROSS EARLY POSTNATAL DEVELOPMENT

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Laura Mediavilla Santos[1], Christine Cross[1], Nick Whiteley[2], Michael Ashby[1]
[1]University of Bristol, School Of Physiology, Pharmacology And Neuroscience, Bristol, United Kingdom, [2]University of Bristol, School Of Mathematics, Bristol, United Kingdom

GABAergic neurons contribute to key aspects of the cortical functional maturation during early postnatal development. Particularly, the timing of GABAergic maturation seems to be aligned to the different developmental trajectories of each cortical region. Although various studies have looked at the local connectivity of these microcircuits, little is known about the dynamics of the functional maturation of GABAergic cortical networks at the large-scale level. In this project, we aimed to define how the activity of GABAergic neurons shapes the maturation of the activity dynamics across the entire neonatal cortex. We used dual-colour widefield calcium imaging to chronically examine the early postnatal cortex-wide dynamics of GABAergic interneurons, as well as excitatory neurons. We focused on the interplay between the spatial and temporal activity dynamics of these two neuronal populations, before and after active sensing. The activity maps of inhibitory networks show a complex mixture of small events confined to a single brain region, and larger events of simultaneous patterns across distant areas. These postnatal activity patterns vary with age and cortical region, becoming rapidly more complex at later stages of development. We found dynamic spatiotemporal fluctuations in the relative activation of excitatory and GABAergic neuronal populations during bouts of spontaneous cortical activity. In vivo manipulation of inhibition disrupts these fluctuations affecting the local and the wider cortical functional network. The study of cortex-wide dynamics,and particularly the role of local and long-range GABAergic signalling in the control of cortex-wide neural activity maturation, is key to understand normal brain development.

A general principle of dendritic constancy: A neuron's size- and shape-invariant excitability.
Reducing neuronal size results in less membrane and therefore lower input conductance. Smaller neurons are thus more excitable, as seen in their responses to somatic current injections. However, the impact of a neuron's size and shape on its voltage responses to dendritic synaptic activation is much less understood. Here we use analytical cable theory to predict voltage responses to distributed synaptic inputs in unbranched cables, showing that these are entirely independent of dendritic length. For a given synaptic density, neuronal responses depend only on the average dendritic diameter and intrinsic conductivity. This remains valid for a wide range of morphologies irrespective of their arborization complexity. Spiking models indicate that morphology-invariant numbers of spikes approximate the percentage of active synapses. In contrast to spike rate, spike times do depend on dendrite morphology. In summary, neuronal excitability in response to distributed synaptic inputs is largely unaffected by dendrite length or complexity.

Synthesis and Neuroprotective Properties of N-Substituted -Dialkoxyphosphorylated Nitrones.
Herein, we report the synthesis and neuroprotective power of some N-substituted -(dialkoxy)phosphorylated nitrones -, by studying their ability to increase the cell viability, as well as their capacity to reduce necrosis and apoptosis. We have identified ()---butyl-1-(diethoxyphosphoryl)methanimine oxide () as the most potent, nontoxic, and neuroprotective agent, with a high activity against neuronal necrotic cell death, a result that correlates very well with its great capacity for the inhibition of the superoxide production (72%), as well as with the inhibition of lipid peroxidation (62%), and the 5-lipoxygenase activity (45%) at 100 μM concentrations. Thus, nitrone could be a convenient promising compound for further investigation.

Loss of causes altered neurogenesis in a mouse model of a childhood neurodegenerative disorder.

Neural stem/progenitor cells (NPCs) generate new neurons in the brain throughout an individual's lifetime in an intricate process called neurogenesis. Neurogenic alterations are a common feature of several adult-onset neurodegenerative diseases. The neuronal ceroid lipofuscinoses (NCLs) are the most common group of inherited neurodegenerative diseases that mainly affect children. Pathological features of the NCLs include accumulation of lysosomal storage material, neuroinflammation and neuronal degeneration, yet the exact cause of this group of diseases remains poorly understood. The function of the CLN5 protein, causative of the CLN5 disease form of NCL, is unknown. In the present study, we sought to examine neurogenesis in the neurodegenerative disorder caused by loss of Our findings demonstrate a newly identified crucial role for CLN5 in neurogenesis. We report for the first time that neurogenesis is increased in -deficient mice, which model the childhood neurodegenerative disorder caused by loss of Our results demonstrate that, in deficiency, proliferation of NPCs is increased, NPC migration is reduced and NPC differentiation towards the neuronal lineage is increased concomitantly with functional alterations in the NPCs. Moreover, the observed impairment in neurogenesis is correlated with increased expression of the pro-inflammatory cytokine IL-1β. A full understanding of the pathological mechanisms that lead to disease and the function of the NCL proteins are critical for designing effective therapeutic approaches for this devastating neurodegenerative disorder.

OLFACTORY-DRIVEN BETA BAND ENTRAINMENT OF CORTICAL-HIPPOCAMPAL NETWORKS DURING NEONATAL DEVELOPMENT

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Johanna Kostka
Center for Molecular Neurobiology, University Medical Center Hamburg-Eppendorf, Institute Of Developmental Neurophysiology, Hamburg, Germany

Cognitive processing relies on the functional refinement of the limbic circuitry during the first two weeks of life. During this developmental period, when most sensory systems are still immature, the sense of olfaction acts as “door to the world”, providing the main source of environmental inputs. However, it is unknown whether early olfactory processing shapes the activity in cortical-hippocampal networks during neonatal development. Here, we address this question by combining simultaneous *in vivo* recordings from the olfactory bulb (OB), lateral entorhinal cortex (LEC), hippocampus (HP), and prefrontal cortex (PFC) with olfactory stimulation and opto- and chemogenetic manipulations of mitral/tufted cells (M/TCs) in the OB of non-anesthetized neonatal mice. We show that the neonatal OB synchronizes the LEC-HP-PFC circuity in beta frequency range. Moreover, M/TC activity drives neuronal and network activity in LEC, as well as subsequently, HP and PFC via long-range projections from mitral cells (MCs) to HP-projecting LEC neurons. Thus, OB activity shapes the communications within cortical-hippocampal networks during neonatal development.

Inhibition of influenza virus activity by multivalent glycoarchitectures with matched sizes.
We describe the synthesis of a series of sialic acid-conjugated, polyglycerol-based nanoparticles with diameters in the range of 1-100 nm. Particle sizes were varied along with the degree of functionalization to match the corresponding virus size and receptor multiplicity in order to achieve maximum efficiency. To build up these architectures, we used biocompatible, hyperbranched polyglycerols as scaffolds and recently developed polyglycerol-based nanogels, the sizes of which can be varied between 2-4 nm and 40-100 nm, respectively. We demonstrate here that such multivalent nanoparticles inhibit influenza A virus cell binding and fusion and consequently infectivity. The potential of multivalency is evident from larger particles showing very efficient inhibition of viral infection up to 80 %. Indeed, both the size of the nanoparticle and the amount of ligand density are important determinants of inhibition efficiency. The inhibitory activity of the tested polymeric nanoparticles drastically increased with size. Particles with similar dimensions to the virus (50-100 nm) are exceedingly effective. We also observed a saturation point in degree of surface functionalization (i.e. ligand density), above which inhibition was not significantly improved. Our study emphasizes the importance of matching particle sizes and ligand densities to mimic biological surfaces and improve interactions; this is a vital concept underlying multivalent interactions.

Coordinated electrical activity in the olfactory bulb gates the oscillatory entrainment of entorhinal networks in neonatal mice.
Although the developmental principles of sensory and cognitive processing have been extensively investigated, their synergy has been largely neglected. During early life, most sensory systems are still largely immature. As a notable exception, the olfactory system is functional at birth, controlling mother-offspring interactions and neonatal survival. Here, we elucidate the structural and functional principles underlying the communication between olfactory bulb (OB) and lateral entorhinal cortex (LEC)-the gatekeeper of limbic circuitry-during neonatal development. Combining optogenetics, pharmacology, and electrophysiology in vivo with axonal tracing, we show that mitral cell-dependent discontinuous theta bursts in OB drive network oscillations and time the firing in LEC of anesthetized mice via axonal projections confined to upper cortical layers. Acute pharmacological silencing of OB activity diminishes entorhinal oscillations, whereas odor exposure boosts OB-entorhinal coupling at fast frequencies. Chronic impairment of olfactory sensory neurons disrupts OB-entorhinal activity. Thus, OB activity shapes the maturation of entorhinal circuits.

Neural Correlates of Anesthesia in Newborn Mice and Humans.
Monitoring the hypnotic component of anesthesia during surgeries is critical to prevent intraoperative awareness and reduce adverse side effects. For this purpose, electroencephalographic (EEG) methods complementing measures of autonomic functions and behavioral responses are in use in clinical practice. However, in human neonates and infants existing methods may be unreliable and the correlation between brain activity and anesthetic depth is still poorly understood. Here, we characterized the effects of different anesthetics on brain activity in neonatal mice and developed machine learning approaches to identify electrophysiological features predicting inspired or end-tidal anesthetic concentration as a proxy for anesthetic depth. We show that similar features from EEG recordings can be applied to predict anesthetic concentration in neonatal mice and humans. These results might support a novel strategy to monitor anesthetic depth in human newborns.

Bursting mitral cells time the oscillatory coupling between olfactory bulb and entorhinal networks in neonatal mice.
During early postnatal development, mitral cells show either irregular bursting or non-bursting firing patterns Bursting mitral cells preferentially fire during theta bursts in the neonatal olfactory bulb, being locked to the theta phase Bursting mitral cells preferentially fire during theta bursts in the neonatal lateral entorhinal cortex and are temporally related to both respiration rhythm- and theta phase Bursting mitral cells act as a cellular substrate of the olfactory drive that promotes the oscillatory entrainment of entorhinal networks ABSTRACT: Shortly after birth, the olfactory system provides not only the main source of environmental inputs to blind, deaf, non-whisking and motorically-limited rodents, but also the drive boosting the functional entrainment of limbic circuits. However, the cellular substrate of this early communication remains largely unknown. Here, we combine in vivo and in vitro patch-clamp and extracellular recordings to reveal the contribution of mitral cell (MC) firing to early patterns of network activity in both the neonatal olfactory bulb (OB) and the lateral entorhinal cortex (LEC), the gatekeeper of limbic circuits. We show that MCs predominantly fire either in an irregular bursting or non-bursting pattern during discontinuous theta events in the OB. However, the temporal spike-theta phase coupling is stronger for bursting than non-bursting MCs. In line with the direct OB-to-LEC projections, both bursting and non-bursting discharge augments during co-ordinated patterns of entorhinal activity, albeit with higher magnitude for bursting MCs. For these neurons, temporal coupling to the discontinuous theta events in the LEC is stronger. Thus, bursting MCs might drive the entrainment of the OB-LEC network during neonatal development.

The cerebral cortex contains an extraordinary diversity of excitatory projection neuron (PN) and inhibitory interneurons (IN), wired together to form complex circuits. Spatiotemporally coordinated execution of intrinsic molecular programs defines both PN and IN subtype diversity. Spontaneous neuronal activity in the early stages of development, as well as evoked activity by external stimuli can contribute to the formation of balanced microcircuits. Alterations of these delicate processes, indeed, have often been associated to neurological/neurodevelopmental disorders. However, it is still unclear how cortical neuronal diversity influences early spontaneous activity, and whether subtype-specific molecular features (i.e. ion channel repertoire) can correlate with distinctive functional roles in the early assembly. In this study, we combined in utero genetic perturbations via CRISPR/Cas9 system and pharmacological inhibition of selected ion channels (i.e HCN1Hyperpolarization Activated Cyclic Nucleotide Gated Potassium Channel 1) with RNA-sequencing and live imaging technologies to identify the activity-regulated processes controlling the development of different cortical PN classes, their wiring and the acquisition of subtype specific features. Our preliminary results suggests that HCN1 channel, which is associated with infantile genetic epilepsy, is a possible modulator of spontaneous electrical activity in developing cerebral cortex and proposes HCN-current as a fundamental signal to drive cortical wave propagation during development. Further validation of this finding would support HCN1 as potential intervention targets for developmental epilepsies.

Instituto de Neurociencias De Alicante, Developmental Neurobiology, San Juan de Alicante, Spain

Patterns of neuronal activity emerge spontaneously in the developing brain and play a pivotal role in the maturation of sensory circuits. However, it remains unclear to what extent different immature sensory cortices exhibit specific patterns of activity. Using meso-scale functional imaging in embryonic and early postnatal mice and classification algorithms for the data analysis, we show that specific patterns of spontaneous activity could be associated to distinct sensory cortical territories. These patterns of spontaneous activity are influenced by the pattern of activity from peripheral structures. We showed that embryonic removal of the eyes modifies the normal pattern of activity in V1 with the appearance of larger and more correlated waves and bilateral co-activations. These changes in spontaneous activity in V1 were also evident at later postnatal life as shown by multielectrode recordings and predict a perturbed sensory processing in the adult.

Local and Volume-Conducted Contributions to Cortical Field Potentials.
Brain field potentials (FPs) can reach far from their sources, making difficult to know which waves come from where. We show that modern algorithms efficiently segregate the local and remote contributions to cortical FPs by recovering the generator-specific spatial voltage profiles. We investigated experimentally and numerically the local and remote origin of FPs in different cortical areas in anesthetized rats. All cortices examined show significant state, layer, and region dependent contribution of remote activity, while the voltage profiles help identify their subcortical or remote cortical origin. Co-activation of different cortical modules can be discriminated by the distinctive spatial features of the corresponding profiles. All frequency bands contain remote activity, thus influencing the FP time course, in cases drastically. The reach of different FP patterns is boosted by spatial coherence and curved geometry of the sources. For instance, slow cortical oscillations reached the entire brain, while hippocampal theta reached only some portions of the cortex. In anterior cortices, most alpha oscillations have a remote origin, while in the visual cortex the remote theta and gamma even surpass the local contribution. The quantitative approach to local and distant FP contributions helps to refine functional connectivity among cortical regions, and their relation to behavior.

MATURATION OF ELECTROPHYSIOLOGICAL PROPERTIES OF MOTOR CORTEX NEUROS ALLOWS A FINER MOTOR CONTROL IN ADULT RATS

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Introduction: Rodents are mainly sessile during the first postnatal week, produce primitive hindlimb-based ambulation during the second week and perform complex locomotor behaviors as in adult animals by third week. Achieving these distinctive movements require the maturation of a great variety of specialized neural circuits that are refined with age. **Aim:** The aim of this study is to understand how the neuronal membrane properties mature to achieve an efficient motor control in the adult population. **Methods:** Using whole cell patch clamp recordings, we have studied the changes in the electrophysiological properties of layer V pyramidal neurons of the rat primary motor cortex during postnatal development. Neurons were divided into 3 groups: newborn (P2-P7), infantile (P11-P17) and adult (>P22). **Results:** Newborn neurons are recruited at very low currents and in a narrow range (10-70 pA) compared to the other groups (infantile: 40-240 pA; adult: 60-400 pA). Maturation also produced a wider distribution of the data in parameters such as maximum frequency (12-27 AP/s; 11-37 AP/s; 12-60 AP/s), cancellation current (100-295 pA; 200-960 pA; 400-2000 pA), working range (45-275 pA; 60-845 pA; 340-1855 pA) and capacitance (16-57 pF; 20-97 pF; 23-140 pF). **Conclusions**: The narrower ranges found in newborn animals may support the rapid, ballistic movements observed prior to the beginning of the accurate motor control. The diversification among motor neurons properties with age may allow more adaptable schemes as the complexity of the motor behaviors increases during later stages of postnatal maturation.

DISSECTING THE ROLE OF HCN1 IN DEVELOPMENTAL AND EPILEPTIC ENCEPHALOPATHY (DEE) BY EXPLOITING PATIENT-SPECIFIC MODELS OF CEREBRAL CORTEX DEVELOPMENT IN VIVO

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Giulia Demenego[1], Sara Mancinelli[1], Filippo Mirabella[2], Elena Ticozzi[1], Christel Depienne[3], Davide Pozzi[1,4], Simona Lodato[1]
[1]Humanitas University, Neuroscience Department, Pieve Emanuele, Italy, [2]IRCCS Humanitas Clinical and Research Center, Neuro Center, Rozzano, Italy, [3]Institute of Human Genetics, 3university Hospital Essen, Essen, Germany, [4]IRCCS Humanitas Research Center, Pharmacology And Brain Pathology Laboratory, MILANO, Italy

Epilepsy is the most common neurological condition in childhood (1% prevalence), and constitutes a public health burden worldwide. Within the broad classification of infantile/pediatric epilepsies, particularly devastating are the developmental and epileptic encephalopathies (DEE), a group of heterogeneous conditions characterized by very early onset and spontaneous, recurrent and pharmaco-resistant seizures. Recent advancements in genome sequencing have expanded our knowledge on DEE, revealing a complex genetic architecture. Interestingly, the Hyperpolarization-activated Cyclic Nucleotide-gated (HCN1) gene has been recently linked to a particularly devastating subtype of DEE, namely DEE24. Indeed, growing evidence now supports a critical role for ion channels (classically studied exclusively in mature neurons) in controlling immature neuronal behavior and in brain pathology. In this work, we aim at understanding how developmental processes are altered by HCN1 pathogenic variants associated with DEE24. We selected 3 *de novo* HCN1 variants (M153I, G391D, A387S) showing association with both epileptic, autistic/behavioral and morphological traits and evaluated their effect on electrophysiological properties in both heterologous cell lines and neurons. Moreover, we generated chimeric brain harboring the patient-specific HCN1 variants ($HCN1^{mut}$) via *in utero* electroporation and analyzed cell intrinsic (e.g. migration, differentiation, dendritogenesis) as well as not-cell autonomous effects of the mutations on early cortical development. Our preliminary results suggest that the generation of personalized (patient-specific) in vivo models allows to identify the specific endophenotypes of distinct genetic HCN1 variants and their effects on cortical assembly.These valuable models, bridging genetic and clinical data with cellular and molecular neurodevelopment, will potentially inspire tailored therapeutic avenues.

Primary sensory areas of the neocortex are determined by their connectivity with the thalamus, receiving specific projections from distinct first-order (FO) thalamic nuclei. FO thalamocortical axons (TCA) are oriented during embryogenesis towards their cortical target and display a perinatal waiting period before innervating specific area. If TCA are initially misguided, they show an extraordinary capacity to reorient after birth within the neocortex, thereby reaching their proper cortical target. The roles of such sequential targeting and adaptation steps onto areal map formation in normal and pathological conditions remains to be fully understood. Here, using a mutant mouse model in which the trajectory of embryonic TCA is shifted, we found that TCA postnatal rewiring is preceded by a prenatal apoptosis of FO thalamic nuclei, together enabling the formation of sharp, albeit drastically reduced, primary somatosensory (S1) and visual (V1) areas. We furthermore showed that the remarkable postnatal TCA plasticity occurs within a short time-window and is drastically impaired by preterm birth, leading to a maintenance of misguided axons and a blurring of V1 molecular border. At the molecular level, TCA plasticity was regulated by levels of serotonin, which are reduced by preterm birth. Overall, our study reveals sequential embryonic and postnatal checkpoints that enable concerted adaptations of TCA and cortical areas. It also demonstrated that preterm birth impairs a serotonin-dependent plastic time-window which is essential for the rescue of prenatal miswiring and adaptation of cortical map to incoming sensory inputs. Garel S. and Lokmane L., contributed equally to this work

Transplanting stem cell derived cortical neurons to restore higher function in diseased brains, no longer seems like a distant dream, but many hurdles remain. What are the optimal conditions under which transplanted cells can restore function? Using our recently developed xenotransplantation technique, we study how juvenile human pluripotent stem cell derived cortical pyramidal neurons integrate in the adult mouse brain. We show that human transplanted cortical neurons develop at their own intrinsic pace; nevertheless they integrate robustly and gain detailed sensory responses. It remains unclear to what extent transplanted neurons can to form meaningful output connections with the host circuit. We address this question by expressing the red-shifted opsin ChRmine in the human cells we transplant and engaging the animal in a visual behavioural paradigm. Mice are trained to detect the appearance of visual stimuli with multiple contrasts (range [3 - 100]%). To isolate the contribution of transplanted human neurons in driving decisions, we optogenetically activate a small number of human neurons in the visual cortex of the mouse. Our results indicate that detection performance levels for optogenetic stimulation and weak visual stimuli are indistinguishable and above chance level. Using identical optogenetic stimulation parameters in an animal where human cells were not detected yields chance level performance. These findings suggest that young human neurons can integrate into mature mouse cortical circuit and take up a functional role. In future experiments, we will use circuit mapping techniques to establish how the activity of transplanted human cells propagate to the host circuit.

AREA-SPECIFIC ABNORMAL DEVELOPMENT OF CORTICAL CIRCUIT IN A 22Q11 DELETION MOUSE MODEL

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Eline Balavoine[1], Jimmy Olusakin[2], Greta Limoni[3], Esther Klingler[1], Denis Jabaudon[1]
[1]University of Geneva, Department Of Basic Neurosciences, Geneva, France, [2]University of Maryland School of Medecin, Department Of Anatomy And Neurobiology, Baltimore MD, United States of America, [3]Ecole Polytechnique Fédérale de Lausanne, Brain Mind Institute, School Of Life Sciences, Lausanne, Switzerland

DiGeorge syndrome (or 22q11 deletion syndrome) is a human developmental disorder caused by a 1.5 to 3.0 MB microdeletion on chromosome 22 characterized by cardiovascular and craniofacial malformations and cognitive impairment. It is the genetic neurodevelopmental disorder with the highest association with schizophrenia, making it an interesting condition to identify genes underlying neuropsychiatric disorders. “LgDel” mice have a microdeletion of chromosome 16, which recapitulates the human chromosomic deletion as most gene homologs are located in one portion of this chromosome; little is known about the impact of the deletion on distinct cell types and distinct brain regions during circuit development. Here, we investigated the transcriptional trajectories of distinct cortical cell types in wild-type and LgDel mice during postnatal development using single-cell RNA sequencing in various cortical areas. Our results suggest cell-type and area-specific anomalies that may contribute to behavioural phenotypes of this disorder.

[1]INSERM - Aix-Marseille Université, Inmed Umr1249, Marseille, France, [2]Institut du Fer à Moulin, Cortical Development And Pathology, Paris, France, [3]Sorbonne Université, Sciences, Paris, France, [4]Inserm, U1270, Paris, France, [5]Max Planck Institute of Psychiatry, Developmental Neurobiology, Munich, Germany

Aims: Cortical representations of the sensory periphery – or somatosensory maps – are topographically organized sub-fields of the murine somatosensory cortex. Among these, the so-called barrel field is composed of neuronal aggregates (barrels) in layer 4 (L4) that receive thalamocortical afferents (TCAs) and form a somatotopic map of facial whiskers. Here, we investigated the development of barrels and TCAs in two murine models of grey matter heterotopia (GMH), in which masses of ectopic neurons (or heterotopia) accumulate below the cortex and create an apparent duplicated cortex. Our aim is to determine if whisker maps are properly formed, altered or duplicated in this context. **Methods:** We used viral tracing approaches and immunohistochemistry to characterize the development of whisker maps and TCAs in two GMH mouse models resulting from the conditional, telencephalon-specific knockout (cKO) of Eml1 or RhoA. **Results:** In the two models, aggregates of neurons with a L4 identity are present at the expected location in the cortex, forming topographically organized barrels receiving TCAs. Unexpectedly, we also observed in the heterotopia similar barrel-like aggregates of ectopic L4 neurons that receive TCAs navigating either ventrally to the heterotopia in Eml1-cKO or dorsally in RhoA-cKO. This duplicated, ectopic whisker map is aligned with the normally positioned one, denoting an areal conservation between the heterotopia and cortex. **Conclusions:** Ectopic L4 neurons maintain their ability to instruct TCA connectivity, suggesting that intrinsic cortical programs are sufficient for areal specification of the barrel field.

STUDY OF THE INFLUENCE OF THE CEREBELLUM IN THE THALAMOCORTICAL NETWORK

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Sara Camacho García, Martina Riva, Raquel Murcia-Ramón, Juan Antonio Moreno-Bravo
Instituto de Neurociencias de Alicante, Developmental Neurobiology, San Juan de Alicante, Spain

The cerebral cortex is involved in multiple functions, such as cognition, motion, language, emotion and receives afferent inputs from several regions, including the cerebellum. The cerebellum is connected with the cerebral cortex through the thalamus. The cerebellum is one of the most consistently altered brain regions reported in Autism Spectrum Disorders (ASD). According to the developmental diaschisis, meaning that one brain region could affect a remote one because they are connected, we are interested in studying how the cerebellum influences the thalamocortical network. Under this light, the closed-loop cerebello-thalamo-cortical circuit could explain the possible influence of the cerebellum in cortical development and its complex functions.
First of all, we aim at unraveling how the cerebello-thalamo-cortical circuit develops, in particular, when and where the cerebellum is connected with the cortex through the thalamus. After having assessed which thalamic nuclei receive the cerebellar afferences, we want to find out specifically how the thalamocortical network is established during development. We show which cortical regions are receiving the cerebellar inputs through the thalamus using viral and CTB tracing injections strategies. In particular, we describe that thalamic axons coming from cerebellum connect with the Front associative cortical region (Fra) and motor cortical areas such as M1 and M2.
Investigating how the cerebello-thalamo-cortical circuit emerges during development is essential for understanding cerebellar origin of neurodevelopmental disorders.

Host oligodendrogliopathy and α-synuclein strains dictate disease severity in multiple system atrophy.
Multiple system atrophy is a progressive neurodegenerative disease with prominent autonomic and motor features. During early stages different subtypes of multiple system atrophy are distinguished by their predominant parkinsonian or cerebellar symptoms reflecting the heterogeneous nature of the disease. The pathognomonic feature of multiple system atrophy is the presence of α-synuclein (αSyn) protein deposits in oligodendroglial cells. αSyn can assemble in specific cellular or disease environments and form αSyn strains with unique structural features but the ability of αSyn strains to propagate in oligodendrocytes remains elusive. More recently, it was shown that multiple multiple system atrophy strains with related conformations exist in the brain of patients. Here, we investigated if different αSyn strains can influence multiple system atrophy progression in a strain-dependent manner. To this aim, we injected two recombinant αSyn strains (fibrils and ribbons) in multiple system atrophy transgenic mice and found that αSyn protein strains determine disease severity in multiple system atrophy via host-restricted and cell-specific pathology in vivo. αSyn strains significantly impact disease progression in a strain-dependent way via oligodendroglial, neurotoxic and immune-related mechanisms. Neurodegeneration and brain atrophy were accompanied by unique microglial and astroglial responses and the recruitment of central and peripheral immune cells. The differential activation of microglial cells correlated with the structural features of αSyn strains both in vitro and in vivo. Spectral analysis showed that ribbons propagate oligodendroglial inclusions that are structurally distinct from those of fibrils, with resemblance to oligodendroglial inclusions in multiple system atrophy patient brain. This study therefore shows that the multiple system atrophy phenotype is governed by both the αSyn strain nature and the host environment and that by injecting αSyn strains in a multiple system atrophy animal model a more comprehensive phenotype can be established.

THE DEVELOPMENT OF THE CEREBELLO-THALAMIC TRACT

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Raquel Murcia-Ramón[1], Belén Andrés[1], Guillermina López-Bendito[2], Juan Antonio Moreno-Bravo[2]

Classically, the cerebellum has been considered a pure motor brain structure. However, mounting evidence has suggested that it also has essential contributions to nonmotor functions, such as cognition and emotion. The cerebellum is well poised to contribute to these complex behaviors because it is connected to the cerebral cortex which controls these functions. The main efferent connections from the cerebellum to the cortex are made through the thalamus. Importantly, early abnormalities of this circuit have been related to diverse neurodevelopmental disorders, such as autism spectrum disorders. Thus, understanding how the cerebello-thalamic pathway develops is the required step to understanding the cerebellar contribution to high-order neurodevelopmental disorders. Here we have performed different strategies, including tracing methods and transgenic approaches, to specifically target the cerebellum and its long-range projections. By combining these techniques together with clearing methods and 3D light-sheet microscopy, we have defined the cerebellothalamic connectivity. Our data shows that the cerebellar axons invade the contralateral thalamus as early as embryonic day (E)17. At E18, cerebellar projections mainly contact to the ventromedial and the ventral anterior-lateral complex, but also to the mediodorsal and parafascicular thalamic nuclei. The cerebellothalamic innervation continues evolving during postnatal stages innervating several motor and non-motor thalamic nuclei. Our data reveal a remarkable complexity of the cerebellothalamic connectivity during late embryonic and early postnatal stages. These results suggest a potential role of the cerebellum in impacting complex and immature thalamocortical networks.

Properties of the epileptiform activity in the cingulate cortex of a mouse model of LIS1 dysfunction.
Dysfunction of the LIS1 gene causes lissencephaly, a drastic neurological disorder characterized by a deep disruption of the cortical structure. We aim to uncover alterations of the cortical neuronal networks related with the propagation of epileptiform activity in the Lis1/sLis1 mouse, a model lacking the LisH domain in heterozygosis. We did extracellular field-potential and intracellular recordings in brain slices of the anterior cingulate cortex (ACC) or the retrosplenial cortex (RSC) to study epileptiform activity evoked in the presence of bicuculline (10 µM), a blocker of GABA receptors. The sensitivity to bicuculline of the generation of epileptiform discharges was similar in wild type (WT) and Lis1/sLis1 cortex (EC 1.99 and 2.24 µM, respectively). In the Lis1/sLis1 cortex, we observed a decreased frequency of the oscillatory post-discharges of the epileptiform events; also, the propagation of epileptiform events along layer 2/3 was slower in the Lis1/sLis1 cortex (WT 47.69 ± 2.16 mm/s, n = 25; Lis1/sLis1 37.34 ± 2.43 mm/s, n = 15; p = 0.004). The intrinsic electrophysiological properties of layer 2/3 pyramidal neurons were similar in WT and Lis1/sLis1 cortex, but the frequency of the spontaneous EPSCs was lower and their peak amplitude higher in Lis1/sLis1 pyramidal neurons. Finally, the propagation of epileptiform activity was differently affected by AMPA receptor blockers: CNQX had a larger effect in both ACC and RSC while GYKI53655 had a larger effect only in the ACC in the WT and Lis1/sLis1 cortex. All these changes indicate that the dysfunction of the LIS1 gene causes abnormalities in the properties of epileptiform discharges and in their propagation along the layer 2/3 in the anterior cingulate cortex and in the restrosplenial cortex.

Role in the Development of the Habenula and the Fasciculus Retroflexus.
is one of the morphogenes that controls the specification and differentiation of neuronal populations in the developing central nervous system. The habenula is a diencephalic neuronal complex located in the most dorsal aspect of the thalamic prosomere. This diencephalic neuronal population is involved in the limbic system and its malfunction is related with several psychiatric disorders. Our aim is to elucidate the role in the habenula and its main efferent tract, the fasciculus retroflexus,

development. In order to achieve these objectives, we analyzed these structures development in a lack of function mouse model. The habenula was generated in our model, but it presented an enlarged volume. This alteration was due to an increment in habenular neuroblasts proliferation rate. The fasciculus retroflexus also presented a wider and disorganized distribution and a disturbed final trajectory toward its target. The mid-hindbrain territories that the tract must cross were miss-differentiated in our model. The specification of the habenula is independent. Nevertheless, it controls its precursors proliferation rate. expressed in the isthmic organizer is vital to induce the midbrain and rostral hindbrain territories. The alteration of these areas is responsible for the fasciculus retroflexus axons misroute.

Neuronal tangential migration from Nkx2.1-positive hypothalamus.

During the development of the central nervous system, the immature neurons suffer different migration processes. It is well known that Nkx2.1-positive ventricular layer give rise to critical tangential migrations into different regions of the developing forebrain. Our aim was to study this phenomenon in the hypothalamic region. With this purpose, we used a transgenic mouse line that expresses the tdTomato reporter driven by the promotor of Nkx2.1. Analysing the Nkx2.1-positive derivatives at E18.5, we found neural contributions to the prethalamic region, mainly in the zona incerta and in the mes-diencephalic tegmental region. We studied the developing hypothalamus along the embryonic period. From E10.5 we detected that the Nkx2.1 expression domain was narrower than the reporter distribution. Therefore, the Nkx2.1 expression fades in a great number of the early-born neurons from the Nkx2.1-positive territory. At the most caudal positive part, we detected a thin stream of positive neurons migrating caudally into the mes-diencephalic tegmental region using time-lapse experiments on open neural tube explants. Late in development, we found a second migratory stream into the prethalamic territory. All these tangentially migrated neurons developed a gabaergic phenotype. In summary, we have described the contribution of interneurons from the Nkx2.1-positive hypothalamic territory into two different rostrocaudal territories: the mes-diencephalic reticular formation through a caudal tangential migration and the prethalamic zona incerta complex through a dorsocaudal tangential migration.

Gestational Exposure to Sodium Valproate Disrupts Fasciculation of the Mesotelencephalic Dopaminergic Tract, With a Selective Reduction of Dopaminergic Output From the Ventral Tegmental Area.

Gestational exposure to valproic acid (VPA) is known to cause behavioral deficits of sociability, matching similar alterations in human autism spectrum disorder (ASD). Available data are scarce on the neuromorphological changes in VPA-exposed animals. Here, we focused on alterations of the dopaminergic system, which is implicated in motivation and reward, with relevance to social cohesion. Whole brains from 7-day-old mice born to mothers given a single injection of VPA (400 mg/kg b.wt.) on E13.5 were immunostained against tyrosine hydroxylase (TH). They were scanned using the iDISCO method with a laser light-sheet microscope, and the reconstructed images were analyzed in 3D for quantitative morphometry. A marked reduction of mesotelencephalic (MT) axonal fascicles together with a widening of the MT tract were observed in VPA treated mice, while other major brain tracts appeared anatomically intact. We also found a reduction in the abundance of dopaminergic ventral tegmental (VTA) neurons, accompanied by diminished tissue level of DA in ventrobasal telencephalic regions (including the nucleus accumbens (NAc), olfactory tubercle, BST, substantia innominata). Such a reduction of DA was not observed in the non-limbic caudate-putamen. Conversely, the abundance of TH+ cells in the substantia nigra (SN) was increased, presumably due to a compensatory mechanism or to an altered distribution of TH+ neurons occupying the SN and the VTA. The findings suggest that defasciculation of the MT tract and neuronal loss in VTA, followed by diminished dopaminergic input to the ventrobasal telencephalon at a critical time point of embryonic development (E13-E14) may hinder the patterning of certain brain centers underlying decision making and sociability.

EFFECTS OF LIS1 GENE LOSS IN PARVALBUMIN EXPRESSING CELLS ON THE MOUSE CEREBELLAR CORTEX

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Emilio Geijo-Barrientos, Abraham Andreu-Cervera, Ana María Jiménez, Francisca Almagro-García, Diego Echevarría, Salvador Martínez
Universidad Miguel Hernández-CSIC, Instituto De Neurociencias, San Juan, Alicante, Spain

The formation of cerebellar neuronal circuits and the development of the physiological functions of the cerebellar cortex require a precise sequence of neural differentiation and migration steps. The *Lis1* gene regulates the dynein dependent axonal transport, mediates neuronal migration in the developing brain, and supports synaptic integrity in the mature brain. In human, defects in *LIS1* expression produce lissencephaly type I. *Lis1* is expressed throughout the entire lifespan of the central nervous system. We have studied the cerebellar alterations caused by *Lis1* selective inactivation in parvalbumin (PV) expressing cells; PV is highly expressed in cerebellar Purkinje cell layer during development of the cerebellar cortex. For this we have created a conditional *Lis1* knockout mouse in PV^{+} neurons ($Lis1^{cKO\text{-}PV+}$). During prepuberal stages (P15-P21), $Lis1^{cKO\text{-}PV+}$ mice presented a strong ataxic locomotor phenotype, reflecting possible dysfunctions in the cerebellum. Purkinje cell layer (PCL) displayed a clear impaired organization. Purkinje cells presented an abnormal soma with a rudimentary and atrophic dendritic arborization. Moreover, staining against V-Glut1, a glutamatergic neuronal terminal marker, showed an abnormal organization of the excitatory basket nets generated by these terminals around the Purkinje cell soma. Altogether, these data suggest that *Lis1* expression in Purkinje cells is not only required for their proper development and therefore the PCL organization but also for the normal synaptogenetic mechanisms leading to the organisation of the glutamatergic presynaptic terminals. These results also indicate the presence of non-cell autonomous effects of *Lis1* dysfunction. Funding: MCIN grant PID2020-118171RB-I00 and GVA-Prometeo Grant 2018/041. POSTNATAL GABAERGIC TRANSMISSION SCULPTS CALLOSAL CONNECTIVITY

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Lorena Bragg-Gonzalo[1], Candela Gonzalez-Arias[2], Gertrudis Perea[2], Marta Nieto[1]

Neuronal circuits are developmentally shaped by genetic and activity-dependent mechanisms. Activity results from two opposing forces, excitation and inhibition (E/I), which depend on pyramidal cells and interneurons (INs). Cortical INs are born in the ventral telencephalon and only subsequently migrate into the cortex. Defects in INs are implicated in diverse neurodevelopmental disorders (NDDs). However, whether the integration of INs influences the assembly of excitatory networks is unknown. Here, we pharmacologically and genetically altered E/I balance to characterize its impact on the interhemispheric connections that constitute the corpus callosum (CC). This structure coordinates higher-order sensory, motor, and cognitive functions often affected in NDD. After postnatal treatments with the GABA agonist diazepam, stereotaxic injections of the retrograde tracer cholera toxin B (CTB) were performed directly into the CC to label the somatosensory and visual callosal circuits. GABAergic enhancement rearranges the adult interhemispheric circuit. Such rewiring potential is restricted to an early window, progressively diminishing with time. The most striking result is found in layer (L) 4 neurons –the paradigm of local connectivity– which exhibit a fourfold increase in callosal projections. The reprogrammed neurons receive fewer thalamic afferents and show smaller amplitude responses to intracolumnar stimulation. Aiming to pinpoint the physiological regulator of this rewiring, we genetically ablated somatostatin (SST) INs, one of the earliest cortical inhibitory subpopulations. SST deletion reproduces the L4 callosal phenotype. Hence, INs integration into the emerging excitatory circuits determines the choice between interhemispheric and local connectivity. Moreover, we describe a temporal window to pharmacologically manipulate callosal circuits.

Development and plasticity of the corpus callosum.
The corpus callosum (CC) connects the cerebral hemispheres and is the major mammalian commissural tract. It facilitates bilateral sensory integration and higher cognitive functions, and is often affected in neurodevelopmental diseases. Here, we review the mechanisms that contribute to the development of CC circuits in animal models and humans. These species comparisons reveal several commonalities. First, there is an early period of massive axonal projection. Second, there is a postnatal temporal window, varying between species, in which early callosal projections are selectively refined. Third, sensory-derived activity influences axonal refinement. We also discuss how defects in CC formation can lead to mild or severe CC congenital malformations.

Genetic and activity dependent-mechanisms wiring the cortex: Two sides of the same coin.
The cerebral cortex is responsible for the higher-order functions of the brain such as planning, cognition, or social behaviour. It provides us with the capacity to interact with and transform our world. The substrates of cortical functions are complex neural circuits that arise during development from the dynamic remodelling and progressive specialization of immature undefined networks. Here, we review the genetic and activity-dependent mechanisms of cortical wiring focussing on the importance of their interaction. Cortical circuits emerge from an initial set of neuronal types that engage in sequential forms of embryonic and postnatal activity. Such activities further complement the cells' genetic programs, increasing neuronal diversity and modifying the electrical properties while promoting selective connectivity. After a temporal window of enhanced plasticity, the main features of mature circuits are established. Failures in these processes can lead to neurodevelopmental disorders whose treatment remains elusive. However, a deeper dissection of cortical wiring will pave the way for innovative therapies.

DEVELOPMENTAL TARGETS OF CALLOSAL PROJECTION NEURONS (CPNS)

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Irene Varela Martínez, Marta Nieto
Spanish National Centre for Biotechnology (CNB-CSIC), Molecular And Celullar Biology Department, Madrid, Spain

The mammalian cortex contains multiple classes of neurons distributed across and within cortical layers. CPNs connect the hemispheres of the brain, increasing the complexity of cortical processing. Many cortical neurons send transient axons during development, which endow them with the capacity of forming different circuits. In the lab, we try to identify the significance, targets, and limits of this plasticity. By combining stereotaxic injections of the retrotracer CTB into the corpus callosum (CC) with immunolabeling of the neuronal marker NeuN, we determined the percentage of CPNs at different postnatal days. We observed that a considerable number of cortical neurons send transient projections to the contralateral hemisphere, which are then gradually eliminated during development in layer-specific manners. Most of them are upper-layer neurons, the ones with a more recent evolutionary origin; but some reside in the deep layers. Thereafter, we evaluated if developing CPNs explore subcortical territories as well. Simultaneous injections of CTB in the CC and the thalamus or the cerebral peduncle at sequential postnatal stages showed that callosal and subcortical labeling was always segregated into different cells, indicating that CPNs do not explore long-range subcortical targets. However, we detected short-range callosal branches exploring the dorsal region of the basal ganglia, which were confirmed by in utero electroporation. These findings demonstrate that, although callosal axons undergo massive remodeling during development, the plasticity of their long-range projections is restricted to cortical territories. This helps us to define the orchestrated freedom of the cortex.

The topology of neuronal networks is decisive for how information is processed, transferred and stored in the human brain. Engineered neural networks can be used to recapitulate key aspects of this topology in a confined and controlled environment *in vitro*, providing an invaluable tool to understand how the underlying structural motifs shape the dynamics of neural circuitries in healthy and perturbed conditions. Such modelling platforms thus enable the recapitulation and study of micro- and mesoscale network reconfigurations and how they impact a network´s functional output. Here we show that a microfluidic device with axon guiding channels with a geometry inspired by a Tesla valve can be used to engineer hierarchical neural networks *in vitro* with controllable afferent and efferent connectivity. In this way we can directly influence the network´s functional attributes, as demonstrated electrophysiologically by interfacing the platforms with nanoporous microelectrode arrays. This approach supports advanced comparative studies of network information processing capabilities in anatomically relevant circuitries in healthy versus pathological states. The relevant micro- and mesoscale investigations are per definition not possible *in vivo*. As such, these models have the potential to provide novel insights into neuroplasticity mechanisms in healthy and perturbed neural circuitries.

MOLECULAR BASIS AND BEHAVIOURAL SIGNIFICANCE OF A SEX SPECIFIC CIRCUIT SWITCH IN DROSOPHILA

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Erika Donà[1,2], Marina Gkantia[1], Dana Galili[1], Istvan Taisz[1], Gregory Jefferis[1]
[1]MRC LMB, Neurobiology, Cambridge, United Kingdom, [2]CNR-IN, Neurobiology, Vedano al Lambro, Italy

Sex-specific behavioural differences are driven by differences in circuit architecture established through development and genetically controlled. However finding a causal link between genetic, circuit and behavioural differences is challenging. The circuit responding to the male pheromone 11-cis-vaccenyl acetate (cVA) in Drosophila melanogaster offers a powerful entry point to this question. cVA has been shown to promote courtship in females and aggression in males (Kurtovic A, et al, 2007, Wang L & Anderson DJ, 2010). cVA information flow is redirected by a switch formed by two types of interneurons, aSP-g and aSP-f, with sexually dimorphic dendritic projections (Cachero S et al, 2010; Kohl J et al, 2013), whose sex is cell-autonomously controlled by the master regulator of sex-differentiation fruitless. We investigated the molecular underpinnings of sex-specific connectivity by transcriptionally profiling aSP-gs and aSP-fs in females, males and masculinised females during pupation. We identified a set of differentially expressed genes, whose function was addressed by a loss-of-function screen. We also found cell-type specific molecular markers, which gave us genetic access to these neurons. Through optogenetic activation experiments we showed that aSP-gs increase female sexual receptivity, while aSP-fs reduce male copulation success, demonstrating that the circuit switch has the hypothesised impact on behaviour. Additionally, in line with the idea that cVA induces attraction towards males by activating aSP-g neurons, their masculinisation resulted in reduced female receptivity. Together our work is revealing causal links between sex-specifc circuit architecture and behaviour, as well as the molecular genetic basis of these circuit differences.

A central question in brain development concerns how neuronal diversity guides the formation of neural connections. In the developing cortex, there exists a transient class of glutamatergic neurons known as Cajal-Retzius cells (CRs). CRs populate layer 1 of the cortex and arise from at least three distinct ontogenetic origins. The conundrum is that all three populations are thought to share common features, however recent studies have begun to identify some molecular heterogeneity among them. We sought to systematically profile CRs and ask whether neurons of distinct origin are differentially embedded in early cortical circuits. To address this, we first captured the distribution of CRs at postnatal (P) ages by utilizing genetic fate mapping, combined with CLARITY and mesoSPIM lightsheet microscopy. We find that, unlike at embryonic time points, postnatal CRs do not segregate in the cortex but rather intermingle. By performing single cell mRNA sequencing of CRs at P6 we revealed that this class of cells displays unappreciated genetic heterogeneity, also at the level of synaptic genes. Using monosynaptic pseudotyped-rabies virus tracings, we identified shared dense layer 1 presynaptic partners, but also distinct connections from subplate neurons and subcortical structures depending on CRs origin. These connectivity differences produce CRs specific sensory driven responses *in vivo*, identified via wide-field calcium imaging. This study uncovers the diversity of ontogenetically distinct CRs at the molecular, anatomical, and functional level and paves the way for revealing their role in the formation and function of cortical circuits.

Postmitotic Prox1 Expression Controls the Final Specification of Cortical VIP Interneuron Subtypes.
Throughout development, neuronal identity is controlled by key transcription factors that determine the unique properties of a cell. During embryogenesis, the transcription factor Prox1 regulates VIP-positive cortical interneuron migration, survival, and connectivity. Here, we explore the role of Prox1 as a regulator of genetic programs that guide the final specification of VIP interneuron subtypes in early postnatal life. Synaptic electrophysiology in male and female mice shows that postnatal Prox1 removal differentially affects the dynamics of excitatory inputs onto VIP bipolar and multipolar subtypes. RNA sequencing reveals that one of the downstream targets of Prox1 is the postsynaptic protein Elfn1, a constitutive regulator of presynaptic release probability. Further genetic, pharmacological, and electrophysiological experiments demonstrate that removing Prox1 reduces Elfn1 function in VIP multipolar but not in bipolar cells. Finally, overexpression experiments and analysis of native mRNA expression reveal that Elfn1 levels are differentially controlled at the post-transcriptional stage. Thus, in addition to activity-dependent processes that contribute to the developmental trajectory of VIP cells, genetic programs engaged by Prox1 control the final differentiation of multipolar and bipolar subtypes. The transcription factor Prox1 generates functional diversification of cortical VIP interneuron subtypes in early postnatal life, thus expanding the inhibitory repertoire of the cortex.

Topoisomerase IIβ Selectively Regulates Motor Neuron Identity and Peripheral Connectivity through Hox/Pbx-Dependent Transcriptional Programs.
Vital motor functions, such as respiration and locomotion, rely on the ability of spinal motor neurons (MNs) to acquire stereotypical positions in the ventral spinal cord and to project with high precision to their peripheral targets. These key properties of MNs emerge during development through transcriptional programs that dictate their subtype identity and connectivity; however, the molecular mechanisms that establish the transcriptional landscape necessary for MN specification are not fully understood. Here, we show that the enzyme topoisomerase IIβ (Top2β) controls MN migration and connectivity. Surprisingly, Top2β is not required for MN generation or survival but has a selective role in columnar specification. In the

absence of , phrenic MN identity is eroded, while other motor columns are partially preserved but fail to cluster to their proper position. In -/- mice, peripheral connectivity is impaired as MNs exhibit a profound deficit in terminal branching. These defects likely result from the insufficient activation of Hox/Pbx-dependent transcriptional programs as and genes are downregulated in the absence of . mutants recapitulate many aspects of mutant mice, such as MN disorganization and defects in medial motor column (MMC) specification. Our findings indicate that , a gene implicated in neurodevelopmental diseases such as autism spectrum disorders, plays a critical, cell-specific role in the assembly of motor circuits.

Parallel Pbx-Dependent Pathways Govern the Coalescence and Fate of Motor Columns.
The clustering of neurons sharing similar functional properties and connectivity is a common organizational feature of vertebrate nervous systems. Within motor networks, spinal motor neurons (MNs) segregate into longitudinally arrayed subtypes, establishing a central somatotopic map of peripheral target innervation. MN organization and connectivity relies on Hox transcription factors expressed along the rostrocaudal axis; however, the developmental mechanisms governing the orderly arrangement of MNs are largely unknown. We show that Pbx genes, which encode Hox cofactors, are essential for the segregation and clustering of neurons within motor columns. In the absence of Pbx1 and Pbx3 function, Hox-dependent programs are lost and the remaining MN subtypes are unclustered and disordered. Identification of Pbx gene targets revealed an unexpected and apparently Hox-independent role in defining molecular features of dorsally projecting medial motor column (MMC) neurons. These results indicate Pbx genes act in parallel genetic pathways to orchestrate neuronal subtype differentiation, connectivity, and organization.
Neuron, 2016; 91
24746670: Jung H, Mazzoni EO, Soshnikova N, Hanley O, Venkatesh B, Duboule D, Dasen JS
Evolving Hox activity profiles govern diversity in locomotor systems.
The emergence of limb-driven locomotor behaviors was a key event in the evolution of vertebrates and fostered the transition from aquatic to terrestrial life. We show that the generation of limb-projecting lateral motor column (LMC) neurons in mice relies on a transcriptional autoregulatory module initiated via transient activity of multiple genes within the HoxA and HoxC clusters. Repression of this module at thoracic levels restricts expression of LMC determinants, thus dictating LMC position relative to the limbs. This suppression is mediated by a key regulatory domain that is specifically found in the Hoxc9 proteins of appendage-bearing vertebrates. The profile of Hoxc9 expression inversely correlates with LMC position in land vertebrates and likely accounts for the absence of LMC neurons in limbless species such as snakes. Thus, modulation of both Hoxc9 protein function and Hoxc9 gene expression likely contributed to evolutionary transitions between undulatory and ambulatory motor circuit connectivity programs.

Inhibitory gamma-aminobutyric (GABA)-positive interneurons are indispensable for information processing in the mammalian neocortex. Defects in interneuron function lead to an imbalance of neuronal excitation and inhibition associated with severe neuropsychiatric diseases and syndromes. In this context, dysregulated critical milestones of interneuron development are suggested to cause these neurodevelopmental disorders and manifest into severe pathologies such as schizophrenia, epilepsy or autism spectrum disorders. Proper interneuron development is crucially determined by epigenetic mechanisms such as DNA methylation, histone modifications or non-coding RNAs emerged as regulators of various neurodevelopmental processes. In a previous study, we found an essential implication of the DNA methyltransferase 1 (DNMT1) in promoting the long-range migration of inhibitory cortical interneurons generated in the embryonic pre-optic area (POA). By crosstalk with histone modifications, DNMT1 maintains the migratory morphology and the survival of these cells.
Here, we show that DNMT1 is likewise involved in regulating the migration of interneurons generated in the medial ganglionic eminence (MGE), achieved by its canonical DNA methylation function. Decreased *Dnmt1* expression resulted in altered cellular motility and directionality of cellular migration. In contrast to POA-derived interneurons, the motility of MGE-derived cells was not regulated via DNMT1-dependent modulation of their migratory morphology. Instead, we found that DNMT1 affects the endocytic capacity of embryonic MGE-interneurons. Endocytosis in turn is a critical process guaranteeing the controlled internalization of adhesive complexes for proper migration. Conclusively, we hypothesize that DNMT1-dependent regulation of MGE interneuron migration essentially relies on modifying endocytic rate in these cells during their development.

EMERGING TRANSCRIPTIONAL IDENTITIES OF DEVELOPING THALAMOCORTICAL NEURONS.

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Quentin Lo Giudice[1], Robin Wagener[1], Philipp Abe[1], Pierre Fabre[1], Denis Jabaudon[2]
[1]University of Geneva, Centre medical universitaire, Department Of Basic Neurosciences, Geneva, Switzerland, [2]University of Geneva, Centre Medical universitaire, Department Of Basic Neurosciences, Geneva, Switzerland

The thalamus is an essential gateway for peripheral sensory signals on their way to the cortex. It organizes into nuclei containing molecularly distinct cell types with specific inputs and projection targets; however, how this diversity emerges during development remains poorly understood. To address this question, here we use single-cell transcriptomics to investigate intrinsic and extrinsic transcriptional controls over thalamic neuron diversity during embryogenesis and early postnatal life. Working in mice, we identify sequential transcriptional waves underlying differentiation into different types of thalamic neurons and their requirement for sensory input. Our study provides insights into the developmental transcriptional trajectories of input-(in)dependent differentiation and diversification of thalamocortical neurons.

SPONTANEOUS ACTIVITY REGULATES THALAMIC CIRCUITRY SPECIFICATION DURING DEVELOPMENT

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Lorenzo Puche-Aroca[1], Ana Espinosa[1], Verónica Moreno-Juan[1], Irene Huerga-Gómez[1], Jose P. Lopez-Atalaya[2], Guillermina López-Bendito[1]
[1]Institute of Neuroscience of Alicante, Universidad Miguel Hernández de Elche - Consejo Superior de Investigaciones Científicas (UMH-CSIC), Group Of Development, Plasticity And Regeneration Of Thalamocortical Circuits, San Juan de Alicante, Spain, [2]Universidad Miguel Hernández de Elche - Consejo Superior de Investigaciones Científicas (UMH-CSIC), Group Of Cellular Plasticity And Neuropathology, San Juan de Alicante, Spain

The presence of spontaneous patterns of neuronal activity is a distinctive feature of the developing thalamus. However, the underlying gene programs regulating these activity patterns remain largely unknown. To this aim, we performed longitudinal transcriptional profiling of sensory thalamic neurons in control animals and in mice lacking synchronous neuronal activity (*Th*^{Kir} mice). This approach revealed gene programs related to thalamocortical connectivity and neural cell proliferation. Moreover, we found that spontaneous activity is necessary for the expression of nuclei-specific gene signatures. Genes related with ion channel activity and neural cell differentiation were deregulated in *Th*^{Kir} mice. In sum, our data reveals the molecular logic underlying the patterns of spontaneous activity in the developing thalamus. These results deepen our understanding of the developmental regulatory mechanisms of the distinct sensory-modality nuclei.

Astrocytes and neurons share region-specific transcriptional signatures that confer regional identity to neuronal reprogramming.
Neural cell diversity is essential to endow distinct brain regions with specific functions. During development, progenitors within these regions are characterized by specific gene expression programs, contributing to the generation of diversity in postmitotic neurons and astrocytes. While the region-specific molecular diversity of neurons and astrocytes is increasingly understood, whether these cells share region-specific programs remains unknown. Here, we show that in the neocortex and thalamus, neurons and astrocytes express shared region-specific transcriptional and epigenetic signatures. These signatures not only distinguish cells across these two brain regions but are also detected across substructures within regions, such as distinct thalamic nuclei, where clonal analysis reveals the existence of common nucleus-specific progenitors for neurons and astrocytes. Consistent with their shared molecular signature, regional specificity is maintained following astrocyte-to-neuron reprogramming. A detailed understanding of these regional-specific signatures may thus inform strategies for future cell-based brain repair.

CELF1 IS INVOLVED IN THE EARLY LAMINAR ORGANIZATION IN HUMAN FETAL BRAIN

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Janja Kopic[1], Alisa Junakovic[1], Mladen Roko Rasin[2], Ivica Kostovic[1], Zeljka Krsnik[1]
[1]Croatian Institute for Brain Research, School of Medicine, University of Zagreb, Department For Developmental Neuroscience, Zagreb, Croatia, [2]Robert Wood Johnson Medical School, Rutgers University, Department Of Neuroscience & Cell Biology, Piscataway, United States of America

Expression and activity of molecular networks involved in cell proliferation, migration and neuronal specification can be seen during late “preplate” and early cortical plate phase (7.5-10 PCW) in the human brain. Spatio-temporal overlapping of these neurogenetic processes leads to proper positioning of the future deep cortical layer neurons and subplate neurons. Laminar rhythm of future projection neurons is established by the expression of molecular markers which determine their identity and final destination [1]. RNA binding protein CELF1, as marker of future projection neurons is present in the mouse brain during early neurogenesis [2], but its role in formation of early laminar structure in the human brain, during the “preplate” phase remains unreveild. Thus, our aim was to analyze expression pattern of CELF1 and TBR1 (subplate neurons marker) utilizing immunofluorescence on prenatal postmortem human brain to reveal CELF1 spatio-temporal expressin pattern during the late “preplate” and early cortical plate phase. According to our results, CELF1 shows slight positivity in proliferative zones where intermediate progenitor cells reside, as well as in the “preplate” neurons. TBR1 is positive in “preplate” neurons as well as in transient neurons of the future subplate. CELF1 and TBR1 staining, alongside with the deeper cortical layer-enriched markers (TLE4, CTIP2, SOX5) showed that majority of CELF1+ and TBR1+ cells colocalize with those markers. Our results confirm that studing an early laminar organization is esential for understanding specification of neuronal identity and establishment of functional cortical connectivity.

Molecules, Mechanisms, and Disorders of Self-Domestication: Keys for Understanding Emotional and Social Communication from an Evolutionary Perspective.
The neural crest hypothesis states that the phenotypic features of the domestication syndrome are due to a reduced number or disruption of neural crest cells (NCCs) migration, as these cells differentiate at their final destinations and proliferate into different tissues whose activity is reduced by domestication. Comparing the phenotypic characteristics of modern and prehistoric man, it is clear that during their recent evolutionary past, humans also went through a process of self-domestication with a simultaneous prolongation of the period of socialization. This has led to the development of social abilities and skills, especially language, as well as neoteny. Disorders of neural crest cell development and migration lead to many different conditions such as Waardenburg syndrome, Hirschsprung disease, fetal alcohol syndrome, DiGeorge and Treacher-Collins syndrome, for which the mechanisms are already relatively well-known. However, for others, such as Williams-Beuren syndrome and schizophrenia that have the characteristics of hyperdomestication, and autism spectrum disorders, and 7dupASD syndrome that have the characteristics of hypodomestication, much less is known. Thus, deciphering the biological determinants of disordered self-domestication has great potential for elucidating the normal and disturbed ontogenesis of humans, as well as for the understanding of evolution of mammals in general.

Transient Subplate Sublayer Forms Unique Corridor for Differential Ingrowth of Associative Pulvinar and Primary Visual Projection in the Prospective Visual Cortical Areas of the Human Fetal Occipital Lobe.
Cytoarchitectonical parcellation of the visual cortex into the striate and extrastriate cortex requires complex histogenetic events within a precise spatio-temporal frame to attain the specification of areal domains and associated thalamocortical

connections during the fetal brain development. We analyzed a deep subplate cellular monolayer (subplate "corridor" cells) present during a restricted period of 13-15 postconceptional weeks, showing the 3D caudo-ventro-medial position in the human fetal occipital lobe, corresponding to the segregation point of pulvinocortical and geniculocortical fibers at the prospective area 17/18 border. Immunofluorescence stainings revealed subplate "corridor" cells as the specific class of the deepest subplate neurons (NeuN+, Tbr1+, Cplx3+) expressing axon guidance molecules (Sema-3A+, EphA6+), presumably for the attraction of pulvinocortical axons and the repulsion of geniculocortical axons growing at that time (SNAP25+, Syn+, FN+). Furthermore, quantitative analysis of the subplate "corridor" region of interest, considering cell number, immunofluorescence signal intensity per cell and per region, revealed significant differences to other regions across the tangential circumference of the developing cerebral wall. Thus, our study sheds new light on the deepest subplate sublayer, strategically aligned along the growing axon systems in the prospective visual system, suggesting the establishment of the area 17/18 border by differential thalamocortical input during the fetal brain development.

NEURONAL LAMINAR IDENTITY MARKERS DELINEATE REGIONAL DIFFERENCES DURING THE PRIMATE-SPECIFIC SUBPLATE EXPANSION PERIOD IN THE HUMAN FETAL CORTEX

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Alisa Junakovic, Janja Kopic, Ivica Kostovic, Zeljka Krsnik
Croatian Institute for Brain Research, School of Medicine, University of Zagreb, Department For Developmental Neuroscience, Zagreb, Croatia

Development of the cortical anlage begins with the formation of the preplate (mantle by His), which is split by the first cohort of cortical plate (CP) cells in that way the specific marginal zone (MZ) containing Cajal-Retzius neurons (CRN) and presubplate (P-SP) are formed. The period between 13 and 15 postconceptional weeks (PCW) is characterized by a transformation (cell spread-down) of the deep portion of the CP. During this human-characteristic event, thalamocortical and basal forebrain afferent fibers penetrate tangentially and obliquely in the CP. In that way, cells of the deep portion of the CP are secondarily displaced downwards („second“ CP) forming the future expanded subplate (SP). Future SP neurons are born in the proliferative zones simultaneously as prospective cortical layer VI neurons. Importantly, future layer VI neurons are not secondarily dispersed during the SP formation period. Thus, our study aimed to show regional expression patterns of specific transcription factors, i.e. projection neurons markers, as well as synaptic markers with the special emphasis on the SP expansion period utilizing immunofluorescence. Our results show that markers of projection neurons demonstrate characteristic regional differences in the neocortical part of the cerebral wall during the process of SP expansion. We concluded that projection neurons markers of cortical layers V, VI, and projection neuronal population of prospective glutamatergic SP neurons are the key players in the establishment of early regional differences of the neocortex during the SP formation period.

CHARACTERIZATION OF THE EARLIEST THALAMOCORTICAL INTERACTIONS IN THE HUMAN FETAL BRAIN

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Sara Bandiera, Zoltán Molnár
University of Oxford, Physiology Anatomy And Genetics, Oxford, United Kingdom

While there is evidence for early control of patterning that is intrinsic to the neocortex, a major extrinsic source of patterning is provided by the early thalamocortical afferents (TCAs). In the human brain, the thalamocortical interactions start from very early stages and they continue over a prolonged period, thus potentially affecting corticogenesis in a crucial manner. To understand these interactions, we traced early projections from the thalamus with carbocyanine dyes in fixed post-mortem human brains at midgestational stages (16-17 post-conception weeks, PCW). By 17 PCW, the TCAs already reached their target cortical area, where they innervate the subplate zone, a well-known transient target of these axons. Surprisingly, TCAs also develop projections towards the germinal compartments underlying them, in particular the outer subventricular zone (OSVZ). Although both the subplate and the OSVZ are massively expanded in the fetal human brain, and they are associated with its increase in size and complexity, these two compartments contain different cell types (postmitotic neurons and mitotic progenitors, respectively). This suggests that the early-arriving TCAs might influence intrinsic neurogenic events by modulating the activity of different cortical cell populations. In particular, we selected VGF (non-acronymic) as a candidate thalamic factor that might account for the simultaneous modulation of both cortical neurons and progenitors, and we are currently validating this pathway by using available transcriptomic datasets of the human developing brain and immunohistochemical analysis. This characterization of the early thalamocortical interactions shall unravel some unique aspects of the specialization and the evolution of the human cerebral cortex.

Combination of In Situ Lcn2 pRNA-RNAi Nanotherapeutics and iNSC Transplantation Ameliorates Experimental SCI in Mice.
Spinal cord injury (SCI) is a debilitating neurological condition characterized by different cellular and molecular mechanisms that interplay in exacerbating the progression of the pathology. No fully restorative therapies are yet available, and it is thus becoming recognized that combinatorial approaches aimed at addressing different aspects of SCI will likely results in greater functional outcomes. Here we employed packaging RNA-mediated RNA interference (pRNA-RNAi) nanotherapeutics to downregulate in situ the expression of lipocalin 2 (Lcn2), a known mediator of neuroinflammation and autocrine mediator of reactive astrogliosis, and to create a more amenable niche for the subsequent transplantation of induced neural stem cells (iNSCs). To our knowledge, this is the first approach that takes advantage of the modular and multifunctional pRNA three-way junction platform in the SCI niche, while also exploiting the therapeutic potential of immune-compatible and feasible iNSC transplants. We show the combination of such treatments in a mouse model of contusion thoracic SCI leads to significant improvement of locomotor function, albeit not better than single pRNA-RNAi treatment, and results in synergistic histopathological effects, such as reduction of glial scar volume, diminished pro-inflammatory response, and promotion of neuronal survival. Our results provide evidence for a novel combinatorial approach for treating SCI.

RNA Nanotherapeutics for the Amelioration of Astroglial Reactivity.
In response to injuries to the CNS, astrocytes enter a reactive state known as astrogliosis, which is believed to be deleterious in some contexts. Activated astrocytes overexpress intermediate filaments including glial fibrillary acidic protein (GFAP) and vimentin (Vim), resulting in entangled cells that inhibit neurite growth and functional recovery. Reactive astrocytes also secrete inflammatory molecules such as Lipocalin 2 (Lcn2), which perpetuate reactivity and adversely affect other cells of the CNS. Herein, we report proof-of-concept use of the packaging RNA (pRNA)-derived three-way junction (3WJ) motif as a platform for the delivery of siRNAs to downregulate such reactivity-associated genes. In vitro, siRNA-3WJs induced a significant knockdown of Gfap, Vim, and Lcn2 in a model of astroglial activation, with a concomitant reduction in protein expression. Knockdown of Lcn2 also led to reduced protein secretion from reactive astroglial cells, significantly impeding the

perpetuation of inflammation in otherwise quiescent astrocytes. Intralesional injection of anti-Lcn2-3WJs in mice with contusion spinal cord injury led to knockdown of Lcn2 at mRNA and protein levels in vivo. Our results provide evidence for siRNA-3WJs as a promising platform for ameliorating astroglial reactivity, with significant potential for further functionalization and adaptation for therapeutic applications in the CNS.

SPECIFICATION AND FUNCTIONAL MATURATION OF CORTICAL LONG-RANGE SST+ NEURONS

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Elia Micoli, Lynette Lim
VIB-Center for Brain and Disease, KU-Leuven, Department Of Neuroscience, Leuven, Belgium

In the mammalian neocortex, inhibition is driven mainly by local interneurons to gate the excitation of projections. However, one key exception is somatostatin (SST+) expressing cortical long-range inhibitory neurons, a unique population that connects different cortical and subcortical areas. While their synaptic connections have been well established, less in known about the molecular mechanisms that drive their fate specification and maintenance – an important first step to decipher the cellular logic of long-range inhibitory circuit assembly and to design novel cell replacement therapies for brain disorders. In this work, we characterized the developmental trajectories of SST+ long-range inhibitory neurons and SST+ interneurons by single cell RNA sequencing and found that the factors driving their maturation are completely distinctive. Specifically, we identify *POU3f2/Brn2*, a homeobox POU class III transcription factor, to be highly enriched in developing cortical long-range inhibitory neurons and in the progenitors that generate these cells. Using two conditional mutant mouse lines that lack *POU3f2* in either post-mitotic long-range inhibitory neurons or their progenitors, we found that the conditional removal of *POU3f2* leads to an exclusive and strong reduction of long-range inhibitory neurons in the cortex. Interestingly, the temporal dynamics of long-range cell loss in post-mitotic removal of *POU3f2* only occur at second postnatal week, highlighting that *POU3f2* have both roles in neuronal specification and fate maintenances. Our work is the first to provide molecular insights toward the development and assembly of this specialized brain circuits.

CELL-TYPE-SPECIFIC PLASTICITY OF CORTICAL NEURON FATE

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Sabine Fièvre, Ilaria Morassut, Natalia Baumann, Giorgia Bartolini, Esther Klingler, Denis Jabaudon
University of Geneva, Basic Neuroscience, Geneva, Switzerland

The somatosensory cortex is composed of a diversity of specialized neurons with specific connectivities, location, morphologies and molecular identities. Following their birth, these distinct neuronal identities emerge from interactions between intrinsic genetic programs and environmental cues. A proper balance between intrinsic developmental programs and external signals is essential for the differentiation and assembly of neurons into circuits, yet the cell-type specific contribution of these two types of processes during cortical development remains unclear. To determine to which extent the acquisition of distinct neuronal identity is driven by environmental determinants during the early postnatal critical period, we followed the developmental trajectories of newborn somatosensory neurons *in vivo* and compared them with *in vitro* models, where newborn neurons are deprived from their original environment. To do so, we microdissected and cultured mouse somatosensory cortex at E16, and compared transcriptional signatures, electrophysiological and connectivity features between *in vivo* neurons and their *in vitro* counterparts. We took advantage of high throughput single nucleus RNA sequencing technology and deep neuronal network-based machine learning approaches to classify and follow the identity of *in vivo* and *in vitro* neurons. Together, our results provide a cell-type specific account of environmental sensitivity in different types of cortical neurons.

[1]University of Geneva, Department Of Basic Neurosciences, Geneva, Switzerland, [2]Institut du Fer à Moulin, Cortical Development And Pathology, Paris, France, [3]Sorbonne Université, Sciences, Paris, France, [4]Inserm, U1270, Paris, France, [5]Max Planck Institute of Psychiatry, Developmental Neurobiology, Munich, Germany

The mammalian brain develops along a well-defined timeline. Neocortical neurons are born sequentially during embryonic development after the division of apical progenitors (APs) located in germinal zones, close to the ventricles. Migrating neurons use AP radial processes as a scaffold in order to reach the cortical plate, where they organise in six layers and form functional circuits. Neuronal migration defects can lead to adverse consequences, ranging from minor displacement of neurons to an important remodelling of the cortical cyto-architecture, such as cortical heterotopias. Beside structural impairments, defects also trigger connectivity alterations, leading to epilepsy and intellectual disability. Recently, in humans but also mouse and rat models, mutations in genes coding for the microtubule associated protein Eml1 and the GTPase RhoA were shown to give rise to heterotopias. In these cases, AP primary cilia and radial processes were identified as key alterations in the development of such major anatomical perturbations. How cortical malformations affect neuronal maturation, identity and connectivity remains largely unknown. Here, by combining single nuclei RNA sequencing, viral tracings and high-throughput single-cell connectivity analysis, we observed an overall conservation of neuronal molecular identities but specific alterations of superficial layer neuron circuits. These findings highlight neuron-type specific alterations in the connectivity of neurons in cortical malformations.

[1]University of Oslo, Department Of Molecular Medicine, Oslo, Norway, [2]University of Melbourne, The Florey Department Of Neuroscience And Mental Health, VIC, Australia, [3]ISN Psychology, Institute For Social Neuroscience, VIC, Australia, [4]Deakin University, The Institute For Mental And Physical Health And Clinical Translation, VIC, Australia

The dopaminergic system undergoes major developments during adolescence, a period especially vulnerable to mental disorders. Dopaminergic cells are primarily located in the substantia nigra and ventral tegmental area, reaching parts of the forebrain through axonal projections. Forebrain neurons expressing dopamine 1 and 2 receptors (D1R and D2R, respectively) are particularly sensitive to dopaminergic input, and contribute to higher cognitive functions such as attention, goal-directed behaviour, and reward processing. Knowledge about the typical development of the dopaminergic system is required to understand its impact on the ontogeny of different mental disorders, but such information is sparse and scattered across publications investigating one or at most a few brain regions. We have digitized and organized microscopic images of immunostained sections from 152 male and female mice at five stages of development (P17, P25, P35, P49, and adult), showing D1R and D2R expressing neurons across the forebrain. All images are registered to the Allen Mouse brain Common Coordinate Framework, for the P17-P35 age groups spatially modified to match the morphology of young brains. The high-resolution images are shared via an interactive web-microscopy viewer and as downloadable files via the EBRAINS Knowledge Graph. Spanning five age groups and including both males and females, the DOPAMAP data enables quantitative analysis of cells across sex, age, and genotype. The collection is an important resource for researchers interested in studying forebrain regions with D1R and D2R positive cells. Funded from EU Horizon 2020, Specific Grant Agreement No. 945539 (Human Brain Project SGA3) and the HBP voucher

program.

EARLY POSTNATAL DISRUPTION OF NEUROKININ RECEPTOR 3 FUNCTION LEADS TO IRREGULAR STRIATAL CHOLINERGIC ACTIVITY AND AUTISTIC-LIKE BEHAVIOURS.

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Nathan Reynolds[1], Shaam Al Abed[1], Yovina Sontani[1], Alexandre Rcom-H'Cheo-Gauthier[1], Beau Johnston[2], Nathalie Dehorter[1]
[1]The Australian National University, Eccles Institute Of Neuroscience, Acton, Australia, [2]The Australian National University, The Research School Of Computer Science, Acton, Australia

Molecular control of interneuron activity is critical during striatal development and perturbing this can lead to neurodevelopmental conditions, such as autism spectrum disorder (ASD). One molecule that has been functionally linked to ASD is the neuromodulator Neurokinin receptor 3 (NK3R). While NK3R is known to be activity-dependent and to increase firing in some adult striatal cholinergic interneurons (CINs), its developmental function is unknown. To address this, we aimed to understand how the expression and activity of NK3R shapes striatal maturation. Using western blotting, qRT-PCR and immunohistochemistry, we revealed high expression of NK3R in CINs during postnatal days 6-10 (P6-10), an important period for striatal cellular and network development. Concurrently, we performed in-vitro patch clamp recordings and found that compared to adult, P6-10 acute NK3R activation with the specific agonist Senktide exacerbates spontaneous CIN firing. We hypothesised that altering NK3R activity through this period would significantly modify CIN physiology. Following blockade of NK3R with the specific antagonist Osanetant, we revealed retention of immature firing patterns and altered synaptic inputs onto adult CINs. Accompanying this were striatum-related autistic-like behaviours including deficits in social interactions and increased repetitive behaviours. To further investigate the specific cellular underpinnings of these alterations, we have engineered CRISPR-edited NK3R conditional knockout mice which we are currently investigating. Overall, our results identify for the first time a novel critical period for NK3R function to shape CIN maturation and striatum-related behaviours. Further exploration of the early role of NK3R will provide important insights into ASD pathophysiology.

A Second Wave for the Neurokinin Tac2 Pathway in Brain Research.
Despite promising advances in basic research of the neurokinin B/Tac2 pathway in both animals and humans, clinical applications are yet to be implemented. This is likely because of our limited understanding of the action of the pathway in the brain. While this system controls neuronal activity in multiple regions, the precise impact of Tac2-induced cellular responses on behavior remains unclear. Recently, elegant studies revealed a key contribution to stress-related behaviors and memory. Here, we discuss the crucial importance of bridging the gap between the Tac2 pathway's involvement in cell physiology and cognition to comprehend its role in health and disease. We propose that a better understanding of the Tac2 pathway in the brain could provide an essential perspective for basic investigations, which in turn will feed clinical research.

REGIONAL CHANGES IN DENSITY AND SPATIAL DISTRIBUTION OF CALBINDIN- AND PARVALBUMIN EXPRESSING NEURONS IN THE DEVELOPING MOUSE BRAIN

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Olga Rogulina[1,2], Monika Overdevest[1,2], Menno Witter[2], Trygve Leergaard[1], Ingvild Elise Bjerke[1]
[1]University of Oslo, Institute Of Basic Medical Sciences, Oslo, Norway, [2]Norwegian University for Science and technology, Kavli Institute For Systems Neuroscience Faculty Of Medicine And Health Sciences, Trondheim, Norway

The brain undergoes major reorganization and development during adolescence, involving dynamic changes in the number and distribution of various cell types. Neurons expressing the calcium binding proteins parvalbumin and calbindin are widely distributed across the adult brain, and during development they contribute to the maturation of neural networks underlying a range of functions, e.g. fear memory processing and social behavior. However, information about the number and distribution of calbindin and parvalbumin cells in the developing mouse brain is fragmented, with most studies investigating only one or a few brain regions. We here present a comprehensive collection of microscopic image data from the developing mouse brain (postnatal days 9, 14, 21, and 35), immunohistochemically stained for calbindin and parvalbumin. Images were spatially registered to age-specific volumetric brain atlases, allowing quantification of calbindin and parvalbumin cell numbers using the QuickNII-ilastik-Nutil (QUINT) workflow provided by the EBRAINS research infrastructure (https://ebrains.eu/services/atlases). Our study focuses on areas of the mouse brain associated with social behavior (including the hypothalamus and insular cortex) and fear memory (including the basolateral amygdala, pre-, and infralimbic cortex). However, all data resulting from the project will be publicly shared through the EBRAINS research infrastructure, thus allowing researchers to investigate regional changes in mouse brain architecture through adolescence across the entire brain. Funded from EU Horizon 2020, Specific Grant Agreement No. 945539 (Human Brain Project SGA3). Rogulina and Overdevest contributed equally to this work and are co-presenting authors.

DISTRIBUTION AND DEVELOPMENTAL-BASED CLASSIFICATION OF CRF NEURONS IN THE CHICKEN CENTRAL EXTENDED AMYGDALA

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Alessandra Pross[1,2], Alek H. Metwalli[1,2], Antonio Abellan[1,2], Ester Desfilis[1,2], Loreta Medina[1,2]
[1]IRBLleida, Evolutionary And Developmental Neurobiology, Lleida, Spain, [2]University of Lleida, Experimental Medicine, Lleida, Spain

Understanding the neural regulation of stress is essential to know how different animals respond to stressors and should be considered to improve animal welfare. In mammals, the central extended amygdala (EAce) is a major controller of the activation of the hypothalamic-pituitary-adrenal axis and the autonomic nervous system during stress response. Corticotropin releasing factor (CRF) is a key neuropeptide of this network, being involved in anxiety responses, and is present in a neuron subpopulation of mammalian EAce. Our group used an evolutionary developmental biology approach to study EAce in the chicken, identifying several areas and cell populations likely homologous to those of mammalian EAce. We aimed to understand the CRF cells of chicken EAce within this developmental context. We study their distribution at prehatching stages. To know their embryonic origin, we performed triple labelling studies, combining fluorescent in situ hybridization (CRF mRNA) with immunofluorescence using different region-specific transcription factors. We found that CRF neurons are spread through several EAce areas, with a significant population in lateral bed nucleus of the stria terminalis (BSTL) and smaller groups more laterally in EAce. All these neurons co-express Foxg1 meaning that they are of telencephalic origin. In addition, CRF cells of EAce included different subpopulations, such as cells co-expressing Pax6 derived from the dorsal striatal division, cells co-expressing Islet1 derived from the ventral striatal division and cells co-expressing Nkx2.1 derived from the pallidal division. Our results open new venues to study the implication of CRF cells with different embryonic origins in stress.

Embryonic Exposure to Valproic Acid Affects Social Predispositions for Dynamic Cues of Animate Motion in Newly-Hatched Chicks.
Early predispositions to preferentially orient toward cues associated with social partners have been documented in several vertebrate species including human neonates and domestic chicks. Human newborns at high familiar risk of Autism Spectrum Disorder (ASD) show differences in their attention toward these predisposed stimuli, suggesting potential impairments in the social-orienting mechanisms in ASD. Using embryonic exposure to valproic acid (VPA) we modeled ASD behavioral deficits in domestic chicks. To investigate social predispositions toward animate motion in domestic chicks, we focused on self-propulsion, using two video-animations representing a simple red circle moving at constant speed (speed-constant) or one that was changing its speed (accelerating and decelerating; speed-change). Using a spontaneous choice test for the two stimuli, we compared spontaneous preferences for stimuli that autonomously change speed between VPA- and vehicle-injected chicks. We found that the preference for speed changes was abolished in VPA-injected chicks compared to vehicle-injected controls. These results add to previous findings indicating similar impairments for static social stimuli and suggest a specific effect of VPA on the development of mechanisms that enhance orienting toward animate stimuli. These findings strengthen the hypothesis of an early impairment of predispositions in the early development of ASD. Hence, early predispositions are a potentially useful tool to detect early ASD symptoms in human neonates and to investigate the molecular and neurobiological mechanisms underlying the onset of this neurodevelopmental disorder.

DYNAMICS AND MECHANISMS OF PROJECTION OF BIFURCATING NEURONS IN DROSOPHILA VISUAL SYSTEM

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Najate Benhra, Raghuvanshi Rajesh, Claude Desplan
New York University Abu Dhabi, Cgsb, Abu Dhabi, United Arab Emirates

Drosophila optic lobe (OL) is one of the largest structures in the *Drosophila* brain. Interestingly, a large number of specialized neurons innervating the OL terminate in the appropriate ganglia in a specific layer, following a consistent neuronal topology- a process known as retinotopy. However, the molecular cues involved in the proper targeting of neurons to their final site remain poorly known. Here we focused our studies on a particular cell type called transmedullary (TmY) neuron. TmYs neurons innervate the medulla ganglia to then project to two other OL ganglia (lobula and lobula plate) through a characteristic neurite bifurcation. Interestingly, their morphology is very similar to Tm neurons with the exception that Tms only target the Lobula. Very little is known about TmY neurons and our goal is to characterize in detail their morphology, their dynamic of projection throughout development as well as the molecular mechanisms underlying their dendritic and axonal bifurcation and pathfinding. We are also studying a specific visual projection neuron termed TmY14, which projects to the central brain in addition to the OL ganglia. To address these questions, we take advantage of the available scRNAseq dataset of the *Drosophila* optic lobe from which we identified several TmY clusters as well as Gal4 and LexA drivers specifically expressed in sub-classes of TmYs. Here we show data on TmY's dynamic of projection during early developmental stages on fixed tissue and live-imaging. We also present results aiming to test the requirement of the lobula plate in TmY's bifurcating process.

DEVELOPMENTAL DEFICITS IN MGE-DERIVED INTERNEURONS UNDERLIE CIRCUIT MALFORMATION IN A CNTNAP2 KNOCKOUT MOUSE MODEL OF AUTISM SPECTRUM DISORDER

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Noorya Ahmed[1], Yumeng Wang[2], Yovina Sontani[3], Isabel Del Pino[4], Rhys Knowles[1], Nathalie Dehorter[5]
[1]Australian National University, The Eccles Institute Of Neuroscience, Canberra, Australia, [2]Australian National University, Eccles Institute Of Neuroscience, Canberra, Australia, [3]The Australian National University, Eccles Institute Of Neuroscience, Acton, Australia, [4]Centro de Investigacion Principe Felipe (CIPF), Neuronal Plasticity Team, Valencia, Spain, [5]Australian National University, The Eccles Institute Of Neuroscience, Acton, Australia

Interneurons have a fundamental role in maintaining the excitation-inhibition balance in brain structures such as the prefrontal cortex (PFC) and striatum. While interneurons have been shown to play a key role in autism spectrum disorder (ASD) pathophysiology in adults, little is known about their contribution in the developing autistic brain. Taking advantage of the specific expression of the transcription factor Lhx6 (LIM Homeobox domain 6) in interneurons derived from the medial ganglionic eminence (MGE), we aimed to track developing interneurons and elucidate their molecular and physiological alterations in the Cntnap2 knockout mouse model of ASD. Using immunohistochemical staining at various developmental time-points, we observed a temporal shift in the canonical window of developmental cell death in the PFC and striatum, indicating that the developmental trajectory of Lhx6-expressing interneurons in ASD is perturbed. This was associated with changes in markers of cell maturation and activity dependent factors, such as NMDA receptor subunits, metabotropic receptors, and transcription factors, assessed using qRT-PCR and immunohistochemistry. In addition, we explored the resulting intrinsic perturbations to interneuron properties and network activity with electrophysiology and calcium imaging recordings. Overall, this study describes specific physiological, cellular, and molecular alterations in MGE derived interneurons in autism during development. Uncovering the shifted state of this neuronal population will aid in designing new therapeutic strategies targeting these specific cells early in development.

Er81 Transcription Factor Fine-Tunes Striatal Cholinergic Interneuron Activity and Drives Habit Formation.
The molecular mechanisms tuning cholinergic interneuron (CIN) activity, although crucial for striatal function and behavior, remain largely unexplored. Previous studies report that the Etv1/Er81 transcription factor is vital for regulating neuronal maturation and activity. While Er81 is known to be expressed in the striatum during development, its specific role in defining CIN properties and the resulting consequences on striatal function is unknown. We report here that Er81 is expressed in CINs and its specific ablation leads to prominent changes in their molecular, morphologic, and electrophysiological features. In particular, the lack of Er81 amplifies intrinsic delayed-rectifier and hyperpolarization-activated currents, which subsequently alters the tonic and phasic activity of CINs. We further reveal that Er81 expression is required for normal CIN pause and time-locked responses to sensorimotor inputs in awake mice. Overall, this study uncovers a new cell type-specific control of CIN function in the striatum which drives habit formation in adult male mice. Although previous studies have shown that cholinergic interneurons drive striatal activity and habit formation, the underlying molecular mechanisms controlling their function are unknown. Here we reveal that key cholinergic interneuron physiological properties are controlled by Er81, a transcription factor regulating neuronal activity and development in a cell-specific manner. Moreover, our findings uncover a link between the Er81-dependent molecular control of cholinergic interneuron function and habit formation in mice. These insights will contribute to the future enhancement of our understanding of disorders that involve behavioral inflexibility, such as autism and addiction.

New Insights Into Cholinergic Neuron Diversity.
Cholinergic neurons comprise a small population of cells in the striatum but have fundamental roles in fine tuning brain function, and in the etiology of neurological and psychiatric disorders such as Parkinson's disease (PD) or schizophrenia. The

process of developmental cell specification underlying neuronal identity and function is an area of great current interest. There has been significant progress in identifying the developmental origins, commonalities in molecular markers, and physiological properties of the cholinergic neurons. Currently, we are aware of a number of key factors that promote cholinergic fate during development. However, the extent of cholinergic cell diversity is still largely underestimated. New insights into the biological basis of their specification indicate that cholinergic neurons may be far more diverse than previously thought. This review article, highlights the physiological features and the synaptic properties that segregate cholinergic cell subtypes. It provides an accurate picture of cholinergic cell diversity underlying their organization and function in neuronal networks. This review article, also discusses current challenges in deciphering the logic of the cholinergic cell heterogeneity that plays a fundamental role in the control of neural processes in health and disease.

ANALYSIS OF THE REGULATION OF CORTICAL INTERNEURON MIGRATION BY THE D1 RECEPTOR IN THE MOUSE

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Anne-Gaëlle Toutain[1], Julien Puech[2], Aude Muzerelle[1], Sophie Scotto-Lomassese[2], Denis Herve[1], Christine Métin[2]
[1]Institut du Fer a Moulin, Biologie, Paris, France, [2]Institut du Fer à Moulin, Umr-s 1270 Inserm/sorbonne Université, Paris, France

Neurodevelopmental disorders are believed to play a role in the etiology of schizophrenia. Abnormalities in parvalbumin (PV) interneurons have been reported in schizophrenic patients. Although the *Drd1* gene that encodes D1 receptor (D1R) is highly expressed in the developing forebrain, the role of dopamine signaling in cortical interneuron (cIN) development is poorly understood, especially in the context of schizophrenia. To address this question, we cultured wild type (WT) and *Drd1-KO* explants from the region of origin of PV(+) cINs, the medial ganglionic eminence (MGE), on a synthetic permissive substrate of migration (Ncadherin + laminin). We observed that D1R ablation impaired the migration of MGE cells. We then characterized the pattern of expression of D1R during development in a D1-GFP transgenic mouse strain that expresses GFP under the control of the *Drd1* promoter. Because of the strong GFP expression in the developing cortex, we investigated the role of Drd1 expressed in the cortical substrate on the migration of interneurons in co-cultures. Live cell imaging and analyses of fixed material indeed revealed a significant role of D1R expressed in the cortical substrate on the migration of MGE cells. Results identify D1R as a receptor able to regulate the migration and final distribution of MGE-derived cINs to the cortex in both cell autonomous and non-cell autonomous ways and invite to analyze the number and distribution of cIN at both embryonic and adult stages, in WT and Drd1-KO animals.

PROBABILITY-DEPENDENT ANTICIPATORY EYE MOVEMENTS ACROSS DEVELOPMENT

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Anna Montagnini, Chloé Pasturel, Christine Deruelle, Guillaume Masson
Institut de Neurosciences de la Timone (UMR7289), Aix-marseille University And Cnrs, Marseille, France

Humans exploit regularities in their environment to efficiently anticipate and react to expected events. In healthy adults, regularities in a visual object's motion can elicit anticipatory smooth eye movements (ASEM) towards the expected movement direction, with ASEM velocity proportional to direction probability. Such exquisite adaptive behaviour relies on the efficient integration of probabilistic information across different time scales, and on the transformation of this memory signal into the appropriate motor command. Both these functions are plausibly dependent on the cortical pre-frontal network, which is known to complete its maturation around 25 years. Here we investigated whether probability-dependent ASEM are already present during childhood and adolescence. We recorded eye movements in a large group of participants (N=109, 7-21 years old), instructed to accurately track a small target moving horizontally. The probability *p* of target motion direction (Right/Left) was changed at different moments during the session. We report robust probability-dependent ASEM for all subjects, including at the youngest age. However, the *sensitivity* to the probability bias (as quantified by the slope of the linear regression of ASEM-velocity upon *p*) increases significantly with age. Importantly, this difference cannot be attributed to a general lower performance in smooth eye tracking at early stages of development, as all the parameters of visually-guided eye movements (with the exception of latency) were overall comparable across participants. We speculate that the children's lower sensitivity to the environment's regularities for visuomotor adaptation might be related to a less precise (*noisier*) information-processing pipeline, rather than to oculomotor control deficits.

LONG-TERM FUNCTIONAL AND CYTOARCHITECTONIC EFFECTS OF THE SYSTEMIC ADMINISTRATION OF THE HISTAMINE H1 RECEPTOR ANTAGONIST/INVERSE AGONIST CHLORPHENIRAMINE DURING GESTATION IN THE RAT OFFSPRING MOTOR CORTEX

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Rocio Valle-Bautista[1,2], Berenice Márquez-Valadez[2], Gabriel Herrera-López[3], Ernesto Griego[3], Emilio J. Galván[3], Néstor-Fabián Díaz[2], José-Antonio Arias-Montaño[1], Anayansi Molina-Hernández[2]

Sede Sur, Farmacobiología, Mexico City, Mexico

The transient histaminergic system is among the first neurotransmitter systems to appear during development in the rat brain. Histamine increases FOXP2 deep-layer neuron differentiation of cortical neural stem cells through H1R activation *in vitro*. The *in utero* or systemic administration of chlorpheniramine (H1R antagonist/inverse agonist) during deep-layer cortical neurogenesis decreases FOXP2 neurons in the developing cortex. Due to the role of H1R in cortical neurogenesis, the purpose of this study was to evaluate the postnatal impact of the systemic administration of chlorpheniramine during deep-layer cortical neuron differentiation (E12–14) in the primary motor cortex of neonates (P0) and 21-day-old pups (P21). Chlorpheniramine or vehicle was systemically administered (5 mg/kg, i.p.) to pregnant Wistar rats at gestational days 12–14, and the expression and distribution of deep (FOXP2 and TBR1) and superficial-layer (SATB2) neuronal cortical markers were analyzed in neonates from both groups. The qRT-PCR analysis revealed a reduction in the expression of Satb2 and FoxP2. However, Western blot and immunofluorescence showed increased protein levels in the chlorpheniramine-treated group. In P21 pups, the three markers showed impaired distribution and increased immunofluorescence in the experimental group. The Sholl analysis evidenced altered dendritic arborization of deep-layer neurons, with lower excitability in response to histamine, as evaluated by whole-cell recordings, as well as diminished depolarization-evoked [^{3}H]-glutamate release from striatal slices. Overall, these results suggest long-lasting effects of blocking H1Rs during early neurogenesis that may impact the pathways involved in voluntary motor activity and cognition.

Long-Term Functional and Cytoarchitectonic Effects of the Systemic Administration of the Histamine H Receptor Antagonist/Inverse Agonist Chlorpheniramine During Gestation in the Rat Offspring Primary Motor Cortex.
The transient histaminergic system is among the first neurotransmitter systems to appear during brain development in the rat mesencephalon/rhombencephalon. Histamine increases FOXP2-positive deep-layer neuron differentiation of cortical neural stem cells through H receptor activation . The or systemic administration of chlorpheniramine (H receptor antagonist/inverse agonist) during deep-layer cortical neurogenesis decreases FOXP2 neurons in the developing cortex, and HR- or histidine decarboxylase-knockout mice show impairment in learning and memory, wakefulness and nociception, functions modulated by the cerebral cortex. Due to the role of HR in cortical neural stem cell neurogenesis, the purpose of this study was to evaluate the postnatal impact of the systemic administration of chlorpheniramine during deep-layer cortical neuron differentiation (E12-14) in the primary motor cortex (M1) of neonates (P0) and 21-day-old pups (P21). Chlorpheniramine or vehicle were systemically administered (5 mg/kg, i.p.) to pregnant Wistar rats at gestational days 12-14, and the expression and distribution of deep- (FOXP2 and TBR1) and superficial-layer (SATB2) neuronal cortical markers were analyzed in neonates from both groups. The qRT-PCR analysis revealed a reduction in the expression of Satb2 and FoxP2. However, Western blot and immunofluorescence showed increased protein levels in the chlorpheniramine-treated group. In P21 pups, the three markers showed impaired distribution and increased immunofluorescence in the experimental group. The Sholl analysis evidenced altered dendritic arborization of deep-layer neurons, with lower excitability in response to histamine, as evaluated by whole-cell patch-clamp recording, as well as diminished depolarization-evoked [H]-glutamate release from striatal slices. Overall, these results suggest long-lasting effects of blocking HRs during early neurogenesis that may impact the pathways involved in voluntary motor activity and cognition.

Impaired Cortical Cytoarchitecture and Reduced Excitability of Deep-Layer Neurons in the Offspring of Diabetic Rats.
Maternal diabetes has been related to low verbal task scores, impaired fine and gross motor skills, and poor performance in graphic and visuospatial tasks during childhood. The primary motor cortex is important for controlling motor functions, and embryos exposed to high glucose show changes in cell proliferation, migration, and differentiation during corticogenesis. However, the existing studies do not discriminate between embryos with or without neural tube defects, making it difficult to conclude whether the reported changes are related to neural tube defects or other anomalies. Furthermore, postnatal effects on central nervous system cytoarchitecture and function have been scarcely addressed. Through molecular, biochemical, morphological, and electrophysiological approaches, we provide evidence of impaired primary motor cerebral cortex lamination and neuronal function in pups from diabetic rats, showing an altered distribution of SATB2, FOXP2, and TBR1, impaired cell migration and polarity, and decreased excitability of deep-layer cortical neurons, suggesting abnormalities in cortico-cortical and extra-cortical innervation. Furthermore, phase-plot analysis of action potentials suggests changes in the activity of potassium channels. These results indicate that high-glucose insult during development promotes complex changes in migration, neurogenesis, cell polarity establishment, and dendritic arborization, which in turn lead to reduced excitability of deep-layer cortical neurons.

Maternal Diabetes and Fetal Programming Toward Neurological Diseases: Beyond Neural Tube Defects.
The purpose of this review was to search for experimental or clinical evidence on the effect of hyperglycemia in fetal programming to neurological diseases, excluding evident neural tube defects. The lack of timely diagnosis and the inadequate control of diabetes during pregnancy have been related with postnatal obesity, low intellectual and verbal coefficients, language and motor deficits, attention deficit with hyperactivity, problems in psychosocial development, and an increased predisposition to autism and schizophrenia. It has been proposed that several childhood or adulthood diseases have their origin during fetal development through a phenomenon called fetal programming. However, not all the relationships between the outcomes mentioned above and diabetes during gestation are clear, well-studied, or have been related to fetal programming. To understand this relationship, it is imperative to understand how developmental processes take place in health, in order to understand how the functional cytoarchitecture of the central nervous system takes place; to identify changes prompted by hyperglycemia, and to correlate them with the above postnatal impaired functions. Although changes in the establishment of patterns during central nervous system fetal development are related to a wide variety of neurological pathologies, the mechanism by which several maternal conditions promote fetal alterations that contribute to impaired neural development with postnatal consequences are not clear. Animal models have been extremely useful in studying the effect of maternal pathologies on embryo and fetal development, since obtaining central nervous system tissue in humans with normal appearance during fetal development is an important limitation. This review explores the state of the art on this topic, to help establish the way forward in the study of fetal programming under hyperglycemia and its impact on neurological and psychiatric disorders.

EYE MOVEMENTS BUT NOT VISUAL EXPERIENCE DRIVES THE DEVELOPMENT OF PALISADE ENDINGS

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Génova Carrero Rojas[1], Johannes Streicher[2], Paula Martín Calvo[3], Rosa Rodríguez De La Cruz[3], Angel Pastor[3], Roland Blumer[1]
[1]Medical University of Vienna, Anatomy And Cell Biology, Vienna, Austria, [2]Karl Landsteiner University of Health and Science, Anatomy And Biomechanics, Krems an der Donau, Austria, [3]Universidad de Sevilla, Fisiología, Sevilla, Spain

Aims: Palisade endings are a peculiar nerve structure, which are regularly present in extraocular muscles (EOMs) of frontal-eyed species (human, monkey, cat, dog, ferret). In a previous study, we have shown in cat that palisade endings develop after birth in a heterochronic sequence. Here we tested whether external influences like visual experience and/or eye movements guide the development of palisade endings. **Methods**: Both eyes of newborn cats (n=3) were covered for a period of 45 days and the right eye of newborn cats (n=3) was covered for 30 days. Seven cats received a Botulinum toxin-A (BoNT-A) injection at birth into the retrobulbar space of the left orbit. The survival time was 45 or 95 days. EOM whole mount preparations were triple-immunolabeled with anti-neurofilament, anti-synaptophysin or anti-growth associated protein 43 (GAP43), and phalloidin. Analyses were done in the confocal laser-scanning microscope. **Results:** After bilateral/unilateral light deprivation, palisade endings were present in all rectus muscles and they were qualitatively and quantitatively equal to control palisade endings. After BoNT-A treatment for a period of 45 days, palisade endings were only present in the inferior and medial rectus, and not until the age of 95 days, palisade endings were observed in all rectus muscles. Additionally, following BoNT-A administration the number of palisade endings was reduced in all rectus muscles. There was no difference in the GAP43 expression between palisade endings after BoNT-A treatment and untreated palisade endings. **Conclusions:** Our study demonstrates that eye immobilization but not dark rearing affects the development of palisade endings.

MIF versus SIF Motoneurons, What Are Their Respective Contribution in the Oculomotor Medial Rectus Pool?
Multiply-innervated muscle fibers (MIFs) are peculiar to the extraocular muscles as they are non-twitch but produce a slow build up in tension on repetitive stimulation. The motoneurons innervating MIFs establish en grappe terminals along the entire length of the fiber, instead of the typical en plaque terminals that singly-innervated muscle fibers (SIFs) motoneurons establish around the muscle belly. MIF motoneurons have been proposed to participate only in gaze holding and slow eye movements. We aimed to discern the function of MIF motoneurons by recording medial rectus motoneurons of the oculomotor nucleus. Single-unit recordings in awake cats demonstrated that electrophysiologically-identified medial rectus MIF motoneurons participated in different types of eye movements, including fixations, rapid eye movements or saccades, convergences, and the slow and fast phases of the vestibulo-ocular nystagmus, the same as SIF motoneurons did. However, MIF medial rectus motoneurons presented lower firing frequencies, were recruited earlier and showed lower eye position (EP) and eye velocity (EV) sensitivities than SIF motoneurons. MIF medial rectus motoneurons were also smaller, had longer antidromic latencies and a lower synaptic coverage than SIF motoneurons. Peristimulus time histograms (PSTHs) revealed that electrical stimulation to the myotendinous junction, where palisade endings are located, did not recurrently affect the firing probability of medial rectus motoneurons. Therefore, we conclude there is no division of labor between MIF and SIF motoneurons based on the type of eye movement they subserve. In addition to the common singly-innervated muscle fiber (SIF), extraocular muscles also contain multiply-innervated muscle fibers (MIFs), which are non-twitch and slow in contraction. MIF motoneurons have been proposed to participate only in gaze holding and slow eye movements. In the present work, by single-unit extracellular recordings in awake cats, we demonstrate, however, that both SIF and MIF motoneurons, electrophysiologically-identified, participate in the different types of eye movements. However, MIF motoneurons showed lower firing rates (FRs), recruitment thresholds, and eye-related sensitivities, and could thus contribute to the fine adjustment of eye movements. Electrical stimulation of the myotendinous junction activates antidromically MIF motoneurons but neither MIF nor SIF motoneurons receive a synaptic reafferentation that modifies their discharge probability.

Muscle Progenitors Derived from Extraocular Muscles Express Higher Levels of Neurotrophins and their Receptors than other Cranial and Limb Muscles.
Extraocular muscles (EOMs) show resistance to muscle dystrophies and sarcopenia. It has been recently demonstrated that they are endowed with different types of myogenic cells, all of which present an outstanding regenerative potential. Neurotrophins are important modulators of myogenic regeneration and act promoting myoblast proliferation, enhancing myogenic fusion rates and protecting myotubes from inflammatory stimuli. Here, we adapted the pre-plate cell isolation technique to obtain myogenic progenitors from the rat EOMs, and quantified their in vitro expression of neurotrophins and their receptors by RT-qPCR and immunohistochemistry, respectively. The results were compared with the expression on progenitors isolated from buccinator, tongue and limb muscles. Our quantitative analysis of brain-derived neurotrophic factor (BDNF), nerve growth factor (NGF) and neurotrophin-3 (NT-3) transcripts showed, for the first time, that EOMs-derived cells express more of these factors and that they expressed TrkA, but not TrkB and TrkC receptors. On the contrary, the immunofluorescence analysis demonstrated high expression of p75 on all myogenic progenitors, with the EOMs-derived cells showing higher expression. Taken together, these results suggest that the intrinsic trophic differences between EOMs-derived myogenic progenitors and their counterparts from other muscles could explain why those cells show higher proliferative and fusion rates, as well as better regenerative properties.

Sources and lesion-induced changes of VEGF expression in brainstem motoneurons.
Motoneurons of the oculomotor system show lesser vulnerability to neurodegeneration compared to other cranial motoneurons, as seen in amyotrophic lateral sclerosis (ALS). The overexpression of vascular endothelial growth factor (VEGF) is involved in motoneuronal protection. As previously shown, motoneurons innervating extraocular muscles present a higher amount of VEGF and its receptor Flk-1 compared to facial or hypoglossal motoneurons. Therefore, we aimed to study the possible sources of VEGF to brainstem motoneurons, such as glial cells and target muscles. We also studied the regulation of VEGF in response to axotomy in ocular, facial, and hypoglossal motor nuclei. Basal VEGF expression in astrocytes and microglial cells of the cranial motor nuclei was low. Although the presence of VEGF in the different target muscles for brainstem motoneurons was similar, the presynaptic element of the ocular neuromuscular junction showed higher amounts of Flk-1, which could result in greater efficiency in the capture of the factor by oculomotor neurons. Seven days after axotomy, a clear glial reaction was observed in all the brainstem nuclei, but the levels of the neurotrophic factor remained low in glial cells. Only the injured motoneurons of the oculomotor system showed an increase in VEGF and Flk-1, but such an increase was not detected in axotomized facial or hypoglossal motoneurons. Taken together, our findings suggest that the ocular motoneurons themselves upregulate VEGF expression in response to lesion. In conclusion, the low VEGF expression observed in glial cells suggests that these cells are not the main source of VEGF for brainstem motoneurons. Therefore, the higher VEGF expression observed in motoneurons innervating extraocular muscles is likely due either to the fact that this factor is more avidly taken up from the target muscles, in basal conditions, or is produced by these motoneurons themselves, and acts in an autocrine manner after axotomy.

Cajal-Retzius cells (CRs) are transient neurons playing key roles during cortical development. Unlike most neurons, they almost completely disappear by programmed cell death (PCD) during the first postnatal weeks in mice. Abnormal survival of CRs is detected in pathological conditions exhibiting epilepsy, suggesting that their persistence at postnatal stages might hamper cortical functions. Here, using a mouse model preventing PCD of a CR subtype, we evaluate the functional impact of CRs persistence in the establishment of adult cognitive and neuronal functions. While no differences were detected in juvenile animals, we observed an impairment of hippocampus-dependent behaviors in adults. Both male and female mutants showed deficits in novel object recognition and spatial learning but not in associative memory formation. At the cellular level, we detected enhanced survival of CRs in both juvenile and adult mice, as well as an increased number of NPY^+ GABAergic cells and spine density of CA1 pyramidal neurons. At the synaptic level, this was associated with an enhanced frequency of inhibitory currents in adult animals. Moreover, adult mutants displayed an increased susceptibility to develop lethal tonic-clonic seizures upon kainate injection and a switch of the activity pattern from bursting to seizures in cortico-hippocampal slices. Finally, multi-site recordings from the dorsal hippocampus confirmed stronger gamma activity in mutants, together with the sporadic presence of sharp (10-15 ms) interictal-like spikes confined to the CA1 region. These results show that aberrant survival of even a small proportion of CRs results in alteration of behaviour and epilepsy prone phenotypes in adults.

FUNCTIONAL DEVELOPMENT OF THE MOUSE FRONTO-STRIATAL NETWORK

POSTER SESSION 03 - SECTION: DEVELOPMENT OF CORTICAL CIRCUITRY

Guoming Man[1], Mattia Chini[2], Sebastian Bitzenhofer[3], Ileana Hanganu-Opatz[4]
[1]University Medical Center Hamburg-Eppendorf, Institute Of Development Neurophysiology, Center For Molecular Neurobiology, Hamburg, Germany, [2]Zentrum für Molekulare Neurobiologie (ZMNH), Institute Of Developmental Neurophysiology, Hamburg, Germany, [3]University Medical Center Hamburg-Eppendorf, Developmental Neurophysiology, Hamburg, Germany, [4]University Medical Center Hamburg-Eppendorf, Inst. Dev. Neurophysiol., Hamburg, Germany

The prefrontal cortex (PFC) acts as a hub of complex cortico-subcortical networks accounting for higher cognitive processing. For example, behavioral flexibility has been reported to relay on fronto-striatal communication. The PFC monosynaptically projects to the striatum (STR) which, in turn, is connected to the PFC through the thalamus, thereby forming a multi-synaptic loop. Despite the critical function of this circuit in adult brain, little is known about its structural and functional development. To fill this knowledge gap, we combined retrograde neural tracing and in vivo extracellular recordings from the PFC and STR of mouse pups of 5 to 12 days of age. Already during the first postnatal week, prefrontal afferents target the STR. In both areas, single unit spiking activity (SUA) and the broadband local field potential (LFP) power exponentially increased over age. The fronto-striatal coupling through synchrony was tight as mirrored by the high values of imaginary coherence in theta frequency range. Directionality analysis revealed that, in contrast to the ingrowth of projections, the STR drives the PFC during early development and the driving force decreases with age. These results give first insights into the maturation of fronto-striatal communication and represent the substrate for further dissection of circuits in relationship to the behavioral development.

LEARNING-EVOKED CHANGES IN INTRINSIC EXCITABILITY OF GABAERGIC INTERNEURONS IN THE SOMATOSENSORY CORTEX OF MICE.

POSTER SESSION 03 - SECTION: NEURONS AND GLIA: CELL EXCITABILITY

Dominik Kanigowski, Joanna Urban-Ciećko
Nencki Institute of Experimental Biology PAS, Laboratory Of Electrophysiology, Warsaw, Poland

The GABAergic interneurons can be divided into three subclasses: somatostatin- (SST), parvalbumin- (PV), and ionotropic serotonin 5HT3a receptor-expressing (5HT3aR) cells. The last group is further divided into vasoactive intestinal polypeptide-expressing (VIP) and non-VIP-expressing cells. Several areas of evidence suggest that GABAergic interneurons are essential for basic information flow in the neuronal networks, as well as for learning and memory processing. **Aim** Here, we asked a question whether a simple model of learning in mice changes the intrinsic excitability of SST-, PV- and VIP-interneurons. **Methods** To answer this question we subjected mice to a conditioning paradigm where whiskers tactical stimulation was paired with electric tail shocks or to pseudoconditioning where these stimulations were applied randomly. After the learning procedure, we performed *in vitro* whole-cell patch-clamp recordings in the somatosensory cortex. **Results** We found that conditioning in mice leads to a rise of intrinsic excitability in low-threshold spiking SST-expressing interneurons in layer 4 of the cortical representation of stimulated whiskers. In contrast, we discovered that pseudoconditioning causes a decrease in intrinsic excitability of fast-spiking PV-expressing cells. However, changes in the intrinsic excitability of VIP-expressing interneurons are more complex and are characteristic for the learning paradigm and cell firing phenotype. **Conclusions** Our results indicate that changes in intrinsic excitability of the GABAergic interneurons are a common form of plastic alternations in the inhibitory circuit after various paradigms of learning. These changes may be critical for proper memory function and precision in information streaming through the cortical net. Polish Science Centre grant: UMO-2015/18/E/NZ4/00721

Learning-induced plasticity in the barrel cortex is disrupted by inhibition of layer 4 somatostatin-containing interneurons. Gaba-ergic neurons are a diverse cell class with extensive influence over cortical processing, but their role in experience-dependent plasticity is not completely understood. Here we addressed the role of cortical somatostatin- (SOM-INs) and vasoactive intestinal polypeptide- (VIP-INs) containing interneurons in a Pavlovian conditioning where stimulation of the vibrissae is used as a conditioned stimulus and tail shock as unconditioned one. This procedure induces a plastic change observed as an enlargement of the cortical functional representation of vibrissae activated during conditioning. Using layer-targeted, cell-selective DREADD transductions, we examined the involvement of SOM-INs and VIP-INs activity in learning-related plastic changes. Under optical recordings, we injected DREADD-expressing vectors into layer IV (L4) barrels or layer II/III (L2/3) areas corresponding to the activated vibrissae. The activity of the interneurons was modulated during all conditioning sessions, and functional 2-deoxyglucose (2DG) maps were obtained 24 h after the last session. In mice with L4 but not L2/3 SOM-INs suppressed during conditioning, the plastic change of whisker representation was absent. The behavioral effect of conditioning was disturbed. Both L4 SOM-INs excitation and L2/3 VIP-INs inhibition during conditioning did not affect the plasticity or the conditioned response. We found the activity of L4 SOM-INs is indispensable in the formation of learning-induced plastic change. We propose that L4 SOM-INs may provide disinhibition by blocking L4 parvalbumin interneurons, allowing a flow of information into upper cortical layers during learning.

Parametric working memory (PWM) represents the ability to maintain and manipulate transient quantitative information such as a number, the frequency of a sound or the size of an object. The mechanisms underlying PWM are still poorly understood. *In vivo* experiments in humans, monkeys and rats indicate that PWM involves graded persistent activity (GPA) in the prefrontal cortex (PFC). GPA scales with and outlasts remembered information. Models of recurrent neural networks such as found in the PFC suggest that GPA requires conditional bistability (CB). CB is a form of cellular memory that depends on sustained sub-threshold network inputs to memorize a transient input. In a biophysical model, we previously demonstrated that layer V PFC pyramidal neurons may underlie CB. However, the existence and mechanisms of CB still remain unknown in rat PFC circuits. To address these gaps, we used patch-clamp electrophysiology in acute PFC slices from adult rats. We show that **(1)** a subset of PFC layer V pyramidal neurons exhibits CB, **(2)** CB is fine-tuned by acetylcholine (97% of CB neurons in presence of carbachol vs. 14% in control conditions), **(3)** carbachol-induced CB relies on changes in fast and slow afterpolarization potentials mediated through calcium-activated non-selective cationic channels, and **(4)** CB is not modulated by other common neuromodulators such as dopamine, serotonin and noradrenaline. **Uncovering CB, a novel PFC intrinsic neuronal property, and its ionic mechanisms, will be crucial to assess its effective role in the emergence of PWM and other executive functions in frontal cortical areas.**

ACCELERATED SIGNAL PROPAGATION SPEED IN HUMAN NEOCORTICAL MICROCIRCUITS

POSTER SESSION 03 - SECTION: NEURONS AND GLIA: CELL EXCITABILITY

Rajmund Lákovics[1], Gáspár Oláh[1], Pal Barzo[2], Gábor Molnár[1], Gábor Tamás[1]
[1]University of Szeged, Department Of Physiology, Anatomy And Neuroscience, Szeged, Hungary, [2]University of Szeged, Department Of Neurosurgery, Szeged, Hungary

Human-specific cognitive abilities depend on information processing in the cerebral cortex, where neurons are significantly larger and sparser compared to rodents. We found that, in synaptically connected layer 2/3 pyramidal cells, the soma-to-soma signal propagation delay is similar in humans and rodents. Thus, to compensate for the increase in neurons' size, membrane potential changes must propagate faster in human axons and/or dendrites. Using dual somato-dendritic and somato-axonal patch recordings, we found that the propagation speed of somatically-evoked action potentials is similar in human and rat axons but is 1.7-fold faster in human dendrites.

COOPERATIVE MODULES OF IONIC CURRENTS AND THEIR EFFECT ON ELECTRICAL FEATURES OF BIOPHYSICALLY DETAILED MODELS.

POSTER SESSION 03 - SECTION: NEURONS AND GLIA: CELL EXCITABILITY

Maria Reva, Alexis Arnaudon, Mickael Zbili, Henry Markram, Werner Van Geit
École polytechnique fédérale de Lausanne, Blue Brain Project, Geneva, Switzerland

Neuronal membrane potential is sculptured by numerous ionic currents present in the cell. Different values of neuronal electrical features can be observed from the combination of various numbers of ionic current densities. While electrophysiological experiments provide us with a general understanding of the contribution of currents to certain electrical features, we lack a systematic exploration of the effect of the interplay between ionic currents on neuronal electrical behaviour. However, detailed biophysical models allow us to tackle this issue by unravelling the inner mechanisms of the interactions between currents. In this study, we identify modules of ionic currents and their role in shaping neuronal electrical features using statistical methods and information theory.
Using Monte Carlo Markov Chain methods, we generated thousands of non-identical electrical models with experimentally plausible electrophysiological characteristics for cells with various firing patterns. Based on the obtained parameter and feature value set we used information theory methods to detect interactions between model parameters and features at all orders, beyond pairwise correlations. We show that most features depend on the synergetic or redundant combinations of several parameters. Only a small fraction of the features was influenced by one to two ionic currents while most depended on more than 5 model parameters. In our models, we were able to map the cooperative modules of ionic currents and their relation to the electrical features. Further we aim to assess the stability of the identified modules and their possible relation to the gene expression levels and morphological properties of the cells.

HIPPOCAMPAL-MEDIAL ENTORHINAL CIRCUIT IS DIFFERENTLY ORGANIZED ALONG THE DORSOVENTRAL AXIS IN RODENTS

POSTER SESSION 03 - SECTION: NEURONS AND GLIA: CELL EXCITABILITY

Shinya Ohara[1,2], Märt Rannap[3], Ken-Ichiro Tsutsui[1], Andreas Draguhn[3], Alexei Egorov[3], Menno Witter[2]
[1]Tohoku University, Graduate School Of Life Sciences, Sendai, Japan, [2]Norwegian University for Science and technology, Kavli Institute For Systems Neuroscience Faculty Of Medicine And Health Sciences, Trondheim, Norway, [3]Heidelberg University, Institute Of Physiology And Pathophysiology, Heidelberg, Germany

Layer V of the medial entorhinal cortex (MEC) is considered to form the major target of hippocampal outputs. Recent studies show that MEC layer V is divided into two sub-layers: LVa neurons project to telencephalic structures, whereas LVb neurons project locally, forming a recurrent entorhinal-hippocampal loop. Recent studies have shown that in dorsal MEC hippocampal input mainly targets neurons in LVb that have only sparse connections to LVa. This suggests that dorsal MEC might not efficiently convey hippocampal information to the neocortex, challenging current concepts on the hippocampal-neocortical dialogue. In this study, we aimed to identify the main source of hippocampal inputs to MEC LVa neurons by reexamining the hippocampal-MEC projections along the dorsoventral axis in rodents. By using anterograde tracing and in vitro electrophysiology, we show that the organization of hippocampal projections to MEC is markedly different along the dorsoventral axis: dorsal hippocampal projections target mainly LVb neurons in dorsal MEC, whereas ventral projections target LVa neurons in both ventral and dorsal MEC. This contrasts with previous anatomical concepts suggesting that the organization of the entorhinal-hippocampal circuits is relatively identical along the dorsoventral axis. Our findings indicate that ventral hippocampus may play an important role in regulating LVa-mediated entorhinal-neocortical outputs from both dorsal and ventral MEC. These findings may be relevant to understanding the neuronal basis of memory consolidation in hippocampal-entorhinal-cortical networks.

POSITION DEPENDENT DIFFERENCES IN RESPONSE FEATURES OF INDIVIDUAL CELLS WITHIN THE SAME TYPE- INTRACELLULAR DOUBLE RECORDINGS OF MECHANOSENSORY T CELLS OF THE LEECH

POSTER SESSION 03 - SECTION: NEURONS AND GLIA: CELL EXCITABILITY

Jana Marie Sleeboom, Sonja Meiser, Jutta Kretzberg
University of Oldenburg, Computational Neuroscience, Oldenburg, Germany

The medical leech is known for its precise localization of tactile input to its skin, e.g. in the local bend reflex, a behavior with similar precision as the human fingertip. This behavior is elicited by only a few mechanosensory neurons, including three bilateral pairs of T (touch) cells. All T-cells in each ganglion are coupled via polysynaptic chemical and electrical connections. They are distinguished by their different receptive fields in the skin, and by their soma position within the ganglion, but are usually treated as one homogeneous cell type. We tested whether cells at two different soma positions (T2 and T3) differ in their responses to intracellular electrical stimulation and their mutual synaptic influence. In intracellular double recordings, we recorded and stimulated all possible ipsi- and contralateral combinations of T2 and T3 within the isolated ganglia. We found significant differences: Cells at the position T2 are more excitable than at the position T3. The pre-synaptic T2 cell has a higher spike count, and the postsynaptic T2 cell has a higher integral, amplitude, and length of post synaptic potentials. Additionally, only for cells at soma position T3 the postsynaptic potential features are significantly larger for ipsilateral than for contralateral inputs. Hence, this well-studied cell type falls into two different classes correlated with the soma position, indicating potential differences in ion channel properties and in synaptic interactions with the network via interneurons. The mutual feedback by these network interactions could play a major role in the leech's surprisingly precise sensory information processing.

THE SOUND OF SILENCE – ELECTROPHYSIOLOGICAL COMPARISON OF THREE CELL TYPES

POSTER SESSION 03 - SECTION: NEURONS AND GLIA: CELL EXCITABILITY

Oda Riedesel, Jens-Steffen Scherer, Sonja Meiser, Jutta Kretzberg
University of Oldenburg, Computational Neuroscience, Oldenburg, Germany

Some neuronal cell types react to external stimuli in a flexible way by changing their response properties over time. This was recently shown for the mechanosensory touch (T-) cells in the medicinal leech. Previous studies reported that repeated intracellular current injections in T-cells lead to a hyperpolarization of the resting membrane potential over time and an increase in spike count. Here, we investigated if these changes require high spike activity and if they also occur in other leech neurons, the mechanosensory pressure (P-) cell and the neurosecretory Retzius (Rz) cell. For this purpose, an intracellular current stimulation protocol was established, consisting of a single 1 nA current pulse of 500 ms duration that was applied every 5 minutes. During this extended time without stimulation, the spike activity developed in a cell-type specific way. In P- and T-cells, the spike count elicited by the repeated current pulse raised unexpectedly, even though no spikes were elicited during the long absence of stimulation between the pulses. In contrast, the spontaneously active Rz-cells decreased the number of spikes in response to the repeated current pulses. From that, we can conclude two things: First, the changes in excitability are cell-type specific with the two mechanosensory cell types (T and P) behaving similarly, but different from the Rz cells. Second, the increase in spike count in T- and P-cells over extended recording periods does not require spike activity between the test pulses.

Synaptic glycoprotein neuropastin (Np) is involved in synaptic plasticity and complex molecular events underlying learning and memory formation. Np exists in two isoforms, Np55 and Np65. Being a membrane protein, its function and localization within specific membrane subdomains like lipid rafts (LR) are most probably affected by specific lipid microenvironment. This study aimed to investigate the effect of membrane ganglioside composition on total and brain regional protein expression and submembrane localization of Np using *St8sia1 null* mice with impaired synthesis of gangliosides. Brains of adult wild type (WT) and *null* mice littermates were used. Protein expression of both Np isoforms in homogenates was analyzed by Western blotting. Immunohistochemical staining was performed on frozen brain tissue slices using an antibody specific for both isoforms. LR and non-raft (nLR) fractions from cortices and cerebella were isolated by ultracentrifugation in discontinuous sucrose gradients, and submembrane localization of Np isoforms analyzed by Western blotting. Results revealed statistically lower amounts of Np55 and Np65 in both cortices and cerebella of *null* mice compared to their WTs. Immunohistochemical staining revealed lower intensity of Np staining in the cortex and cerebellar molecular layer of *null* mice compared to WT mice. The amount of both isoforms positioned within cortical LR of *null* mice was statistically lower than those positioned within LR derived from WT animals. Results show that proper ganglioside environment is critical for specific Np functions, indicating novel roles of gangliosides as co-players in molecular basis of cognitive processes.

Plasma Membrane Calcium ATPase-Neuroplastin Complexes Are Selectively Stabilized in GM1-Containing Lipid Rafts.
The recent identification of plasma membrane (Ca)-ATPase (PMCA)-Neuroplastin (Np) complexes has renewed attention on cell regulation of cytosolic calcium extrusion, which is of particular relevance in neurons. Here, we tested the hypothesis that PMCA-Neuroplastin complexes exist in specific ganglioside-containing rafts, which could affect calcium homeostasis. We analyzed the abundance of all four PMCA paralogs (PMCA1-4) and Neuroplastin isoforms (Np65 and Np55) in lipid rafts and bulk membrane fractions from GM2/GD2 synthase-deficient mouse brains. In these fractions, we found altered distribution of Np65/Np55 and selected PMCA isoforms, namely PMCA1 and 2. Cell surface staining and confocal microscopy identified GM1 as the main complex ganglioside co-localizing with Neuroplastin in cultured hippocampal neurons. Furthermore, blocking GM1 with a specific antibody resulted in delayed calcium restoration of electrically evoked calcium transients in the soma of hippocampal neurons. The content and composition of all ganglioside species were unchanged in Neuroplastin-deficient mouse brains. Therefore, we conclude that altered composition or disorganization of ganglioside-containing rafts results in changed regulation of calcium signals in neurons. We propose that GM1 could be a key sphingolipid for ensuring proper location of the PMCA-Neuroplastin complexes into rafts in order to participate in the regulation of neuronal calcium homeostasis.

HIPPOCAMPAL OUTPUT PROCESSING IN LAYER VI OF THE MEDIAL ENTORHINAL CORTEX

POSTER SESSION 03 - SECTION: NEURONS AND GLIA: CELL EXCITABILITY

Märt Rannap, Janis Winterstein, Andreas Draguhn, Alexei Egorov
Heidelberg University, Institute Of Physiology And Pathophysiology, Heidelberg, Germany

The entorhinal cortex (EC) constitutes a major interface between the hippocampus and neocortex. Sensory information enters the hippocampal formation via superficial layers (II/III) of the EC. In turn, deep layers (V/VI) receive a substantial part of the hippocampal output. Recently, we investigated the processing of hippocampal output signals within layer V of the medial EC (mEC). It is still, however, unknown how hippocampal activity patterns propagate to layer VI (LVI). Here, we performed whole-cell patch-clamp recordings from mEC LVI neurons combined with field potential recordings from the hippocampal CA1 area in horizontal mouse brain slices. Location and morphology of recorded neurons were confirmed by labeling of biocytin-filled cells and immunostaining for Ctip2 (marker for LVb neurons). Morphologically, LVI was mainly found to comprise horizontal pyramidal or multipolar neurons. The axons of LVI neurons travelled towards the subiculum and to superficial layers of the mEC, indicating far-reaching innervation. In the vast majority of LVI glutamatergic neurons electrophysiological recordings revealed a characteristic delayed firing pattern. Reciprocal connections between excitatory LVI neurons in paired recordings were relatively sparse (6/105). To study the propagation of hippocampal output signals to mEC LVI, we injected a ChR2-expressing AAV into the ventral hippocampus (CA1/subiculum) and activated the axons of infected neurons by illuminating LVI with blue light. Most LVI neurons showed strong monosynaptic responses from the ventral hippocampus. Correspondingly, a naturally occurring hippocampal activity pattern, the sharp wave-ripple complex, propagated efficiently to LVI neurons. These findings suggest a critical involvement of mEC LVI in hippocampal-neocortical signal propagation.

ANATOMICAL AND ELECTROPHYSIOLOGICAL CHARACTERIZATION OF HYPOTHALAMIC NEURONS INVOLVED IN FEMALE SEXUAL BEHAVIOR.

POSTER SESSION 03 - SECTION: NEURONS AND GLIA: CELL EXCITABILITY

Inês Dias, Nicolas Gutierrez-Castellanos, Susana Lima
Champalimaud Foundation, Champalimaud Research, Lisboa, Portugal

Throughout the reproductive cycle, fluctuating levels of sex hormones coordinate female behavior with their reproductive capacity by modulating the activity of neuronal circuits expressing their specific receptors. The ventrolateral division of the ventromedial hypothalamus (VMHvl) is rich in neurons expressing receptors for sex hormones and its function is intimately linked to female sexual receptivity. However, recent findings suggest that the VMHvl is functionally heterogeneous. To gain insight in the possible underlying causes of such functional heterogeneity, we used whole electrophysiological recordings, viral tracing, and neuronal reconstructions tools to characterize the electrophysiological and anatomical properties of individual VMHvl neurons in naturally cycling females. We found that the properties of progesterone receptor expressing (PR+) neurons, but not PR– neurons, depended systematically on the neuron's location along the anterior-posterior (AP) axis of the VMHvl and the phase within the reproductive cycle. The observations reveal the existence of phenotypes within the PR+ subpopulation, supporting the anatomic and functional subdivision of the VMHvl and its possible role in the orchestration of different aspects of female socio-sexual behavior.

The Structural and Electrophysiological Properties of Progesterone Receptor-Expressing Neurons Vary along the Anterior-Posterior Axis of the Ventromedial Hypothalamus and Undergo Local Changes across the Reproductive Cycle.
Sex hormone levels continuously fluctuate across the reproductive cycle, changing the activity of neuronal circuits to coordinate female behavior and reproductive capacity. The ventrolateral division of the ventromedial hypothalamus (VMHvl) contains neurons expressing receptors for sex hormones and its function is intimately linked to female sexual receptivity. However, recent findings suggest that the VMHvl is functionally heterogeneous. Here, we used whole recordings and intracellular labeling to characterize the electrophysiological and morphologic properties of individual VMHvl neurons in naturally cycling females and report the existence of multiple electrophysiological phenotypes within the VMHvl. We found that the properties of progesterone receptor expressing (PR+) neurons, but not PR- neurons, depended systematically on the neuron's location along the anterior-posterior (AP) axis of the VMHvl and the phase within the reproductive cycle. Prominent among this, the resting membrane potential of anterior PR+ neurons decreased during the receptive phase, while the excitability of medial PR+ neurons increased during the non-receptive phase. During the receptive phase of the cycle, posterior PR+ neurons simultaneously showed an increase in dendritic complexity and a decrease in spine density. These findings reveal an extensive diversity of local rules driving structural and physiological changes in response to fluctuating levels of sex hormones, supporting the anatomic and functional subdivision of the VMHvl and its possible role in the orchestration of different aspects of female socio-sexual behavior.

Aims: cerebellar basket cells (BC), located in the bottom 1/3 of molecular layer, play an important role in controlling the activity of Purkinje cells (PC) via inhibitory synaptic transmission. BCs receive excitatory synaptic inputs from parallel fibers (pf) and transmit inhibitory synaptic inputs to BCs and PCs. We reconstructed a multi-compartmental biophysically realistic BC model in Python-NEURON to investigate the intrinsic and synaptic electrophysiological properties. Methods: 3D morphologies of mouse BC were reconstructed from fluorescent images obtained with a confocal microscope and analyzed with Neurolucida. Ionic channels were located according to immunohistochemistry. The maximum ionic conductances ($G_{i\text{-}max}$) were tuned to match the firing pattern revealed by whole-cell patch-clamp recordings from mice cerebellar slices. BC discharges elicited by step current injections were used as templates to extract the features needed to assess the optimization fitness function. $G_{i\text{-}max}$ tuning was performed using the multi-objective genetic algorithm in the BluePyOpt Library. Results: BC detailed models were generated starting from morphological reconstructions and automatically fitted using electrophysiological recordings as templates. Validated models reproduced whole-cell and loose cell-attached patch-clamp experimental results, showing (1) autorhythmic activity, (2) correct spike shape amplitude, (3) a linear I/O relationship following positive current injections, (4) Afterhyperpolarization (AHP) duration after positive current injections, (5) Sag following negative current injections, (6) Excitatory postsynaptic potentials (EPSPs) following pf inputs. Conclusions: optimization technique gave satisfactory results, reproducing the BC electrophysiological behaviors. The model provided a valuable tool to investigate the molecular layer interneurons function in cerebellar network activity.

EXPLORING THE DYNAMICS OF NEURONAL EXCITABILITY BY OPTOGENETICS IN EX VIVO CORTICAL CULTURES

POSTER SESSION 03 - SECTION: NEURONS AND GLIA: CELL EXCITABILITY

Elena Gjorgievska, Michele Giugliano
International School of Advanced Studies (SISSA), Neurobiology, Trieste, Italy

It is currently still unclear how the excitability of cortical neurons changes dynamically, over distinct timescales and across cell types. We designed a medium-throughput method, combining multisite extracellular recordings with wide-field photoactivation, and targeted specific cortical genetic cell types. We focused on *ShChR/CaMKIIα*-expressing neurons (i.e., putative glutamatergic cells) and asked how they intrinsically respond to very long trains of photo stimuli repeated at different frequencies. We then analyzed spike probability and spike latency as proxies of excitability. In accordance with previous reports (Gal et al., 2010), we observed a rich temporal dynamics of neuronal responses, across a wide range of stimulation frequencies. A transient and an intermittent/chaotic phase occurred, with the latter key for our quantification of a considerable heterogeneity of neuronal responses. Our data challenge the homogeneity often conceptually assumed for the *glutamatergic cell type*, its computation and role within a circuit. However, we found the macroscopic statistical features of evoked responses to be identical, across different stimulation regimes when above a critical stimulation rate. Indeed, the very long-term fluctuations in the spike probability all resemble a *fractional* stochastic process, indicating that intrinsic neuronal activity is significantly affected by past stimuli over unexpectedly broad timescales. All in all, our work is extremely relevant to the development of better quantitative models which are capable of more accurately capturing *in silico* the biological excitability, a) across spatiotemporally diverse electrophysiological types and b) over behaviorally relevant, extended timescales.

Repetitive Transcranial Magnetic Stimulation (rTMS), either at classically-used high intensity (in Teslas, T) or sub-excitation low intensity (mT; LI-rTMS), can increase neural circuit plasticity and shows promise in treating human neurological dysfunction. However, the processes activated by magnetic fields at the single neuron level remain largely unknown, preventing the optimization of potentially therapeutic rTMS protocols.
We investigated the impact of continuous focal 10-Hz LI-rTMS on neuronal excitability with in vivo intracellular and electrocorticographic (ECoG) recordings from the primary somatosensory cortex in sufentanil-sedated rats of either sex. Neuronal electrical properties were compared before and after 10 minutes LI-rTMS, so that each neuron was its own control. All experiments were in accord with the European Union directive.
In pyramidal cortical neurons (n=16), this LI-rTMS produced: (1) large hyperpolarization of membrane potential, (2) near complete abolition of spontaneous firing and (3) decreased amplitude of ongoing synaptic events. This altered spontaneous activity and significantly changed neuronal membrane input resistance. Also, the relation linking firing frequency to intensity of injected current (F-I curves) before and after LI-rTMS was modified in all tested neurons. There was a gradual and persistent increase in the threshold of injected current required to fire cortical neurons.
These findings indicate that a short period of continuous 10-Hz LI-rTMS can strongly, and durably, reduce the membrane and synaptic properties of somatosensory cortical neurons. We are currently further investigating the functional outcome of this time-dependent modulation of cortical excitability by analyzing the ECoG patterns and whisker-evoked sensory responses before and after LI-rTMS.

MICRO-CIRCUITRY AND OUTPUT CONNECTIVITY OF THE STRIOSOME NETWORK

POSTER SESSION 03 - SECTION: NEURONS AND GLIA: CELL EXCITABILITY

Martha Torres Nupan, Marine Chazalon, Serge Schiffmann
Université Libre de Bruxelles, Faculty Of Medicine, Brussels, Belgium

AIMS: The striatum constitutes the main input structure of the basal ganglia and is mainly composed of GABAergic medium spiny neurons (MSNs) giving rise to the direct and indirect pathways. An additional compartmentalization of the striatum, consisting in the striosomes and the matrix was described decades ago. The respective network organization and functions of these compartments are much less understood along with the differences in their MSNs intrinsic properties. Our aim is therefore, to assess the intrinsic properties of the striosomal and matrix neurons and to characterize the functional connectivity of these compartments. METHODS: Using a BAC-Cre transgenic mouse combined with stereotactic injections of Cre-dependent viral constructs and patch clamp experiments, we measured the passive and active membrane properties of the striosomal and matrix neurons. Using optogenetics to assess functional connectivity, we obtained light induced post-synaptic responses in several striosome target structures. RESULTS: Striosomal neurons displayed increased spiking and a substantial shift in spike threshold and rheobase when compared to matrix neurons without differences in other properties. Light stimulation induced short term synaptic plasticity of striosomal MSN-GPe synapses. CONCLUSIONS: These results indicate a greater excitability of striosome MSNs compared with matrix MSNs. Previous studies of characterization of striatal MSN-GPe synapses, without specific identification of striosome and matrix MSNs, have reported short term facilitation as a signature in these types of synapses. Our results may suggest the existence of subtle differences in the synaptic dynamic when stimulating exclusively striosomal MSN-GPe synapses.

Cognitive and Behavioral Disorders in Children with Neurofibromatosis Type 1.
The last systematic review of research on the behavior of children with neurofibromatosis type 1 (NF1) was in 2012. Since then, several important findings have been published. Therefore, the study aim was to synthesize recent relevant work related to this issue.

James Parkinson and his essay on "shaking palsy", two hundred years later.
In 1817, British physician James Parkinson published a 66-page document entitled "Essay on the Shaking Palsy". This brief text became a classical and fundamental piece in the history of Medicine and, in particular, of neurology. The authors of this article wish to pay tribute to this great pioneer of neurology, 200 years after the publication of his findings, which would, in turn, immortalize his name and give rise to the renaming on the entity in 1860 by Professor Jean Martin Charcot, father of neurology. It would be known, henceforth as Parkinson's disease.

Motor cortex comprises the primary descending circuits for flexible control of voluntary movements and is critically involved in motor skill learning. However, due to the complexity of motor cortex circuits, precise mechanisms of motor control and skill learning are still not well understood. Here we have used transgenic mice, electrophysiology and neural tract-tracing methods to target genetically defined cell types expressing D1 and D2 dopamine receptors. We observed that D1+ and D2+ neurons are organized in a separate, largely non-overlapping populations, as evidenced by the laminar distribution of their cell bodies, colocalization and projection patterns. Moreover, based on ex vivo patch-clamp recordings we shown that D1+ and D2+ cells have distinct electrophysiological properties. Furthermore, we traced D1+ and D2+ cells dendritic trees and based on prepared 3D models, we compared their complexity using Sholl analysis. Finally, we observed that chemogenetic inhibition of D2+, but not D1+ neurons disrupt skilled forelimb reaching in adult mice. These results suggest that dopamine receptor-expressing cells in motor cortex are organized into separate, non-overlapping circuits and that they play specialized roles in fine motor control. We believe that a better understanding of the function of these dopamine-sensitive circuits can be a key to the development of new and more effective therapies for people suffering from neurological disorders and stroke. OXYTOCIN ACTS ON ASTROCYTES IN THE CENTRAL AMYGDALA TO PROMOTE A POSITIVE EMOTIONAL STATE

POSTER SESSION 03 - SECTION: NEURONS AND GLIA: CELL EXCITABILITY

Angel Baudon
University of Strasbourg, Inci Cnrs Upr 3212, Strasbourg, France

Oxytocin is a hypothalamic neuropeptide with a large range of functions. From its crucial role in delivery to its implication in maternal behaviour, the functions of oxytocin have been widely studied for decades. Many studies have recently highlighted its implication in complex behaviours, such as individual recognition and preference, pain control, or anxiety modulation. However, oxytocin effect on glia have been left behind. Therefore, the actual dogma is that oxytocin, like other neuropeptides, acts exclusively via neuronal receptors in the central nervous system. Because the anxiolytic effect of oxytocin in the central amygdala is well described, we have investigated the effect of this neuropeptide on the central amygdalar circuit. Using patch clamp recording and calcium imaging, we have shown that astrocytes respond before neurons to an endogenous oxytocin release. Moreover, blocking or stimulating those glial cells can respectively decrease or mimic the effect of oxytocin on neuronal activity. Having these elements in mind, we decided to test whether astrocyte activity can affect the effect of oxytocin *in vivo*. Thanks to the deletion of the oxytocin receptor on central amygdalar astrocytes, we have shown that oxytocin-induced astrocyte activity is essential to the effect of this neuropeptide in the amygdala. On the other hand, we demonstrate that an optogenetic activation of those glial cells is sufficient to mimic the behavioural effects of oxytocin. Unveiling this neuro-astro-neuronal circuit, this work aims to highlight that neuropeptides, like other neurotransmitters, can modulate astrocyte calcium activity, modulating *in fine* the neuronal networks.

Aims: Maternal depression experienced during pregnancy endangers both mother and her offspring. Antidepressant treatment during pregnancy relieves maternal depression and prevents its negative effects on offspring. However, antidepressants themselves may affect directly offspring development. *Methods:* Adult female Sprague-Dawley rats were used. Rats were subjected to randomly alternating stressors to create a model of depression. Antidepressant mirtazapine was administered to pregnant rats from the 10th-20th days of pregnancy at the dose of 10 mg/kg/day. Animals from the control group were administered with a vehicle. Hippocampal neurons were isolated from pups (P0) of mothers which were: 1) unstressed, 2) unstressed and treated with mirtazapine, 3) stressed, and 4) stressed and treated with mirtazapine. Hippocampal excitability was measured in neuronal culture (DIV8-10) using a whole-cell patch clamp in the current-clamp configuration. *Results:* Pyramidal hippocampal neurons were visually identified by their morphology. Resting membrane potential (V_{rest}), input resistance (R_{input}), and the generation and parameters (threshold, amplitude, rise time, width) of action potentials (AP) were monitored. V_{rest} in the neurons of the stress + mirtazapine group was significantly hyperpolarized compared to the other groups. We also observed a significant decrease in R_{inp} in both stressed groups compared to the non-stressed groups. Individual AP parameters were not significantly altered in any group. Higher depolarization was required to initiate an AP firing in the stressed group. This activation shift was compensated by mirtazapine. *Conclusions:* Administration of the antidepressant mirtazapine during gestation has only a minor effect on hippocampal excitability of offspring. *Acknowledgment:* Supported by APVV-19-0435 grant.

SIMILAR LEVELS OF ENERGY POWER FIRING ACTIVITY IN EXCITATORY AND INHIBITORY NEURONS OF DIFFERENT SIZES IN MOUSE AND HUMAN

POSTER SESSION 03 - SECTION: NEURONS AND GLIA: CELL EXCITABILITY

Linhe Xu, Suzana Herculano-Houzel
Vanderbilt University, Psychology, Nashville, United States of America

Across species, neurons have higher diversity in cell sizes than non-neuronal brain cells and most other cell types in the body, despite strong evolutionary conservation of neuron-specific protein-coding and regulatory DNA sequences. Enrichment of highly conserved neuron-specific genes related to transport and signal transduction, as well as similarly highly conserved musculature and heart-specific genes, led us to hypothesize that the diversity in neuronal cell size is a response to conserved molecular pathways associated with firing activities through trade-offs between cell size and excitability in neurons. In this study, we examine whether larger neurons have progressively lower firing rates by analyzing the relationships between electrophysiological and morphological features of human and mouse cortical neurons in the Allen Cell Type Database. We find that larger excitatory neurons do have progressively lower levels of firing activities, while firing rates in inhibitory neurons show no correlation with cell size. Inhibitory neurons, however, show lower membrane capacitance than excitatory neurons of similar cell sizes, and the membrane capacitance of inhibitory neurons increases much more slowly with cell size than in excitatory neurons. As a result, we find that both excitatory and inhibitory neurons, in both human and mouse cortices, maintain a fairly constant estimated power towards recharging the membrane capacitance independently of neuronal cell size or firing rate. The finding that the reported relationships apply equally to mouse and human species suggests an evolutionarily conserved trade-off between firing activity and neuronal cell volume that might originate from physical constraints to energy supply and neuronal activity.

Mcgill University, Department Of Physiology And Cell Information Systems Group, Montreal, Canada

Chronic pain is a debilitating disease, which affects more than a third of the world's population and has a significant cost to society. Current therapeutic approaches, which include opioids, do not provide definitive relief to patients, and are often limited by harmful side effects. A research effort is therefore necessary to identify new pharmacological targets that are more effective but also safer. Recent results show that dorsal root ganglion (DRG) primary sensory neurons, which convey sensory information to the central nervous system, carry out active signal processing involving the cannabinoid system. Normalization of aberrant nociceptive processing in DRG neurons via cannabinoid-based treatment should be explored as an emerging strategy to manage chronic pain. In this work, we report for the first time the effect of cannabidiol (CBD), an FDA-approved non-psychoactive cannabinoid, on the intrinsic excitability of human small diameter DRG neurons. CBD significantly reduces the rheobase of human sensory neurons. We also show that CBD produces a significant depolarizing shift in the action potential threshold. Phase plane plot analysis of the AP shape also revealed kinetic differences in rise and decay time constants without affecting the peak amplitude. Taken together, our results suggest that CBD dampen nociceptor excitability in human, demonstrating an effect potentially relevant to chronic pain treatment. This research was funded in part by Desert Harvest Inc.

Aims: Neuronal stimulation exerts beneficial effects on restorative processes following many debilitating neurological disorders. Current drive to create lightweight and wireless devices for electrical stimulation aims to improve quality of life of patients. Organic photocapacitors (photocaps), rapidly charging upon illumination, create electric field used for stimulation of cells in their vicinity. The aim of the study was to elicit molecular changes in stimulated neurons. Methods: We cultivated primary neurons from postnatal rats on photocaps (round shape, 11 mm ø p-n layer of H2PC-PTCDI, 30 mm ø back electrode of Au-ITO). Afterwards, the cells were stimulated by light pulses for 30 minutes with an LED red light source (10 W). Neuronal activation was assessed by c-fos immunoreactivity with fluorescent staining. Neurotrophin (BDNF, NGF, NT-3, NT-4) expression was analysed with real-time qRT-PCR Results: Cells exposed to light pulses showed increased expression of c-fos protein compared to the controls without light stimulation, proving neuronal activation on the molecular level. Whilst a broad c-fos positivity was observed in these cells, the signal intensity was lower than that of positive controls exposed to glutamate. Three hours post-stimulation no significant change in the neurotrophin mRNA expression was detectable. Conclusion: Translation of c-fos was increased in light-stimulated cells grown on photocaps as compared to the non-stimulated group, indicating a widespread activation of neuronal networks *in vitro.* Whether lack of change in the neurotrophin levels lies on the stimulation protocol, photocap design or intrinsic temporal dynamics of the gene transcription will be addressed by future experiments.

DYSFUNCTIONAL POTASSIUM-CHANNEL ACTIVATION IN A GENETIC MOUSE MODEL OF SCHIZOPHRENIA

POSTER SESSION 03 - SECTION: NEURONS AND GLIA: CELL EXCITABILITY

María Pascual García, Sara Hijazi, Steven Kushner
Erasmus MC, Psychiatry, Rotterdam, Netherlands

Microdeletion of chromosome 22q11.2 is one of the most well-known genetic risk factors for schizophrenia. 22q11 deletion syndrome (22q11DS) is a neurodevelopmental disorder with neural circuit and behavioural disruptions as key features. Recent studies have shown that network synchronization is disturbed in patients with schizophrenia. Parvalbumin (PV) interneurons have shown function deficits in animal models harbouring the 22q11 microdeletion. These interneurons are crucial for maintaining proper excitation-inhibition balance in the neocortex, for which neuropsychiatric disease-related impairments of network activity have often been linked to aberrant PV neuron activity. However, the molecular mechanism behind such PV interneuron deficits remain largely unknown. In this study, we aimed to investigate the electrophysiological properties of PV interneurons in Df1 mice, a mouse model of the 22q11DS. Using whole-cell patch-clamp recordings in hippocampal PV interneurons, we found a significant increase in their excitability. Next, in order to restore PV interneuron excitability, we applied a selective Kv1.1 activator. We found that Kv1.1 activation did not induce any discernible change in the excitability of PV interneurons in Df1 mice, despite robustly decreasing PV interneuron excitability in control mice. Furthermore, we observed a decrease in the number of PV cells that were positive for Kv1. Our findings suggest that increased excitability of PV interneurons in the CA1 region of Df1 mice might result from decreased expression or function of Kv1 channels.

INFLUENCE OF DOPAMINE ON THETA RHYTHM: ROLE OF D2 RECEPTORS IN SST AND PV INTERNEURONS

POSTER SESSION 03 - SECTION: NEURONS AND GLIA: CELL EXCITABILITY

Pola Tuduri[1], Emmanuel Valjent[2], Jeanne Ster[3]
[1]IGF, Université Montpellier, CNRS, INSERM, Molecular And Neural Coding Of Behavior (mncb)lab, MONTPELLIER, France, [2]IGF, Université Montpellier, CNRS, Inserm, Molecular And Neural Coding Of Behavior (mncb)lab, Montpellier, France, [3]IGF, Université Montpellier, CNRS, INSERM, Molecular And Neural Coding Of Behavior (mncb)lab, Montpellier, France

Aims: The hippocampus is essential for memory and novelty processing. These functions are underpinned by synchronous network activity. Recent evidence suggest that dopamine facilitates the encoding of novel spatial memories. While the role of the hippocampal D1 receptor in mnesic functions has been extensively studied, the contribution of the D2 receptor (D2R) remains elusive. We characterize the functional role of D2R in the hippocampus network by combining anatomo-functional approaches. Methods: *In situ* hybridization – Patch clamp Results: *In situ* hybridization analysis indicated that parvalbumin (PV) and somatostatin (Sst) interneurons of the hippocampal CA1 subfield expressed *Drd2* mRNAs. These interneuron subtypes entrain pyramidal cells to orchestrate information processing and are instrumental in generating hippocampal oscillations. Using electrophysiological recordings of pyramidal cells, we observed that application of D2R-like agonist quinpirole (10µM) in the presence of methacholine (muscarinic agonist, 50 nM) increases the number of theta oscillation periods by acting through the D2R on the Sst cells (Sst-D2R-Cko). To get insights into the mechanism of how D2Rs alter hippocampal theta rhythms, we next examined the intrinsic excitability of D2R-expressing cells. Our data suggest that pharmacological D2R activation alters the intrinsic excitability of these hippocampal interneurons, by increasing the firing of action potential in Sst cells and decreasing the firing of PV cells by using different intracellular signaling pathway. Conclusion: These data show that activation of D2R of hippocampal interneurons modulates the activity of the hippocampal network. Ultimately this work should provide a better understanding of mnesic deficiency observed in dopaminergic transmission dysfunctions.

ELUCIDATING HOW NON-NEURONAL ACTION POTENTIALS GENERATED BY MIDLINE RADIAL GLIA INITIATE MOTOR BEHAVIOUR

POSTER SESSION 03 - SECTION: NEURONS AND GLIA: CELL EXCITABILITY

Agathe Lafont, Kalaimakan Arulkandarajah, Hervé Le Corronc, Christine Mouffle, Pascal Legendre, Jean-Marie Mangin
INSERM / Sorbonne Université / CNRS, Laboratoire Neuroscience Paris Seine, Paris, France

In the vertebrate spinal cord, waves of spontaneous neuronal activity (SNA) trigger the first motor behavior - around 12 days of embryonic development in mice - and play a critical role in the development of the neuromuscular system. However, it remains unclear how these waves of electrical activity are generated and propagate along the spinal cord at a stage when the first synapses are just starting to form. Our team recently demonstrated that midline radial glia located in the floor-plate have the unique ability to generate calcium action potentials (AP) via T-type voltage-gated calcium channels and to propagate them through gap-junctions along the spinal cord. In order to study the influence of radial glia APs on neurons during SNA, we visualized neuronal activity by calcium imaging using the Rhod2-AM indicator. We discovered that SNA events not only propagate rostro-caudally but also along a medio-lateral sequence starting from the midline. Using a transgenic line that expresses the genetically encoded calcium indicator GCaMP6f in spinal motoneurons, we showed that motoneuron columns were sequentially activated from the midline during SNA. Application of TTA-P2, a T-type calcium channel blocker, or β18-GA, a gap-junction blocker, abolished this medio-lateral activation of motor columns and strongly decrease SNA propagation speed along the rostro-caudal axis. Finally, we found that specific optogenetic stimulation of midline radial glia was sufficient to trigger SNA events in spinal neurons. In conclusion, our results suggest that radial glia excitability is responsible for patterning motoneuron activity and initiating the first motor behavior in vertebrates.

THERAPEUTIC EFFECT OF HIF PROLYL HYDROXYLASE (PHD) INHIBITION IN AN IN VITRO HYPOXIA MODEL

POSTER SESSION 03 - SECTION: NEURONS AND GLIA: CELL EXCITABILITY

Mariya Savyuk[1], Alexey Poloznikov[2], Elena Mitroshina[1], Mariya Vedunova[1]
[1]Lobachevsky University, Ibbm, Nizhny Novgorod, Russian Federation, [2]High School of Economics, Faculty Of Biology And Biotechnology, Moskow, Russian Federation

It is well known that hypoxia is crucial to stroke and contributes to neurodegeneration in traumas, Alzheimer's, etc. HIF-1 dimerization is a trigger for adaptation and survival nervous cells in hypoxia. Under normal conditions, the dimerization does not occur because of the work of the PHD. The aim of the work was studying the effects of PHD inhibition on the neuron-glial network calcium activity under hypoxia modelling in vitro. The research was carried out on primary hippocampal cultures obtained from mouse embryos (E18). Modeling of hypoxia in vitro was performed on 14 DIV. In vitro treatment of the of the PHD low molecular weight inhibitor D014-0030 (1 μM) was performed 2 hours after hypoxia modeling and then daily. The calcium imaging was executed on 21 DIV. We analyzed both individual parameters of calcium events (duration, frequency of calcium oscillations) and general network parameters (signal speed, the degree of calcium signal correlation etc.). Intact cultures activity are highly correlated (correlation 0.51±0.04). This is consistent with the data on the functioning of normal neuron-glial cultures on the 21st day cultivation. There is a significant degradation of network effects in the "Hypoxia" group (correlation level 1.45±0.71). The PHD inhibitor treatment cause the effect of mainteined the degree of correlation of calcium dynamics in neighboring cells but not in distantly located cells and increased the number of working cells, suggesting a potential for network recovery. This research was funded by the Ministry of Science and Higher Education of the Russian Federation (0729-2020-0061).

Hypoxia-Inducible Factor (HIF) in Ischemic Stroke and Neurodegenerative Disease.
Hypoxia is one of the most common pathological conditions, which can be induced by multiple events, including ischemic injury, trauma, inflammation, tumors, etc. The body's adaptation to hypoxia is a highly important phenomenon in both health and disease. Most cellular responses to hypoxia are associated with a family of transcription factors called hypoxia-inducible factors (HIFs), which induce the expression of a wide range of genes that help cells adapt to a hypoxic environment. Basic mechanisms of adaptation to hypoxia, and particularly HIF functions, have being extensively studied over recent decades, leading to the 2019 Nobel Prize in Physiology or Medicine. Based on their pivotal physiological importance, HIFs are attracting increasing attention as a new potential target for treating a large number of hypoxia-associated diseases. Most of the experimental work related to HIFs has focused on roles in the liver and kidney. However, increasing evidence clearly demonstrates that HIF-based responses represent an universal adaptation mechanism in all tissue types, including the central nervous system (CNS). In the CNS, HIFs are critically involved in the regulation of neurogenesis, nerve cell differentiation, and neuronal apoptosis. In this mini-review, we provide an overview of the complex role of HIF-1 in the adaptation of neurons and glia cells to hypoxia, with a focus on its potential involvement into various neuronal pathologies and on its possible role as a novel therapeutic target.

Double-Edged Sword of Vitamin D3 Effects on Primary Neuronal Cultures in Hypoxic States.
The use of vitamin D3 along with traditional therapy opens up new prospects for increasing the adaptive capacity of nerve cells to the effects of a wide range of stress factors, including hypoxia-ischemic processes. However, questions about prophylactic and therapeutic doses of vitamin D3 remain controversial. The purpose of our study was to analyze the effects of vitamin D3 at different concentrations on morpho-functional characteristics of neuron-glial networks in hypoxia modeling in vitro. We showed that a single administration of vitamin D3 at a high concentration (1 μM) in a normal state has no significant effect on the cell viability of primary neuronal cultures; however, it has a pronounced modulatory effect on the functional calcium activity of neuron-glial networks and causes destruction of the network response. Under hypoxia, the use of vitamin

D3 (1 μM) leads to total cell death of primary neuronal cultures and complete negation of functional neural network activity. In contrast, application of lower concentrations of vitamin D3 (0.01 μM and 0.1 μM) caused a pronounced dose-dependent neuroprotective effect during the studied post-hypoxic period. While the use of vitamin D3 at a concentration of 0.1 μM maintained cell viability, preventive administration of 0.01 μM not only partially preserved the morphological integrity of primary neuronal cells but also maintained the functional structure and activity of neuron-glial networks in cultures. Possible molecular mechanisms of neuroprotective action of vitamin D3 can be associated with the increased expression level of transcription factor HIF-1α and maintaining the relationship between the levels of BDNF and TrkB expression in cells of primary neuronal cultures.

Neuroprotective Effect of Kinase Inhibition in Ischemic Factor Modeling In Vitro.
The contribution of many neuronal kinases to the adaptation of nerve cells to ischemic damage and their effect on functional neural network activity has not yet been studied. The aim of this work is to study the role of the four kinases belonging to different metabolic cascades (SRC, Ikkb, eEF2K, and FLT4) in the adaptive potential of the neuron-glial network for modeling the key factors of ischemic damage. We carried out a comprehensive study on the effects of kinases blockade on the viability and network functional calcium activity of nerve cells under ischemic factor modeling in vitro. Ischemic factor modelling was performed on day 14 of culturing primary hippocampal cells obtained from mouse embryos (E18). The most significant neuroprotective effect was shown in the blockade of FLT4 kinase in the simulation of hypoxia. The studies performed revealed the role of FLT4 in the development of functional dysfunction in cerebrovascular accidents and created new opportunities for the study of this enzyme and its blockers in the formation of new therapeutic strategies.

Signatures of the Consolidated Response of Astrocytes to Ischemic Factors In Vitro.
Whether and under what conditions astrocytes can mount a collective network response has recently become one of the central questions in neurobiology. Here, we address this problem, investigating astrocytic reactions to different biochemical stimuli and ischemic-like conditions in vitro. Identifying an emergent astrocytic network is based on a novel mathematical approach that extracts calcium activity from time-lapse fluorescence imaging and estimates the connectivity of astrocytes. The developed algorithm represents the astrocytic network as an oriented graph in which the nodes correspond to separate astrocytes, and the edges indicate high dynamical correlations between astrocytic events. We demonstrate that ischemic-like conditions decrease network connectivity in primary cultures in vitro, although calcium events persist. Importantly, we found that stimulation under normal conditions with 10 μM ATP increases the number of long-range connections and the degree of corresponding correlations in calcium activity, apart from the frequency of calcium events. This result indicates that astrocytes can form a large functional network in response to certain stimuli. In the post-ischemic interval, the response to ATP stimulation is not manifested, which suggests a deep lesion in functional astrocytic networks. The blockade of Connexin 43 during ischemic modeling preserves the connectivity of astrocytes in the post-hypoxic period.

Neuroprotective Effect of HIF Prolyl Hydroxylase Inhibition in an In Vitro Hypoxia Model.
A novel potent analog of the branched tail oxyquinoline group of hypoxia-inducible factor (HIF) prolyl hydroxylase inhibitors, neuradapt, has been studied in two treatment regimes in an in vitro hypoxia model on murine primary hippocampal cultures. Neuradapt activates the expression of HIF1 and HIF2 target genes and shows no toxicity up to 20 μM, which is more than an order of magnitude higher than its biologically active concentration. Cell viability, functional activity, and network connectivity between the elements of neuronal networks have been studied using a pairwise correlation analysis of the intracellular calcium fluctuations in the individual cells. An immediate treatment with 1 μM and 15 μM neuradapt right at the onset of hypoxia not only protects from the death, but also maintains the spontaneous calcium activity in nervous cells at the level of the intact cultures. A similar neuroprotective effect in the post-treatment scenario is observed for 15 μM, but not for 1 μM neuradapt. Network connectivity is better preserved with immediate treatment using 1 μM neuradapt than with 15 μM, which is still beneficial. Post-treatment with neuradapt did not restore the network connectivity despite the observation that neuradapt significantly increased cell viability at 1 μM and functional activity at 15 μM. The preservation of cell viability and functional activity makes neuradapt promising for further studies in a post-treatment scenario, since it can be combined with other drugs and treatments restoring the network connectivity of functionally competent cells.

VISUALIZATION AND QUANTITATIVE ANALYSIS OF NANOSCALE PHOSPHOINOSITIDE DISTRIBUTION ON NEURONAL CELL MEMBRANES OF MOUSE CEREBELLUM AT ELECTRON MICROSCOPIC LEVEL

POSTER SESSION 03 - SECTION: NEURONS AND GLIA: CELL EXCITABILITY

Kohgaku Eguchi, Ryuichi Shigemoto
Institute of Science and Technology Austria, Molecular Neuroscience, Klosterneuburg, Austria

Phosphoinositides (PIs) play essential roles in many aspects of neuronal functions. Although it is important to know how PIs distribute on neuronal membranes to understand their roles, this has not yet been investigated at the electron microscopic level. In this study, we aimed to observe the nanoscale distribution of a PI stereoisomer, phosphatidylinositol-4,5-bisphosphate ($PI(4,5)P_2$), on neuronal cell membranes and to address their potential roles in neuronal activities using SDS-digested freeze-fracture replica labeling method with a GST-tagged pleckstrin homology domain of phospholipase Cδ1 as a specific probe for $PI(4,5)P_2$. Using replicas of mouse cerebellar tissues, we found that gold particles for $PI(4,5)P_2$ make clusters broadly distributed on the cytoplasmic side of Purkinje cells (PCs) and parallel fiber (PF) bouton membranes. $PI(4,5)P_2$ was concentrated at active zones and co-localized with P/Q-type Ca^{2+} channels in PF boutons, indicating that $PI(4,5)P_2$ may contribute to the regulation of synaptic vesicle release. In the PC dendrites, $PI(4,5)P_2$ was co-localized with a metabotropic glutamate receptor mGluR1α and a G protein-gated inward-rectifying potassium channel subunit GIRK3. The co-localization of $PI(4,5)P_2$ with mGluR1α is selective to spines and may be necessary for the effective second messenger production upon the receptor activation and its coupling to PLC. The $PI(4,5)P_2$ distribution close to GIRK3 also suggests its potential role in the regulation of PC excitability, as PIP_2 has been reported to induce conformational changes in GIRKs. Manipulation of the co-localization between $PI(4,5)P_2$ and those key molecules would be useful to elucidate the potential implications of our present findings.

Accurate working memory performance depends on neuromodulatory systems functioning within a narrow range of concentrations. In the case of dopamine and noradrenaline, for example, both excessive activation and suppression of these systems are linked to working memory deficits. These deficits are accompanied by suppression of persistent firing, a potential mechanism of working memory in which a cell retains task relevant information by continuing to fire during the delay period between the stimulus and the learned response. However, the effect of neuromodulation on persistent firing at the single cell level is not yet fully understood. Additionally, these neuromodulatory systems have predominantly been studied in the prefrontal cortex, a brain region long thought to play the role of central executive in complex cognitive function. However, they are relatively sparsely investigated in sensory cortex, despite evidence that persistent firing also occurs in sensory cortices and may play an important role in working memory. In this study, we used whole cell patch clamp electrophysiology in ex vivo mouse auditory cortex preparations to analyze the effects of dopaminergic and noradrenergic modulation of persistent neuronal activity. The effects of these neurotransmitters were tested both alone, and in the presence of the cholinergic agonist carbachol, which is known to support long lasting persistent firing. Our results indicate that while dopamine may not have a direct effect on persistent firing in the mouse auditory cortex, norepinephrine can both enhance low levels of carbachol-supported persistent firing, and support persistent firing itself in a subset of auditory cortex cells.

THE EFFECT OF RADIOFREQUENCY ELECTROMAGNETIC FIELDS ON NEURONAL ACTIVITY: IMPLICATION OF MICROTUBULES

POSTER SESSION 03 - SECTION: NEURONS AND GLIA: CELL EXCITABILITY

Ibtissam Echchgadda[1], Anna Sedelnikova[2], Jody Cantu[3]
[1]Air Force Research Laboratory, Bioeffects Division, Radio Frequency Bioeffects Branch, Fort Sam Houston, United States of America, [2]Science Applications International Corporation, Bioeffects Division, Fort Sam Houston, United States of America, [3]General Dynamics Information Technology, Bioeffects Division, Fort Sam Houston, United States of America

Tubulin post-modifications (PTMs) play an important role in the functional diversity of microtubules (MTs). PTMs affect MT dynamics/stability, organization, and interactions with other cellular components. We previously showed that exposure to radiofrequency (RF) waves tuned to 3.0 GHz frequency altered intracellular MTs distribution in cultured neuronal cells and caused changes in neuronal excitability. Additionally, changes in the assembly and polymerization rates of MTs have been observed due to exposure to electromagnetic (EM) fields. In this study, we investigated if the observed effect on MT dynamics could be associated with changes in PTMs of tubulin and MTs. We specifically examined the effect of RF exposures at different frequencies on tubulin detyrosination, phosphorylation, and acetylation in neuronal cells. We exposed neuronal cells in an environmentally controlled EM exposure setup at three different RF frequencies for 1 hour at a constant E-field. We investigated changes following RF exposures using Western blotting, fluorescence imaging, and current- and voltage-clamp electrophysiology techniques. The exposure of neuronal cells to three tested RF frequencies showed a clear difference in the distribution of endogenous MTs. Specifically, fluorescent MTs were primarily localized within the cytoplasm compared to membrane localization in the unexposed neuronal cells. Furthermore, RF exposure affected the morphology of the cells, which exhibited reduced action potential (AP) amplitude, increased resting membrane potential, and increased spontaneous AP firing. The results also showed reduced acetylated tubulin following RF exposure, which suggest that reduced acetylation following RF exposure could be related to changes in MT dynamics and localization.

GUANOSINE MODULATES K+ MEMBRANE CURRENTS IN SH-SY5Y CELLS: INVOLVEMENT OF ADENOSINE RECEPTORS

POSTER SESSION 03 - SECTION: NEURONS AND GLIA: CELL EXCITABILITY

Giuditta Gambino, Daniele Gallo, Miriana Scordino, Giulia Urone, Giuseppe Ferraro, Giuseppa Mudò, Pierangelo Sardo, Valentina Di Liberto, Giuseppe Giglia

Background: Guanosine (GUO) is implicated in the regulation of numerous cellular processes and mediates several effects within the central nervous system. While its interaction with neural membranes has been described, GUO still is an orphan neuromodulator. Within the context of excitability control, it has been hypothesized that, among the possible cellular targets of GUO, potassium channels and adenosine (ADO) receptors (ARs) could play a major role. **Aim:** In this light, we aim to investigate the effects of GUO on the bioelectric activity of human neuroblastoma SH-SY5Y cells, which have been considered an invaluable experimental model for studying the effects of GUO in the attempt to fully uncover its role within purinergic signaling. **Methods:** We apply whole-cell patch-clamp recordings to first explore the contribution of voltage-dependent K^+ channels and, besides this, the role of ARs in the regulation of GUO-dependent cellular electrophysiology. **Results:** Our data support that GUO is able to specifically modulate K^+-dependent outward currents over cell membranes. The present findings suggest that K^+ outward membrane channels may be targeted by GUO with an implication of adenosine receptors in SH-SY5Y cells, but also support the hypothesis of a functional interaction with ADO. **Conclusions:** The present research runs through the leitmotif of the deorphanization of GUO, adding insight into the interplay with adenosinergic signaling and suggesting GUO as a powerful modulator of SH-SY5Y excitability.

CSPα/DNAJC5 IN GLUTAMATERGIC SYNAPTIC FUNCTION AND MAINTENANCE

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Cristina Mesa Cruz[1], Nozha Borjini[1,2], José Luis Nieto-González[1], Rafael Fernández-Chacón[1]
[1]Instituto de Biomedicina de Sevilla (IBiS, HUVR/CSIC/Universidad de Sevilla), Depto. De Fisiología Médica Y Biofísica & Ciberned, Sevilla, Spain, [2]Instituto de Biomedicina de Sevilla (IBiS, HUVR/CSIC/Universidad de Sevilla, Depto. De Fisiología Médica Y Biofísica & Ciberned, Sevilla, Spain

Cysteine String Protein (CSPα/DNAJC5) is a synaptic co-chaperone that prevents activity-dependent degeneration of synapses. CSPα/DNAJC5 knock-out mice suffer from a neurological phenotype and early postnatal lethality soon after the first month of age. CSPα/DNAJC5 is critical to maintain the levels of the SNARE protein SNAP25, especially in highly active synapses. Indeed, the decrease in SNAP25 levels is thought to be a key event leading to presynaptic neurodegeneration. We are interested in studying the synaptic effects of removing CSPα/DNAJC5 from adult glutamatergic neurons that operate at a low activity regime. For this purpose we have generated CaMK^{CreERT2}:Ai27D:*Dnajc5*^{flox} mice to conditionally target *Dnajc5* in adult hippocampal glutamatergic neurons. This line also expresses channelrhodopsin2 fused to the fluorescent reporter td-tomato (Ai27D) in targeted neurons. CSPα/DNAJC5 conditional knock-out mice survive and do not develop an evident neurological phenotype. We have analyzed synaptic transmission in two hippocampal synapses: (1) synapses formed by mossy fibers at CA3 pyramidal neurons (MF-CA3 synapse) and (2) synapses formed by Schaffer collaterals at CA1 pyramidal neurons (SC-CA1 synapse). Interestingly, those synapses show different phenotypes in the absence of CSPα/DNAJC5. We are investigating the molecular mechanisms of such a phenotype to understand why those apparently similar synapses have different requirement of CSPα/DNAJC5 and how those differences might be related to SNAP25. We are grateful to Prof. Angel Barco (INA) and Prof. G. Schütz (DKFZ) for kindly providing CaMK^{CreERT2} mice. Synapses operate throughout life, but synaptic proteins last only for several days or weeks. The mechanisms by which synaptic proteins are maintained are not well understood yet. We are interested in the role of the synaptic co-chaperone CSPα/DNAJC5. Conventional KO mice lacking CSPα/DNAJC5 develop presynaptic degeneration and die soon after birth, preventing studies in adulthood. We have bred mice bearing the *Dnajc5* floxed allele (Nieto Gonzalez et al. PNAS. 2019) against UBC-Cre-ERT2 mice (Ruzankina et al. Cell Stem Cell. 2007) to target *Dnajc5* ubiquitously in a time-controlled manner. CSPα/DNAJC5 is almost undetected in hippocampal cultures of *UBC-Cre-ERT2;Dnajc5*$^{flox/flox}$ mice after 13 days in tamoxifen. To investigate the function of CSPα/DNAJC5 in adulthood, we fed 2 months old *UBC-Cre-ERT2;Dnajc5*$^{flox/flox}$ mice with tamoxifen during 30 days. Two weeks after tamoxifen, they exhibited weight loss and a neurological phenotype characterized by loss of spontaneous activity, strength and motor coordination. This lead, two weeks later, to early death. The time-controlled induction of the phenotype has opened potential opportunities to rescue the phenotype that we are investigating by using viral vectors engineered to cross the blood brain-barrier to deliver CSPα/DNAJC5 to the central nervous system. We aim to define the time-window in which the rescue is feasible to unveil which dysfunctional mechanisms are amenable for restorative intervention. CORTICAL WIRING BY SYNAPSE-SPECIFIC CONTROL OF LOCAL PROTEIN SYNTHESIS

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Clémence Bernard[1,2], David Exposito-Alonso[1,2], Martijn Selten[1,2], Stella Sanalidou[1,2], Alicia Hanusz-Godoy[1,2], Beatriz Rico[1,2], Oscar Marín[1,2]

Compared to other cell types, neurons have a highly arborised morphology, and form and receive an astonishing number of synapses. It is thought that local protein synthesis has evolved in neurons as a mechanism to support this morphological complexity which requires independent control across multiple subcellular compartments. Local translation is ubiquitous in neuronal pre- and postsynaptic compartments. However, to what extent local translation is differentially regulated at the level of specific synapses during wiring of neural circuits is not known. Here we identify a dedicated signalling pathway that regulates synaptic protein synthesis for the formation of excitatory synapses on parvalbumin (PV+) interneurons in the mouse cerebral cortex. We first show that mTOR hyperactivity in interneurons leads to wiring defects in a cell type-specific and synapse-specific manner. We then find that the interneuron-specific receptor tyrosine kinase ErbB4 regulates the synaptic activity of mTOR at excitatory synapses on PV+ interneurons. By using a RiboTRAP strategy, we identify a set of synaptic proteins regulated by ErbB4. We further show that ErbB4 enhances the local synthesis of these proteins and that they are necessary for the correct wiring of cortical interneurons. Multiple lines of evidence suggest that deficits in the excitation/inhibition balance are underlying several neurodevelopmental disorders. In particular, an impaired excitatory drive on PV+ interneurons seems to be a potential hub for autism and schizophrenia. Our work deciphers a molecular mechanism by which these synapses are formed and maintained, through a synapse-specific control of local translation.

Otx2 binding to perineuronal nets persistently regulates plasticity in the mature visual cortex.
Specific transfer of (orthodenticle homeobox 2) Otx2 homeoprotein into GABAergic interneurons expressing parvalbumin (PV) is necessary and sufficient to open, then close, a critical period (CP) of plasticity in the developing mouse visual cortex. The accumulation of endogenous Otx2 in PV cells suggests the presence of specific Otx2 binding sites. Here, we find that perineuronal nets (PNNs) on the surfaces of PV cells permit the specific, constitutive capture of Otx2. We identify a 15 aa domain containing an arginine-lysine doublet (RK peptide) within Otx2, bearing prototypic traits of a glycosaminoglycan (GAG) binding sequence that mediates Otx2 binding to PNNs, and specifically to chondroitin sulfate D and E, with high affinity. Accordingly, PNN hydrolysis by chondroitinase ABC reduces the amount of endogenous Otx2 in PV cells. Direct infusion of RK peptide similarly disrupts endogenous Otx2 localization to PV cells, reduces PV and PNN expression, and reopens plasticity in adult mice. The closure of one eye during this transient window reduces cortical acuity and is specific to the RK motif, as an Alanine-Alanine variant or a scrambled peptide fails to reactivate plasticity. Conversely, this transient reopening of plasticity in the adult restores binocular vision in amblyopic mice. Thus, one function of PNNs is to facilitate the persistent internalization of Otx2 by PV cells to maintain CP closure. The pharmacological use of the Otx2 GAG binding domain offers a novel, potent therapeutic tool with which to restore cortical plasticity in the mature brain.

Toward libraries of biotinylated chondroitin sulfate analogues: from synthesis to in vivo studies.
Chondroitin sulfate-E (CS-E) oligosaccharidic analogues (di to hexa) were prepared from lactose. In these compounds, the 2-acetamido group was replaced by a hydroxyl group. This modification speeded up the synthesis, and large oligosaccharides were constructed in a few steps from a lactose-originated block. The protecting groups used were as follows; Fmoc for hydroxyl groups to be glycosylated, allyl group for anomeric position protection, and trichoroacetimidate leaving groups were used to prepare up to octasaccharides. We took advantage of the presence of allyl group to develop a click biotinylation, through its transformation into a 3-azido-2-hydroxyl propyl group in two steps (epoxidation and sodium azide epoxide opening). The biotinylating agent was a water-soluble propargylated and biotinylated triethylene glycol (PEG). By using

surface plasmon resonance (SPR), it was shown that the di-, tetra-, and hexasaccharides display a binding affinity and selectivity toward HSF/GSF and CXCL12 similar to that of CS-E. A parallel study confirmed their mimicry of natural compounds, based on the hexasaccharide interaction with Otx2, a homeodomain protein involved in brain maturation, thus validating our simplification approach to synthesize bioactive GAG.

Graded Otx2 activities demonstrate dose-sensitive eye and retina phenotypes.
In the human, mutations of OTX2 (Orthodenticle homeobox 2 transcription factor) translate into eye malformations of variable expressivity (even between the two eyes of the same individual) and incomplete penetrance, suggesting the existence of subtle thresholds in OTX2 activity. We have addressed this issue by analyzing retinal structure and function in six mutant mice with graded Otx2 activity: Otx2(+/+), Otx2(+/AA), Otx2(+/GFP), Otx2(AA/AA), Otx2(AA/GFP) and Otx2(GFP/GFP). Null mice (Otx2(GFP/GFP)) fail to develop the head and are embryonic lethal, and compound heterozygous Otx2(AA/GFP) mice show a truncated head and die at birth. All other genotypes develop until adulthood. We analyzed eye structure and visual physiology in the genotypes that develop until adulthood and report that phenotype severity parallels Otx2 activity. Otx2(+/AA) are only mildly affected whereas Otx2(+/GFP) are more affected than Otx2(+/AA) but less than Otx2(AA/AA) mice. Otx2(AA/AA) mice later manifest the most severe defects, with variable expressivity. Electrophysiological and histological analyses of the mouse retina revealed progressive death of bipolar cells and cone photoreceptors that is both Otx2 activity- and age-dependent with the same ranking of phenotypic severity. This study demonstrates the importance of gene dosage in the development of age-dependent pathologies and underscores the fact that small gene dosage differences can cause significant pathological states.

Otx2-PNN Interaction to Regulate Cortical Plasticity.
The ability of the environment to shape cortical function is at its highest during critical periods of postnatal development. In the visual cortex, critical period onset is triggered by the maturation of parvalbumin inhibitory interneurons, which gradually become surrounded by a specialized glycosaminoglycan-rich extracellular matrix: the perineuronal nets. Among the identified factors regulating cortical plasticity in the visual cortex, extracortical homeoprotein Otx2 is transferred specifically into parvalbumin interneurons and this transfer regulates both the onset and the closure of the critical period of plasticity for binocular vision. Here, we review the interaction between the complex sugars of the perineuronal nets and homeoprotein Otx2 and how this interaction regulates cortical plasticity during critical period and in adulthood.

A Mouse Model for Conditional Secretion of Specific Single-Chain Antibodies Provides Genetic Evidence for Regulation of Cortical Plasticity by a Non-cell Autonomous Homeoprotein Transcription Factor.
During postnatal life the cerebral cortex passes through critical periods of plasticity allowing its physiological adaptation to the environment. In the visual cortex, critical period onset and closure are influenced by the non-cell autonomous activity of the Otx2 homeoprotein transcription factor, which regulates the maturation of parvalbumin-expressing inhibitory interneurons (PV cells). In adult mice, the maintenance of a non-plastic adult state requires continuous Otx2 import by PV cells. An important source of extra-cortical Otx2 is the choroid plexus, which secretes Otx2 into the cerebrospinal fluid. Otx2 secretion and internalization requires two small peptidic domains that are part of the DNA-binding domain. Thus, mutating these "transfer" sequences also modifies cell autonomous transcription, precluding this approach to obtain a cell autonomous-only mouse. Here, we develop a mouse model with inducible secretion of an anti-Otx2 single-chain antibody to trap Otx2 in the extracellular milieu. Postnatal secretion of this single-chain antibody by PV cells delays PV maturation and reduces plasticity gene expression. Induced adult expression of this single-chain antibody in cerebrospinal fluid decreases Otx2 internalization by PV cells, strongly induces plasticity gene expression and reopens physiological plasticity. We provide the first mammalian genetic evidence for a signaling mechanism involving intercellular transfer of a homeoprotein transcription factor. Our single-chain antibody mouse model is a valid strategy for extracellular neutralization that could be applied to other homeoproteins and signaling molecules within and beyond the nervous system.

Genetic Otx2 mis-localization delays critical period plasticity across brain regions.
Accumulation of non-cell autonomous Otx2 homeoprotein in postnatal mouse visual cortex (V1) has been implicated in both the onset and closure of critical period (CP) plasticity. Here, we show that a genetic point mutation in the glycosaminoglycan recognition motif of Otx2 broadly delays the maturation of pivotal parvalbumin-positive (PV+) interneurons not only in V1 but

also in the primary auditory (A1) and medial prefrontal cortex (mPFC). Consequently, not only visual, but also auditory plasticity is delayed, including the experience-dependent expansion of tonotopic maps in A1 and the acquisition of acoustic preferences in mPFC, which mitigates anxious behavior. In addition, Otx2 mis-localization leads to dynamic turnover of selected perineuronal net (PNN) components well beyond the normal CP in V1 and mPFC. These findings reveal widespread actions of Otx2 signaling in the postnatal cortex controlling the maturational trajectory across modalities. Disrupted PV+ network function and deficits in PNN integrity are implicated in a variety of psychiatric illnesses, suggesting a potential global role for Otx2 function in establishing mental health.

Non-cell Autonomous OTX2 Homeoprotein Regulates Visual Cortex Plasticity Through Gadd45b/g.
The non-cell autonomous transfer of OTX2 homeoprotein transcription factor into juvenile mouse cerebral cortex regulates parvalbumin interneuron maturation and critical period timing. By analyzing gene expression in primary visual cortex of wild-type and Otx2+/GFP mice at plastic and nonplastic ages, we identified several putative genes implicated in Otx2-dependent visual cortex plasticity for ocular dominance. Cortical OTX2 infusion in juvenile mice induced Gadd45b/g expression through direct regulation of transcription. Intriguingly, a reverse effect was found in the adult, where reducing cortical OTX2 resulted in Gadd45b/g upregulation. Viral expression of Gadd45b in adult visual cortex directly induced ocular dominance plasticity with concomitant changes in MeCP2 foci within parvalbumin interneurons and in methylation states of several plasticity gene promoters, suggesting epigenetic regulation. This interaction provides a molecular mechanism for OTX2 to trigger critical period plasticity yet suppress adult plasticity.

OTX2 Non-Cell Autonomous Activity Regulates Inner Retinal Function.
OTX2 is a homeoprotein transcription factor expressed in photoreceptors and bipolar cells in the retina. OTX2, like many other homeoproteins, transfers between cells and exerts non-cell autonomous effects such as promoting the survival of retinal ganglion cells that do not express the protein. Here we used a genetic approach to target extracellular OTX2 in the retina by conditional expression of a secreted single-chain anti-OTX2 antibody. Compared with control mice, the expression of this antibody by parvalbumin-expressing neurons in the retina is followed by a reduction in visual acuity in 1-month-old mice with no alteration of the retinal structure or cell type number or aspect. The a-waves and b-waves measured by electroretinogram were also indistinguishable from those of control mice, suggesting no functional deficit of photoreceptors and bipolar cells. Mice expressing the OTX2-neutralizing antibody did show a significant doubling in the flicker amplitude and a reduction in oscillatory potential, consistent with a change in inner retinal function. Our results show that interfering with OTX2 non-cell autonomous activity in the postnatal retina leads to an alteration in inner retinal cell functions and causes a deficit in visual acuity.

Subcellular sorting of neuregulins controls the assembly of excitatory-inhibitory cortical circuits.
The assembly of specific neuronal circuits relies on the expression of complementary molecular programs in presynaptic and postsynaptic neurons. In the cerebral cortex, the tyrosine kinase receptor ErbB4 is critical for the wiring of specific populations of GABAergic interneurons, in which it paradoxically regulates both the formation of inhibitory synapses as well as the development of excitatory synapses received by these cells. Here, we found that Nrg1 and Nrg3, two members of the neuregulin family of trophic factors, regulate the inhibitory outputs and excitatory inputs of interneurons in the mouse cerebral cortex, respectively. The differential role of Nrg1 and Nrg3 in this process is not due to their receptor-binding EGF-like domain, but rather to their distinctive subcellular localization within pyramidal cells. Our study reveals a novel strategy for the assembly of cortical circuits that involves the differential subcellular sorting of family-related synaptic proteins.

OTX2 Homeoprotein Functions in Adult Choroid Plexus.
The choroid plexus is an important blood barrier that secretes cerebrospinal fluid, which essential for embryonic brain development and adult brain homeostasis. The OTX2 homeoprotein is a transcription factor that is critical for choroid plexus development and remains highly expressed in adult choroid plexus. Through RNA sequencing analyses of constitutive and conditional knockdown adult mouse models, we reveal putative functional roles for OTX2 in adult choroid plexus function, including cell signaling and adhesion, and show that OTX2 regulates the expression of factors that are secreted into the cerebrospinal fluid, notably transthyretin. We also show that expression impacts choroid plexus immune and stress

responses, and affects splicing, leading to changes in the mRNA isoforms of proteins that are implicated in the oxidative stress response and DNA repair. Through mass spectrometry analysis of OTX2 protein partners in the choroid plexus, and in known non-cell-autonomous target regions, such as the visual cortex and subventricular zone, we identify putative targets that are involved in cell adhesion, chromatin structure, and RNA processing. Thus, OTX2 retains important roles for regulating choroid plexus function and brain homeostasis throughout life.

CODING THE IDENTITY OF A SINGLE SYNAPSE TYPE: THE CLIMBING FIBER/PURKINJE CELL SYNAPSE

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Maela Paul, Fekrije Selimi
Collège de France, Cirb, Paris, France

Brain function is based on the establishment of highly stereotyped neuronal networks through precise and diverse synaptic contacts. While Sperry postulated the chemo-affinity hypothesis in the 1960s, implying a molecular combination for each synapse type, the existence and nature of this combination has not been demonstrated. We searched for the molecular combination underlying a synapse key for computation in the cerebellum and its associated motor and cognitive functions: the climbing fiber/Purkinje cell synapse. Combining neuron-specific gene expression profiling and quantitative transcriptomics in mice and bioinformatics analyses, we have identified a combination of four genes with a developmental profile and coding for proteins with structural properties coherent with their role in the specification of the climbing fiber/Purkinje cell synapse. Functional screening of these genes during postnatal development is currently performed to confirm their synaptogenic role. Our work will demonstrate the instructive role of this unique combination of presynaptic proteins for the specification of the climbing fiber/Purkinje cell synapse. This work will shed light on the rules controlling the establishment of proper network connectivity and brain function.

Neurons are the most highly compartmentalized and morphologically complex cells of the body. In particular, synapses are dynamic nanomachines composed by a unique repertoire of molecules arranged in multimolecular complexes. For this reason, their correct development and function require sophisticated mechanisms to target proteins and lipids to their site of action in the right amount at the right time. However, how this daunting task is achieved is largely unknown. Here, we focus on the role of the first stations of the secretory pathway, namely the Endoplasmic Reticulum (ER) and the Golgi Apparatus (GA), in the transport of newly synthetized neuronal proteins to their final destination. In particular, we investigate the role of the molecular diversity of SEC24, a component of the inner coat of COPII vesicles involved in cargo selection. To this aim, we developed a proteomic screen based on proximity-dependent biotinylation to identify the protein interaction networks of distinct SEC24 isoforms. Preliminary data obtained from heterologous cells and primary cultures of cortical neurons indicate that SEC24 proteins fused to the biotin ligase are enriched at the ER exit sites, interact with protein cargoes and, upon biotin administration, efficiently biotinylate proteins in an isoform-specific manner. Second, we are also investigating the subcellular localization of SEC24 isoforms in neuronal compartments to assess their potential role in directing cargoes to specific transport pathways. Together, our approaches may shed the light on the contribution of the early secretory pathway to neurodevelopment and unravel novel mechanisms underlying the formation and function of synaptic connections.

Human cortical circuit assembly is critical to neurodevelopment and higher-order cognition, but our understanding of this process is limited *in vivo*. Much remains unknown about cortical circuit assembly failure in neurodevelopmental conditions such as Down Syndrome (DS). We recently used transplanted donor-derived induced pluripotent stem cells and longitudinal imaging to find that DS grafts have increased synaptic structural stability and decreased neuronal oscillatory activity. These changes could help explain some DS cognitive symptoms. Here, we investigate the mechanisms of such alterations, focusing on cell-type composition. Immunohistochemistry indicated that DS and isogenic control cortical grafts contain equivalent distributions of immature neurons (Pax6+, Ki67+) and deep layer excitatory neurons (Tbr1+, Ctip2+). However, we found an overproduction of astrocytes (GFAP+) and a reduction in upper layer cortical neurons (SATB2+) in DS grafts. We reasoned that differences in cell-type proportions could underlie previously detected changes in synaptic turnover and neural network activity. Therefore, we normalised the contribution of SATB2+ and GFAP+ cells by modifying induction and differentiation protocols. We monitored subsequent neural network activity and synaptic stability with 2-photon microscopy. Importantly, the turnover rate of axonal en-passant boutons at 3-5 months post-transplantation (mpt) and the frequency and amplitude of somatic calcium fluctuations at 1-3-5-7 mpt were not different between genotypes when comparable proportions of GFAP+ and SATB2+ cells were present. Future work will attempt to isolate individual contributions of GFAP+ and SATB2+ cells. Rescue experiments will be performed on each cell type separately, and effects on synaptic stability and neural activity will be analyzed.

PSYCHOSIS RISK CANDIDATE ZNF804A - A KEY PLAYER IN SYNAPTOGENESIS BY REGULATING PROTEIN SYNTHESIS?

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Laura Sichlinger, Afra Aabdien, Pooja Raval, Anthony Vernon, Deepak Srivastava
Institute of Psychiatry, Psychology and Neuroscience, King's College London, Department Of Basic And Clinical Neuroscience, London, United Kingdom

Genome wide association studies identified a robust link for schizophrenia and variants of ZNF804A. Previous literature implicated ZNF804A in multiple cellular processes including protein synthesis, synapse maintenance and formation, and activity-dependent signalling. Further, gene expression peaks during the second trimester of foetal development indicating a critical role for the susceptibility gene during neurodevelopment. However, the exact mode of action mediating these processes remains to be elucidated. In this study, human induced pluripotent stem cell-derived immature neurons combined with a CRISPR/Cas9 approach were used to evaluate ZNF804A functioning during synaptogenesis. Bulk RNA sequencing of immature neurons carrying a mutation in the gene revealed a strong association with cell adhesion molecules. Interestingly, a high-throughput imaging approach showed that not only pre- and postsynaptic protein expression was affected by ZNF804A mutations but also expression of ribosomal proteins. Furthermore, translational efficiency is decreased in mutation lines indicating a crucial role for ZNF804A in translational control. This seems to be governed by disruptions of the Erk1/2 pathway leading to dysregulation of translation initiation factors such as ribosomal protein S6 and initiation factor 4E binding protein (4EBP). These findings indicate a critical role for ZNF804A in protein synthesis initiation by mediating Erk1/2 signalling cascades downstream of cell adhesion molecules. Determining specific neurobiological functioning of genetic risk factors may help to decipher the underlying aetiology of complex disorders such as schizophrenia and may provide targets for future therapeutic interventions.

Human neurons of the neocortex are morphologically more complex than those of other species including great apes. Their dendrites are more ramified, they form more synaptic connections and develop over longer time scales. These features reflect human-specific regulations of neuronal morphogenesis and synaptic development. Yet their molecular underpinning is poorly understood. Here, we characterize the role of *FRMPD2B* (FERM and PDZ Domain containing 2B), a human-specific gene almost exclusively expressed in excitatory neurons of the neocortex. *FRMDP2B* is the product of a partial gene duplication that occurred during the transition between *Autralopithecus* and *Homo*. Using whole-length transcript nanopore sequencing, we show that *FRMPD2B* encodes a 320 amino-acids protein corresponding to the C-terminus of the ancestral copy FRMPD2A. When sparsely expressed in mouse layer 3 cortical pyramidal neurons, FRMPD2B increases dendritic branching and spine density. FRMPD2B localizes to and regulates endolysosomes, organelles that play a key role in proteostasis. Together, our results suggest that *FRMPD2B* has contributed to human neuron and cortical circuit evolution through unique regulations of the endolysosomal pathway.

A MICROFLUIDIC BASED IN VITRO MODEL TO RECONSTRUCT THE CORTICOSTRIATAL SYNAPSE IN THE STUDY OF HUNTINGTON'S DISEASE

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Clelia Introna
university of Barcelona, Biomedicine, Barcelona, Spain

Aim Huntington's disease (HD) is a severe neurodegenerative characterized by the selective loss of Medium Spiny Neurons (MSNs) within the Caudate/Putamen brain nuclei. These neurons promotes initiation of movements and are highly interconnected with several areas of the brain as the cortex. To better understand how this connection is degraded in HD and enable testing of potential new treatments, we have combined the advantages of microfluidic devices and human pluripotent stem cell (hPSC) differentiation, building a model that allows the *in vitro* study of the human pathology, by modelling the cortico-striatal circuit affected in HD. **Methods:** Our new microfluidic device was built by culturing hPSC-derived cortical cells and MSNs in different compartments interconnected by microchannels for axon isolation. **Results:** We showed that cortical and striatal neurons remain isolated in their respective compartments. Furthermore, we demonstrated that the two cultures can be seeded and maintained in parallel with two different differentiation protocols during a time long enough to allow the completion of hPSC differentiation into mature neurons and stablish synaptic connections. Moreover, the device correctly allows MSN differentiation from HD patient-derived hPSCs which survived and were targeted by glutamatergic projections, coming from the cortical compartment and passing through the microfluidic channels. **Conclusions:** Our microfluidic devices represent a suitable model for uncovering mechanisms of altered development in HD would allow a better understanding of early phases of the pathology and contribute to find out new therapeutic targets that could be addressed in its very premature stages to prevent the neurodegeneration of MSNs.

Inflammatory cytokines such as interferon gamma (IFNg) are thought to be an important link between maternal immune activation and disrupted brain and behavioral development. Previously, we showed that acute exposure of cultured human neurons and neuroprogenitors to IFNg results in altered cellular morphology and gene expression phenotypes that resemble those in neurodevelopmental disorders, including downregulated expression of presynaptic genes associated with synaptic vesicles. We further extend this work using a neurogenin 2 (*NGN2*) optimized inducible overexpression ioGlutamatergic cell line, which allows accelerated differentiation of glutamatergic neurons. We studied the effects of IFNg on synaptic gene and protein expression at a very early phase of synaptogenesis, finding multiple effects even in the absence of glial cells. We found using quantitative PCR that acute IFNg exposure results in significantly increased major histocompatibility complex I (*MHCI*) gene expression. Consistent with this, immunocytochemistry showed there was increased MHCI protein expression. MHCI is thought to regulate synapse number and plasticity. We also observed increased expression of complement component 4A (*C4A*) mRNA. In parallel, there was decreased synapsin I protein in the neurons, but no effect on expression of select synaptic genes. IFNg is known to act through JAK-STAT signaling, although several signaling pathways are thought to be activated in parallel. We have thus tested whether JAK-STAT signaling mediates these various protein and RNA-level changes. The *NGN2* inducible expression line could thus be used to further understand the intrinsic effects of IFNg on glutamatergic neurons and how this may contribute to neurodevelopmental disorder-associated phenotypes.

Combined Atoh1 and Neurod1 Deletion Reveals Autonomous Growth of Auditory Nerve Fibers.
Ear development requires the transcription factors ATOH1 for hair cell differentiation and NEUROD1 for sensory neuron development. In addition, NEUROD1 negatively regulates Atoh1 gene expression. As we previously showed that deletion of the Neurod1 gene in the cochlea results in axon guidance defects and excessive peripheral innervation of the sensory epithelium, we hypothesized that some of the innervation defects may be a result of abnormalities in NEUROD1 and ATOH1 interactions. To characterize the interdependency of ATOH1 and NEUROD1 in inner ear development, we generated a new Atoh1/Neurod1 double null conditional deletion mutant. Through careful comparison of the effects of single Atoh1 or Neurod1 gene deletion with combined double Atoh1 and Neurod1 deletion, we demonstrate that NEUROD1-ATOH1 interactions are not important for the Neurod1 null innervation phenotype. We report that neurons lacking Neurod1 can innervate the flat epithelium without any sensory hair cells or supporting cells left after Atoh1 deletion, indicating that neurons with Neurod1 deletion do not require the presence of hair cells for axon growth. Moreover, transcriptome analysis identified genes encoding axon guidance and neurite growth molecules that are dysregulated in the Neurod1 deletion mutant. Taken together, we demonstrate that much of the projections of NEUROD1-deprived inner ear sensory neurons are regulated cell-autonomously.

SYNAPTIC RELEASE POTENTIATION AT AGING AUDITORY HAIR CELL RIBBON SYNAPSES

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Thibault Peineau[1], Yohan Bouleau[1,2], Didier Dulon[2]

Age-related hearing loss (ARHL or presbycusis), manifested by a decrease in speech intelligibility in noisy environment, is the most prevalent form of sensory disability in human populations. ARHL is often found associated with hyperacusis, a highly debilitating condition that can be defined as an exacerbated noise sensitivity. The mechanisms of ARHL-associated hyperacusis remain essentially unknown, in particular we don't know whether it finds its origin at peripheral or central synapses. Here, we characterized this aging process in inner hair cell (IHCs) ribbon synapses of C57BL/6J mice, a strain which is known to carry a cadherin23 mutation and experiences early hearing loss with age. These mice, while displaying a large increase in auditory thresholds due to 50 % loss of IHC afferent synaptic ribbons at middle age (postnatal day 365), paradoxically show enhanced acoustic startle reflex suggesting a hyperacusis-like response. Ca^{2+} imaging in aging IHCs indicated larger presynaptic Ca^{2+} microdomains and an increased capacity to sustain high rate of exocytosis. This exocytotic potentiation was linked to larger presynaptic ribbon structures, higher density of Ca^{2+} channels and larger postsynaptic AMPA GLUA2 receptor clusters. In addition, the fast repolarizing BK currents of IHCs, known to negatively control transmitter release, was severely decreased. In conclusions, our study brings novel evidence that points to the origin of ARHL and hyperacusis at the peripheral cochlear ribbon synapses, the very first synaptic afferent relay from cochlear hair cells whose function become abnormally potentiated with aging. This work is supported by the Fondation Pour l'Audition and Entendre SAS

PHYSICAL ACTIVITY ADAPTS THE BDNF/TRKB SIGNALLING TOWARDS A MOLECULAR FATIGUE-RESISTANT PHENOTYPE AT THE NMJ

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Laia Just Borràs[1], Victor Cilleros-Mañé[1], Aleksandra Polishchuk[1], Marta Balanyà Segura[1], Olivier Biondi[2], Frédéric Charbonnier[2], Marta Tomàs[1], Neus García[1], Josep Tomàs[1], Maria Angel Lanuza[1]

Several motor units innervate the set of myocytes in one muscle to generate a complete contraction in accordance with its functional requirements. Exercise improves resistance to fatigue and reinforces neuroprotective mechanisms in central and peripheral nervous system. In particular, TrkB signalling is a retrograde neurotrophic signalling tightly related with this process at the neuromuscular junction (NMJ), as it is involved in ACh release control, influencing both the neurotrophic and synaptic control. This study analyses the adaptations of the BDNF/TrkB signalling in the skeletal muscle as an intermediate step between physical activity and morphological changes. To do it, B6SJLF1/J mice were trained between 70 and 115 days of age following either running or swimming protocols, 20 minutes, 5 days/week. Western blotting of plantaris muscle was used to characterize the full pathway and immunofluorescence served to morphometrically analyse NMJ and characterise motor neurons size and number in lumbar spinal cord sections. Results report that TrkB signalling shifts from a fast to a slow molecular phenotype in the plantaris muscle, proportionally to the intensity of the training protocol. In accordance, NMJ area also increased proportionally to the intensity of the training protocol. On the other hand, exercise did not modify soma size with exercise. Thus, TrkB signalling seems to mediate for the beneficial effects of exercise at the NMJ due to the triggering of a molecular shift towards a resistant phenotype in fatigable muscles that affects NMJ morphology and that can be useful to prevent neuromuscular atrophy in diseases like Amyotrophic Lateral Sclerosis.

Running and Swimming Differently Adapt the BDNF/TrkB Pathway to a Slow Molecular Pattern at the NMJ.
Physical exercise improves motor control and related cognitive abilities and reinforces neuroprotective mechanisms in the nervous system. As peripheral nerves interact with skeletal muscles at the neuromuscular junction, modifications of this bidirectional communication by physical activity are positive to preserve this synapse as it increases quantal content and resistance to fatigue, acetylcholine receptors expansion, and myocytes' fast-to-slow functional transition. Here, we provide the intermediate step between physical activity and functional and morphological changes by analyzing the molecular adaptations in the skeletal muscle of the full BDNF/TrkB downstream signaling pathway, directly involved in acetylcholine release and synapse maintenance. After 45 days of training at different intensities, the BDNF/TrkB molecular phenotype of trained muscles from male B6SJLF1/J mice undergo a fast-to-slow transition without affecting motor neuron size. We provide further knowledge to understand how exercise induces muscle molecular adaptations towards a slower phenotype, resistant to prolonged trains of stimulation or activity that can be useful as therapeutic tools.

Running and swimming prevent the deregulation of the BDNF/TrkB neurotrophic signalling at the neuromuscular junction in mice with amyotrophic lateral sclerosis.
Nerve-induced muscle contraction regulates the BDNF/TrkB neurotrophic signalling to retrogradely modulate neurotransmission and protect the neuromuscular junctions and motoneurons. In muscles with amyotrophic lateral sclerosis, this pathway is strongly misbalanced and neuromuscular junctions are destabilized, which may directly cause the motoneuron degeneration and muscular atrophy observed in this disease. Here, we sought to demonstrate (1) that physical exercise, whose recommendation has been controversial in amyotrophic lateral sclerosis, would be a good option for its therapy, because it normalizes and improves the altered neurotrophin pathway and (2) a plausible molecular mechanism underlying its positive effect. SOD1-G93A mice were trained following either running or swimming-based protocols since the beginning of

the symptomatic phase (day 70 of age) until day 115. Next, the full BDNF pathway, including receptors, downstream kinases and proteins related with neurotransmission, was characterized and motoneuron survival was analysed. The results establish that amyotrophic lateral sclerosis-induced damaging molecular changes in the BDNF/TrkB pathway are reduced, prevented or even overcompensated by precisely defined exercise protocols that modulate TrkB isoforms and neurotransmission regulatory proteins and reduce motoneuron death. Altogether, the maintenance of the BDNF/TrkB signalling and the downstream pathway, particularly after the swimming protocol, adds new molecular evidence of the benefits of physical exercise to reduce the impact of amyotrophic lateral sclerosis. These results are encouraging since they reveal an improvement even starting the therapy after the onset of the disease.

Overview of Impaired BDNF Signaling, Their Coupled Downstream Serine-Threonine Kinases and SNARE/SM Complex in the Neuromuscular Junction of the Amyotrophic Lateral Sclerosis Model SOD1-G93A Mice.
Amyotrophic lateral sclerosis (ALS) is a chronic neurodegenerative disease characterized by progressive motor weakness. It is accepted that it is caused by motoneuron degeneration leading to a decrease in muscle stimulation. However, ALS is being redefined as a distal axonopathy, in that neuromuscular junction dysfunction precedes and may even influence motoneuron loss. In this synapse, several metabotropic receptor-mediated signaling pathways converge on effector kinases that phosphorylate targets that are crucial for synaptic stability and neurotransmission quality. We have previously shown that, in physiological conditions, nerve-induced muscle contraction regulates the brain-derived neurotrophic factor/tropomyosin-related kinase B (BDNF/TrkB) signaling to retrogradely modulate presynaptic protein kinases PKC and PKA, which are directly involved in the modulation of acetylcholine release. In ALS patients, the alteration of this signaling may significantly contribute to a motor impairment. Here, we investigate whether BDNF/TrkB signaling, the downstream PKC (cPKCβI, cPKCα, and nPKCε isoforms), and PKA (regulatory and catalytic subunits) and some SNARE/SM exocytotic machinery proteins (Munc18-1 and SNAP-25) are altered in the skeletal muscle of pre- and symptomatic SOD1-G93A mice. We found that this pathway is strongly affected in symptomatic ALS mice muscles including an unbalance between (I) BDNF and TrkB isoforms, (II) PKC isoforms and PKA subunits, and (III) Munc18-1 and SNAP-25 phosphorylation ratios. Changes in TrkB.T1 and cPKCβI are precociously observed in presymptomatic mice. Altogether, several of these molecular alterations can be partly associated with the known fast-to-slow motor unit transition during the disease process but others can be related with the initial disease pathogenesis.

PKA and PKC Balance in Synapse Elimination during Neuromuscular Junction Development.
During the development of the nervous system, synaptogenesis occurs in excess though only the appropriate connections consolidate. At the neuromuscular junction, competition between several motor nerve terminals results in the maturation of a single axon and the elimination of the others. The activity-dependent release of transmitter, cotransmitters, and neurotrophic factors allows the direct mutual influence between motor axon terminals through receptors such as presynaptic muscarinic ACh autoreceptors and the tropomyosin-related kinase B neurotrophin receptor. In previous studies, we investigated the synergistic and antagonistic relations between these receptors and their downstream coupling to PKA and PKC pathways and observed a metabotropic receptor-driven balance between PKA (stabilizes multinnervation) and PKC (promotes developmental axonal loss). However, how much does each kinase contribute in the developmental synapse elimination process? A detailed statistical analysis of the differences between the PKA and PKC effects in the synapse elimination could help to explore this point. The present short communication provides this analysis and results show that a similar level of PKA inhibition and PKC potentiation would be required during development to promote synapse loss.

M and M mAChRs activate PDK1 and regulate PKC βI and ε and the exocytotic apparatus at the NMJ.
Neuromuscular junctions (NMJ) regulate cholinergic exocytosis through the M and M muscarinic acetylcholine autoreceptors (mAChR), involving the crosstalk between receptors and downstream pathways. Protein kinase C (PKC) regulates neurotransmission but how it associates with the mAChRs remains unknown. Here, we investigate whether mAChRs recruit the classical PKCβI and the novel PKCε isoforms and modulate their priming by PDK1, translocation and activity on neurosecretion targets. We show that each M and M mAChR activates the master kinase PDK1 and promotes a particular priming of the presynaptic PKCβI and ε isoforms. M recruits both primed-PKCs to the membrane and promotes Munc18-1, SNAP-25, and MARCKS phosphorylation. In contrast, M downregulates PKCε through a PKA-dependent pathway, which inhibits Munc18-1 synthesis and PKC phosphorylation. In summary, our results discover a co-dependent balance between muscarinic autoreceptors which orchestrates the presynaptic PKC and their action on ACh release SNARE-SM mechanism. Altogether, this molecular signaling explains previous functional studies at the NMJ and guide toward potential therapeutic

targets.

The M muscarinic receptor, in association to M , regulates the neuromuscular PKA molecular dynamics.
Muscarinic acetylcholine receptor 1 subtype (M) and muscarinic acetylcholine receptor 2 subtype (M) presynaptic muscarinic receptor subtypes increase and decrease, respectively, neurotransmitter release at neuromuscular junctions. M involves protein kinase A (PKA), although the muscarinic regulation to form and inactivate the PKA holoenzyme is unknown. Here, we show that M signaling inhibits PKA by downregulating Cβ subunit, upregulating RIIα/β and liberating RIβ and RIIα to the cytosol. This promotes PKA holoenzyme formation and reduces the phosphorylation of the transmitter release target synaptosome-associated protein 25 and the gene regulator cAMP response element binding. Instead, M signaling, which is downregulated by M , opposes to M by recruiting R subunits to the membrane. The M and M reciprocal actions are performed through the anchoring protein A kinase anchor protein 150 as a common node. Interestingly, M modulation on protein expression needs M signaling. Altogether, these results describe the dynamics of PKA subunits upon M muscarinic signaling in basal and under presynaptic nerve activity, uncover a specific involvement of the M receptor and reveal the M /M balance to activate PKA to regulate neurotransmission. This provides a molecular mechanism to the PKA holoenzyme formation and inactivation which could be general to other synapses and cellular models.

The Impact of Kinases in Amyotrophic Lateral Sclerosis at the Neuromuscular Synapse: Insights into BDNF/TrkB and PKC Signaling.
Brain-derived neurotrophic factor (BDNF) promotes neuron survival in adulthood in the central nervous system. In the peripheral nervous system, BDNF is a contraction-inducible protein that, through its binding to tropomyosin-related kinase B receptor (TrkB), contributes to the retrograde neuroprotective control done by muscles, which is necessary for motor neuron function. BDNF/TrkB triggers downstream presynaptic pathways, involving protein kinase C, essential for synaptic function and maintenance. Undeniably, this reciprocally regulated system exemplifies the tight communication between nerve terminals and myocytes to promote synaptic function and reveals a new view about the complementary and essential role of pre and postsynaptic interplay in keeping the synapse healthy and strong. This signaling at the neuromuscular junction (NMJ) could establish new intervention targets across neuromuscular diseases characterized by deficits in presynaptic activity and muscle contractility and by the interruption of the connection between nervous and muscular tissues, such as amyotrophic lateral sclerosis (ALS). Indeed, exercise and other therapies that modulate kinases are effective at delaying ALS progression, preserving NMJs and maintaining motor function to increase the life quality of patients. Altogether, we review synaptic activity modulation of the BDNF/TrkB/PKC signaling to sustain NMJ function, its and other kinases' disturbances in ALS and physical and molecular mechanisms to delay disease progression.

Opposed Actions of PKA Isozymes (RI and RII) and PKC Isoforms (cPKCβI and nPKCε) in Neuromuscular Developmental Synapse Elimination.
During neuromuscular junction (NMJ) development, synapses are produced in excess. By sensing the activity-dependent release of ACh, adenosine, and neurotrophins, presynaptic receptors prompt axonal competition and loss of the unnecessary axons. The receptor action is mediated by synergistic and antagonistic relations when they couple to downstream kinases (mainly protein kinases A and C (PKA and PKC)), which phosphorylate targets involved in axonal disconnection. Here, we directly investigated the involvement of PKA subunits and PKC isoforms in synapse elimination.

nPKCε Mediates SNAP-25 Phosphorylation of Ser-187 in Basal Conditions and After Synaptic Activity at the Neuromuscular Junction.
Protein kinase C (PKC) and substrates like SNAP-25 regulate neurotransmission. At the neuromuscular junction (NMJ), PKC promotes neurotransmitter release during synaptic activity. Thirty minutes of muscle contraction enhances presynaptic PKC isoform levels, specifically cPKCβI and nPKCε, through retrograde BDNF/TrkB signaling. This establishes a larger pool of these PKC isoforms ready to promote neuromuscular transmission. The PKC phosphorylation site in SNAP-25 has been mapped to the serine 187 (Ser-187), which is known to enhance calcium-dependent neurotransmitter release in vitro. Here, we localize SNAP-25 at the NMJ and investigate whether cPKCβI and/or nPKCε regulate SNAP-25 phosphorylation. We also investigate whether nerve and muscle cell activities regulate differently SNAP-25 phosphorylation and the involvement of BDNF/TrkB signaling. Our results demonstrate that nPKCε isoform is essential to positively regulate SNAP-25 phosphorylation on Ser-187 and that muscle contraction prevents it. TrkB and cPKCβI do not regulate SNAP-25 protein level

or its phosphorylation during neuromuscular activity. The results provide evidence that nerve terminals need both pre- and postsynaptic activities to modulate SNAP-25 phosphorylation and ensure an accurate neurotransmission process.

BDNF-TrkB Signaling Coupled to nPKCε and cPKCβI Modulate the Phosphorylation of the Exocytotic Protein Munc18-1 During Synaptic Activity at the Neuromuscular Junction.
Munc18-1, a neuron-specific member of the Sec1/Munc18 family, is involved in neurotransmitter release by binding tightly to syntaxin. Munc18-1 is phosphorylated by PKC on Ser-306 and Ser-313 which reduces the amount of Munc18-1 able to bind syntaxin. We have previously identified that PKC is involved in neurotransmitter release when continuous electrical stimulation imposes a moderate activity on the NMJ and that muscle contraction through TrkB has an important impact on presynaptic PKC isoforms levels, specifically cPKCβI and nPKCε. Therefore, the present study was designed to understand how Munc18-1 phosphorylation is affected by (1) synaptic activity at the neuromuscular junction, (2) nPKCε and cPKCβI isoforms activity, (3) muscle contraction , and (4) the BDNF/TrkB signaling in a neuromuscular activity-dependent manner. We performed immunohistochemistry and confocal techniques to evidence the presynaptic location of Munc18-1 in the rat diaphragm muscle. To study synaptic activity, we stimulated the phrenic nerve (1 Hz, 30 min) with or without contraction (abolished by μ-conotoxin GIIIB). Specific inhibitory reagents were used to block nPKCε and cPKCβI activity and to modulate the tropomyosin receptor kinase B (TrkB). Main results obtained from Western blot experiments showed that phosphorylation of Munc18-1 at Ser-313 increases in response to a signaling mechanism initiated by synaptic activity and directly mediated by nPKCε. Otherwise, cPKCβI and TrkB activities work together to prevent this synaptic activity-induced Munc18-1 phosphorylation by a negative regulation of cPKCβI over nPKCε. Therefore, a balance between the activities of these PKC isoforms could be a relevant cue in the regulation of the exocytotic apparatus. The results also demonstrate that muscle contraction prevents the synaptic activity-induced Munc18-1 phosphorylation through a mechanism that opposes the TrkB/cPKCβI/nPKCε signaling.

LSD1 (KDM1a) is an enzyme that, associated with co-repressors such as CoREST (RCOR1), erases activating epigenetic marks to repress transcription of a plethora of neuronal genes. LSD1 has a neuronal variant, neuroLSD1, which differs from the ubiquitous LSD1 (uLSD1) by a 4-amino acid microdomain. neuroLSD1 exerts less transcriptional repressive capacity than uLSD1, allowing it to be proposed as a dominant-negative for the actions of uLSD1. neuroLSD1 and uLSD1 coexist in a ratio of about 50%, which is rapidly and transiently modified by neuronal activity. NeuroLSD1-null mice were shown to be less responsive to stress and exhibit altered synaptic plasticity, suggesting that neuroLSD1 might regulate dopaminergic neurotransmission. To test this idea, we studied basal and amphetamine (AMPH)-induced dopamine efflux in the nucleus accumbens (NAc) of wild-type (WT) and neuroLSD1-null mice. Fast scan cyclic voltammetry (FSCV) and microdialysis were used to assess dopamine efflux. Basal synaptic dopamine levels in the NAc were similar in WT mice and null for neuroLSD1. However, AMPH-induced dopamine efflux was lower in NAc from neuroLSD1-null mice than in WT mice, as studied with FSCV and microdialysis. The tissue content of dopamine in the striatum was similar in both genotypes. Taken together, our data show that neuroLSD1 is involved in the dopaminergic response to psychostimulants.

THE ROLE OF ACTIVE ZONE-ATTACHED SYNAPTIC RIBBONS IN VESICLE RELEASE DURING CONE PHOTORECEPTOR DEVELOPMENT

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Adam Davison, Kaspar Gierke, Johann Helmut Brandstätter, Norbert Babai
Friedrich-Alexander-Universität Erlangen-Nürnberg, Animal Physiology, Department Of Biology, Erlangen, Germany

The presence of synaptic ribbons at photoreceptor terminal active zones (AZ) was first shown more than half a century ago, but their exact function in regulating synaptic vesicle (SV) release is still unsolved. Here, we have investigated the effect of the attachment of the synaptic ribbon to the AZ on the physiological properties of SV release during postnatal cone photoreceptor development. We used a combination of patch-clamp recordings of mouse cone photoreceptors and postsynaptic horizontal cells alongside electrical stimulation and pharmacological interventions. The developmental switch from free-floating to AZ-attached cone photoreceptor synaptic ribbons was measured using a combination of electron microscopy and immunocytochemistry. The main change occurred between the day when synaptic ribbons first appear at the AZ and the eye-opening period. Our measurements suggest that the increase in the number of AZ-attached synaptic ribbons increases the readily releasable SV pool in cone photoreceptors. We also found that SV release kinetics, SV replenishment rate and Ca^{2+} sensitivity of evoked SV release were significantly altered through the developmental appearance of AZ-attached synaptic ribbons. These results suggest that the synaptic ribbon has an important role in shaping the physiological parameters of evoked SV release, which probably help to satisfy the high demand for continuous and fast signaling to postsynaptic neurons during visual information processing.

MOLECULAR AND ULTRASTRUCTURAL ANALYSIS OF DOPAMINE SYNAPSES CONTACTING CORTICO-STRIATAL GLUTAMATERGIC SYNAPSES

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Paul Lapios[1], Vincent Paget-Blanc[1], Robin Anger[2], Etienne Herzog[1], Rémi Fronzes[2], David Perrais[1]

Dopamine is an essential neuromodulator involved in reward and motor control in the striatum which are altered in Parkinson's disease and addiction. Dopamine contained in vesicles is released by axons and binds to metabotropic receptors to modulate glutamate and GABA transmission onto Spiny Projection Neurons (SPNs). However, the basic features of dopamine release sites, e.g. their location relative to receptors and other neuronal processes, are still largely unknown. We have shown recently with fluorescent tagging of dopaminergic neurons, sorting of synaptosomes with flow cytometry (FASS) and quantitative analysis with immunocytochemistry, that a vast proportion of dopaminergic varicosities contact specifically glutamatergic terminals, which are themselves contacting the SPNs. We named these multipartite structures **Hub synapses**. (https://doi.org/10.1101/2020.02.18.952978) Here, our goal is to characterize the ultrastructure of hub synapses. First, we have used super-resolution microscopy (**Tau-STED**) to show that the presence of dopaminergic terminals next to cortico-striatal glutamatergic synapses correlates with an increase of the presynaptic markers VGLUT1, Bassoon and Rim1a and an altered composition of the post-synaptic proteins PSD95, Homer1a and Synaptopodin. Second, we used cryo-correlative light electron microscopy (**Cryo-CLEM**) to unravel the ultrastructure of dopaminergic-cortico-striatal hub synapses and quantify fundamental parameters, such as vesicle density, vesicle size, size of adhesion between the various hub elements. Our findings will help understanding the basic mechanisms of dopaminergic modulation in the basal ganglia.

Fluc-EGFP reporter mice reveal differential alterations of neuronal proteostasis in aging and disease.
The cellular protein quality control machinery is important for preventing protein misfolding and aggregation. Declining protein homeostasis (proteostasis) is believed to play a crucial role in age-related neurodegenerative disorders. However, how neuronal proteostasis capacity changes in different diseases is not yet sufficiently understood, and progress in this area has been hampered by the lack of tools to monitor proteostasis in mammalian models. Here, we have developed reporter mice for in vivo analysis of neuronal proteostasis. The mice express EGFP-fused firefly luciferase (Fluc-EGFP), a conformationally unstable protein that requires chaperones for proper folding, and that reacts to proteotoxic stress by formation of intracellular Fluc-EGFP foci and by reduced luciferase activity. Using these mice, we provide evidence for proteostasis decline in the aging brain. Moreover, we find a marked reaction of the Fluc-EGFP sensor in a mouse model of tauopathy, but not in mouse models of Huntington's disease. Mechanistic investigations in primary neuronal cultures demonstrate that different types of protein aggregates have distinct effects on the cellular protein quality control. Thus, Fluc-EGFP reporter mice enable new insights into proteostasis alterations in different diseases.

CHLORIDE-MEDIATED MODULATION OF GLUTAMATE RELEASE FROM PRESYNAPTIC NERVE TERMINALS ON HYPOTHALAMIC NEURONS.

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Mario Perez Del Pozo, Tatiana Kuznetsova, Michael Druzin, Staffan Johansson

Regulation of synaptic neurotransmission is essential for neural information processing but the complex mechanisms that control neurotransmitter release from presynaptic terminals are only partially understood. Here we show that spontaneous release of glutamate onto preoptic hypothalamic neurons from rat is, paradoxically, potentiated by activation of presynaptic $GABA_A$- and glycine receptors, which are known as main mediators of neuronal inhibition in the CNS. Application of selective agonists of $GABA_A$- and glycine receptors (GABA, muscimol and glycine, correspondingly) significantly increased the frequency of glutamate-mediated spontaneous excitatory postsynaptic currents (EPSCs) recorded *in vitro* with the patch-clamp technique. A depolarizing efflux of Cl^- via presynaptic $GABA_A$- and glycine receptors was best explaining this effect, suggesting a Cl^- concentration in the presynaptic terminals that is higher than previously estimated for the preoptic neuronal cell bodies. The $GABA_A$- and glycine-receptor induced potentiation of EPSC frequency was sensitive to the Na^+-channel blocker tetrodotoxin, suggesting that GABA- and glycine-evoked presynaptic depolarization *per se* was insufficient, but depended on local presynaptic action potentials, to trigger glutamate release. Blockade of Cl^- extrusion using VU 0463271, a selective antagonist of potassium-chloride cotransporter type 2 (KCC2), further augmented glutamate release in response to presynaptic activation of $GABA_A$- and glycine receptors, suggesting that KCC2 is present in presynaptic terminals and that KCC2-mediated regulation of presynaptic Cl^- homeostasis may play an important role in the control of neurotransmitter release.

Physiological function of the mammalian brain relies on the activity of excitatory and inhibitory synapses in neural circuits to precisely encode information driving cognition and behavior. Genetic alterations in proteins involved in sustaining neuronal function and structure alter the equilibrium, driving an imbalance between excitation and inhibition causing epilepsy. Leucine Rich Glioma Inactivated 1 (LGI1) protein is a secreted protein forming a synaptic bridge, and when dysfunctional causes epilepsy. Here we sought to understand how LGI1 is secreted in neurons and how its abundance at the synapse affects neuronal function. Our hypothesis is that in healthy neurons LGI1 abundance in the synapse could be controlled and modulated by neuronal activity, impacting neuronal function. To approach this long-standing question, we developed a novel optical tool named LGI1-pHluorin, which allows monitoring LGI1 surface localization and trafficking in firing synapses. Using this tool, we found that neuronal activity drives LGI1 translocation at presynaptic terminals, leading to an increased accumulation of LGI1 at the synaptic cleft of firing synapses. Increased surface LGI1 levels at single synapses result in synapse-specific reductions of action potential (AP)-driven Ca2+ entry and glutamate release, suggesting that activity-driven molecular rearrangement of LGI1 trans-synaptic bridges modulates excitatory transmission. We discovered that LGI1 vesicles had distinct properties and were not synaptic vesicles and are likely different organelles. These experiments reveal a critical role for neuronal activity in shaping the molecular architecture of trans-synaptic connections, framing future investigations into the molecular control of neurotransmission by LGI1 and other trans-synaptic molecules.

PARALLEL PROCESSING OF QUICKLY AND SLOWLY MOBILIZED RESERVE VESICLES IN HIPPOCAMPAL SYNAPSES

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Juan Jose Rodriguez Gotor[1], Kashif Mahfooz[2], Mathan K. Raja[3], John Wesseling[1]
[1]Instituto de Neurociencias, Molecular And Cellular Physiology Of Synaptic Transmission, Avenida Santiago Ramon y Cajal, s/n, Spain, [2]University of Oxford, Department Of Pharmacology, Oxford, United Kingdom, [3]CIMA, Departamento De Neurociencias, Pamplona, Spain

Synaptic vesicles within presynaptic terminals are thought to be contained within multiple readily releasable and reserve pools. A widespread premise has been that quickly and slowly mobilized reserves are connected in series. However, results from our electrophysiological studies of short-term synaptic plasticity at excitatory hippocampal synapses were not consistent with the first principles, and suggested instead that quickly and slowly mobilized reserves instead undergo exocytosis in parallel. Using FM-dyes, we now confirm the basic concept that synaptic vesicles are segregated into quickly and slowly mobilized reserves, and the prediction that the two types of reserves are mobilized in parallel. No intermixing was seen over minutes during heavy or light stimulation, providing additional constraints on future models. And, we observed extensive heterogeneity among synapses in the relative sizes of quickly and slowly mobilized reserves that may be relevant to understanding the role of synapses in information processing and storage..

Increased novelty-induced locomotion, sensitivity to amphetamine, and extracellular dopamine in striatum of Zdhhc15-deficient mice.
Novelty-seeking behaviors and impulsivity are personality traits associated with several psychiatric illnesses including attention deficits hyperactivity disorders. The underlying neural mechanisms remain poorly understood. We produced and characterized a line of knockout mice for zdhhc15, which encodes a neural palmitoyltransferase. Genetic defects of zdhhc15 were implicated in intellectual disability and behavioral anomalies in humans. Zdhhc15-KO mice showed normal spatial learning and working memory but exhibited a significant increase in novelty-induced locomotion in open field. Striatal dopamine content was reduced but extracellular dopamine levels were increased during the habituation phase to a novel environment. Administration of amphetamine and methylphenidate resulted in a significant increase in locomotion and extracellular dopamine levels in the ventral striatum of mutant mice compared to controls. Number and projections of dopaminergic neurons in the nigrostriatal and mesolimbic pathways were normal. No significant change in the basal palmitoylation of known ZDHHC15 substrates including DAT was detected in striatum of zdhhc15 KO mice using an acyl-biotin exchange assay. These results support that a transient, reversible, and novelty-induced elevation of extracellular dopamine in ventral striatum contributes to novelty-seeking behaviors in rodents and implicate ZDHHC15-mediated palmitoylation as a novel regulatory mechanism of dopamine in the striatum.

HYDROXYNORKETAMINE AND KETAMINE CONVERGE ON REGULATION OF SYNAPTIC VESICLE RELEASE COMPETENCE VIA INDEPENDENT MECHANISMS

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

[1]Universitätsklinikum Erlangen, Department Of Psychiatry And Psychotherapy, Erlangen, Germany, [2]Charles University, Third Faculty Of Medicine, Prague, Czech Republic

Major depressive disorder (MDD) is a highly prevalent and severe psychiatric disorder. Conventional medication with classical antidepressants targeting the monoaminergic system have varying degrees of efficacy in ameliorating disease symptoms, as it requires prolonged treatment and leave many patients treatment resistant. Ketamine emerged as a potent and rapidly acting antidepressant recently. It acts by modulating glutamatergic neurotransmission, via its action on NMDA and AMPA receptors. However, psychotomimetic and addictive properties of ketamine cannot be disregarded. Hydroxynorketamine (HNK) is the major metabolite of ketamine and was also shown to successfully mitigate depressive symptoms in rodent models. HNK lacks the psychotic side effects of ketamine, making it a promising candidate in neuropsychiatric research. Nonetheless, the know-how regarding effects of HNK and ketamine on critical presynaptic events that regulate neurotransmitter release remain ambiguous. In the present study, we monitored effects of HNK and ketamine on synaptic vesicle (SV) recycling at the level of individual synapses using optical imaging of electrically active mature cultured cortical neurons. We employed pharmacological and genetic tools to dissect the ketamine and HNK-induced presynaptic signalling. Our experiments revealed that ketamine and HNK, albeit acting on specific receptors and downstream signalling, converge on identical regulation of synaptic vesicle pools, directly controlling their release competence in glutamatergic and GABAergic synapses.These data provide an important mechanistic understanding of the cellular signaling that mediates antidepressant effect of ketamine and its metabolite HNK.

INDUCTION OF PHASIC NEUROTRANSMITTER RELEASE VIA PRESYNAPTIC GABAB RECEPTORS ON MEDIAL HABENULA TERMINALS

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Peter Koppensteiner[1], Pradeep Bhandari[1], Cihan Önal[1], Carolina Borges-Merjane[2], Elodie Le Monnier[1], Peter Jonas[2], Ryuichi Shigemoto[1]

Presynaptic $GABA_B$ receptors reduce neurotransmitter release at most synapses. The only known exception is the synaptic connection from the medial habenula (MHb) to the interpeduncular nucleus (IPN), where presynaptic $GABA_B$ receptors induce a massive increase in neurotransmitter release. To identify the mechanisms underlying this unusual effect of $GABA_B$ receptors, we performed whole-cell patch clamp recordings in IPN neurons in mouse brain slices and measured postsynaptic currents in response to electrical stimulation of MHb axons at room temperature. To study the structural correlate of $GABA_B$ receptor-mediated potentiation, we performed timed high-pressure freezing after optogenetic stimulation of MHb terminals (“Flash and Freeze”) in ChAT-ChR2-EYFP mice. Using freeze-fracture replication after “Flash and Freeze”, we immunolabeled vesicle-associated proteins in the presynaptic active zone. Our electrophysiological results indicate that application of the $GABA_B$ receptor agonist baclofen (1 µM) induces a transition in the mode of neurotransmitter release from tonic to phasic release. This transition was mediated by a 3.5 ± 0.6-fold increase in the readily releasable vesicle pool size, as well as a 2.3 ± 0.3-fold increase in release probability (n=17 cells; 7 mice). Structurally, phasic release was associated with a 3.5 ± 0.4-fold increase in the density of docked synaptic vesicles. Molecularly, we identified two vesicle-associated proteins selectively involved in tonic and phasic release, with synaptoporin mediating tonic release augmentation and Ca^{2+}-dependent activator for protein secretion 2 (CAPS2) mediating the priming of phasic vesicles. **Conclusions:** We identified an unexpected two-pool mechanism underlying the potentiation of neurotransmitter release following $GABA_B$ receptor activation on MHb terminals.

AGEING-ASSOCIATED ALTERATIONS IN BDNF/TRKB PATHWAY INVOLVING PKC AND SYNAPTIC TARGETS OF THE NEUROMUSCULAR JUNCTION.

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Ageing of the population in many countries around the world is one of the important challenges of modern society. Age-related conditions, such as sarcopenia or the impaired neuromuscular transmission are, currently, among the leading causes of morbidity and death worldwide. The bidirectional communication between the nervous system and muscles is fundamental for their health. Despite that the molecular mechanisms behind its regulation remain largely unknown, several signaling pathways that control neurotransmission, are crucial for this interaction. The muscle-derived Brain-derived-neurotrophic-factor (BDNF) acting through its receptor, Tropomyosin-related-kinase-B (TrkB) is well known for its neuroprotective functions and has been demonstrated that enhances presynaptic downstream effectors PKC isoforms and exocytotic proteins of synaptic vesicles (SNAP25 and Munc18-1) at the neuromuscular junction (NMJ). However, whether this signaling pathway is compromised in the aged neuromuscular system has not been analysed yet. To address it, we analyze by Western Blot how BDNF/TrkB pathway could be altered in aged Extensor digitorum longus (EDL) rat muscles. Results obtained show that in EDL muscles this signaling cascade is strongly perturbed in aging. Phosphorylation status of PKC isoforms and their exocytotic targets of synaptic vesicles that directly regulate neuromuscular activity are decreased in aged muscles. These results are in concordance with the age-related impairment of the neurotransmission. Thus, considering these results, therapeutic strategies recovering this signaling pathway function should improve NMJ functionality, slowing down the aging of the neuromuscular system and, thus, improving quality of life of aged people. A neuroendocrine pathway modulating osmotic stress in Drosophila.
Environmental factors challenge the physiological homeostasis in animals, thereby evoking stress responses. Various mechanisms have evolved to counter stress at the organism level, including regulation by neuropeptides. In recent years, much progress has been made on the mechanisms and neuropeptides that regulate responses to metabolic/nutritional stress, as well as those involved in countering osmotic and ionic stresses. Here, we identified a peptidergic pathway that links these types of regulatory functions. We uncover the neuropeptide Corazonin (Crz), previously implicated in responses to metabolic stress, as a neuroendocrine factor that inhibits the release of a diuretic hormone, CAPA, and thereby modulates the tolerance to osmotic and ionic stress. Both knockdown of Crz and acute injections of Crz peptide impact desiccation tolerance and recovery from chill-coma. Mapping of the Crz receptor (CrzR) expression identified three pairs of Capa-expressing neurons (Va neurons) in the ventral nerve cord that mediate these effects of Crz. We show that Crz acts to restore water/ion homeostasis by inhibiting release of CAPA neuropeptides via inhibition of cAMP production in Va neurons. Knockdown of CrzR in Va neurons affects CAPA signaling, and consequently increases tolerance for desiccation, ionic stress and starvation, but delays chill-coma recovery. Optogenetic activation of Va neurons stimulates excretion and simultaneous activation of Crz and CAPA-expressing neurons reduces this response, supporting the inhibitory action of Crz. Thus, Crz inhibits Va neurons to maintain osmotic and ionic homeostasis, which in turn affects stress tolerance. Earlier work demonstrated that systemic Crz signaling restores nutrient levels by promoting food search and feeding. Here we additionally propose that Crz signaling also ensures osmotic homeostasis by inhibiting release of CAPA neuropeptides and suppressing diuresis. Thus, Crz ameliorates stress-associated physiology through systemic modulation of both peptidergic neurosecretory cells and the fat body in Drosophila.

PKA-DEPENDENT SNAP-25 AND SYN-1 PHOSPHORYLATION ARE DIFFERENTLY REGULATED BY THE NEUROMUSCULAR ACTIVITY.

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Aleksandra Polishchuk, Victor Cilleros-Mañé, Laia Just Borràs, Maria Durán, Marta Balanyà Segura, Marta Tomàs, Neus García, Josep Tomàs, Maria Angel Lanuza

At the neuromuscular junction (NMJ), PKA enhances ACh release maybe phosphorylating targets from the synaptic vesicle (SV) exocytotic cycle, although this is unknown. Synaptosomal associated protein (SNAP-25), which is part of the SNARE complex, and Synapsin-1 (Syn-1), which controls the release of the SV from the cytoskeleton to promote their docking, are PKA targets that highly influence the SV exocytosis. Although ACh release mechanism is regulated by presynaptic stimulus and retrogradely by the resulting muscle contraction, PKA regulation by the pre- and postsynaptic activities had not been studied until now. To separate the effect of presynaptic activity from that of the resulting muscle contraction on PKA subunits and its activity, the rat phrenic nerve was stimulated (1Hz, 30min) with and without contraction (abolished by μ-conotoxin GIIIB). PKA was pharmacologicaly inhibitited (H-89) to assess the interactions of PKA and its targets (SNAP-25 and Syn-1). We used Western blotting and cytosol/membrane translocation by subcellular fractionation. We demonstrate that the pre- and postsynaptic activities differentially regulate the PKA subunit dynamics to be catalytic active at the NMJ and to phosphorylate SNAP-25 and Syn-1. Synaptic Cβ subunit regulated by RIIβ or RIIα subunits controls activity-dependent phosphorylation of SNAP-25 and Syn-1 respectively. Muscle contraction retrogradly downregulates presynaptic activity-induced pSyn-1 while that enhances pSNAP-25 T138. We hypothesize that both actions could coordinately contribute to decrease the neurotransmitter release at the NMJ. These results provide a molecular mechanism of the bidirectional communication between nerve terminals and muscle cell to balance the optimal process of ACh release. Funding:PID2019-106332GB-I00,2017SGR704,PRE2020-092084,2021-FI-B00755,LE1511314-2014PEJ-04,LE1911587-2019PEJ-04.

Slow-wave sleep and androgens: selective slow-wave sleep suppression affects testosterone and 17α-hydroxyprogesterone secretion.
Levels of steroid hormones such as androgens and cortisol exhibit circadian variation, and their fluctuations are related to the sleep-wake cycle. Currently, the functional role of different stages of sleep in steroid hormone secretion remains unclear. The present study aims to explore the effect of slow-wave sleep (SWS) suppression on morning levels of cortisol and androgens.

PKA and PKC Balance in Synapse Elimination during Neuromuscular Junction Development.
During the development of the nervous system, synaptogenesis occurs in excess though only the appropriate connections consolidate. At the neuromuscular junction, competition between several motor nerve terminals results in the maturation of a single axon and the elimination of the others. The activity-dependent release of transmitter, cotransmitters, and neurotrophic factors allows the direct mutual influence between motor axon terminals through receptors such as presynaptic muscarinic ACh autoreceptors and the tropomyosin-related kinase B neurotrophin receptor. In previous studies, we investigated the synergistic and antagonistic relations between these receptors and their downstream coupling to PKA and PKC pathways and observed a metabotropic receptor-driven balance between PKA (stabilizes multinnervation) and PKC (promotes developmental axonal loss). However, how much does each kinase contribute in the developmental synapse elimination process? A detailed statistical analysis of the differences between the PKA and PKC effects in the synapse elimination could help to explore this point. The present short communication provides this analysis and results show that a similar level of PKA inhibition and PKC potentiation would be required during development to promote synapse loss.

M and M mAChRs activate PDK1 and regulate PKC βI and ε and the exocytotic apparatus at the NMJ.
Neuromuscular junctions (NMJ) regulate cholinergic exocytosis through the M and M muscarinic acetylcholine autoreceptors (mAChR), involving the crosstalk between receptors and downstream pathways. Protein kinase C (PKC) regulates neurotransmission but how it associates with the mAChRs remains unknown. Here, we investigate whether mAChRs recruit the classical PKCβI and the novel PKCε isoforms and modulate their priming by PDK1, translocation and activity on neurosecretion targets. We show that each M and M mAChR activates the master kinase PDK1 and promotes a particular priming of the presynaptic PKCβI and ε isoforms. M recruits both primed-PKCs to the membrane and promotes Munc18-1, SNAP-25, and MARCKS phosphorylation. In contrast, M downregulates PKCε through a PKA-dependent pathway, which inhibits Munc18-1 synthesis and PKC phosphorylation. In summary, our results discover a co-dependent balance between muscarinic autoreceptors which orchestrates the presynaptic PKC and their action on ACh release SNARE-SM mechanism. Altogether, this molecular signaling explains previous functional studies at the NMJ and guide toward potential therapeutic targets.

TWO DISEASE-CAUSING MUTATIONS IN SNAREOPATHY GENE SNAP25 CAUSE DISTINCT NEUROTRANSMISSION IMPAIRMENTS IN HUMAN NEURONS

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Maiken Østergaard Pedersen[1], Paola Barbagallo[1], Henriette Reventlow S Frederiksen[2], Kristine Freude[2], Jakob Sørensen[1]
[1]University of Copenhagen, Department Of Neuroscience, Copenhagen, Denmark, [2]University of Copenhagen, Department Of Veterinary And Animal Sciences, Frederiksberg, Denmark

The SNARE proteins and additional regulatory proteins make up the fusion machinery responsible for precisely timed fusion of synaptic vesicles containing neurotransmitter. To date, human pathogenic *de novo* mutations have been reported for all eight core components of this fusion machinery – the so called SNAREopathy genes – giving rise to diverse neurodevelopmental syndromes, including neurodevelopmental delay, intellectual disability and epileptic encephalopathy. Despite major progress in genetics, the diagnosis and prognosis for patients carrying a SNAREopathy gene mutation are still at a rudimentary stage. There is an urgent need to establish experimental systems, ideally using human neurons, which can help unravel the underlying disease mechanisms and improve patient stratification and prognosis, and be used as a tool to develop successful treatments. In this study we generated human glutamatergic neurons by lentiviral NGN2-expression in CRISPR/Cas9-engineered iPSC lines carrying patient mutations, V48F or I67N in the SNAREopathy gene *Snap25.* Performing whole-cell patch-clamp recordings on these neurons we were able to detect disease-relevant changes in synaptic transmission and provide insight into the underlying disease mechanisms. Our results demonstrate that these pathogenic mutations lead to distinct synaptic phenotypes in human excitatory neurons. The V48F mutation leads to an increase in the frequency of spontaneous release events while impairing Ca^{2+}-triggered release, whereas the I67N mutation causes a decrease in both spontaneous and evoked fusion of synaptic vesicles and affects short-term synaptic plasticity. This indicates that disease-causing mutations in the same SNAREopathy gene can have distinct effects on neurotransmission, which can be detected in iPSC-derived human glutamatergic neurons.

SNARING A SNAREOPATHY – CHARACTERIZING THE RELEASE PHENOTYPE OF PATHOGENIC I192T AND I192N SNAP25 VARIANTS

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Victoria Amstrup Vold, Maiken Østergaard Pedersen, Anna Kádková, Jakob Sørensen
University of Copenhagen, Department Of Neuroscience, Copenhagen N, Denmark

Pathogenic mutations in genes encoding the proteins of the neuronal synaptic transmission machinery cause diseases referred to as “SNAREopathies”, which lead to neurodevelopmental disorders. Such a SNAREopathy gene is *Snap25* coding for the **syn**aptosomal-**a**ssociated **p**rotein of **25**kDa (SNAP25). Two disease-associated SNAP25 variants are I192T and I192N, which are substitutions of the same hydrophobic layer +5 residue that is critical for SNARE complex formation and stability. According to clinical reports, I192N is lethal within the first year of life whereas I192T-patients are currently in their early adolescence. To investigate these differences in terms of disease severity, the two SNAP25 variants were expressed in self-innervating glutamatergic hippocampal neurons from E18 SNAP25-knockout (KO) mice using a lentiviral expression-system. Their release phenotype was characterized by measuring synaptic transmission using patch-clamp electrophysiology. Homozygous and heterozygous conditions were mimicked by expressing the SNAP25 variants alone or in a 1:1 ratio with wild-type (WT) SNAP25, respectively. When co-expressed with the WT protein, I192N-expressing neurons, but not I192T, displayed significantly reduced evoked EPSC amplitudes. In SNAP25 KO neurons only expressing the mutation, both variants exhibited a reduced evoked EPSC amplitudes with I192N being the most severely affected. Assessing protein expression levels of I192T and I192N revealed no apparent difference compared to WT SNAP25. This indicates that the I192T exhibits mainly a loss-of-function phenotype whereas I192N exerts a dominant-negative effect, without affecting expression levels. These data show that different mutations of the same amino acid position in SNAP25 can lead to phenotypes that vary both in severity and dominance.

NEUROPLASTIC EFFECTS OF SEROTONERGIC PSYCHEDELICS AT THE PRESYNAPSE

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Aneta Petrušková[1,2,3], Debarpan Guhathakurta[3], Enes Yagiz Akdas[3], Tomáš Páleníček[1,2], Anna Fejtova[3]
[1]Charles University, Third Faculty Of Medicine, Prague, Czech Republic, [2]National Institute of Mental Health, Experimental Neurobiology, Klecany, Czech Republic, [3]Universitätsklinikum Erlangen, Department Of Psychiatry And Psychotherapy, Erlangen, Germany

Serotonergic psychedelics, including psilocybin, LSD or DMT, have been widely used to induce altered states of consciousness both in traditional rites of indigenous people as well as recreational drugs in modern societies. Recent studies suggest these substances pose significant potential for treatment of psychiatric disorders including depression, post-traumatic stress disorder or addiction. The present study focuses on the molecular mechanisms involved in the acute and persistent effects of serotonergic psychedelics on neuronal networks. We used rat cortical cultures to evaluate changes in synaptic transmission and neuroplasticity induced by these drugs. To visualize neurotransmitter release at the level of individual synapses, we monitored synaptic vesicle recycling using live-cell imaging of electrically stimulated cells expressing SypHy (reporter created by fusion of vesicle protein synaptophysin with pH-sensitive fluorescent protein). Next, we used pharmacological approach to dissect the receptors and signalling pathways involved in the drug induced regulations. Our results show that psychedelics induce time-dependent changes in synaptic transmission and suggest a converging mechanism with the serotonergic neuromodulatory effect. Taken together, this study further unravels the underlying mechanisms of psychedelics-induced neuroplasticity and underscores the importance of the presynaptic component in its action.

SPONTANEOUS NEUROTRANSMISSION IS REGULATED BY NETRIN SIGNALLING

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Samuel Vernon, Evelyne Ruchti, Soumya Banerjee, Brian Mccabe
EPFL, Brain Mind Institute, Lausanne, Switzerland

Spontaneous neurotransmitter release events, also known as miniature neurotransmission or ‘minis’, occur when synaptic vesicles are released in the absence of an action potential. Since their discovery over 70 years ago, miniature events have been confirmed as a universal feature of fast chemical synapses. The functional requirement for spontaneous release events however has been more recalcitrant, but recent studies have established the singular and essential necessity of miniature neurotransmission for the structural maturation and maintenance of synapses. Here, we now demonstrate that the frequency of spontaneous release events can be regulated autonomously of evoked neurotransmission. We establish that a novel presynaptic Netrin signalling pathway bidirectionally regulates the rate of miniature events and influences adult synaptic structural maintenance. Our results challenge the historical view of miniature neurotransmission as spontaneous noise and support that miniature events are an independently regulated parallel mode of transsynaptic chemical communication with unique activites.

STUDYING SNARE MUTATIONS UNDERLYING BRAIN DYSFUNCTION AND DEVELOPMENTAL DISORDERS USING ZEBRAFISH

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Meera Chandra, Rafael Almeida
University of Edinburgh, Centre For Discovery Brain Sciences, Edinburgh, United Kingdom

Neurotransmission is a complex process involving the generation, endocytosis and exocytosis and recycling of vesicles. Exocytosis depends on soluble N-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) proteins located on the vesicular and presynaptic membranes forming a complex that drives membrane fusion. At synapses, the vesicular SNARE mediating neurotransmitter release is a Vesicle Associated Membrane Protein (VAMP) homologue - VAMP2 in most neurons. Human mutations in *VAMP2* have been recently discovered and lead to autistic and epileptic phenotypes among others. The effect of *VAMP2* mutations on individual cell and circuit development and function, leading to such phenotypes, is unclear. We employ zebrafish, owing to their highly conserved SNAREs and to their transparency, which enables non-invasive, high resolution live imaging of the intact vertebrate nervous-system. Here, using time-lapse imaging, we analyse vamp2-mediated exocytosis in individual neurons as well as glia by sparsely expressing a wildtype or mutant vamp2-pHluorin reporter. In this reporter, pH-sensitive GFP pHluorin is fused to the C-terminus of *vamp2* and localized in acidic vesicle lumen which fluoresces upon pH neutralization on exocytosis. Using this reporter, we are able to measure how the frequency, amplitude, and duration of exocytosis is affected by the three mutations causing the most severe phenotypes in humans. Our in vivo approach enables elucidation of role of *VAMP2*, linking molecular defects to cellular and circuit dysfunction. Understanding the pathophysiology of neurological conditions driven by SNARE mutations in the zebrafish in vivo model may lead to the identification of therapeutic targets to ameliorate these conditions in the future.

THE ROLE OF ACTIVITY-DEPENDENT PHOSPHORYLATION IN THE PRESYNAPTIC FUNCTION OF α-SYNUCLEIN

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Elysa Carr[1], Holly Melland[1], Kasper Engholm-Keller[2,3], Mark Graham[3], Sarah Gordon[1]
[1]University of Melbourne, The Florey Institute Of Neuroscience And Mental Health, Parkville, Australia, [2]University of Copenhagen, Department Of Food Science, Frederiksberg, Denmark, [3]Children's Medical Research Institute, Synapse Proteomics, Westmead, Australia

Repeated rounds of synaptic vesicle exocytosis and endocytosis play a critical role in the maintenance of neurotransmission. α-Synuclein, a protein extensively studied for its role in Parkinson's disease, is a known modulator of this synaptic vesicle cycle. However, its exact function remains unclear. This has been elucidated by examining post-translational modifications as a regulatory mechanism of the protein's presynaptic function. Through a phosphoproteomic screen of primary hippocampal neuron lysates we identified two α-synuclein residues that become more highly phosphorylated with neuronal activity. These novel activity-dependent phosphorylation sites were studied by transfecting α-synuclein knockout hippocampal neuron cultures with variants of α-synuclein that mimicked or abolished phosphorylation at these residues. Neurons were subjected to live cell imaging and changes in fluorescence intensity quantified synaptic vesicle and protein trafficking in real time. The presence of different α-synuclein phosphomutants impacted the distribution between plasma membrane and synaptic vesicles of the SNARE protein synaptobrevin-2, a known binding partner of α-synuclein crucial for efficient synaptic vesicle fusion. We found that the phosphorylation state of one of the identified residues specifically affected the endocytic retrieval of synaptobrevin-2 during neuronal activity. This constitutes the first evidence that dynamic, activity-dependent phosphorylation of α-synuclein modulates synaptic vesicle protein trafficking. Loss of this form of synaptic vesicle cycle regulation in disease may interfere with efficient neurotransmission, especially considering that α-synuclein is sequestered into Lewy bodies in Parkinson's disease and Lewy body dementia. As such, disruption of activity-dependent α-synuclein phosphorylation has the potential to contribute to the underlying pathogenesis of these synucleinopathies.

QUANTIFYING THE SYNAPTIC CALCIUM-BINDING KINETICS OF SYNAPTOTAGMIN-1, THE CALCIUM SENSOR FOR TRANSMITTER RELEASE IN THE FOREBRAIN

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Grit Bornschein, Simone Brachtendorf, Abdelmoneim Eshra, Jens Eilers, Stefan Hallermann, Hartmut Schmidt
University Leipzig, Medical Faculty, Carl-ludwig-institute Of Physiology, Leipzig, Germany

The Ca^{2+} sensitivity of transmitter release is a major determinant of synaptic fidelity and plasticity. Two Synaptotagmin (Syt) isoforms, Syt1 and Syt2, are the main Ca^{2+} sensors triggering fast release in the brain; however, only Ca^{2+} binding to Syt2, the dominant isoform in the hindbrain, has been studied in detail. For Syt1, the dominating sensor in the forebrain, similar quantitative detail from brain synapses is not available at present. To quantify the Ca^{2+}-binding kinetics of Syt1 in the context of the intact release machinery we adapted a method combining Ca^{2+}-uncaging, two-photon G/R Ca^{2+}-imaging and patch-clamp electrophysiology to pairs of connected layer 5 pyramidal neurons in the S1 somatosensory cortex of mature mice. To define the local intracellular free Ca^{2+} concentration ($[Ca^{2+}]_i$) at the release sensor, $[Ca^{2+}]_i$ was uniformly elevated in the presynaptic terminal from a caged Ca^{2+} compound by brief UV-flashes. Changes in the presynaptic G/R fluorescence were measured from individual boutons by point-mode two-photon imaging and converted to $d[Ca^{2+}]_i$ based on cuvette calibrations. The corresponding EPSCs were recorded and synaptic delays and deconvolution-based release rates (RR) were quantified. Release started at $d[Ca^{2+}]_i$ above ~1.5 µM and peak RR increased until $d[Ca^{2+}]_i$ of ~25 µM, saturating thereafter with no substantial further increase up to $d[Ca^{2+}]_i$ of ~120 µM. Synaptic delays decreased concomitantly. In comparison to Syt2, the slope of the $[Ca^{2+}]_i$-dependency of Syt1-triggered release was shallower and saturated at higher $[Ca^{2+}]_i$. A model with reduced forward-binding rates is capable of predicting our experimental results.

AREA-SPECIFIC DIFFERENTIATION OF NEOCORTICAL SYNAPTIC COUPLING DISTANCES

POSTER SESSION 03 - SECTION: SYNAPTIC FUNCTION AND NEUROTRANSMISSION

Max Schwarze, Grit Bornschein, Simone Brachtendorf, Jens Eilers, Hartmut Schmidt
University of Leipzig, Carl-ludwig-institute For Physiology, Leipzig, Germany

The physical coupling distance between presynaptic Ca^{2+} channels and transmitter-filled synaptic vesicles is a fundamental determinant of their release probability (p_v). Investigations at different excitatory synapses in different parts of the matured brain, including brainstem, cerebellum and neocortex, indicate that highly reliable synapses processing sensory information operate with tight coupling, while highly plastic excitatory synapses in the hippocampus were found to use loose coupling. Hence, it appears that in the mature brain tight coupling is favored by reliable synapses and loose coupling by highly plastic synapses. To probe this hypothesis at the same type of synapses within the same part of the matured brain, we focused on two functionally distinct areas of the neocortex, the prefrontal (PFC) and the somatosensory (S1) cortex and analyzed coupling distances at synapses between pyramidal neurons in layer 2/3 (L2/3PNs) and layer 5 (L5PNs). We preformed whole-cell recordings from L5PNs in acute slices and stimulated connected L2/3PNs extracellularly. Synapses in PFC showed paired-pulse facilitation, while synapses in S1 possessed paired-pulse depression, indicating that p_v in PFC is lower than in S1. The Ca^{2+} chelator EGTA-AM decreased EPSCs in PFC significantly to 66% of the control value (P=0.03), whereas EPSCs in S1 remained unchanged (102%; P=0.9). These findings suggest that L2/3PN to L5PN synapses in PFC operate with loose coupling as opposed to tight coupling in S1. Our results show that coupling distances of the same synapses differ between cortical areas, thus, providing evidence that the presynaptic nanostructure is adapted to its cortex-area related function.

OPTICAL MANIPULATION AND INTERROGATION OF GLUN2B-NMDA RECEPTORS IN THE BRAIN

POSTER SESSION 03 - SECTION: GLUTAMATE RECEPTORS AND THEIR MODULATION

Antoine Sicard, Meilin Tian, Pierre Paoletti, Laetitia Mony
Ecole Normale Supérieure, INSERM U1024, CNRS UMR 8197, Institut De Biologie, Paris, France

NMDA receptors (NMDARs) are glutamate-gated ion channel receptors broadly expressed in the brain playing a crucial role in synaptic transmission and plasticity. They are tetrameric complexes usually incorporating two GluN1 and two GluN2 subunits. There are 4 types of GluN2 subunits (GluN2A-D), leading to multiple subpopulations of NMDARs with unique biophysical, pharmacological and signaling properties. Understanding the physiological role of each of these subpopulations is of great interest to develop specific therapies to counteract the deleterious effects of their dysfunction, since both their hyper- and hypo-activation are linked to neurological and psychiatric diseases. However, *in vivo* targeting of specific NMDAR subpopulations is currently limited by the weak target specificity and spatio-temporal resolution of classical pharmacological agents. By combining the power of light, genetics and molecular pharmacology, optogenetic pharmacology can overcome these limitations. Using this approach, we developed an innovative photoswitchable tool (Opto-2B) to selectively and reversibly potentiate (up to 3-fold) the activity of GluN2B-NMDARs with light. Using this tool, we investigated the subcellular and temporal regulation of synaptic and extrasynaptic GluN2B-NMDAR expression during development in hippocampal brain slices, as well as the role of these receptors in hippocampal synaptic plasticity. By allowing the control of GluN2B-NMDARs with unrivaled molecular, cellular and sub-cellular specificity, the Opto2B tool should allow unraveling the long-debated roles of GluN2B receptors in synapse and brain function, and offer novel strategies for the treatment of pathologies linked to NMDAR hypofunction such as schizophrenia or age-dependent cognitive decline.

OPTICAL CONTROL OF GLUN2B-NMDA RECEPTORS

POSTER SESSION 03 - SECTION: GLUTAMATE RECEPTORS AND THEIR MODULATION

Chloé Geoffroy[1], Isabelle Mccort-Tranchepain[2], Mariano Casado[1], Pierre Paoletti[1], Laetitia Mony[1]
[1]Ecole Normale Supérieure, INSERM U1024, CNRS UMR 8197, Institut De Biologie, Paris, France, [2]Université de Paris, Laboratoire De Chimie Et Biochimie Pharmacologiques Et Toxicologiques, Cnrs Umr8601, Paris, France

NMDA receptors (NMDARs) are glutamate-gated ion channels playing a central role in synaptic transmission and plasticity but also involved in many neuropsychiatric disorders. NMDARs are tetramers usually composed of two GluN1 and two GluN2 subunits. There are four GluN2 subunits (GluN2A-D), resulting in many receptor subtypes having distinct anatomical, biophysical, pharmacological and signaling properties. Understanding the functional role of these individual subtypes is fundamental to develop strategies to counteract the deleterious effects of NMDAR deregulation. NMDARs containing the GluN2B subunit (GluN2B-NMDARs) play key roles in the brain, with evidence for both pro-cognitive and pro-excitotoxic actions. Yet these roles are still under debate. Methodologies commonly used to study GluN2B-NMDARs, either pharmacological or genetic, have important shortcomings, limiting their use in native tissues. Taking advantage of the unrivaled spatio-temporal resolution of light, optopharmacology, a technique based on the use of photosensitive ligands, allows overcoming these barriers. We developed OptoNAM-3, a photoswitchable negative allosteric modulator selective for GluN2B-NMDARs that can reversibly alternate between a *trans* and a *cis* configuration with light. We found that *trans*-OptoNAM-3 is a potent inhibitor of GluN2B-NMDARs, while *cis*-OptoNAM-3 is inactive, allowing fast and robust modulation of GluN2B-NMDAR activity with light. We furthermore demonstrate a photosensitive action of OptoNAM-3 on glutamate-induced neuronal toxicity in cultured neurons as well as *in vivo* on the locomotion of Xenopus tadpoles. By acting as a light-operated drug enabling precise and reversible photocontrol of endogenous GluN2B-NMDARs, OptoNAM-3 should advance our understanding of the role of this NMDAR class in brain function and dysfunction.

PHOTOCONTROL OF NMDA RECEPTORS WITH SUBUNIT STOICHIOMETRY RESOLUTION

POSTER SESSION 03 - SECTION: GLUTAMATE RECEPTORS AND THEIR MODULATION

Laetitia Mony[1], Meilin Tian[1,2], Antoine Sicard[2], Zakaria Mostefai[1], Joseph Zamith[1], Nora Assendorp[1], Pierre Paoletti[3]
[1]Ecole Normale Supérieure, INSERM U1024, CNRS UMR 8197, Institute Of Biology, Paris, France, [2]Ecole Normale Supérieure, INSERM U1024, CNRS UMR 8197, Institut De Biologie, Paris, France, [3]Ecole normale supérieure, Institut De Biologie, Paris, France

A current challenge lies in understanding the molecular determinants of neurotransmitter receptor functional diversity in the brain. NMDA receptors (NMDARs) are a class of glutamate−gated channels involved in synaptic transmission and plasticity, but also in several neurological and psychiatric diseases. NMDARs are tetramers usually composed of two GluN1 and two GluN2 subunits encoded by four different genes (GluN2A-D), resulting in a large number of receptor subtypes having distinct anatomical, biophysical, pharmacological and signaling properties. The three major NMDAR populations in the adult forebrain are 2A/2A and 2B/2B di-heteromers (containing two identical GluN2 subunits) and 2A/2B tri-heteromers (containing one GluN2A and one GluN2B subunit), whose relative involvement in processes like synaptic plasticity or neurotoxicity are still highly debated. Current genetic and pharmacological approaches, limited in specificity and spatio-temporal resolution, cannot target each NMDAR population in isolation. Optogenetic pharmacology, on the other hand, which combines the power of light, genetics and pharmacology, allows controlling receptors and ion channels with unrivaled spatio-temporal, cellular and molecular specificity. We have developed in the lab the first optopharmacological tool to selectively potentiate 2B/2B di-heteromers with light (Opto2B). The specificity of Opto2B even goes beyond NMDAR molecular nature, since it allowed us to independently probe the synaptic and extrasynaptic populations of 2B/2B NMDARs in cortical brain slices. By allowing control of an NMDAR subpopulation with the most exquisite molecular and subcellular resolution so far, the Opto2B tool should bring light to the debated role of 2B/2B NMDARs in the brain and the translational potential of their potentiation.

CONTRIBUTION OF AMBIENT GLUTAMATE AND GLUTAMATE TRANSPORTERS TO RETINAL GANGLION CELL VULNERABILITY IN EXPERIMENTAL MULTIPLE SCLEROSIS

POSTER SESSION 03 - SECTION: GLUTAMATE RECEPTORS AND THEIR MODULATION

Isabella Boccuni[1], Andreas Draguhn[1], Claus Bruehl[1], Richard Fairless[2]
[1]Heidelberg University, Institute Of Physiology And Pathophysiology, Heidelberg, Germany, [2]University Clinic Heidelberg, Department Of Neurology, Heidelberg, Germany

Glutamate transporter (GluT)-mediated neurotransmitter uptake allows for low, but relevant, ambient glutamate levels in neuronal tissue which can activate extrasynaptic NMDARs (esNMDARs). In pathological situations, esNMDARs have been shown to be major initiators of neurodegeneration. Here we analysed the regulation of ambient glutamate around retinal ganglion cells (RGCs). These cells express consistent pools of esNMDARs, and are vulnerable during early stages of multiple sclerosis, possibly triggered by tonic excitation of esNMDARs. Patch clamp electrophysiology was performed on rat retinal whole-mount preparations to study αON- and αOFF-RGC subtypes, since we previously demonstrated αOFF-RGCs to be more vulnerable than αON-RGCs to degeneration during experimental autoimmune encephalomyelitis (EAE), a disease model of multiple sclerosis. αRGCs were classified according to their ON/OFF light responses and ambient glutamate-induced tonic currents were measured in both healthy and EAE conditions. Under these conditions, tonic currents were observed in both αON and αOFF RGC subtypes, which were partially blocked by application of the NMDAR antagonist MK-801. Perfusion of the retina with TBOA, a pan-GluT inhibitor, induced an increase in the tonic current of between 50-150 fold. However, both the magnitude of the TBOA-induced currents and the relative esNMDAR-mediated components were different between αON/OFF-RGC subtypes in healthy and EAE conditions. These data suggest the physiological presence of ambient glutamate around αRGCs. Impaired GluT function under neuroinflammatory conditions may lead to an increase of ambient glutamate causing over-activation of esNMDARs. A differential proportion of activated NMDARs between the αON/OFF-RGC subtypes could underlie their type-specific vulnerability in multiple sclerosis.

INVESTIGATION OF GLUTAMATE RECEPTOR MODULATION BY INTEGRAL MEMBRANE PROTEINS

POSTER SESSION 03 - SECTION: GLUTAMATE RECEPTORS AND THEIR MODULATION

Javeria Shaukat, Michael Hollmann
Ruhr University Bochum, Biochemistry I - Receptor Biochemistry, Bochum, Germany

Ionotropic glutamate receptors are tetrameric ligand-gated cation channels that are responsible for synaptic signal transmission. They are known to be modulated via auxiliary subunits and various chaperone proteins. The investigation of new potential auxiliary subunits is therefore very interesting. It has been observed in our lab that some members of the claudin protein family are able to interact with homomeric α-amino-3-hydroxy-4-methylisoxazole-5-propionic acid receptors (AMPARs) and alter their current amplitudes. However, AMPARs in vivo mostly form heteromers. Therefore, the goal of the study was to investigate the potential modulatory effects of claudins and characterize their possible properties as auxiliary subunits for heteromeric AMPARs. Besides their effects on receptor steady-state current amplitudes, channel properties such as desensitization were also addressed. cRNAs of AMPARs and claudins were injected into *Xenopus laevis* oocytes in different combinations, and electrophysiological measurements using the two-electrode voltage clamp method were performed to compare the modulation of homomeric and heteromeric receptors when coexpressed with varying amounts of auxiliary proteins. Our data indicate that in some of the heteromeric receptor subunit combinations higher potentiation is observable in comparison to homomeric subunits. However, some of the investigated claudins elicit higher potentiation when the expression level of the receptor is low and obtained currents are moderate in size. Our results illustrate that the current amplitudes of heteromeric AMPARs are distinctly affected by several of the investigated claudins and depend on the level of expressed receptor. The latter finding hints at the importance of a defined stoichiometric expression of claudins and AMPARs.

Tetraspanins as Potential Modulators of Glutamatergic Synaptic Function.
Tetraspanins (Tspans) comprise a membrane protein family structurally defined by four transmembrane domains and intracellular N and C termini that is found in almost all cell types and tissues of eukaryotes. Moreover, they are involved in a bewildering multitude of diverse biological processes such as cell adhesion, motility, protein trafficking, signaling, proliferation, and regulation of the immune system. Beside their physiological roles, they are linked to many pathophysiological phenomena, including tumor progression regulation, HIV-1 replication, diabetes, and hepatitis. Tetraspanins are involved in the formation of extensive protein networks, through interactions not only with themselves but also with numerous other specific proteins, including regulatory proteins in the central nervous system (CNS). Interestingly, recent studies showed that Tspan7 impacts dendritic spine formation, glutamatergic synaptic transmission and plasticity, and that Tspan6 is correlated with epilepsy and intellectual disability (formerly known as mental retardation), highlighting the importance of particular tetraspanins and their involvement in critical processes in the CNS. In this review, we summarize the current knowledge of tetraspanin functions in the brain, with a particular focus on their impact on glutamatergic neurotransmission. In addition, we compare available resolved structures of tetraspanin family members to those of auxiliary proteins of glutamate receptors that are known for their modulatory effects.

PROTEINS OF THE TETRASPANIN FAMILY AS POTENTIAL MODULATORS OF AMPA RECEPTORS.

POSTER SESSION 03 - SECTION: GLUTAMATE RECEPTORS AND THEIR MODULATION

Amina Becic, Aron Struß, Michael Hollmann
Ruhr University Bochum, Biochemistry I - Receptor Biochemistry, Bochum, Germany

Glutamate is the major excitatory neurotransmitter in the brain where it acts via glutamate-gated ion channels. Dysfunction of glutamate receptors is connected to various disorders such as Parkinson´s and Alzheimer´s disease. This work is focused on one subfamily of ionotropic glutamate receptors, the so-called AMPA receptors. These tetrameric receptor complexes are functionally modulated by several auxiliary proteins, including TARPs (transmembrane AMPA receptor regulatory proteins). Based on the structural similarity of TARPs and proteins from the large tetraspanin family, as well as arising evidence of tetraspanin importance in synapses, five different tetraspanins were tested for their potential modulatory effects on AMPA receptors. Experiments were performed using the *Xenopus* oocyte heterologous expression system and two-electrode voltage clamp electrophysiology. Tetraspanin cDNAs, isolated from human brain tissue were in vitro-transcribed to obtain cRNAs that were injected into oocytes. Whole-cell glutamate-activated steady-state current amplitudes of eight different AMPA receptor subunit combinations were recorded and compared to currents in oocytes where additionally tetraspanin cRNAs were expressed. Further, tetraspanins and glutamate receptors were tagged with green and red fluorescent proteins to observe their subcellular localization in the oocyte using confocal microscope. The strongest modulatory effects observed were that Tspan28 and Tspan30 significantly increase glutamate-activated currents of GluA4(Q)flip, while Tspan28 decreases the currents of GluA1(Q)flip and GluA2(Q)i+GluA2(R)flip channels. Furthermore, Tspan7 increases the currents of GluA1(Q)flip up to 3-fold. Our electrophysiological data demonstrates that the investigated tetraspanins clearly modulate AMPA receptor amplitudes, while our confocal microscopy results confirm colocalization of tetraspanins and receptors in the plasma membrane.

Mesenchymal Stem/Stromal Cell-Derived Extracellular Vesicles and Their Potential as Novel Immunomodulatory Therapeutic Agents.
Extracellular vesicles (EVs), such as exosomes and microvesicles, have been identified as mediators of a newly-discovered intercellular communication system. They are essential signaling mediators in various physiological and pathophysiological processes. Depending on their origin, they fulfill different functions. EVs of mesenchymal stem/stromal cells (MSCs) have been found to promote comparable therapeutic activities as MSCs themselves. In a variety of in vivo models, it has been observed that they suppress pro-inflammatory processes and reduce oxidative stress and fibrosis. By switching pro-

inflammatory into tolerogenic immune responses, MSC-EVs very likely promote tissue regeneration by creating a pro-regenerative environment allowing endogenous stem and progenitor cells to successfully repair affected tissues. Accordingly, MSC-EVs provide a novel, very promising therapeutic agent, which has already been successfully applied to humans. However, the MSC-EV production process has not been standardized, yet. Indeed, a collection of different protocols has been used for the MSC-EV production, characterization and application. By focusing on kidney, heart, liver and brain injuries, we have reviewed the major outcomes of published MSC-EV in vivo studies.

MOLECULAR MECHANISMS UNDERLYING PLASTICITY OF GLUA3-CONTAINING AMPA-RECEPTORS

POSTER SESSION 03 - SECTION: GLUTAMATE RECEPTORS AND THEIR MODULATION

Karin Koymans, Niels Reinders, Helmut Kessels
University of Amsterdam, Cellular And Computational Neuroscience, Amsterdam, Netherlands

Background: Pyramidal neurons in the CA1 region of the hippocampus mainly express two types of AMPARs: GluA1/2s and GluA2/3s. Unlike GluA1/2s, GluA2/3s are predominantly in a closed state under basal conditions. However, upon a strong increase in intracellular cAMP levels, the GluA2/3s can convert to an open state. We previously found that this effect of cAMP on GluA2/3s is dependent on Ras. **Aim:** Investigate which signaling cascade(s) are responsible for GluA3-dependent plasticity. **Methods**: After ≥7 days *in vitro* electrophysiology was performed in the CA1 of mouse organotypic hippocampal cultures. Sindbis virus was used to (over)express various proteins (e.g. GFP-PTEN, SEP-GluA3) for 48 hours before patching/imaging. **Results:** The two main signaling cascades downstream of Ras are Erk and PI3K. Inhibition of the Erk pathway did not prevent the opening of GluA2/3s, while inhibiting PI3K did, suggesting that the PI3K pathway is important for the opening of GluA2/3s. Overexpression of PTEN, an inhibitor of the PI3K pathway, decreased synaptic currents in a GluA3-dependent manner and prevented the opening of GluA2/3s. PTEN does so without affecting the synaptic fraction of GluA2/3s, suggesting that PTEN affects the opening of the channel, rather than trafficking. **Conclusions**: Together these experiments demonstrate that activation of the PI3K pathway leads to GluA3-dependent plasticity, while activation of PTEN blocks this potentiation. Understanding how PI3K and PTEN affect GluA2/3s is important for unraveling the mechanisms behind GluA3 plasticity, and is especially relevant for Alzheimer's disease research, as both GluA2/3s and PTEN have been implicated in this disease.

PSD-95 protects synapses from β-amyloid.
Beta-amyloid (Aβ) depresses excitatory synapses by a poorly understood mechanism requiring NMDA receptor (NMDAR) function. Here, we show that increased PSD-95, a major synaptic scaffolding molecule, blocks the effects of Aβ on synapses. The protective effect persists in tissue lacking the AMPA receptor subunit GluA1, which prevents the confounding synaptic potentiation by increased PSD-95. Aβ modifies the conformation of the NMDAR C-terminal domain (CTD) and its interaction with protein phosphatase 1 (PP1), producing synaptic weakening. Higher endogenous levels or overexpression of PSD-95 block Aβ-induced effects on the NMDAR CTD conformation, its interaction with PP1, and synaptic weakening. Our results indicate that increased PSD-95 protects synapses from Aβ toxicity, suggesting that low levels of synaptic PSD-95 may be a molecular sign indicating synapse vulnerability to Aβ. Importantly, pharmacological inhibition of its depalmitoylation increases PSD-95 at synapses and rescues deficits caused by Aβ, possibly opening a therapeutic avenue against Alzheimer's disease.

IMMUNOCYTOCHEMICAL LOCALIZATION OF AMPA GLUTAMATE RECEPTORS SUBTYPE GLUR2&3 IN THE SQUID OPTIC LOBE

POSTER SESSION 03 - SECTION: GLUTAMATE RECEPTORS AND THEIR MODULATION

Kyung-Min Kwon[1], Jae-Hong Pak[2], Chang-Jin Jeon[1]
[1]Kyungpook National University, Research Institute For Dok-do And Ulleung-do Island, Department Of Biology, School Of Life Sciences, Bk21 Four Knu Creative Bio-research Group, College Of Natural Sciences, Brain Science And Engineering Institute, Daegu, Korea, Republic of, [2]Kyungpook National University, Research Institute For Dok-do And Ulleung-do Island, Department Of Biology, Daegu, Korea, Republic of

Glutamate is a major excitatory neurotransmitter in the cephalopod visual system. The α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) glutamate receptors are known to mediate relatively fast ionotropic glutamate signaling and have four different subtypes. In cephalopod central nervous systems, optic lobes (OL) process visual inputs and are involved in learning and memory. The purpose of present study is to identify immunocytochemical localization of AMPA glutamate receptor subtype 2 and 3 (GluR2&3)-immunoreactive (IR) neurons in the OL of pacific flying squid, *Tordarodes pacificus*. GluR2&3-IR neurons were predominantly located in the tangential zone of medulla of OL. Morphologically diverse GluR2&3-IR neurons were observed, including multipolar stellate, multipolar round/oval, small unipolar round/oval, and horizontal types. Medium-to-large sized GluR2&3-IR neurons were prevalently observed. The diameter and area of the neuron ranged between 13.63–29.74 μm (20.18 ± 3.22 μm) and 145.83–694.72 μm^2 (328.39 ± 106.98 μm^2), respectively (mean ± standard deviation). The distribution patterns and cell morphologies of calcium binding proteins (CBPs), calbindin-D28K, calretinin, and parvalbumin-IR neurons were similar to those of GluR2&3-IR neurons. However, none of these CBPs-IR neurons were colocalized with GluR2&3-IR neurons. The result showed specific localization and diverse types of GluR2&3-IR neurons in squid OL. The present findings further complemented glutamatergic visual systems in cephalopod and provide some insights for understanding their vision.

The Organization of Somatostatin-Immunoreactive Cells in the Visual Cortex of the Gerbil.
Somatostatin (SST) is widely expressed in the brain and plays various, vital roles involved in neuromodulation. The purpose of this study is to characterize the organization of SST neurons in the Mongolian gerbil visual cortex (VC) using immunocytochemistry, quantitative analysis, and confocal microscopy. As a diurnal animal, the Mongolian gerbil provides us with a different perspective to other commonly used nocturnal rodent models. In this study, SST neurons were located in all layers of the VC except in layer I; they were most common in layer V. Most SST neurons were multipolar round/oval or stellate cells. No pyramidal neurons were found. Moreover, 2-color immunofluorescence revealed that only 33.50%, 24.05%, 16.73%, 0%, and 64.57% of SST neurons contained gamma-aminobutyric acid, calbindin-D28K, calretinin, parvalbumin, and calcium/calmodulin-dependent protein kinase II, respectively. In contrast, neuropeptide Y and nitric oxide synthase were abundantly expressed, with 80.07% and 75.41% in SST neurons, respectively. Our immunocytochemical analyses of SST with D and D dopamine receptors and choline acetyltransferase, α and β nicotinic acetylcholine receptors suggest that dopaminergic and cholinergic fibers contact some SST neurons. The results showed some distinguishable features of SST neurons and provided some insight into their afferent circuitry in the gerbil VC. These findings may support future studies investigating the role of SST neurons in visual processing.

INVESTIGATIONS ON THE MODULATION OF GLUTAMATE RECEPTOR FUNCTION BY ACCESSORY PROTEINS

POSTER SESSION 03 - SECTION: GLUTAMATE RECEPTORS AND THEIR MODULATION

Jennifer Leifeld, Michael Hollmann
Ruhr University Bochum, Biochemistry I - Receptor Biochemistry, Bochum, Germany

Ionotropic glutamate receptors (iGluRs) are ligand-gated cation channels and key players of central nervous system (CNS) synaptic function. They include, among others, AMPA and NMDA receptors, whose interplay provides the molecular basis for higher-level brain functions such as learning and memory formation. For AMPARs in particular, many interacting proteins are already known, which often share a similar transmembrane topology, and which have a significant impact on physiological receptors. Connexins and pannexins have a topology very similar to many of these proteins. Canonical connexins are involved in the formation of gap junctions, although many members of this family have not yet been functionally characterized. Even less is known about pannexins. Given the similar topology of known auxiliary proteins compared to connexins and pannexins, it is conceivable that some members of these two families may also function as modulatory subunits of iGluRs. Hence, the aim of this project is to identify and subsequently characterize possible new accessory proteins of iGluRs in the connexin and pannexin families. Therefore, all genes of the connexin and pannexin families expressed in the CNS have been isolated and will subsequently be electrophysiologically investigated for possible receptor-modulating properties, by co-expression with AMPARs and NMDARs using the two-electrode voltage-clamp technique. Although preliminary data from the two pannexins and connexins tested so far showed only minor changes of receptor-mediated currents, the insights gained from further experiments may enrich our knowledge not only in the field of iGluRs, but also with respect to potentially novel functions of certain connexins and pannexins.

Tetraspanins as Potential Modulators of Glutamatergic Synaptic Function.
Tetraspanins (Tspans) comprise a membrane protein family structurally defined by four transmembrane domains and intracellular N and C termini that is found in almost all cell types and tissues of eukaryotes. Moreover, they are involved in a bewildering multitude of diverse biological processes such as cell adhesion, motility, protein trafficking, signaling, proliferation, and regulation of the immune system. Beside their physiological roles, they are linked to many pathophysiological phenomena, including tumor progression regulation, HIV-1 replication, diabetes, and hepatitis. Tetraspanins are involved in the formation of extensive protein networks, through interactions not only with themselves but also with numerous other specific proteins, including regulatory proteins in the central nervous system (CNS). Interestingly, recent studies showed that Tspan7 impacts dendritic spine formation, glutamatergic synaptic transmission and plasticity, and that Tspan6 is correlated with epilepsy and intellectual disability (formerly known as mental retardation), highlighting the importance of particular tetraspanins and their involvement in critical processes in the CNS. In this review, we summarize the current knowledge of tetraspanin functions in the brain, with a particular focus on their impact on glutamatergic neurotransmission. In addition, we compare available resolved structures of tetraspanin family members to those of auxiliary proteins of glutamate receptors that are known for their modulatory effects.

Reelin restricts dendritic growth of interneurons in the neocortex.
Reelin is a large secreted glycoprotein that regulates neuronal migration, lamination and establishment of dendritic architecture in the embryonic brain. Reelin expression switches postnatally from Cajal-Retzius cells to interneurons. However, reelin function in interneuron development is still poorly understood. Here, we have investigated the role of reelin in interneuron development in the postnatal neocortex. To preclude early cortical migration defects caused by reelin deficiency, we employed a conditional reelin knockout (RelncKO) mouse to induce postnatal reelin deficiency. Induced reelin deficiency caused dendritic hypertrophy in distal dendritic segments of neuropeptide Y-positive (NPY+) and calretinin-positive (Calr+) interneurons, and in proximal dendritic segments of parvalbumin-positive (Parv+) interneurons. Chronic recombinant Reelin

treatment rescued dendritic hypertrophy in Relncko interneurons. Moreover, we provide evidence that RelncKO interneuron hypertrophy is due to presynaptic GABABR dysfunction. Thus, GABABRs in RelncKO interneurons were unable to block N-type (Cav2.2) Ca2+ channels that control neurotransmitter release. Consequently, the excessive Ca2+ influx through AMPA receptors, but not NMDA receptors, caused interneuron dendritic hypertrophy. These findings suggest that reelin acts as a 'stop-growth-signal' for postnatal interneuron maturation.

CALCIUM REGULATION AND MULTI-KINASE SIGNALING CASCADES CONTRIBUTE TO OUABAIN NEUROPROTECTION IN GLUTAMATE- AND HOMOCYSTEINE-INDUCED NEUROTOXICITY.

POSTER SESSION 03 - SECTION: GLUTAMATE RECEPTORS AND THEIR MODULATION

Mariia Ivanova, Polina Abushik, Dmitry Sibarov, Sergei Antonov
Sechenov Institute Of Evolutionary Physiology And Biochemistry Russian Academy Of Sciences, Laboratory Of Comparative Neurophysiology, Saint-Petersburg, Russian Federation

Ouabain is a cardiac glycoside, which was previously shown to induce neuroprotection in excitotoxic stress caused by ionotropic glutamate receptor agonists. It is widely accepted that glutamate and homocysteine-induced neurodegeneration is caused by the permanent plasma membrane depolarization and cytosolic Ca2+ overload of neurons. Pathological homocysteine accumulation in the human plasma, known as hyperhomocysteinemia, exacerbates neurodegenerative diseases because this amino acid acts as an inherent agonist of ionotropic NMDA receptors in the brain. We studied the effects of 0.1–1 nM ouabain on intracellular Ca2+ signaling, mitochondrial inner membrane voltage (φmit), and cell viability in primary cultures of rat cortical neurons during glutamate and homocysteine neurotoxic insults. In addition, apoptosis-related protein expression and the involvement of some kinases in ouabain-mediated effects were evaluated. In short insults, homocysteine was less potent than glutamate as a neurotoxic agent and induced a 20% loss of φmit, whereas glutamate caused a 70% decrease of this value. Subnanomolar ouabain exhibited immediate and postponed neuroprotective effects on neurons. For instance, ouabain rapidly abolished the Ca2+ overload of neurons and loss of φmit evoked by glutamate and homocysteine that rescued neurons in short insults.In prolonged (24h) excitotoxic insults, ouabain prevented neuronal apoptosis, triggering proteinkinase A and proteinkinase C dependent intracellular neuroprotective cascades for homocysteine, but not for glutamate. We, therefore, demonstrated here the role of PKC and PKA involving pathways in neuronal survival caused by ouabain in excitotoxicity, which suggests existence of different appropriate pharmacological treatment for hyperhomocysteinemia and glutamate excitotoxicity. Supported with Russian Science Foundation grant #21-15-00403.

Calcium Export from Neurons and Multi-Kinase Signaling Cascades Contribute to Ouabain Neuroprotection in Hyperhomocysteinemia.
Pathological homocysteine (HCY) accumulation in the human plasma, known as hyperhomocysteinemia, exacerbates neurodegenerative diseases because, in the brain, this amino acid acts as a persistent -methyl-d-aspartate receptor agonist. We studied the effects of 0.1-1 nM ouabain on intracellular Ca signaling, mitochondrial inner membrane voltage (φ), and cell viability in primary cultures of rat cortical neurons in glutamate and HCY neurotoxic insults. In addition, apoptosis-related protein expression and the involvement of some kinases in ouabain-mediated effects were evaluated. In short insults, HCY was less potent than glutamate as a neurotoxic agent and induced a 20% loss of φ, whereas glutamate caused a 70% decrease of this value. Subnanomolar ouabain exhibited immediate and postponed neuroprotective effects on neurons. (1) Ouabain rapidly reduced the Ca overload of neurons and loss of φ evoked by glutamate and HCY that rescued neurons in short insults. (2) In prolonged 24 h excitotoxic insults, ouabain prevented neuronal apoptosis, triggering proteinkinase A and proteinkinase C dependent intracellular neuroprotective cascades for HCY, but not for glutamate. We, therefore, demonstrated here the role of PKC and PKA involving pathways in neuronal survival caused by ouabain in hyperhomocysteinemia, which suggests existence of different appropriate pharmacological treatment for hyperhomocysteinemia and glutamate excitotoxicity.

Astrocyte remodeling in the beneficial effects of long-term voluntary exercise in Alzheimer's disease.
Increased physical exercise improves cognitive function and reduces pathology associated with Alzheimer's disease (AD). However, the mechanisms underlying the beneficial effects of exercise in AD on the level of specific brain cell types remain

poorly investigated. The involvement of astrocytes in AD pathology is widely described, but their exact role in exercise-mediated neuroprotection warrant further investigation. Here, we investigated the effect of long-term voluntary physical exercise on the modulation of the astrocyte state.

Aims To determine the antibody pathogenicity in patients with encephalitis associated with antibodies against the metabotropic glutamate receptors 5 (mGluR5) in a mouse model of cerebroventricular transfer of antibodies. **Methods** Mice received continuous cerebroventricular infusion of patients' or controls' IgG for 14 days, followed by a 15-day wash-out. Visuospatial memory, anxiety-like behavior, locomotor activity and hippocampal mGluR5 cluster density were assessed. **Results** Animals infused with patients' IgG, but not controls' IgG, showed memory impairment and increased anxiety. Brain tissue studies showed brain-bound human antibodies predominantly in the hippocampus. Confocal microscopy showed decreased total and synaptic neuronal surface mGluR5 clusters. After antibody clearance, both behavioral and molecular changes reversed to baseline conditions. **Conclusions** These findings support the pathogenicity of the antibodies associated with anti-mGluR5 encephalitis, establishing a link between behavioral deficits and antibody-mediated reduction of mGluR5 levels, and offer a model for testing experimental therapies.

Allosteric modulation of NMDA receptors prevents the antibody effects of patients with anti-NMDAR encephalitis.
Anti-N-methyl-d-aspartate receptor (NMDAR) encephalitis is an immune-mediated disease characterized by a complex neuropsychiatric syndrome in association with an antibody-mediated decrease of NMDAR. About 85% of patients respond to immunotherapy (and removal of an associated tumour if it applies), but it often takes several months or more than 1 year for patients to recover. There are no complementary treatments, beyond immunotherapy, to accelerate this recovery. Previous studies showed that SGE-301, a synthetic analogue of 24(S)-hydroxycholesterol, which is a potent and selective positive allosteric modulator of NMDAR, reverted the memory deficit caused by phencyclidine (a non-competitive antagonist of NMDAR), and prevented the NMDAR dysfunction caused by patients' NMDAR antibodies in cultured neurons. An advantage of SGE-301 is that it is optimized for systemic delivery such that plasma and brain exposures are sufficient to modulate NMDAR activity. Here, we used SGE-301 to confirm that in cultured neurons it prevented the antibody-mediated reduction of receptors, and then we applied it to a previously reported mouse model of passive cerebroventricular transfer of patient's CSF antibodies. Four groups were established: mice receiving continuous (14-day) infusion of patients' or controls' CSF, treated with daily subcutaneous administration of SGE-301 or vehicle (no drug). The effects on memory were examined with the novel object location test at different time points, and the effects on synaptic levels of NMDAR (assessed with confocal microscopy) and plasticity (long-term potentiation) were examined in the hippocampus on Day 18, which in this model corresponds to the last day of maximal clinical and synaptic alterations. As expected, mice infused with patient's CSF antibodies, but not those infused with controls' CSF, and treated with vehicle developed severe memory deficit without locomotor alteration, accompanied by a decrease of NMDAR clusters and impairment of long-term potentiation. All antibody-mediated pathogenic effects (memory, synaptic NMDAR, long-term potentiation) were prevented in the animals treated with SGE-301, despite this compound not antagonizing antibody binding. Additional investigations on the potential mechanisms related to these SGE-301 effects showed that (i) in cultured neurons SGE-301 prolonged the decay time of NMDAR-dependent spontaneous excitatory postsynaptic currents suggesting a prolonged open time of the channel; and (ii) it significantly decreased, without fully preventing, the internalization of antibody-bound receptors suggesting that additional, yet unclear mechanisms, contribute in keeping unchanged the surface NMDAR density. Overall, these findings suggest that SGE-301, or similar NMDAR modulators, could potentially serve as complementary treatment for anti-NMDAR encephalitis and deserve future investigations.

The unconventional glycine-binding GluN3A subunit confers to N-methyl-D-aspartate (NMDA) receptors atypical biophysical and signaling properties. GluN3A containing NMDARs are highly expressed during postnatal development, when they are thought to modulate synapse maturation and stabilization. GluN3A expression declines in the transition to adulthood but is maintained at significant levels in several specific brain areas. Recent evidence suggest that GluN3A operates in the adult brain by associating with the glycine-binding subunit GluN1, to form excitatory GluN1/GluN3A receptors activated by glycine only (eGlyRs) which control neuronal excitability and emotional behaviors. Here we investigate eGlyRs in the adult mouse hippocampus and disclose regional differences, cell specificity and endogenous mode of activation with the purpose of unveiling eGlyR cellular physiology and implication in behavior. We show that eGlyRs reside in specific neuronal populations including CA1 pyramidal cells and SST-positive interneurons but not CA3 pyramidal cells and granule cells of the dentate gyrus. Within CA1 pyramidal neurons, eGlyR functional expression follows a marked dorso-ventral gradient, with no expression in the dorsal region but high expression in the ventral one. Unlike CA1 pyramidal neurons, SST-positive interneurons express eGlyRs in both the dorsal and the ventral region. eGlyRs are tonically active, sensing endogenous glycine levels and controlling neuronal excitability in pyramidal cells and SST-positive interneurons. Thus, eGlyRs establish a signaling system in the adult hippocampus with unique functional properties and expression that strikingly differ from conventional NMDARs. Our work opens new perspectives on the exploration of eGlyRs in hippocampal function with an emphasis on ventral hippocampus related behaviors.

NMDA receptors (NMDARs) constitute key components of the excitatory neurotransmission and play central roles in brain development and function. Classical GluN1/GluN2 NMDARs are specialized in detection of the excitatory neurotransmitter glutamate using glycine or D-serine as a co-agonist. The exclusivity of such a ubiquitous working model was challenged by the finding that GluN1 subunits could co-assemble with GluN3 subunits to form 'unconventional' GluN1/GluN3 receptors gated by glycine only. The existence of GluN1/GluN3 NMDARs in native neuronal tissue has long been controversial. Recent work revealed that GluN1/GluN3A receptors are genuine neuronal receptors, constituting a new type of excitatory glycine receptors (eGlyRs). However, how this unusual receptor controls neuronal function and circuits in the adult brain is still mostly unknown. Combining multi-disciplinary approaches, we now provide evidence that GluN1/GluN3A receptors control the function of adult cortical and amygdalar circuits. In the primary somatosensory cortex (S1) eGlyRs are selectively expressed at high levels in somatostatin interneurons while in basolateral amygdala (BLA), GluN1/GluN3A mediated currents are detected in glutamatergic principal neurons. In both cell types, eGlyRs are mostly extrasynaptic and control neuronal excitability through the generation of tonic excitatory currents driven by extracellular glycine, which can be modulated by the dopaminergic system. Finally, we report that eGlyRs are important for behavior-dependent modulation of spontaneous pyramidal cell activity in the S1, as well as consolidation of fear memories in the BLA. Overall, our results reveal unique molecular, anatomical and functional attributes of eGlyRs, opening new vistas on the diversity of NMDAR signaling and glycinergic neurotransmission.

STUDYING THE SPECIFICITY OF AUTOANTIBODIES AGAINST GLUTAMATE RECEPTORS AND AUXILIARY PROTEINS IN RASMUSSEN'S ENCEPHALITIS

POSTER SESSION 03 - SECTION: GLUTAMATE RECEPTORS AND THEIR MODULATION

Rebecca Bake, Alexander Beyer, Ralf Trippe, Christina Klein-Schmidt, Michael Hollmann
Ruhr-Universität Bochum, Department Of Biochemistry I, Bochum, Germany

Rasmussen's Encephalitis (RE) is a chronic inflammatory disease of the brain. Several studies have found autoantibodies against certain subtypes of ionotropic glutamate receptors (iGluRs) of the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) type in blood sera of RE-patients. Plasmapheresis mitigated the RE-symptoms, supporting the assumption that autoantibodies may have an impact on the development of the disease. Since experimental studies produced inconsistent results regarding the involvement of AMPAR autoantibodies in RE, we aimed at optimising experimental procedures to improve the reliability of RE-autoantibody detection in blood sera. We employ immunofluorescent double staining (human immunoglobulin and transfection marker tag antibodies) of HEK293T cells cotransfected with myc-tagged GluA2 and GluA3 to check for autoantibodies against iGluRs in RE-sera. Preabsorbing the used blood sera on untransfected HEK cells decreased background staining and thus improved the signal-to-noise ratio. Using this approach, we detected autoantibodies only of the IgG type, confirming published data in the literature. Next we tested the RE-sera for autoantibodies against transmembrane AMPAR regulatory proteins (TARPs), which are frequently associated with AMPARs. Here, we show that some RE-sera appear to contain IgG autoantibodies against several TARPs. These preliminary results provide further hints to the processes involved in RE.

AMPA-type glutamate receptors (AMPARs) are key players for excitatory synaptic transmission in the central nervous system. In particular, the fine-tuned synaptic incorporation of receptors is responsible for activity-dependent synaptic plasticity. Here we show that secreted Olfactomedin 1-3 (Olfm1-3), which are established constituents of macromolecular AMPAR complexes, are important determinants for availability and dynamics of functional receptors at the cell surface. By unbiased quantitative proteomic analysis of affinity isolated Olfm1 protein from native brain we gained molecular insights which provide a firm basis for understanding their role at synaptic and extra-synaptic sites. They interact with core subunits of AMPARs and form contacts to secreted ligands, extracellular matrix, presynaptic adhesion proteins and a GPI-anchored neurotrophic factor. The latter has a regulatory function by stabilizing Olfm1 at the plasma membrane. We studied the consequences of a complete removal of Olfm1-3 proteins on AMPAR physiology in the hippocampus formation by freeze-fracture electron microscopy and the measure of electrophysiological properties of neurons in acute brain slices. As a result, we show that in the absence of Olfm1-3 the number of receptors at dendritic surfaces and postsynaptic densities of CA1 pyramidal cells are reduced by about 70%. Respectively, AMPAR mediated synaptic transmission as well as synaptic plasticity (LTP) is strongly impaired. Together, we present molecular details and mechanisms important for recruitment and positioning of AMPARs at the synapse. Olfm1-3 proteins are therefore essential by building a multi-protein complex with AMPARs and guide their synaptic incorporation and trans-synaptic tethering.

ABSTRACT mGlu7 homodimers have an apparent very low affinity for glutamate much lower than that of the other mGluRs. We hypothese that mGlu7 is mainly present on the brain as heterodimer. It was already highlighted that mGlu7 subunit is able to heterodimerize, especially with the mGlu2 subunit. Here we determined the pharmacological in order properties of mGlu7/2 and compared it to those of mGlu7 and mGlu2 homodimers. Our final aim is to be able to recognize the imprint of mGlu7/2 in vivo. We used the IPOne assay to study the pharmacological properties of mGlu2, mGlu7 and mGlu7/2 transiently expressed in HEK cells together with the chimeric G protein GqTop. For the mGlu7/2, we used the optimized quality control system based on the GABAB receptor to make sure that only the heterodimer reached the cell surface. Both orthosteric and allosteric ligands for mGlu2 and mGlu7 was tested on each homodimer, and then tested on mGlu7/2 heterodimers. We identified a specific combination of ligands that can be used as a pharmacological signature of this heterodimer relative to the homodimers, as already found for the mGlu2-4 heterodimer. Functionnally, we have a symmetric activation of the heterodimer mGlu7/2 with an mGlu7 G protein coupling. The assays on mGlu2-7 permit us to identified ligands that act differently on mGlu7 whether in a homo or heterodimeric form. This pharmacological signature will be used to identify mGlu7/2 heterodimers in the brain. **Keywords:** Neuropharmacology, Metabotropic glutamate receptor, Heterodimer, FRET

FRAGILE X MENTAL RETARDATION PROTEIN MEDIATES BDNF-INDUCED INCREASE OF SYNAPTIC NMDA RECEPTORS CONTENT

POSTER SESSION 03 - SECTION: GLUTAMATE RECEPTORS AND THEIR MODULATION

Elisa Corti[1], Paulo Pinheiro[1,2], Ramiro Almeida[3,4], Carlos Duarte[4]
[1]Universidade de Coimbra, Cnc (center For Neuroscience And Cell Biology), Coimbra, Portugal, [2]University of Coimbra, Interdisciplinary Research Institute, Coimbra, Portugal, [3]University of Aveiro, Institute Of Biomedicine, Aveiro, Portugal, [4]University of Coimbra, Center For Neuroscience And Cell Biology, Coimbra, Portugal

Brain-Derived Neurotrophic Factor (BDNF) is a mediator of synaptic plasticity and long-term synaptic potentiation. The facilitatory effects of BDNF on glutamatergic synapses depend on local translation. A master regulator of local protein synthesis at the synapse is Fragile X Mental Retardation Protein (FMRP), that exerts translational control on a subset of neuronal transcripts. However, it is still unclear whether FMRP mediates the effects of BDNF on protein synthesis at the synapse. In this work we investigated whether FMRP regulates the synaptic content of GluN2A- and GluN2B-containing NMDA receptors (NMDAR) and acts downstream of the BDNF-TrkB signalling pathway. We knocked down (KD) *Fmr1* expression in cultured hippocampal neurons using two different sets of shRNAs and treated the cells with BDNF. Surface GluN2A and GluN2B were stained with antibodies against an extracellular epitope. We also evaluated the phosphorylation (activation) of TrkB on tyrosine 816 by immunocytochemistry. Synaptic localisation of surface GluN2A and GluN2B, as well as phosphorylated TrkB, were assessed by colocalization with the post- and pre-synaptic markers PSD95 and vGlut. Fmr1 KD had no effect on the surface synaptic content of GluN2A and GluN2B but abolished BDNF-induced upregulation of synaptic NMDAR. Finally, we observed that TrkB phosphorylation is not affected by Fmr1 KD. In conclusion, our data show a role for FMRP in BDNF-induced facilitation at the glutamatergic synapse. Since KD of FMRP was without effect of BDNF-induced activation of TrkB, the RNA-binding protein is likely to act downstream of the receptors to mediate BDNF-induced upregulation of glutamatergic synapses.

Dopaminergic and glutamatergic pathways interact at dendritic spines of medium spiny neurons in the striatum. Notably, NMDA and AMPA glutamatergic receptors colocalize with dopaminergic receptors influencing neural excitability and promoting synaptic plasticity. This interaction is critical for mediating top-down control, reward processing, and depressive mood; however, little is known about the molecular mechanisms underlying the crosstalk between dopamine and glutamate. The aim of our work was to unveil the effect of the deletion of the dopamine transporter (DAT) on the homeostasis of the glutamate synapse in the striatum and its role in electrophysiological transmission to further deepening features of dopamine-glutamate interaction. Taking advantage of targeted inactivation of the dopamine transporter in rats (DATko), which caused a hyperdopaminergic condition, we found a reduced expression of the main subunits of both NMDA and AMPA receptors, as well as of their specific glutamatergic scaffolding proteins in the post-synaptic density of the striatum. These changes were paralleled by an increased trafficking at the extra-synaptic sites of both NMDA and AMPA receptors, suggesting a lateral diffusion toward the extra-synapse. Moreover, we found an upregulation of the glial antiporter xCT, suggesting an increased extra-synaptic release of glutamate. Interestingly, such reduced retention of glutamate receptors in the membrane was accompanied by an impairment in both LTP and LTD post-synaptic transmission in the striatum of DATko animals. Taken together, these data suggest that a condition of hyperdopaminergia has reorganized the glutamatergic synapse in the striatum, causing an overall destabilization and depotentiation of the glutamatergic neurotransmission.

Hypersensitivity to amphetamine's psychomotor and reinforcing effects in serotonin transporter knockout rats: Glutamate in the nucleus accumbens.
Amphetamine (AMPH) use disorder is a serious health concern, but, surprisingly, little is known about the vulnerability to the moderate and compulsive use of this psychostimulant and its underlying mechanisms. Previous research showed that inherited serotonin transporter (SERT) down-regulation increases the motor response to cocaine, as well as moderate (as measured during daily 1-h self-administration sessions) and compulsive (as measured during daily 6-h self-administration sessions) intake of this psychostimulant. Here, we sought to investigate whether these findings generalize to AMPH and the underlying mechanisms in the nucleus accumbens.

Long access to cocaine self-administration dysregulates the glutamate synapse in the nucleus accumbens core of serotonin transporter knockout rats.
It is well established that the nucleus accumbens and glutamate play a critical role in the motivation to take drugs of abuse. We have previously demonstrated that rats with ablation of the serotonin (5-HT) transporter (SERT rats) show increased cocaine intake reminiscent of compulsivity.

Single Exposure to the Cathinones MDPV and α-PVP Alters Molecular Markers of Neuroplasticity in the Adult Mouse Brain.
Synthetic cathinones have gained popularity among young drug users and are widely used in the clandestine market. While the cathinone-induced behavioral profile has been extensively investigated, information on their neuroplastic effects is still

rather fragmentary. Accordingly, we have exposed male mice to a single injection of MDPV and α-PVP and sacrificed the animals at different time points (i.e., 30 min, 2 h, and 24 h) to have a rapid readout of the effect of these psychostimulants on neuroplasticity in the frontal lobe and hippocampus, two reward-related brain regions. We found that a single, low dose of MDPV or α-PVP is sufficient to alter the expression of neuroplastic markers in the adult mouse brain. In particular, we found increased expression of the transcription factor , increased ratio between the vesicular GABA transporter and the vesicular glutamate transporter together with changes in the expression of the neurotrophin , confirming the widespread impact of these cathinones on brain plasticity. To sum up, exposure to low dose of cathinones can impair cortical and hippocampal homeostasis, suggesting that abuse of these cathinones at much higher doses, as it occurs in humans, could have an even more profound impact on neuroplasticity.

Repeated exposure to cocaine during adolescence enhances the rewarding threshold for cocaine-conditioned place preference in adulthood.
Previous studies have shown that adolescent exposure to cocaine increases drug use in adulthood, albeit incubation of cocaine seeking was found to be attenuated in rats trained to self-administer cocaine during adolescence. We here hypothesize that adolescent exposure to cocaine could alter the rewarding properties of the psychostimulant in adulthood. By employing two of the most widely used animal-experimental-preclinical models to investigate drug addiction, we evaluated whether contingent versus non-contingent cocaine self-administration during adolescence modulates its rewarding threshold in adulthood evaluated by conditioned place preference (CPP). Cocaine self-administration during adolescence increases the rewarding threshold in adulthood; CPP for cocaine was observed at the higher (20 mg/kg), but not at the lower (10 mg/kg), dose employed. Rats exposed to either contingent or non-contingent cocaine during adolescence exhibited the same behavior in the CPP paradigm suggesting that, under our experimental conditions, cocaine rewarding properties are shaped by the psychostimulant itself and not by its motivational effects. From a mechanistic standpoint, the preference for the 20 mg/kg cocaine-paired side in a CPP paradigm appears to depend, at least partially, upon the formation of GluA2-lacking Ca -permeable AMPA receptors and the consequent increase of αCaMKII activity in the NAc, both of which are instead reduced when the 10 mg/kg dose was used. In conclusion, contingent or non-contingent cocaine exposure during adolescence desensitizes adult animals to a rewarding dose of cocaine (10 mg/kg) elevating the rewarding threshold necessary (20 mg/kg) to drive conditioned place preference, an effect that may predispose to higher consumption of cocaine during adulthood.

MGLU5 RECEPTOR FUNCTION DEPENDS ON MEMBRANE VOLTAGE

POSTER SESSION 03 - SECTION: GLUTAMATE RECEPTORS AND THEIR MODULATION

Marin Boutonnet, Nathalie Bouquier, Yan Chastagnier, Julie Perroy
University of Montpellier, CNRS, Inserm, Institute Of Functional Genomics, Montpellier, France

Objectives G-Protein Coupled Receptors (GPCR) are seven transmembrane domain receptors found in a large variety of organs where they transduce extracellular signals such as hormones or neurotransmitters. In neurons they are exposed to wide membrane voltage variations recently shown to be an important direct modulator of some GPCRs activity but still remains unwell characterized. Metabotropic glutamate receptor 5 (mGlu5) is a class C GPCR localized on the glutamatergic post-synapse where it modulates synaptic transmission and plasticity. We investigated the sensitivity of mGlu5 to the neuronal membrane voltage. Methods We worked on Human Embryonic Kidney 293T (HEK 293T) cell lines stably expressing human mGlu5. We used a FRET-based sensor to report conformational changes (activation / inactivation) of mGlu5 triggered by agonist and antagonists following membrane depolarization by K^+. Moreover, thanks to a fluorescent calcium sensor and microscopy imaging we studied mGlu5 induced calcium oscillations. Results We show that membrane depolarization potentiates the inactive-like conformation of mGlu5 triggered by LY341495 antagonist. Consistently, mGlu5 agonist-induced intracellular calcium increase was impaired by depolarization of the cell membrane. This global inhibition is the result of a reduced number of cells responding to the stimulation combined with a decreased mGlu5-induced calcium spiking activity in cells responding to the stimulation. Put together, these results reflect a disturbance of the mGlu5 functionality during depolarization. Conclusion Our findings support a role of membrane voltage on mGlu5 pharmacological activation and signaling in HEK 293T. This singular property of mGlu5 is of interest for glutamatergic synaptic transmission understanding.

OPTICAL BIOSENSORS OF NATIVE MEMBRANE PROTEIN COMPLEXES REVEAL A HIGH PROPORTION OF MGLU HETERODIMERS IN THE BRAIN

POSTER SESSION 03 - SECTION: GLUTAMATE RECEPTORS AND THEIR MODULATION

Jiyong Meng[1], Chanjuan Xu[2], Pierre-André Lafon[3], Jianfeng Liu[2], Philippe Rondard[3], Jean-Philippe Pin[1]
[1]Univ Montpellier - CNRS, Institut De Genomique Fonctionnelle, Montpellier, France, [2]Huazhong University of Science and Technology, College Of Life Science And Technology, Wuhan, China, [3]Université de Montpellier, Institut De Génomique Fonctionnelle, Montpellier, France

Metabotropic Glutamate receptor play key roles in regulating many synapses in the brain. Eight mGluRs have been identified, sub-classified into group-I (mGlu1 & 5), group-II (mGlu2 & 3) and group-III (mGlu4, 6, 7 & 8)[1]. These receptors are mandatory dimers[2]. Although assumed to be exclusively homodimers, we reported 10 years ago that mGlu subunits can associate into heterodimers[3]. While both group-I subunits can associate, any group-II and -III subunits can form heterodimers, generating 16 possible additional mGluRs with specific properties[4-6]. In this study, we developed a method for detecting mGlu homo and heterodimers in native tissues. Our method relies on nanobody-based biosensors which enable the proximity detection between subunits by FRET. Additionally, given conformation-specific nanobodies, activation of these native complexes can be recorded. Applied to the metabotropic glutamate receptors 2 and 4 subunits, this approach revealed the clear existence of functional mGlu2-4 heterodimers in addition to mGlu2 and mGlu4 homodimers. Strikingly, the mGlu4 subunits appear to be mainly in heterodimers in the brain. Overall, these data confirm the existence of mGlu heterodimers in the brain, and provide innovative tools to determine their specific properties in their native environment. There is growing interest in developing biologics as pharmacological tools due to their high target selectivity. The G protein-coupled homo and heterodimeric metabotropic glutamate (mGlu) receptors regulate many synapses and are promising targets for the treatment of numerous brain diseases. Although subtype selective allosteric small molecules have been reported, their effects on the recently discovered heterodimeric receptors are often not known. Here we describe a nanobody that specifically and fully activates homodimeric human mGlu4 receptors. Our studies revealed that the nanobody acts by stabilizing the closed active state of the glutamate binding domain by interacting with both lobes. In contrast, this nanobody does not activate the heterodimeric mGlu2-4, but acts as a pure positive allosteric modulator. These data further demonstrate that nanobodies can be useful tools to discover the specific functional roles of all mGlu subtypes, including the heterodimeric ones.

GROUP III METABOTROPIC GLUTAMATE RECEPTORS AT THE INNER HAIR CELL RIBBON SYNAPSE IN THE COCHLEA

POSTER SESSION 03 - SECTION: GLUTAMATE RECEPTORS AND THEIR MODULATION

Lisa Janina Klotz-Weigand, Ralf Enz
Friedrich-Alexander-Univeristy, Insititute Of Biochemistry, Erlangen, Germany

Hearing impairment is often preceded by neurodegeneration at inner hair-cell (IHC) ribbon synapses in the cochlea. It was suggested that the primary cause of synapse loss during noise and aging in the cochlea is caused by glutamate overexposure. Pre-synaptically localized metabotropic glutamate receptors (mGluRs) are well suited to protect neurons from glutamate excitotoxicity, since they can limit pre-synaptic glutamate release. Interestingly, mGluR7 has been correlated with age-related and noise-induced hearing deficits. Recently, we analysed expression and localization of the mGluR7 isoforms mGluR7a and mGluR7b in mouse cochlear wholemounts, using confocal microscopy and 3D reconstructions. We observed a pre-synaptic localization of both mGluR7 isoforms at the IHC ribbon synapse and a reduced amount of these receptors at synapses encoding higher frequencies and in older animals. We also found a pre-synaptic localization of mGluR4 and mGluR8b at IHC synapses. This enables the possibility to form homo- and/or heterodimeric receptors composed of mGluR4, mGluR7a, mGluR7b and mGluR8b at IHC ribbon synapses. Various studies described the formation of heterodimers of mGluR types that revealed distinct characteristics. The ability of heterodimerization between mGluR4, mGluR7a/b and mGluR8b are unknown. Here, we analyzed the formation of potential heterodimers using co-staining's on cochlear wholemounts and immunoprecipitations from HEK-293 cells and from native tissue. Our data show that all receptor combinations formed heterodimers when co-expressed in HEK-293 cells, while only some of them were detectable in the brain. These receptor complexes might represent new molecular targets suited for pharmacological concepts to protect the cochlea against noxious stimuli and excitotoxicity.

MGluR7 is a presynaptic metabotropic glutamate receptor at ribbon synapses of inner hair cells.
Glutamate is the most pivotal excitatory neurotransmitter in the central nervous system. Metabotropic glutamate receptors (mGluRs) dimerize and can couple to inhibitory intracellular signal cascades, thereby protecting glutamatergic neurons from excessive excitation and cell death. MGluR7 is correlated with age-related hearing deficits and noise-induced hearing loss; however its exact localization in the cochlea is unknown. Here, we analyzed the expression and localization of mGluR7a and mGluR7b in mouse cochlear wholemounts in detail, using confocal microscopy and 3D reconstructions. We observed a presynaptic localization of mGluR7a at inner hair cells (IHCs), close to the synaptic ribbon. To detect mGluR7b, newly generated antibodies were characterized and showed co-localization with mGluR7a at IHC ribbon synapses. Compared to the number of synaptic ribbons, the numbers of mGluR7a and mGluR7b puncta were reduced at higher frequencies (48 to 64 kHz) and in older animals (6 and 12 months). Previously, we reported a presynaptic localization of mGluR4 and mGluR8b at this synapse type. This enables the possibility for the formation of homo- and/or heterodimeric receptors composed of mGluR4, mGluR7a, mGluR7b and mGluR8b at IHC ribbon synapses. These receptor complexes might represent new molecular targets suited for pharmacological concepts to protect the cochlea against noxious stimuli and excitotoxicity.

Localization of group II and III metabotropic glutamate receptors at pre- and postsynaptic sites of inner hair cell ribbon synapses.
Glutamate is the major excitatory neurotransmitter in the CNS binding to a variety of glutamate receptors. Metabotropic glutamate receptors (mGluR1 to mGluR8) can act excitatory or inhibitory, depending on associated signal cascades. Expression and localization of inhibitory acting mGluRs at inner hair cells (IHCs) in the cochlea are largely unknown. Here, we analyzed expression of mGluR2, mGluR3, mGluR4, mGluR6, mGluR7, and mGluR8 and investigated their localization with respect to the presynaptic ribbon of IHC synapses. We detected transcripts for mGluR2, mGluR3, and mGluR4 as well as for mGluR7a, mGluR7b, mGluR8a, and mGluR8b splice variants. Using receptor-specific antibodies in cochlear

wholemounts, we found expression of mGluR2, mGluR4, and mGluR8b close to presynaptic ribbons. Super resolution and confocal microscopy in combination with 3-dimensional reconstructions indicated a postsynaptic localization of mGluR2 that overlaps with postsynaptic density protein 95 on dendrites of afferent type I spiral ganglion neurons. In contrast, mGluR4 and mGluR8b were expressed at the presynapse close to IHC ribbons. In summary, we localized in detail 3 mGluR types at IHC ribbon synapses, providing a fundament for new therapeutical strategies that could protect the cochlea against noxious stimuli and excitotoxicity.-Klotz, L., Wendler, O., Frischknecht, R., Shigemoto, R., Schulze, H., Enz, R. Localization of group II and III metabotropic glutamate receptors at pre- and postsynaptic sites of inner hair cell ribbon synapses.

CRIP1a inhibits endocytosis of G-protein coupled receptors activated by endocannabinoids and glutamate by a common molecular mechanism.
The excitability of the central nervous system depends largely on the surface density of neurotransmitter receptors. The endocannabinoid receptor 1 (CB R) and the metabotropic glutamate receptor mGlu R are expressed pre-synaptically where they reduce glutamate release into the synaptic cleft. Recently, the CB R interacting protein cannabinoid receptor interacting protein 1a (CRIP1a) was identified and characterized to regulate CB R activity in neurons. However, underlying molecular mechanisms are largely unknown. Here, we identified a common mechanism used by CRIP1a to regulate the cell surface density of two different types of G-protein coupled receptors, CB R and mGlu R. Five amino acids within the CB R C-terminus were required and sufficient to reduce constitutive CB R endocytosis by about 72% in the presence of CRIP1a. Interestingly, a similar sequence is present in mGlu R and consistently, endocytosis of mGlu R depended on CRIP1a, as well. Docking analysis and molecular dynamics simulations identified a conserved serine in CB R (S468) and mGlu R (S894) that forms a hydrogen bond with the peptide backbone of CRIP1a at position R82. In contrast to mGlu R, the closely related mGlu R splice-variant carries a lysine (K894) at this position, and indeed, mGlu R endocytosis was not affected by CRIP1a. Chimeric constructs between CB R, mGlu R, and mGlu R underline the role of the identified five CRIP1a sensitive amino acids. In summary, we suggest that CRIP1a negatively regulates endocytosis of two different G-protein coupled receptor types, CB R and mGlu R.

Homodimerization of a proximal region within the C-terminus of the orphan G-protein coupled receptor GPR179.
G-protein coupled receptors exhibit numerous biological functions. The orphan G-protein coupled receptor GPR179 is a central component of a 1 Megadalton large signalling complex in the ON-pathway of the mammalian retina that assembles multiple proteins, including the metabotropic glutamate receptor mGluR6. Dimer formation is a hallmark of G-protein coupled receptors and some use intracellular C-termini for dimerization. Here we tested the dimerization properties of the intracellular C-terminal domains of mGluR6 and GPR179. While the C-termini of GPR179 and mGluR6 did not interact, we detected a robust homodimerization of a proximal region in the GPR179 C-terminus. Mapping studies defined a linear stretch of 64 amino acids as dimerization region. Bioinformatic analysis indicated that this dimerization region might adopt an α-helical structure that is predicted to dimerize by forming a coiled-coil. Based on these data, we speculate that homodimerization of GPR179 might contribute to the formation of large signalling complexes in the mammalian retina.

ENDOGENOUS NMDA RECEPTOR MODULATORS ALTER DENDRITIC ARBOR COMPLEXITY IN CULTURED CORTICAL NEURONS

POSTER SESSION 03 - SECTION: GLUTAMATE RECEPTORS AND THEIR MODULATION

Pascal Jorratt[1,2], Jan Říčný[1], Tomáš Páleníček[1,2]
[1]National Institute of Mental Health, Psychedelics Research Centre, Klecany, Czech Republic, [2]Charles University, 3rd Faculty Of Medicine, Prague, Czech Republic

Schizophrenia is a chronic developmental neuropsychiatry disorder affecting 1% of the population, manifesting through an array of severely disabling symptoms. Hypofunction of NMDA receptor (NMDAR) is one of the main hypothesis for the neurobiology of schizophrenia, as the dissociative anesthetics ketamine and phencyclidine (non-competitive NMDAR antagonists) induce schizophrenia-like symptoms in healthy humans. Evidences from postmortem studies show an alteration in morphology and density of postsynaptic elements in cortical tissue in schizophrenia. While ketamine, phencyclidine and another exogenous antagonist of NMDAR have been used as pharmacological approach for inducing NMDAR hypofunction, little attention has been payed to the endogenous modulators of NMDAR, which emerge to be dysregulated in patients with schizophrenia. We studied the effects of the endogenous NMDAR modulators kynurenic acid, pregnenolone sulfate, spermidine and zinc on neuronal morphology and synaptic density in cortical culture. We found that those modulators did not alter cell viability and glutamate release. In addition, dendritic branching measurements of total dendritic length, number of branches, number of primary branches, number of branch points, and soma size were not different when cultures were treated for 5 days. However, spermidine and pregnenolone sulfate altered dendritic arbor complexity. Finally, pregnenolone sulfate decrease the number of postsynaptic marker PSD-95 and a trend to decrease synapse number. Importantly, these modulators are also ligands for other receptors, so future studies need to assess whether these effects on morphology and synaptic density are by NMDAR-related mechanisms to elucidate the impact of the NMDAR hypofunction by endogenous modulators in schizophrenia.

Endogenous antagonists of N-methyl-d-aspartate receptor in schizophrenia.
Schizophrenia is a chronic neuropsychiatric brain disorder that has devastating personal impact and rising healthcare costs. Dysregulation of glutamatergic neurotransmission has been implicated in the pathobiology of the disease, attributed largely to the hypofunction of the N-methyl-d-aspartate (NMDA) receptor. Currently, there is a major gap in mechanistic analysis as to how endogenous modulators of the NMDA receptors contribute to the onset and progression of the disease. We present a systematic review of the neurobiology and the role of endogenous NMDA receptor antagonists in animal models of schizophrenia, and in patients. We discuss their neurochemical origin, release from neurons and glia with action mechanisms, and functional effects, which might contribute toward the impairment of neuronal processes underlying this complex pathological state. We consider clinical evidence suggesting dysregulations of endogenous NMDA receptor in schizophrenia, and highlight the pressing need in future studies and emerging directions, to restore the NMDA receptor functions for therapeutic benefits.

Neurobiology, Functions, and Relevance of Excitatory Amino Acid Transporters (EAATs) to Treatment of Refractory Epilepsy.
Epilepsy is one of the most prevalent and devastating neurological disorders characterized by episodes of unusual sensations, loss of awareness, and reoccurring seizures. The frequency and intensity of epileptic fits can vary to a great degree, with almost a third of all cases resistant to available therapies. At present, there is a major unmet need for effective and specific therapeutic intervention. Impairments of the exquisite balance between excitatory and inhibitory synaptic processes in the brain are considered key in the onset and pathophysiology of the disease. As the primary excitatory neurotransmitter in the central nervous system, glutamate has been implicated in the process, with the glutamatergic system holding center stage in the pathobiology as well as in developing disease-modifying therapies. Emerging data pinpoint impairments of glutamate clearance as one of the key causative factors in drug-resistant disease forms. Reinstatement of

glutamate homeostasis using pharmacological and genetic modulation of glutamate clearance is therefore considered to be of major translational relevance. In this article, we review the neurobiological and clinical evidence suggesting complex aberrations in the activity and functions of excitatory amino acid transporters (EAATs) in epilepsy, with knock-on effects on glutamate homeostasis as a leading cause for the development of refractory forms. We consider the emerging data on pharmacological and genetic manipulations of EAATs, with reference to seizures and glutamate dyshomeostasis, and review their fundamental and translational relevance. We discuss the most recent advances in the EAATs research in human and animal models, along with numerous questions that remain open for debate and critical appraisal. Contrary to the widely held view on EAATs as a promising therapeutic target for management of refractory epilepsy as well as other neurological and psychiatric conditions related to glutamatergic hyperactivity and glutamate-induced cytotoxicity, we stress that the true relevance of EAAT2 as a target for medical intervention remains to be fully appreciated and verified. Despite decades of research, the emerging properties and functional characteristics of glutamate transporters and their relationship with neurophysiological and behavioral correlates of epilepsy challenge the current perception of this disease and fit unambiguously in neither EAATs functional deficit nor in reversal models. We stress the pressing need for new approaches and models for research and restoration of the physiological activity of glutamate transporters and synaptic transmission to achieve much needed therapeutic effects. The complex mechanism of EAATs regulation by multiple factors, including changes in the electrochemical environment and ionic gradients related to epileptic hyperactivity, impose major therapeutic challenges. As a final note, we consider the evolving views and present a cautious perspective on the key areas of future progress in the field towards better management and treatment of refractory disease forms.

Difference in Perseverative Errors during a Visual Attention Task with Auditory Distractors in Alpha-9 Nicotinic Receptor Subunit Wild Type and Knock-Out Mice.
The auditory efferent system is a neural network that originates in the auditory cortex and projects to the cochlear receptor through olivocochlear (OC) neurons. Medial OC neurons make cholinergic synapses with outer hair cells (OHCs) through nicotinic receptors constituted by α9 and α10 subunits. One of the physiological functions of the α9 nicotinic receptor subunit (α9-nAChR) is the suppression of auditory distractors during selective attention to visual stimuli. In a recent study we demonstrated that the behavioral performance of alpha-9 nicotinic receptor knock-out (KO) mice is altered during selective attention to visual stimuli with auditory distractors since they made less correct responses and more omissions than wild type (WT) mice. As the inhibition of the behavioral responses to irrelevant stimuli is an important mechanism of the selective attention processes, behavioral errors are relevant measures that can reflect altered inhibitory control. Errors produced during a cued attention task can be classified as premature, target and perseverative errors. Perseverative responses can be considered as an inability to inhibit the repetition of an action already planned, while premature responses can be considered as an index of the ability to wait or retain an action. Here, we studied premature, target and perseverative errors during a visual attention task with auditory distractors in WT and KO mice. We found that α9-KO mice make fewer perseverative errors with longer latencies than WT mice in the presence of auditory distractors. In addition, although we found no significant difference in the number of target error between genotypes, KO mice made more short-latency target errors than WT mice during the presentation of auditory distractors. The fewer perseverative error made by α9-KO mice could be explained by a reduced motivation for reward and an increased impulsivity during decision making with auditory distraction in KO mice.

Selective Attention to Visual Stimuli Using Auditory Distractors Is Altered in Alpha-9 Nicotinic Receptor Subunit Knock-Out Mice.
During selective attention, subjects voluntarily focus their cognitive resources on a specific stimulus while ignoring others. Top-down filtering of peripheral sensory responses by higher structures of the brain has been proposed as one of the mechanisms responsible for selective attention. A prerequisite to accomplish top-down modulation of the activity of peripheral structures is the presence of corticofugal pathways. The mammalian auditory efferent system is a unique neural network that originates in the auditory cortex and projects to the cochlear receptor through the olivocochlear bundle, and it has been proposed to function as a top-down filter of peripheral auditory responses during attention to cross-modal stimuli. However, to date, there is no conclusive evidence of the involvement of olivocochlear neurons in selective attention paradigms. Here, we trained wild-type and α-9 nicotinic receptor subunit knock-out (KO) mice, which lack cholinergic transmission between medial olivocochlear neurons and outer hair cells, in a two-choice visual discrimination task and studied the behavioral consequences of adding different types of auditory distractors. In addition, we evaluated the effects of contralateral noise on auditory nerve responses as a measure of the individual strength of the olivocochlear reflex. We demonstrate that KO mice have a reduced olivocochlear reflex strength and perform poorly in a visual selective attention paradigm. These results confirm that an intact medial olivocochlear transmission aids in ignoring auditory distraction during selective attention to visual

stimuli.

Astrocytes are critical players in the regulation of brain development and function. They sense and respond to neuronal activity by elevating intracellular calcium levels, which derive from different sources and display complex spatiotemporal properties. Calcium elevations appear spatially distributed in global (soma and main processes) and focal regions (microdomains). Such astrocytic calcium activity is expected to underlie the astrocyte involvement in synaptic transmission, metabolism, and brain homeostasis. In this work, we studied the IP3 receptor type 2 knockout (IP3R2 KO) mouse model that lacks global calcium elevations in astrocytes to disclose its implications in cognitive function. We found an influence of global astrocyte calcium in long-term memory performance. Thus, we performed a structural and molecular analysis of cortico-limbic regions that revealed a shift to immature spines in pyramidal neurons of the dorsal hippocampus that could support the changes in synaptic plasticity underlying our behavioral observations. The characterization of the IP3R2 KO mouse model provided new insights into the importance of astrocytic calcium-dependent signaling in the modulation of neural activity. These findings broaden the scope of astrocytic modulation of brain circuits.

ASTROCYTES OF NUCLEUS ACCUMBENS CONTROL THE IMPAIRMENTS DERIVED FROM CHRONIC EXPOSURE OF THC

POSTER SESSION 03 - SECTION: ASTROCYTES AND MICROGLIA

Cajal Institute (CSIC), Synaptic Plasticity And Astrocyte-neuron Interactions, Madrid, Spain

Drug use is a growing problem in actual society. Usually, the first experience with drugs takes place during adolescence, being cannabis the most used illicit drug[1]. Although cannabis could be considered a harmless drug, we are beginning to appreciate its consequences. Chronic exposure to addictive drugs has shown to imbalance glutamate homeostasis in Nucleus Accumbens (NAc), altering plasticity mechanisms such as long-term depression. Therefore, it is crucial to elucidate the mechanisms underlying these alterations and how to reverse them. It is known the activation of cannabinoid receptors in astrocytes modulate synaptic plasticity[2,3] and could be involved in glutamate homeostasis. However, the functional role of astrocytes in alterations derived from chronic drug exposure is not fully understood. In this study, we analyzed how astrocytes contribute to alterations produced by tetrahydrocannabinol (THC). Using fiber photometry in vivo we analyzed astrocytic activity (Ca^{2+} and glutamate dynamics) in NAc after 1mg/kg THC chronic administration in wildtype and p38αMAPK$^{-/-}$ (Astrop38α) mice[4] and we performed electrophysiology experiments to analyze synaptic plasticity. Moreover, we performed behavioral tests to assess whether THC had reinforcing properties or affected learning and memory. Furthermore, using chemogenetic approaches (DREADDs) we activated NAc astrocytes to analyze their behavioral implications. We observed: 1)THC increases astrocytic calcium activity; 2)THC induces glutamate release in NAc in wildtype, but not Astrop38α; 3)NAc astrocytes are involved in learning; 4)Removal of p38αMAPK in NAc astrocytes restores THC-related impairments. Altogether, our results reveal astrocytes as critical elements for the maintenance of glutamate signaling, with a significant role in drug-use-related alterations.

AIMS. Bleeding into cerebral parenchyma during head trauma and hemorrhagic stroke leads to tissue anoxia and release of plasmatic content, including amino acids (AA). Although excitotoxic AA have been extensively studied, little is known about non-excitatory AA during hypoxic injury. Hypoxia-induced synaptic depression becomes irreversible with non-excitatory AA in hippocampal slices, corresponding with their intracellular accumulation and increased tissue electrical resistance. METHODS. A combination of four AA (AGQS: L-alanine, glycine, L-glutamine, L-serine) at plasmatic concentrations were applied (30-min) to brain slices from mice expressing EGFP in pyramidal neurons (Thy1/EGFP) or astrocytes (GFAP/EGFP) during normoxia or hypoxia. Simultaneous 2-photon imaging, changes in light transmittance (LT) and electrophysiological field recordings followed by electron microscopy in hippocampal CA1 *st. radiatum* were used to monitor cell swelling and injury, and synaptic function. RESULTS. During normoxia, AGQS-induced increase in LT is due to astroglial but not neuronal swelling. Fast LT increment during hypoxia and AGQS manifests neuronal and astroglial swelling, which was not accompanied by spreading depolarization. AGQS-induced permanent loss of synaptic transmission during hypoxia develops alongside dendritic beading, indicating acute structural damage, as revealed by 2-photon and electron microscopy. Hypoxia without AGQS does not cause cell swelling, leaving dendrites intact. Inhibition of NMDAR prevents neuronal damage and irreversible loss of field potentiaIs. Deleterious effects of AGQS during hypoxia are avoided by alanine-serine-cysteine transporters (ASCT2) and volume-regulated anion channels (VRAC) blockers. CONCLUSIONS. Swelling induced by intracellular accumulation of non-excitatory AA and release of excitotoxins through antiporters and VRAC may exacerbate hypoxia-induced neuronal injury. NIHGrant:N

Intracellular accumulation of amino acids increases synaptic potentials in rat hippocampal slices.
The application of high concentrations of taurine induces long-lasting potentiation of synaptic responses and axon excitability. This phenomenon seems to require the contribution of a transport system with a low affinity for taurine. The prototypic taurine transporter TauT (SLC6A6) was discarded by experimental evidence obtained in TauT-KO mice. The purpose of the present study was to determine whether the proton-coupled amino acid transporter 1 (PAT1; SLC36A1) which is a transport system with low affinity and high capacity for a great variety of amino acids including taurine, contributes to the taurine-induced synaptic potentiation. In rat hippocampal slices, the application of several amino acids (L- and D-alanine, L-glutamine, β-guanidinopropionic acid, glycine, L-histidine, L- and D-serine, sarcosine, L- and D-threonine) imitated the synaptic potentiation induced by taurine. The magnitude of the potentiation caused by some of these amino acids was even greater than that induced by taurine. By contrast, the application of other amino acids (L-arginine, betaine, L-leucine, L-methionine, L- and D-proline, and L-valine) did not induce potentiation. The behaviour of these different amino acids on synaptic potentiation is not compatible with a role of PAT1 in synaptic potentiation. There was a positive correlation between the accumulation of the different amino acids in the slice and the magnitude of synaptic potentiation induced by them. Some of the amino acids inducing synaptic potentiation, like taurine and L-threonine, also increased electrical resistance of the slice, whereas L-

leucine did not modify this parameter. Modifications induced by either taurine or L-threonine in synaptic potentiation, slice resistance and amino acid accumulation were dependent on extracellular chloride concentration. These findings support the idea that the accumulation of amino acids throughout the action of transporters causes cell swelling enhancing the electrical resistance of the slice, which by itself could be sufficient to increase field synaptic potentials.

Hypoxia-induced depression of synaptic transmission becomes irreversible by intracellular accumulation of non-excitatory amino acids.
The intracellular accumulation of some amino acids (AAs), mainly glutamine, can contribute to brain edema observed during liver failure. We recently demonstrated that individual applications of high concentrations (10 mM) of some non-excitatory AAs increase the electrical resistance of hippocampal slices, indicating cell swelling. Therefore, we pondered whether an AA mixture's application might cause cell swelling at a physiological concentration range. In rat hippocampal slices, we carried out extra- and intracellular electrophysiological recordings and AAs analysis to address this question. We applied a mixture of 19 AAs at their plasmatic concentrations (Plasma solution: Ala, Gly, Gln, His, Ser, Tau, Thr, Arg, Leu, Met, Pro, Val, Asn, Cys, Phe, Ile, Lys, Tyr, and Trp). This solution was afterward divided into two according to the individual AAs at 10 mM concentration inducing synaptic potentiation (Plasma1, containing the first seven AAs of Plasma) or not (Plasma2, with the remaining AAs). Plasma application increased evoked field potentials requiring extracellular chloride. This effect was mimicked by the Plasma1 but not the Plasma2 solution. Plasma1-induced potentiation was independent of changes in release probability, basic electrophysiological membrane properties, and NMDAR activation. AAs in Plasma1 act cooperatively to accumulate intracellularly and to induce synaptic potentiation. In the presence of Plasma1, the reversible synaptic depression caused by a 40-min hypoxia period turned into an irreversible disappearance of synaptic potentials through an NMDAR-dependent mechanism. The presence of a system A transport inhibitor did not block Plasma1-mediated effects. These results indicate that cell swelling, induced by the accumulation of non-excitotoxic AAs through unidentified transporters, might foster deleterious effects produced by hypoxia-ischemia episodes.

The Coronavirus Disease 2019 (COVID-19): Key Emphasis on Melatonin Safety and Therapeutic Efficacy.
Viral infections constitute a tectonic convulsion in the normophysiology of the hosts. The current coronavirus disease 2019 (COVID-19) pandemic is not an exception, and therefore the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection, like any other invading microbe, enacts a generalized immune response once the virus contacts the body. Melatonin is a systemic dealer that does not overlook any homeostasis disturbance, which consequently brings into play its cooperative triad, antioxidant, anti-inflammatory, and immune-stimulant backbone, to stop the infective cycle of SARS-CoV-2 or any other endogenous or exogenous threat. In COVID-19, the corporal propagation of SARS-CoV-2 involves an exacerbated oxidative activity and therefore the overproduction of great amounts of reactive oxygen and nitrogen species (RONS). The endorsement of melatonin as a possible protective agent against the current pandemic is indirectly supported by its widely demonstrated beneficial role in preclinical and clinical studies of other respiratory diseases. In addition, focusing the therapeutic action on strengthening the host protection responses in critical phases of the infective cycle makes it likely that multi-tasking melatonin will provide multi-protection, maintaining its efficacy against the virus variants that are already emerging and will emerge as long as SARS-CoV-2 continues to circulate among us.

Presynaptic glutamate replenishment is fundamental to brain function. In high activity regimes, such as epileptic episodes, this process is thought to rely on the glutamate-glutamine cycle between neurons and astrocytes. However the presence of an astroglial glutamine supply, as well as its functional relevance in vivo in the healthy brain remain controversial, partly due to a lack of tools that can directly examine glutamine transfer. Here, we generated a fluorescent probe that tracks glutamine in live cells, which provides direct visual evidence of an activity-dependent glutamine supply from astroglial networks to presynaptic structures under physiological conditions. This mobilization is mediated by connexin43, an astroglial protein with both gap-junction and hemichannel functions, and is essential for synaptic transmission and object recognition memory. Our findings uncover an indispensable recruitment of astroglial glutamine in physiological synaptic activity and memory via an unconventional pathway, thus providing an astrocyte basis for cognitive processes.

SPATIOTEMPORAL ATP RELEASE IN CORTICAL ASTROCYTES

POSTER SESSION 03 - SECTION: ASTROCYTES AND MICROGLIA

Yoshiki Hatashita[1], Zhaofa Wu[2], Yulong Li[2], Takafumi Inoue[1]
[1]Waseda University, Department Of Life Science And Medical Bioscience, Tokyo, Japan, [2]Peking University, School Of Life Sciences, Beijing, China

Astrocytes participate in information processing by modulating synaptic activity through the release of ATP as a gliotransmitter. Since there are approximately 140,000 synapses in the territory of a single astrocyte in rodents, knowledge about the spatiotemporal dynamics of ATP gliotransmission, which is not understood well, will help to understand how astrocytes are involved in the information process at the neuronal circuit-level. Here, we introduced a novel genetically encoded extracellular ATP sensor, $GRAB_{ATP1.0}$, to murine cortical astrocytes by *in utero* electroporation and monitored extracellular ATP changes by two-photon microscopy. In acute slice, tetrodotoxin insensitive spontaneous ATP release events were observed, which were suppressed by an astrocyte specific toxin, fluorocitrate. Typical ATP release events were localized to sub-cellular 50–200 μm^2 areas at concentration of 0.5–5 µM, implying that a single ATP release event can activate purinergic receptors in hundreds of nearby synapses. Dual color imaging of $GRAB_{ATP1.0}$ and a calcium sensor Lck-REX-GECO1 showed that most of the spontaneous ATP release occurred independently of Ca^{2+}elevation. Inhibition of vesicular release with bafilomycin A1 did not suppress ATP release, indicating that astrocytes regulate ATP gliotransmission through non-vesicular Ca^{2+} independent ATP release mechanisms. Classification of ATP release according to the temporal waveforms suggests that astrocytes release ATP in multiple fashions. In conclusion, our findings suggest that astrocyte may locally modulate hundreds of nearby synapses by spontaneously releasing ATP via multiple Ca^{2+} independent mechanisms.

UNRAVELLING THE ROLE OF SPINAL ASTROCYTES IN NOCICEPTION AND PAIN

POSTER SESSION 03 - SECTION: ASTROCYTES AND MICROGLIA

Sibel Ada, Anna Siegert, Danijela Kurija, Jürgen Sandkühler, Ruth Drdla-Schutting

Aim Changes in synaptic plasticity at nociceptive synapses are strongly implicated in the pathogenesis of chronic pain. Astrocytes can profoundly affect synaptic transmission by releasing gliotransmitters and studies highlighted how altered astrocytic activity may contribute to pathogenic changes in nociception. Here, we tested whether the selective activation of astrocytes in the lumbar spinal cord dorsal horn is sufficient to induce synaptic plasticity at nociceptive synapses. **Methods** Male Sprague Dawley rats were used in all experiments. The astrocytes were targeted selectively via cell-specific *G_qDREADDs* (*Designer Receptors Exclusively Activated by Designer Drug*s) which were activated via Clozapine-N-oxide (CNO). To investigate the effect of astrocyte activation on the cellular and synaptic levels, we performed whole cell patch-clamp recordings from dorsal horn neurons in acute spinal cord slices with dorsal roots attached. Additionally, we recorded C-fibre-evoked field potentials in intact, deeply anaesthetized rats to assess synaptic strength in vivo. **Results** The selective activation of spinal astrocytes by CNO induced a robust long-term depression at nociceptive synapses in laminae I/II, both in vitro and in vivo. Furthermore, activation of spinal astrocytes increased spontaneous inhibitory currents in neurons in superficial laminae in the acute slice preparation. **Conclusions** Our study demonstrates that a selective activation of spinal astrocytes using G_q-DREADDs is sufficient to depress synaptic strength at nociceptive synapses. Our findings substantiate the role of astrocytes as active players in nociception, and can provide a rationale for the development of novel curative therapeutic strategies for pain patients . *Support: FWF Austrian Science Fund Medical Neuroscience, FWF fund(DOC 33-B27)*

Astrocytes are key supporters of brain functioning and have been shown to influence neuronal circuits at slow timescales of multiple seconds to minutes to hours. Here, we show that striatal astrocytes can rapidly modulate dopamine release at subsecond timescales. Brief optogenetic manipulation of astrocytes in mouse *ex vivo* slices directly modulates dopamine release, dependent upon activation of nicotinic acetylcholine receptors (nAChRs) on dopamine axons. We identify that striatal astrocytes in mouse are typically found in close apposition to cholinergic interneuron somata in a satellite configuration, a feature rarely observed for striatal projection neurons. As a result, satellite astrocytes potently regulate cholinergic interneuron excitability through tight regulation of extracellular ion concentrations, leading to transient increases in spiking and activation of downstream nAChRs. These rapid and reversible effects from satellite astrocytes on cholinergic interneurons are synapse-independent and not mediated by gap junction coupling, fast ionotropic glutamatergic or GABAergic transmission. Preliminary findings show that cholinergic interneurons also present satellite astrocytes in human *post mortem* striatal tissue. Together, these findings show striatal satellite astrocytes can rapidly modulate cholinergic interneurons and dopamine release at subsecond timescales.

IMPLICATION OF GLIAL CELLS IN ACTIVITY DEPENDENT PLASTICITY OF SPINAL INHIBITION IN THE DORSAL HORN

POSTER SESSION 03 - SECTION: ASTROCYTES AND MICROGLIA

Louise Vial-Markiewicz, Benjamin Léonardon, Rémy Schlichter, Perrine Inquimbert
University of Strasbourg-CNRS, Insitut Des Neurosciences Cellulaires Et Intégratives, Strasbourg, France

The dorsal horn of the spinal cord plays a pivotal role in the reception, integration and transmission of nociceptive information from the periphery to supra-spinal centers. The dorsal horn interneurons, comprised of excitatory glutamatergic neurons and inhibitory glycinergic and GABAergic neurons function as a balance, allowing normal processing of nociceptive information. In some pathological cases, plasticity in the dorsal horn network can lead to a rupture of the excitation/inhibition balance. One of the known mechanisms leading to this rupture is the recruitment of NMDA receptors, by an increase of synaptic excitation. Their role in modulation and plasticity of excitatory transmission in the dorsal horn has been largely studied, but their potential role in modulation of inhibitory GABAergic transmission has not. Our aim is to characterize the effect of NMDA receptor activation on inhibitory synaptic transmission in the dorsal horn and the implication of glial cells. To study a potential target specificity, we used GAD65eGFP mice, differentiating between GAD+ (assumed GABAergic) and GAD- (assumed glutamatergic) cells. We have shown an NMDA-dependent facilitation of synaptic GABAergic transmission in two thirds of recorded cells. Using the gliotoxin fluorocitrate to determine the role of astrocytes in NMDA-dependent facilitation, we showed a smaller proportion of neurons presenting NMDA-dependent facilitation. Interestingly, we found that astrocytes are involved in mediation specifically when recording GAD- cells, underlining a cell-specific involvement of astrocytes in the NMDA effect. Altogether, our results bring new insights in the cross-talk between excitation and inhibition in the dorsal horn, involving NMDA receptors and astrocytes.

Astrocytes are the most abundant glial cells in the brain, presenting a typical star-shaped morphology. Their extended morphology is pivotal to allow their dynamic interactions with neighboring neurons and glia. Therefore, assessing astrocytic morphology is crucial for further insights into their regional distribution and integration in neuronal networks. For that, we used a semi-automatic tool called SNT to evaluate the morphological structure of astrocytes and gather numerous morphometric parameters such as total length, number of processes, and arbor complexity (Sholl and Convex Hull analyses). In this work, we performed a 3D reconstruction of the backbone of hippocampal astrocytes in brain slices of C57BL6/J mice using immunohistochemistry staining of the Glial Fibrillary Acidic Protein (GFAP), the astrocytic cytoskeleton protein. Furthermore, we also studied brain slices from astrocyte-specific RiboTag mice allowing the more detailed identification of the astrocytic structure. Our results show that both preparations allow the detailed reconstruction of the astrocytic backbone, despite the considerable increase in detail provided by the RiboTag approach. Nevertheless, the simpler and more flexible GFAP-immunostaining might be enough to reveal intra-hippocampal heterogeneity.

Astrocytes integrate brain circuits, and they can sense, process, and respond to incoming signals, giving rise to the concept of “tripartite synapse”. These close interactions are due to the complex morphological structure that allows them to extend their processes to cover several synapses. Therefore, assessing astrocytic morphology is pivotal for further insights into their regional distribution and its importance for brain functioning. Here, we evaluated the morphological structure of astrocytes from several layers of the hippocampus, namely CA1 oriens, radiatum, lacunosum moleculare layers, and DG molecular and hilus layers. Furthermore, we also assessed the relevance of astrocyte exocytosis for maintaining the astrocytic backbone in the CA1 radiatum and DG molecular layers. We used the SNT Fiji tool, which allowed the tridimensional reconstruction of the main astrocytic structure. This analysis obtained several morphometric parameters such as total length, number of processes, and arbor complexity (Sholl analysis). Briefly, the results showed that astrocytes from different hippocampal layers display distinct morphological profiles, and these morphological differences are conserved throughout the dorsalventral axis of the hippocampus. Moreover, we also showed that astrocyte exocytosis is also involved in the maintenance of astrocytes structure in the hippocampus.

IP R2 null mice display a normal acquisition of somatic and neurological development milestones.
Astrocytes are key players in the regulation of brain development and function. They sense and respond to the surrounding activity by elevating their intracellular calcium (Ca) levels. These astrocytic Ca elevations emerge from different sources and display complex spatio-temporal properties. Ca elevations are spatially distributed in global (soma and main processes) and/or focal regions (microdomains). The inositol 1,4,5-trisphosphate receptor type 2 knockout (IP R2 KO) mouse model lacks global Ca elevations in astrocytes, and it has been used by different laboratories. However, the constitutive deletion of IP R2 during development may trigger compensating phenotypes, which could bias the results of experiments using developing or adult mice. To address this issue, we performed a detailed neurodevelopmental evaluation of male and female IP R2 KO mice, during the first 21 days of life, as well as an evaluation of motor function, strength and neurological reflexes in adult mice. Our results show that male and female IP R2 KO mice display a normal acquisition of developmental milestones, as compared with wild-type (WT) mice. We also show that IP R2 KO mice display normal motor coordination, strength and neurological reflexes in adulthood. To exclude a potential compensatory overexpression of other IP Rs, we quantified the relative mRNA levels of all 3 subtypes, in brain tissue. We found that, along with the complete deletion of Itpr2, there is no compensatory expression of Itpr1 or Itrp3. Overall, our results show that the IP R2 KO mouse is a reliable model to study the functional impact of global IP R2-dependent astrocytic Ca elevations.

Identification of region-specific astrocyte subtypes at single cell resolution.
Astrocytes, a major cell type found throughout the central nervous system, have general roles in the modulation of synapse formation and synaptic transmission, blood-brain barrier formation, and regulation of blood flow, as well as metabolic support

of other brain resident cells. Crucially, emerging evidence shows specific adaptations and astrocyte-encoded functions in regions, such as the spinal cord and cerebellum. To investigate the true extent of astrocyte molecular diversity across forebrain regions, we used single-cell RNA sequencing. Our analysis identifies five transcriptomically distinct astrocyte subtypes in adult mouse cortex and hippocampus. Validation of our data in situ reveals distinct spatial positioning of defined subtypes, reflecting the distribution of morphologically and physiologically distinct astrocyte populations. Our findings are evidence for specialized astrocyte subtypes between and within brain regions. The data are available through an online database (https://holt-sc.glialab.org/), providing a resource on which to base explorations of local astrocyte diversity and function in the brain.

The Role of Astrocytic Calcium Signaling in the Aged Prefrontal Cortex.
Aging is a lifelong process characterized by cognitive decline putatively due to structural and functional changes of neural circuits of the brain. Neuron-glial signaling is a fundamental component of structure and function of circuits of the brain, and yet its possible role in aging remains elusive. Significantly, neuron-glial networks of the prefrontal cortex undergo age-related alterations that can affect cognitive function, and disruption of glial calcium signaling has been linked with cognitive performance. Motivated by these observations, we explored the possible role of glia in cognition during aging, considering a mouse model where astrocytes lacked IPR2-dependent Ca signaling. Contrarily to aged wild-type animals that showed significant impairment in a two-trial place recognition task, aged IPR2 KO mice did not. Consideration of neuronal and astrocytic cell densities in the prefrontal cortex, revealed that aged IPR2 KO mice present decreased densities of NeuN neurons and increased densities of S100β astrocytes. Moreover, aged IPR2 KO mice display refined dendritic trees in this region. These findings suggest a novel role for astrocytes in the aged brain. Further evaluation of the neuron-glial interactions in the aged brain will disclose novel strategies to handle healthy cognitive aging in humans.

THE ROLE OF ASTROCYTES IN SOMATOSENSORY SYNAPTIC PLASTICITY DURING DEVELOPMENT: INTEGRATION OF DATA AND COMPUTATIONAL MODELING

POSTER SESSION 03 - SECTION: ASTROCYTES AND MICROGLIA

Tiina Manninen[1], Aušra Saudargienė[2], Marja-Leena Linne[1]
[1]Tampere University, Faculty Of Medicine And Health Technology, Tampere, Finland, [2]Lithuanian University of Health Sciences, Neuroscience Institute, Kaunas, Lithuania

Astrocytes have been shown to be important regulators of neural development and circuit maturation, including control of the number of synapses and synaptic connectivity. Recent evidence also indicates that astrocytes modulate synaptic plasticity during postnatal development, at least in somatosensory and prefrontal cortices as well as in hippocampus. Synaptic plasticity, defined as the activity-dependent change in the strength of the synaptic connection between neurons, is expressed in the brain in diverse forms across multiple timescales and orchestrated through complex biophysical and biochemical mechanisms. We have previously analyzed published computational models that involve some of the suggested mechanisms (Manninen et al., 2018). In addition, we have developed a model for a layer 4 to layer 2/3 synapse based on more than 70 references on experimental data in somatosensory cortex during postnatal development and on computational modeling (Manninen et al., 2020). The model links neuronal and astrocytic signaling pathways to the time window of long-term depression (LTD) induction. In the present study, we use our model to address the natural spike pattern-induced LTD by computational means. The modeling results provide insights into the influence of spike frequency on the dynamics of the cellular pathways. Continuous cross-talk between wet-lab experiments and computational modeling is needed to decipher the roles of astrocytes in synaptic computations in developing sensory systems. **Acknowledgements:** The work was supported by Academy of Finland (Nos. 326494, 326495, 345280) and European Union's Horizon 2020 Framework Programme for Research and Innovation under the Specific Grant Agreement No. 945539 (Human Brain Project SGA3).

NOVEL CA2+-MODULATED PHOTOACTIVATABLE IMAGING REVEALS NEURON-ASTROCYTE GLUTAMATERGIC CIRCUITRIES WITHIN THE NUCLEUS ACCUMBENS

POSTER SESSION 03 - SECTION: ASTROCYTES AND MICROGLIA

Irene Serra, Julio Esparza, Cristina Martín-Monteagudo, Laura Delgado, Marta Navarrete
Cajal Institute (CSIC), Synaptic Plasticity And Astrocyte-neuron Interations, Madrid, Spain

Astrocytes have been traditionally studied as a homogeneous group, however, recent research has started to evidence their heterogeneity. Our hypothesis is that specialized astrocyte subsets are responsible for the modulation of specific neuronal circuits. We focused on the Nucleus Accumbens (NAc), an important integrator center in which converges different glutamatergic signals coming primarily from the medial prefrontal cortex (mPFC), basolateral amygdala (Amyg), and ventral hippocampus (vHip). In this work, we analyze whether astrocytes establish segregated populations in the NAc with intrinsic properties and functional consequences for the circuit. To this end, we have used optogenetic manipulations to afferent-specific synaptic stimulation to the NAc combining with a new adapted technique (calcium-modulated photoactivatable ratiometric integrator under GFAP promoter, CaMPARI$_{GFAP}$) to specifically dissect the active astrocyte circuits with spatio-temporal precision. We demonstrate that NAc astrocytes show pathway-specific interactions with the glutamatergic afferents and that this activity does not correlate with the glutamatergic innervation patterns, suggesting unexpected astrocytic connectivity, i.e. activation of precise astrocytic populations in response to specific glutamatergic inputs. Moreover, the spatial activation of these astrocytic networks is not defined by alterations in astrocyte density or uneven expression of mGluR5. Finally, we show that different subpopulations of astrocytes in both NAc regions receive and integrate signals arising from all the excitatory afferents. Our work reveals different neuron-astrocyte glutamatergic circuits in the NAc, showing pathway-specific astrocytic responses mediated by mGluR5. These results highlight the astrocytic contribution to NAc functionality, providing a potential explanation to comprehend how NAc integrates information from multiple glutamatergic inputs.

A specific prelimbic-nucleus accumbens pathway controls resilience versus vulnerability to food addiction.
Food addiction is linked to obesity and eating disorders and is characterized by a loss of behavioral control and compulsive food intake. Here, using a food addiction mouse model, we report that the lack of cannabinoid type-1 receptor in dorsal telencephalic glutamatergic neurons prevents the development of food addiction-like behavior, which is associated with enhanced synaptic excitatory transmission in the medial prefrontal cortex (mPFC) and in the nucleus accumbens (NAc). In contrast, chemogenetic inhibition of neuronal activity in the mPFC-NAc pathway induces compulsive food seeking. Transcriptomic analysis and genetic manipulation identified that increased dopamine D2 receptor expression in the mPFC-NAc pathway promotes the addiction-like phenotype. Our study unravels a new neurobiological mechanism underlying resilience and vulnerability to the development of food addiction, which could pave the way towards novel and efficient interventions for this disorder.

Astrocytic p38α MAPK drives NMDA receptor-dependent long-term depression and modulates long-term memory.
NMDA receptor-dependent long-term depression (LTD) in the hippocampus is a well-known form of synaptic plasticity that has been linked to different cognitive functions. The core mechanism for this form of plasticity is thought to be entirely neuronal. However, we now demonstrate that astrocytic activity drives LTD at CA3-CA1 synapses. We have found that LTD induction enhances astrocyte-to-neuron communication mediated by glutamate, and that Ca signaling and SNARE-dependent vesicular release from the astrocyte are required for LTD expression. In addition, using optogenetic techniques, we show that low-frequency astrocytic activation, in the absence of presynaptic activity, is sufficient to induce postsynaptic AMPA receptor removal and LTD expression. Using cell-type-specific gene deletion, we show that astrocytic p38α MAPK is required for the increased astrocytic glutamate release and astrocyte-to-neuron communication during low-frequency

stimulation. Accordingly, removal of astrocytic (but not neuronal) p38α abolishes LTD expression. Finally, this mechanism modulates long-term memory in vivo.

Nrg1 haploinsufficiency alters inhibitory cortical circuits.
Neuregulin 1 (NRG1) and its receptor ERBB4 are schizophrenia (SZ) risk genes that control the development of both excitatory and inhibitory cortical circuits. Most studies focused on the characterization ErbB4 deficient mice. However, ErbB4 deletion concurrently perturbs the signaling of Nrg1 and Neuregulin 3 (Nrg3), another ligand expressed in the cortex. In addition, NRG1 polymorphisms linked to SZ locate mainly in non-coding regions and they may partially reduce Nrg1 expression. Here, to study the relevance of Nrg1 partial loss-of-function in cortical circuits we characterized a recently developed haploinsufficient mouse model of Nrg1 (Nrg1). These mice display SZ-like behavioral deficits. The cellular and molecular underpinnings of the behavioral deficits in Nrg1 mice remain to be established. With multiple approaches including Magnetic Resonance Spectroscopy (MRS), electrophysiology, quantitative imaging and molecular analysis we found that Nrg1 haploinsufficiency impairs the inhibitory cortical circuits. We observed changes in the expression of molecules involved in GABAergic neurotransmission, decreased density of Vglut1 excitatory buttons onto Parvalbumin interneurons and decreased frequency of spontaneous inhibitory postsynaptic currents. Moreover, we found a decreased number of Parvalbumin positive interneurons in the cortex and altered expression of Calretinin. Interestingly, we failed to detect other alterations in excitatory neurons that were previously reported in ErbB4 null mice suggesting that the Nrg1 haploinsufficiency does not entirely phenocopies ErbB4 deletions. Altogether, this study suggests that Nrg1 haploinsufficiency primarily affects the cortical inhibitory circuits in the cortex and provides new insights into the structural and molecular synaptic impairment caused by NRG1 hypofunction in a preclinical model of SZ.

QUANTIFICATION OF REGIONAL AND INTERSPECIES ASTROCYTE INVOLVEMENT IN SYNAPSES

POSTER SESSION 03 - SECTION: ASTROCYTES AND MICROGLIA

Ivan Strinić[1,2], Nikola Habek[1,2,3]
[1]University of Zagreb School of Medicine, Croatian Institute For Brain Research, Zagreb, Croatia, [2]School of Medicine, University of Zagreb, Centre Of Excellence For Basic, Clinical And Translational Neuroscience, Zagreb, Croatia, [3]School of Medicine, University of Zagreb, Department Of Physiology, Zagreb, Croatia

Evidence suggests that astrocytes play key roles in the structural and functional organization of neuronal circuits. Astrocytes seem to be an integral part of the synapse, according to the tripartite synapse concept. Because recent evidence has demonstrated that astrocytes integrate and process synaptic information and control synaptic transmission, astrocytes could be cellular elements involved in the processing and transfer of information by the nervous system. To investigate tripartite synapse involvement in neural circuit complexity, we wanted to see the regional differences how many synapses astrocytes are involved in and if there is a difference between species.. We performed immunofluorescent staining on human and murine brain sections of different brain areas. Synapses were marked by anti-synaptophysin and the astrocytes were marked with anti-GFAP antibodies. Image acquisition was done by confocal microscope and images were analyzed by ImageJ software. In our preliminary results, we have found that the human brain has much more astrocyte density and involvement in synapses than that of a mouse. This difference in astrocyte and synapse overlap can be a possible explanation of the difference between organisms of higher and lower cognitive function. Acknowledgments: Research was funded by the Centre of Excellence for Basic, Clinical and Translational Neuroscience (project “Experimental and clinical research of hypoxic-ischemic damage in perinatal and adult brain”; GA KK01.1.1.01.0007 funded by the European Union through the European Regional Development Fund) and by the project of the Croatian Science Foundation FURNACE (IP-2018-01-7416).

Astrocyte-derived lactate fuels high-energy demands of neurons and acts as a signal promoting synaptic plasticity and memory consolidation. Recent findings have shown that lactate regulates NMDA receptor activity and modulates gene expression related to synaptic plasticity and neuroprotection. Here, we used patch-clamp recordings in cultured cortical neurons to elucidate further the mechanism of NMDA receptor potentiation by lactate. We found that lactate rapidly enhanced both the amplitude and inactivation time-constant of NMDA receptor currents (I_{NMDAR}) evoked by brief applications of glutamate and glycine. These effects were not observed by agonists of the HCAR1/gpr81 receptor while the lactate-mediated increase in I_{NMDAR} amplitude was prevented by monocarboxylate transporters and lactate dehydrogenase inhibitors. Intracellular infusion of specific CaMKII peptide inhibitors also abolished the potentiation of peak I_{NMDAR} responses by lactate, indicating a mechanism requiring entry of lactate into neurons, its oxidation to pyruvate, and involvement of CaMKII. Moreover, interfering with the binding between CaMKII and GluN2B, using a pharmaco-genetic model consisting of CaMKIIα-expressing HEK293 cells transiently transfected with functional NMDA receptors containing mutant GluN2B subunits, prevented the potentiation of I_{NMDAR} responses by lactate. Proximity ligation assays between GluN2B and the postsynaptic density marker PSD-95 in cultured neurons revealed that lactate induced an accumulation of GluN2B in dendritic spines, an effect that was prevented by a CaMKII peptide inhibitor. Together these observations indicate that lactate uptake stimulates synaptic plasticity by increasing the distribution of NMDA receptors in spines by a mechanism promoting the interaction between CaMKII and GluN2b subunits.

Over the past decade studies have started to focus on the role of the astrocytes as a key modulator of the neuronal network activity. Importantly, the scientific community has now access to advanced tools to study the astrocytic contribution to the modulation of the neuronal network: genetically modified mice or engineered viral vectors. However, those tools remain expensive and therefore not affordable for many laboratories. Taking advantage of a highly studied circuit in which the crucial involvement of astrocytes has recently been described, namely the modulation of central amygdala circuit by the neuropeptide oxytocin, we aimed at providing evidence that pharmacological metabolic silencing of astrocytes can be of interest to modern science. Here, we demonstrated that fluorocitrate is an efficient inhibitor of OT-evoked astroglial calcium activity. We further found that metabolic silencing of astrocytes disturbs astro-neuronal communication without impairing the neuronal network basal activity. Finally, we showed that in vivo local infusion of fluorocitrate efficiently and safely impaired the OT-induced modulation of CeA-related behavior.

Astrocyte distal processes, known as leaflets or perisynaptic astrocyte processes (PAPs), fine-tune synaptic activity by clearing neurotransmitters and limiting extrasynaptic glutamate diffusion. While learning and memory depend on orchestrated synaptic activity of neuronal ensembles within the hippocampus, it is becoming increasingly evident that astrocytes residing in the environment of these synapses play a central role in shaping memories. However, how astroglial synaptic coverage contributes to mnemonic processing remains largely unknown. Here, we targeted astrocyte leaflet structure *in vivo* by depleting Ezrin, an integral leaflet-structural protein, in astrocytes of the adult hippocampal CA1 using a CRISPR-Cas9 genetic approach. This resulted in significantly smaller astrocyte territories and reduced astroglial synaptic coverage. In addition, using genetically encoded glutamate sensors and whole-cell patch-clamp recordings from pyramidal neurons, we found that Ezrin deletion and the resultant manipulation of leaflet structure boosted extrasynaptic glutamate diffusion and NMDA-receptor activation. Importantly, these cellular phenotypes translated to enhanced fear memory expression that was accompanied by increased activation of CA1 pyramidal neurons in the days after learning occurred. We show that Ezrin is critical for astrocyte morphology as well as for adult hippocampal synapse integrity and function. Our data show that astrocyte leaflets structure gates memory strength by regulating glutamate spillover in the vicinity of memory-related synaptic activity.

In the CNS, astrocyte processes regulate synaptic transmission and plasticity. They have also a role in the extra-synaptic signalling, participating with the release of extracellular vesicles. Exosomes are non-classical signal transmission and can indeed participate in volume transmission. ***Aims.*** It is known that cultured astrocytes can release exosomes, but these cells can only marginally mimic the behaviour of astrocytes *in situ*. Here we assess if isolated astrocyte processes could send messages through exosomes. ***Methods*.** We prepared freshly isolated astrocyte processes from the adult rat cerebral cortex and collected extracellular vesicles. By WB, we proved the presence of glial and exosomal markers; the vesicle size was measured with DLS; by EM, we investigated the presence of multivesicular bodies in the processes and the vesicle features. By IF, we assessed the exosome cell target when we added exosomes to a primary astrocyte-neuron co-culture. ***Results*.** Astrocyte processes expressed Alix and TSG101, and presented multivesicular bodies, consistent with their ability to release exosomes. The astrocyte-released extracellular vesicles had the typical cup-shaped appearance, the size, and markers for their parental astrocytic origin and for exosomes. These exosomes were able to selectively target neuronal cells and to be internalized by neurons. ***Conclusions*.** Isolated astrocyte processes, acutely prepared from astrocytes matured in a neuron-astrocyte network in the CNS, might participate to signal transmission by releasing exosomes. Astrocyte-released exosomes might target near or long-distance targets by volume transmission. Moreover, these exosomes might transfer NGB of astrocytic origin to target neurons.

[1]Institut NeuroMyoGène (INMG), Mechanisms in Integrated Life Sciences (MeLiS), INSERM U1314, CNRS UMR 5284, Synatac Team, Lyon, France, [2]Université Claude Bernard Lyon 1, Biologie, Villeurbanne, France, [3]Institut NeuroMyoGène (INMG), Mechanisms in Integrated Life Sciences (MeLiS), Inserm U1314, CNRS UMR 5284, Synatac Team, Lyon, France, [4]Hospices Civils de Lyon (HCL), Centre Maladies Rares Sur Les Syndromes Neurologiques Paranéoplasiques, Bron, France, [5]Centre de Recherche en Neurosciences de Lyon (CNRS), INSERM U1028, CNRS UMR 5292, Forgetting Team, Bron, France

Microglial cells, the resident immune cells of the brain, have particularly dynamic processes. Various studies suggested that beyond a possible role in surveillance, microglial dynamics could be linked to synaptic mechanisms or, at least, to neuronal activity. However, signaling pathways modulating neuronal control of microglial motility remain largely unknown. As vigilance states are characterized by distinct neuronal activities, we first assessed whether and how microglial morphodynamics is modulated during sleep/wake alternation. Our second aim was to identify neuronal signaling pathways involved in the regulation of microglial dynamic. We focused on the fractalkine signaling pathway, a chemokine released by neurons that binds to CX3CR1 expressed by microglia. Microglial morphodynamic changes were monitored through *in vivo* transcranial imaging using two-photon microscopy, while electroencephalogram and electromyogram were recorded to monitor vigilance states. Transgenic CX3CR1-GFP mice were used to observe and analyze fluorescent microglial cells. We evaluated the impact of sleep-wake cycles and fractalkine receptor depletion to figure out their role in microglial dynamic. Consequently, we performed morphodynamic analysis to evaluate process motility and cell complexity. Our results indicate a decrease in microglial morphodynamics during slow wave sleep depending on daytime. We also found that depletion of the fractalkine receptor abolished these sleep-induced morphodynamics changes, indicating that fractalkine could be involved in microglia's detection and/or response to neuronal activity changes. In conclusion, this work identifies fractalkine as potent modulator of microglial dynamics in physiological conditions. This study will lead to a better understanding of microglial functions in the context of synaptic transmission and plasticity.

Adenosine acts as a fine regulator of synaptic plasticity in the adult brain. However, its action during development remains poorly understood. We recently showed that a transient increase of the A_{2A} receptor ($A_{2A}R$) expression during hippocampal synaptogenesis matched with a role in the stabilization of nascent inhibitory GABAergic synapses of the hippocampus (Gomez-Castro et al., Science 374 2021). We asked here if this regulation extends to glutamatergic excitatory synapses. In mixed neuron-glia cultures undergoing synaptogenesis, the suppression of neuronal $A_{2A}R$ with a shRNA approach led to the loss of ~30% of glutamatergic synapses identified with the pre- and post- synaptic markers VGlut1 and PSD95. This suggests that the activation of neuronal $A_{2A}R$ stabilizes nascent glutamatergic synapses. In contrast, blocking $A_{2A}R$ in the mixed neuron-glia cultures with a selective antagonist (SCH58261) tended to increase the density of VGlut1/PSD95 synapses, and significantly reduced the mobility of the AMPA receptor GluR1 subunit within synapses, which was trapped within synapses. On the contrary, activating $A_{2A}R$ in these cultures with a selective agonist (CGS21680) led to synapse loss. Since this effect was blocked upon depletion of glial cells with arabinofuranoside or microglia with L-methylester or PLX or upon application of C1q neutralizing antibodies, we proposed that the activation of microglial $A_{2A}R$ would lead to synaptic pruning through complement-based mechanism. Therefore, neuronal and microglial $A_{2A}R$ have opposite effects on the stabilization of nascent glutamatergic synapses. We are now using conditional approaches to study the contribution of neuronal and microglial $A_{2A}R$ in vitro and in vivo.

IMPAIRED 5-HT SIGNALING TO MICROGLIA IN THE DEVELOPPING BRAIN IMPACTS CIRCUITS REFINEMENT, ADULT SOCIABILITY AND FLEXIBILITY, AND THE RESPONSE TO INFLAMMATION.

POSTER SESSION 03 - SECTION: ASTROCYTES AND MICROGLIA

Giulia Albertini[1], Catherine Béchade[1], Fanny Etienne[2], Ivana D'Andrea[1], Mélanie Druart[3], Nayadoleni Nieves Rivera[1], Corentin Le Magueresse[1], Luc Maroteaux[1], Anne Roumier[1]

Background: Microglia are key factors of brain development, notably through their role in synaptic refinement. Serotonin (5-HT), besides its role of neuromodulator in adulthood, is a neurodevelopmental factor involved in the postnatal formation of somatosensory and emotional circuits. Microglial cells express serotonin receptors, mainly the 5-HT_{2B} subtype, and we have shown that 5-HT can induce an oriented growth of their processes. Aim: Considering the involvement of microglia in normal brain development as well as in neurodevelopmental psychiatric disorders, and their sensitivity to 5-HT, we investigated how 5-HT regulates microglia in the postnatal period and the consequences of abrogating this control. Methods: To this aim, we investigated microglia morphology and synapses in mice conditionally ablated for 5-HT2B receptors in microglia specifically, and the behavioral consequences of this ablation, either since birth or P30. Results: We observed that a deletion of *Htr2b* since birth impacts on microglia development and on synapse density and axonal refinement during adolescence. Absence of this early serotonin-microglia interaction has also detrimental consequences on sociability and behavioral flexibility, and on the response to a systemic inflammation in adulthood. In contrast, invalidation of microglial *Htr2b* at P30 onward has no effect on these behaviors. Conclusion: Our results indicate that a neonatal instruction of microglia by 5-HT, before P30, is required to allow their normal functions in brain development, and that a perturbation of this early control can be a risk factor for neurodevelopmental psychiatric disorders.

MICROGLIAL REMOVAL OF INHIBITORY SYNAPSES UNLEASH THE MULTI-SENSORY POTENTIAL IN THE ASSOCIATION CORTEX

POSTER SESSION 03 - SECTION: ASTROCYTES AND MICROGLIA

Akari Hashimoto
Nagoya University Graduate School of Medicine, Department Of Anatomy And Molecular Cell Biology, Nagoya, Japan

Sensory inputs are essential to detect the external environment, but a part of them is disturbed in the blind and deaf. Traditionally, the concept of cross-modal plasticity has been raised, which an impaired sensory input is compensated by the other sensory systems. Previous study showed whisker-dependent activation of visual cortex in the eye enucleated mice. However, the mechanism of cross-modal plasticity has not been shown yet. In this research, we unravel the effect of early visual deprivation on the activation of the visual cortex with whisker stimulation. We first visualized the axonal projection from S1 (primary somatosensory cortex) to V2 (extrastriate cortex), which has whisker-evoked responses both in normal sighted and monocular deprived mice (MD). Then we detected clear differences of neuronal activity of V2 between MD and control when touched with sandpaper; normal sighted mice showed strong suppression while MD did not. This suggests that visual deprivation triggers the removal of the inherited system that the other modality suppress the cortex. We hypothesized that microglia, mediators for experience-depended synaptic plasticity, can play a part in remodeling of the circuits of V2. Actually, the depletion of microglia with pexidartinib reduced the effect of visual deprivation. We discovered microglia in MD wrap the soma of pyramidal neurons and cut the inputs from parvalbumin-expressing interneurons with immunohistological and electrophysiological methods. Furthermore, interrupting the remodeling of extracellular matrix by inhibiting matrix metalloproproteinase-9 lessens the cross-modal effect. This study will be an important clue to understand the microglial physiological function in experience-depended synaptic plasticity.

Microglia are the resident immune cells of the central nervous system. They widely contribute to the neuroinflammatory process, but their exact function in the non-pathologic brain remains elusive. In non-pathologic conditions, microglia are characterized by highly ramified and dynamic processes that constantly probe the parenchyma and contact synapses. However, the exact purpose of microglia processes motility and its potential regulation by neuronal activity remain to be determined. Recent data from the lab indicate that neuronal activity was associated with changes in microglial morphodynamics. The aim of the present study was to better characterize the interactions between synaptic activity and microglial dynamics. To that end, we used whisker stimulations (WS) *in vivo* to manipulate neuronal activity while performing two-photon imaging. We monitored both microglial morphodynamics and calcium activity of dendritic spines of the corresponding barrel cortex. Our results indicated that WS induced various dendritic spines calcium responses due to the polysynaptic nature of the network. Increase of activity in spines triggered by WS induced a shortening of the distance between the spine and the closest microglial process, an increased probability of contact, and a longer duration of contact in average. Conversely, decrease of activity in spines triggered by WS induced a shortening of the contact duration and remote location of microglial processes in respect to their initial distance. Overall, the present model provides a causal link between neuronal activity and microglial contacts in physiological condition. Our results indicate that microglial processes' proximity with spines is directly controlled by change of activity.

Aims: Microglia are the resident immune cells of the brain. They play an important role in neuroinflammatory processes. However, in recent years their role in physiological processes such as neural excitability and plasticity has been identified. Here we investigated the role of microglia in synaptic plasticity induced by 10 Hz repetitive magnetic stimulation (rMS), a clinically established non-invasive brain stimulation technique. **Methods:** Microglia were depleted from mouse organotypic tissue cultures with PLX3397 (Pexidartinib). Using whole-cell patch-clamp recordings, confocal microscopy, immunohistochemistry, protein and transcriptome analyses, we assessed structural and functional properties of CA1 pyramidal neurons in the presence or absence of microglia, and investigated the effects of 10 Hz rMS on excitatory neurotransmission and microglia. **Results:** The presence of microglia was required for the expression of excitatory synaptic plasticity in CA1 pyramidal neurons after 10 Hz rMS. Although rMS did not alter the morphology or the dynamics of microglia, an increased production and secretion of microglia-related cytokines was observed 3 h after stimulation. Indeed, substitution of these cytokines in microglia-depleted tissue cultures rescued the expression of rMS-induced synaptic plasticity. **Conclusion:** We conclude that clinically employed non-invasive electromagnetic stimulation affects synaptic plasticity by modulating the release of cytokines from microglia. Supported by DFG (SFB/TRR 167) and the MOTI-VATE Program, Faculty of Medicine, University of Freiburg.

All-trans retinoic acid induces synaptopodin-dependent metaplasticity in mouse dentate granule cells.
Previously we showed that the vitamin A metabolite all-trans retinoic acid (atRA) induces synaptic plasticity in acute brain slices prepared from the mouse and human neocortex (Lenz et al., 2021). Depending on the brain region studied, distinct effects of atRA on excitatory and inhibitory neurotransmission have been reported. Here, we used intraperitoneal injections of atRA (10 mg/kg) in adult C57BL/6J mice to study the effects of atRA on excitatory and inhibitory neurotransmission in the mouse fascia dentata-a brain region implicated in memory acquisition. No major changes in synaptic transmission were observed in the ventral hippocampus while a significant increase in both spontaneous excitatory postsynaptic current frequencies and synapse numbers were evident in the dorsal hippocampus 6 hr after atRA administration. The intrinsic properties of hippocampal dentate granule cells were not significantly different and hippocampal transcriptome analysis revealed no essential neuronal changes upon atRA treatment. In light of these findings, we tested for the metaplastic effects of atRA, that is, for its ability to modulate synaptic plasticity expression in the absence of major changes in baseline synaptic strength. Indeed, in vivo long-term potentiation (LTP) experiments demonstrated that systemic atRA treatment improves the ability of dentate granule cells to express LTP. The plasticity-promoting effects of atRA were not observed in synaptopodin-deficient mice, therefore, extending our previous results regarding the relevance of synaptopodin in atRA-mediated synaptic strengthening in the mouse prefrontal cortex. Taken together, our data show that atRA mediates synaptopodin-dependent metaplasticity in mouse dentate granule cells.

All-trans retinoic acid induces synaptic plasticity in human cortical neurons.
A defining feature of the brain is the ability of its synaptic contacts to adapt structurally and functionally in an experience-dependent manner. In the human cortex, however, direct experimental evidence for coordinated structural and functional synaptic adaptation is currently lacking. Here, we probed synaptic plasticity in human cortical slices using the vitamin A derivative all-trans retinoic acid (atRA), a putative treatment for neuropsychiatric disorders such as Alzheimer's disease. Our experiments demonstrated that the excitatory synapses of superficial (layer 2/3) pyramidal neurons underwent coordinated structural and functional changes in the presence of atRA. These synaptic adaptations were accompanied by ultrastructural remodeling of the calcium-storing spine apparatus organelle and required mRNA translation. It was not observed in synaptopodin-deficient mice, which lack spine apparatus organelles. We conclude that atRA is a potent mediator of synaptic plasticity in the adult human cortex.

Monitoring and Modulating Inflammation-Associated Alterations in Synaptic Plasticity: Role of Brain Stimulation and the Blood-Brain Interface.
Inflammation of the central nervous system can be triggered by endogenous and exogenous stimuli such as local or systemic infection, trauma, and stroke. In addition to neurodegeneration and cell death, alterations in physiological brain functions are often associated with neuroinflammation. Robust experimental evidence has demonstrated that inflammatory cytokines affect the ability of neurons to express plasticity. It has been well-established that inflammation-associated alterations in synaptic plasticity contribute to the development of neuropsychiatric symptoms. Nevertheless, diagnostic approaches and interventional strategies to restore inflammatory deficits in synaptic plasticity are limited. Here, we review recent findings on inflammation-associated alterations in synaptic plasticity and the potential role of the blood-brain interface, i.e., the blood-brain barrier, in modulating synaptic plasticity. Based on recent findings indicating that brain stimulation promotes plasticity and modulates vascular function, we argue that clinically employed non-invasive brain stimulation techniques, such as transcranial magnetic stimulation, could be used for monitoring and modulating inflammation-induced alterations in synaptic plasticity.

Interleukin 10 Restores Lipopolysaccharide-Induced Alterations in Synaptic Plasticity Probed by Repetitive Magnetic Stimulation.
Systemic inflammation is associated with alterations in complex brain functions such as learning and memory. However, diagnostic approaches to functionally assess and quantify inflammation-associated alterations in synaptic plasticity are not well-established. In previous work, we demonstrated that bacterial lipopolysaccharide (LPS)-induced systemic inflammation alters the ability of hippocampal neurons to express synaptic plasticity, i.e., the long-term potentiation (LTP) of excitatory neurotransmission. Here, we tested whether synaptic plasticity induced by repetitive magnetic stimulation (rMS), a non-invasive brain stimulation technique used in clinical practice, is affected by LPS-induced inflammation. Specifically, we explored brain tissue cultures to learn more about the direct effects of LPS on neural tissue, and we tested for the plasticity-restoring effects of the anti-inflammatory cytokine interleukin 10 (IL10). As shown previously, 10 Hz repetitive magnetic stimulation (rMS) of organotypic entorhino-hippocampal tissue cultures induced a robust increase in excitatory neurotransmission onto CA1 pyramidal neurons. Furthermore, LPS-treated tissue cultures did not express rMS-induced synaptic plasticity. Live-cell microscopy in tissue cultures prepared from a novel transgenic reporter mouse line [] confirms that LPS administration triggers microglial tumor necrosis factor alpha (TNFα) expression, which is ameliorated in the presence of IL10. Consistent with this observation, IL10 hampers the LPS-induced increase in TNFα, IL6, IL1β, and IFNγ and restores the ability of neurons to express rMS-induced synaptic plasticity in the presence of LPS. These findings establish organotypic tissue cultures as a suitable model for studying inflammation-induced alterations in synaptic plasticity, thus providing a biological basis for the diagnostic use of transcranial magnetic stimulation in the context of brain inflammation.

Microglia, the resident immune cells of the brain, play a complex role in health and disease. They actively survey the brain parenchyma by physically interacting with other cells and structurally shaping the brain. Yet, the mechanisms underlying microglia motility and their significance for synapse stability, especially during adulthood, remain widely unresolved. Here we investigated the impact of neuronal activity on microglia motility and its implication for synapse formation and survival. We used repetitive two-photon *in vivo* imaging in the hippocampus of awake mice to simultaneously study microglia motility and their interaction with synapses. By applying a pharmacological and chemogenetic approach we found that microglia process motility depended on neuronal activity. Simultaneously, more dendritic spines emerged in awake compared to anesthetized mice. Interestingly, microglia contact rates with individual dendritic spines were associated with their stability. These results suggest that microglia are not only sensing neuronal activity, but participate in synaptic rewiring of the hippocampus during adulthood, which has profound relevance for learning and memory processes.

A ROLE OF MICROGLIA ACTIVATION IN TNFα-MEDIATED SYNAPTIC PLASTICITY

POSTER SESSION 03 - SECTION: ASTROCYTES AND MICROGLIA

Dimitrios Kleidonas[1,2,3], Matthias Kirsch[1,4], Geoffroy Andrieux[5], Melanie Boerries[5,6], Andreas Vlachos[1,4,7]
[1]University of Freiburg, Department Of Neuroanatomy, Institute Of Anatomy And Cell Biology, Faculty Of Medicine, Freiburg, Germany, [2]University of Freiburg, Spemann Graduate School Of Biology And Medicine, Freiburg, Germany, [3]University of Freiburg, Faculty Of Biology, Freiburg, Germany, [4]University of Freiburg, Center Brain Links Brain Tools, Freiburg, Germany, [5]University of Freiburg, Institute Of Medical Bioinformatics And Systems Medicine, Medical Center, Faculty Of Medicine, Freiburg, Germany, [6]German Cancer Research Center (DKFZ), Heidelberg, Germany, German Cancer Consortium (dktk) Partner Site Freiburg, Freiburg, Germany, [7]University of Freiburg, Center For Basics In Neuromodulation (neuromodulbasics), Faculty Of Medicine, Freiburg, Germany

Aims: The pro-inflammatory cytokine tumor necrosis factor-α (TNFα) has been implicated in different forms of synaptic plasticity. Even though a wealth of literature suggests that TNFα affects synaptic transmission, the role of TNFα-mediated activation of microglia has not been addressed in this context. Here, we assessed concentration-dependent effects of TNFα on synaptic strength and the activation of microglia. **Methods:** We employed three-week old organotypic entorhino-hippocampal tissue cultures prepared from wild type mice of either sex. Whole-cell patch-clamp recordings of CA1 pyramidal neurons, transcriptomic analysis, immunohistochemistry and live-cell microscopy were used to study the effects of TNFα on synaptic transmission and microglial activation. **Results:** Low concentrations of TNFα promoted synaptic plasticity by enhancing excitatory synaptic strength and not affecting inhibitory neurotransmission. An increase in synaptic GluA1-content was evident 24 h after exposure to TNFα. At higher concentrations TNFα strongly activated microglia and increased inhibitory neurotransmission without affecting excitatory synaptic strength. The passive properties of CA1 pyramidal neurons were not altered by TNFα. Interestingly, microglia-depleted tissue cultures treated with a high concentration of TNFα showed enhanced excitatory neurotransmission comparable to what we observed in non-depleted tissue cultures treated with a low concentration of TNFα. **Conclusions:** These findings extend previous results on the role of TNFα in synaptic plasticity by demonstrating concentration-dependent effects of TNFα on excitatory and inhibitory neurotransmission. They suggest a role of activated microglia in homeostasis of excitatory neurotransmission.

Denervated mouse dentate granule cells adjust their excitatory but not inhibitory synapses following in vitro entorhinal cortex lesion.
Neurons adjust their synaptic strength in a homeostatic manner following changes in network activity and connectivity. While this form of plasticity has been studied in detail for excitatory synapses, homeostatic plasticity of inhibitory synapses remains not well-understood. In the present study, we employed entorhinal cortex lesion (ECL) of organotypic entorhino-hippocampal tissue cultures to test for homeostatic changes in GABAergic neurotransmission onto partially denervated dentate granule cells. Using single and paired whole-cell patch-clamp recordings, as well as immunostainings for synaptic markers, we find that excitatory synaptic strength is robustly increased 3 days post lesion (dpl), whereas GABAergic neurotransmission is not changed after denervation. Even under conditions of pharmacological inhibition of glutamatergic neurotransmission, which prevents neurons to compensate for the loss of input via excitatory synaptic scaling, down-scaling of GABAergic synapses does not emerge 3 days after denervation. We conclude that granule cells maintain structural and functional properties of GABAergic synapses even in the face of substantial changes in network connectivity. Hence, alterations in inhibitory neurotransmission, as seen in pathological brain states, may not simply reflect a homeostatic response to disconnection.
Exp Neurol, 2019; 312

Scavenging Tumor Necrosis Factor α Does Not Affect Inhibition of Dentate Granule Cells Following In Vitro Entorhinal Cortex Lesion.
Neurons that lose part of their afferent input remodel their synaptic connections. While cellular and molecular mechanisms of denervation-induced changes in excitatory neurotransmission have been identified, little is known about the signaling

pathways that control inhibition in denervated networks. In this study, we used mouse entorhino-hippocampal tissue cultures of both sexes to study the role of the pro-inflammatory cytokine tumor necrosis factor α (TNFα) in denervation-induced plasticity of inhibitory neurotransmission. In line with our previous findings in vitro, an entorhinal cortex lesion triggered a compensatory increase in the excitatory synaptic strength of partially denervated dentate granule cells. Inhibitory synaptic strength was not changed 3 days after the lesion. These functional changes were accompanied by a recruitment of microglia in the denervated hippocampus, and experiments in tissue cultures prepared from TNF-reporter mice [] showed increased TNFα expression in the denervated zone. However, inhibitory neurotransmission was not affected by scavenging TNFα with a soluble TNF receptor. In turn, a decrease in inhibition, i.e., decreased frequencies of miniature inhibitory postsynaptic currents, was observed in denervated dentate granule cells of microglia-depleted tissue cultures. We conclude from these results that activated microglia maintain the inhibition of denervated dentate granule cells and that TNFα is not required for the maintenance of inhibition after denervation.

IN VIVO TWO-PHOTON STED IMAGING OF MICROGLIA-SYNAPSE INTERACTIONS

POSTER SESSION 03 - SECTION: ASTROCYTES AND MICROGLIA

Nala Gockel, Stefanie Poll, Martin Fuhrmann
German Center for Neurodegenerative Diseases (DZNE), Neuroimmunology And Imaging, Bonn, Germany

Microglia-synapse interactions have been examined in a variety of contexts, *in vitro* and *in vivo*. Our approach goes beyond the current state-of-the-art and for the first time yields microglia-synapse interactions in super-resolution time-lapse imaging of awake mice. We established two-photon (2P) stimulated emission depletion (STED) microscopy in the hippocampus *in vivo*. This is feasible by implantation of a cranial window and head-fixation of the mice during imaging. 2P imaging enables us to increase imaging depth, decrease light scattering and restrict excitation to a smaller focal volume. At the same time the additional 3D-STED application further minimizes the illumination of the focal point and improves the point spread function not only in the x, y- dimensions but also in the z-dimension. Extensive research has been done on microglia in disease and under inflammatory conditions. However, information how microglia influence synapse stability under normal physiological conditions and related to learning and memory is still scarce. Therefore, our aim is to determine the molecular mechanisms of how microglia maintain synapse stability under normal physiological conditions in relation to learning and memory. Our results show improved resolution of 2P 3D-STED imaging of microglia-synapse interactions and a relationship between dendritic spine formation and previous contact frequency by microglia. These findings will pave the way to visualize nanoscale anatomical structures during microglia-synapse interactions *in vivo* and therefore allows longitudinal and correlative studies in combination with behavioral experiments.

THE ROLE OF MICROGLIA IN SYNAPTIC ADAPTATIONS IN THE NUCLEUS ACCUMBENS AFTER COCAINE-INDUCED CONDITIONED PLACE PREFERENCE

POSTER SESSION 03 - SECTION: ASTROCYTES AND MICROGLIA

Claudia Marchetti[1], Ingrid Reverte[1], Azka Khan[2], Daniele Caprioli[1], Davide Ragozzino[1]
[1]Sapienza, University of Rome, Physiology And Pharmacology, Rome, Italy, [2]Sapienza University of Rome, Department Of Psychology, Rome, Italy

Exposure to cocaine generates silent synapses in the nucleus accumbens. During drug withdrawal, those synapses progressively maturate by recruiting calcium permeable-AMPA receptors (CP-AMPAR). This form of plasticity has been linked to the emergence of drug-sensitization and cue-induced drug-seeking. The study of the molecular substrates that underlie these synaptic adaptations has long focused on neuronal signaling molecules. Recently microglia have emerged as a critical player for experience-dependent synaptic plasticity in the adult brain. We investigated the role of microglia in the maturation of silent synapses by the incorporation of CP-AMPAR in the nucleus accumbens after withdrawal from cocaine-conditioned place preference (CPP). We trained mice for cocaine-induced conditioned place preference. We then depleted microglia with PLX-supplemented diet for three weeks after CPP training. On day 21 we tested the mice for place preference and then performed whole-cell patch clamp recordings to determine the presence of silent synapses and CP-AMPAR.

POSSIBLE ROLES OF AMYLOID-β IN MICROGLIA-MEDIATED SYNAPSE REMODELING

POSTER SESSION 03 - SECTION: ASTROCYTES AND MICROGLIA

Kyllian Ginggen, Rosa Paolicelli
University of Lausanne, Department Of Biomedical Sciences, Lausanne, Switzerland

Microglia, the resident immune cells of the central nervous system, are critical players in neuronal plasticity and function. They are highly dynamic, constantly interacting with neighboring cells and synaptic structures. Experimental evidence indicates that close contacts with synapses are driven by synaptic activity, and are important for microglia-mediated synapse remodeling. A growing literature shows a link between synaptic activity and amyloid-β (Aβ) peptide. Aβ has been widely studied in Alzheimer's disease (AD), being the major component of the extracellular plaques associated with the pathology. Interestingly, intracellular Aβ also correlates with synaptic function. Our data, supportive of high Aβ levels in the postnatal brain, led us to hypothesize that intrasynaptic Aβ might play a role in microglia-mediated synapse remodeling.
Using an AD mouse model (ArcAβ mice) and a pharmacological approach to modulate intraneuronal Aβ load, we aim at investigating the involvement of Aβ in microglial synaptic pruning during brain development. First, we characterized the lipidomic profiles of synaptosomes isolated from ArcAβ and wildtype littermates at postnatal day 15 (P15), identifying candidate molecules that could promote engulfment by microglia. We also found that the synaptic profile in the ArcAβ hippocampus displayed alterations in both pre- and post-synaptic markers already at early time points (P15-P30). Furthermore, microglial density was reduced at P15, indicating that Aβ/humanAPP overexpression is associated with early changes in microglia. Overall, these findings suggest that synaptic and microglial alterations are present at early stages in the brain of an AD mouse model, likely contributing to neurodegeneration later in life.

ROLE OF PV+ BC MYELINATION IN INHIBITORY PRECISION IN THE MOUSE CA1 HIPPOCAMPAL MICROCIRCUIT.

POSTER SESSION 03 - SECTION: ASTROCYTES AND MICROGLIA

David Vandael[1], Maarten Kole[1,2]
[1]Netherlands Institute for Neuroscience, Axonal Signalling Group, Amsterdam, Netherlands, [2]Utrecht University, Cell Biology, Neurobiology And Biophysics, Department Of Biology, Utrecht, Netherlands

The hippocampus is of fundamental importance for the storage and retrieval of episodic memories. In the process of neuronal computations, the reliability of information transfer between neurons is critical. One mechanism to optimise precision and speed within neuronal circuits is the wrapping of neuronal axons with multi-lamellar membrane sheaths of compact myelin, reducing the capacitive load of internodes and thereby increasing conduction velocity. While the speed advantage applies to long-range axonal projections, previous studies in the neocortex suggest that myelination of locally projecting parvalbumin-positive basket cells (PV^+BC) may impact release characteristics. PV^+BC axons allow reliable propagation of high frequency trains of action potentials (APs) and are characterized by synchronous transmitter release at elevated release probabilities. These features allow PV^+BCs to function as clockworks driving network oscillations in the gamma frequency range. Here, to better understand how myelination of hippocampal PV^+BC axons affects synaptic physiology and microcircuit function, we made targeted paired patch-clamp recordings of tdTomato expressing PV^+BCs and CA1 pyramidal neurons and used the unitary inhibitory postsynaptic currents to estimate basal release and vesicle pool dynamics. Control myelinated connections were characterized by a fast onset latency of ~0.8 ms, rise- and decay time of 0.47 ms and ~6 ms, respectively. Furthermore, synapses showed a high P_r of 0.6 together with a readily-releasable-pool of ~460 pA (n = 18 pairs). Presently, using a hypomyelinated- (*Shiverer*) and toxic demyelination (cuprizone) mouse model, we are investigating the direct contribution of compact myelin to the features of synaptic precision in hippocampal area CA1.

ACETYLCHOLINE AND LATERAL HABENULA PARTNERSHIP IN SHAPING PUNISHMENT ANTICIPATION

POSTER SESSION 03 - SECTION: ASTROCYTES AND MICROGLIA

Mauro Congiu[1], Yulong Li[2], Manuel Mameli[1]
[1]University of Lausanne, Fundamental Neuroscience, Lausanne, Switzerland, [2]Peking University, School Of Life Sciences, Beijing, China

The ability to associate a neutral environmental stimulus with an aversive experience is fundamental for animal's survival since it allows to anticipate negative outcomes. The lateral habenula (LHb) is instrumental to compute aversive events and guides actions to avoid them. Recent evidence indicates that LHb neurons express functional acetylcholine (ACh) receptors whose inactivation interferes with optimal decision-making. Here we examine whether and how ACh release modulates LHb neuronal dynamics potentially dictating punishment anticipatory actions. We study neuronal and ACh dynamics in the LHb in head-restrained mice undergoing a discriminatory Pavlovian aversive conditioning task. We employ two-photon calcium imaging and fiber photometry recordings to assess LHb neuronal and ACh dynamics during the conditioning procedure, and perturb LHb function through optogenetic approaches. We find two populations of LHb neurons developing opposite dynamics to a punishment predictive cue (CS+) when mice display punishment anticipatory behaviors (i.e. eye blinking). Optogenetic manipulation of LHb neurons disrupt mouse ability to discriminate between neutral (CS-) and airpuff predictive (CS+) cues. Finally, using an ACh biosensor (GRAB-ACh), we report that ACh-dependent signal develops in the LHb in response to the CS+ after conditioning. Overall, our results indicate that two sub-populations of LHb neurons develop opposite responses to punishment predictive cues, which are relevant for mouse optimal performance. Lastly, increased ACh release arises in the LHb after learning, likely representing the underlying mechanistic substrate for LHb activity changes and mouse ability to anticipate threats appropriately.

Reward and aversion encoding in the lateral habenula for innate and learned behaviours.
Throughout life, individuals experience a vast array of positive and aversive events that trigger adaptive behavioural responses. These events are often unpredicted and engage actions that are likely anchored on innate behavioural programs expressed by each individual member of virtually all animal species. In a second step, environmental cues, that are initially neutral, acquire value through the association with external sensory stimuli, and become instrumental to predict upcoming positive or negative events. This process ultimately prompts learned goal-directed actions allowing the pursuit of rewarding experience or the avoidance of a danger. Both innate and learned behavioural programs are evolutionarily conserved and fundamental for survival. Among the brain structures participating in the encoding of positive/negative stimuli and contributing to innate and learned behaviours is the epithalamic lateral habenula (LHb). The LHb provides top-down control of monoaminergic systems, responds to unexpected appetitive/aversive stimuli as well as external cues that predict the upcoming rewards or punishments. Accordingly, the LHb controls a number of behaviours that are innate (originating from unpredicted stimuli), and learned (stemming from predictive cues). In this review, we will discuss the progresses that rodent's experimental work made in identifying how LHb activity governs these vital processes, and we will provide a view on how these findings integrate within a complex circuit connectivity.

N-Acylethanolamine Acid Amidase Inhibition Potentiates Morphine Analgesia and Delays the Development of Tolerance.
Opioids are essential drugs for pain management, although long-term use is accompanied by tolerance, necessitating dose escalation, and dependence. Pharmacological treatments that enhance opioid analgesic effects and/or attenuate the development of tolerance (with a desirable opioid-sparing effect in treating pain) are actively sought. Among them, N-palmitoylethanolamide (PEA), an endogenous lipid neuromodulator with anti-inflammatory and neuroprotective properties, was shown to exert anti-hyperalgesic effects and to delay the emergence of morphine tolerance. A selective augmentation in endogenous PEA levels can be achieved by inhibiting N-acylethanolamine acid amidase (NAAA), one of its primary

hydrolyzing enzymes. This study aimed to test the hypothesis that NAAA inhibition, with the novel brain permeable NAAA inhibitor AM11095, modulates morphine's antinociceptive effects and attenuates the development of morphine tolerance in rats. We tested this hypothesis by measuring the pain threshold to noxious mechanical stimuli and, as a neural correlate, we conducted in vivo electrophysiological recordings from pain-sensitive locus coeruleus (LC) noradrenergic neurons in anesthetized rats. AM11095 dose-dependently (3-30 mg/kg) enhanced the antinociceptive effects of morphine and delayed the development of tolerance to chronic morphine in behaving rats. Consistently, AM11095 enhanced morphine-induced attenuation of the response of LC neurons to foot-shocks and prevented the attenuation of morphine effects following chronic treatment. Behavioral and electrophysiological effects of AM11095 on chronic morphine were paralleled by a decrease in glial activation in the spinal cord, an index of opioid-induced neuroinflammation. NAAA inhibition might represent a potential novel therapeutic approach to increase the analgesic effects of opioids and delay the development of tolerance.

Neuronal adaptations in the lateral habenula during drug withdrawal: Preclinical evidence for addiction therapy.
The epithalamic lateral habenula (LHb) regulates monoaminergic systems and contributes to the expression of both appetitive and aversive behaviours. Over the past years, the LHb has emerged as a vulnerable brain structure in mental illnesses including addiction. Behavioural and functional evidence in humans and rodents provide substantial support for a role of LHb in the negative affective symptoms emerging during withdrawal from addictive substances. Multiple forms of cellular and synaptic adaptations that take hold during drug withdrawal within the LHb are causally linked with the emergence of negative affective symptoms. These results indicate that targeting drug withdrawal-driven adaptations in the LHb may represent a potential strategy to normalize drug-related behavioural adaptations. In the current review we describe the mechanisms leading to functional alterations in the LHb, as well as the existing interventions used to counteract addictive behaviours. Finally, closing this loop we discuss and propose new avenues to potentially target the LHb in humans in light of the mechanistic understanding stemming from pre-clinical studies. Altogether, we provide an overview on how to leverage cellular-level understanding to envision clinically-relevant approaches for the treatment of specific aspects in drug addiction.

Stress undermines reward-guided cognitive performance through synaptic depression in the lateral habenula.
Weighing alternatives during reward pursuit is a vital cognitive computation that, when disrupted by stress, yields aspects of neuropsychiatric disorders. To examine the neural mechanisms underlying these phenomena, we employed a behavioral task in which mice were confronted by a reward and its omission (i.e., error). The experience of error outcomes engaged neuronal dynamics within the lateral habenula (LHb), a subcortical structure that supports appetitive behaviors and is susceptible to stress. A high incidence of errors predicted low strength of habenular excitatory synapses. Accordingly, stressful experiences increased error choices while decreasing glutamatergic neurotransmission onto LHb neurons. This synaptic adaptation required a reduction in postsynaptic AMPA receptors (AMPARs), irrespective of the anatomical source of glutamate. Bidirectional control of habenular AMPAR transmission recapitulated and averted stress-driven cognitive deficits. Thus, a subcortical synaptic mechanism vulnerable to stress underlies behavioral efficiency during cognitive performance.

Mesolimbic dopamine dysregulation as a signature of information processing deficits imposed by prenatal THC exposure.
Cannabis is the illicit drug most widely used by pregnant women worldwide. Its growing acceptance and legalization have markedly increased the risks of child psychopathology, including psychotic-like experiences, which lowers the age of onset for a first psychotic episode. As the majority of patients with schizophrenia go through a premorbid condition long before this occurs, understanding neurobiological underpinnings of the prodromal stage of the disease is critical to improving illness trajectories and therapeutic outcomes. We have previously shown that male rat offspring prenatally exposed to Δ-tetrahydrocannabinol (THC), a rat model of prenatal cannabinoid exposure (PCE), exhibit extensive molecular and synaptic changes in dopaminergic neurons of the ventral tegmental area (VTA), converging on a hyperdopaminergic state. This leads to a silent psychotic-like endophenotype that is unmasked by a single exposure to THC. Here, we further characterized the VTA dopamine neuron and sensorimotor gating functions of PCE rats exposed to acute stress or a challenge of the D2 receptor agonist apomorphine, by using in vivo single-unit extracellular recordings and Prepulse Inhibition (PPI) analyses. At pre-puberty, PCE male rat offspring display a reduced population activity of VTA dopamine neurons in vivo, the majority of which are tonically active. PCE male progeny also exhibit enhanced sensitivity to dopamine D2 (DAD2) receptor activation and a vulnerability to acute stress, which is associated with compromised sensorimotor gating functions. This data extends our knowledge of the multifaceted sequelae imposed by PCE in the mesolimbic dopamine system of male pre-adolescent rats, which renders a neural substrate highly susceptible to subsequent challenges that may trigger psychotic-like outcomes.

Prenatal THC exposure produces a hyperdopaminergic phenotype rescued by pregnenolone.
The increased legal availability of cannabis has led to a common misconception that it is a safe natural remedy for, among others, pregnancy-related ailments such as morning sickness. Emerging clinical evidence, however, indicates that prenatal cannabis exposure (PCE) predisposes offspring to various neuropsychiatric disorders linked to aberrant dopaminergic function. Yet, our knowledge of how cannabis exposure affects the maturation of this neuromodulatory system remains limited. Here, we show that male, but not female, offspring of Δ-tetrahydrocannabinol (THC)-exposed dams, a rat PCE model, exhibit extensive molecular and synaptic changes in dopaminergic neurons of the ventral tegmental area, including altered excitatory-to-inhibitory balance and switched polarity of long-term synaptic plasticity. The resulting hyperdopaminergic state leads to increased behavioral sensitivity to acute THC exposure during pre-adolescence. The neurosteroid pregnenolone, a US Food and Drug Administration (FDA) approved drug, rescues synaptic defects and normalizes dopaminergic activity and behavior in PCE offspring, thus suggesting a therapeutic approach for offspring exposed to cannabis during pregnancy.

Opposite responses to aversive stimuli in lateral habenula neurons.
Appropriate behavioural strategies to cope with unexpected salient stimuli require synergistic neuronal responses in diverse brain regions. Among them, the epithalamic lateral habenula (LHb) plays a pivotal role in processing salient stimuli of aversive valence. Integrated in the complex motivational circuit, LHb neurons are indeed excited by aversive stimuli, including footshock (Fs). However, whether such excitation is a common feature represented throughout the LHb remains unclear. Here, we combined single-unit extracellular recordings in anaesthetized mice with juxtacellular labelling to describe the nature, location and pharmacological properties of Fs-driven responses within the LHb. We find that, along with Fs-excited cells, about 10% of LHb neurons display Fs-mediated inhibitory responses. Such inhibited neuronal population, in contrast to Fs-excited neurons, display regular and high frequency activity at baseline and is clustered in the medial portion of the LHb. Juxtacellular labelling of Fs-excited and inhibited neurons unravels that both populations are of glutamatergic type, as they co-localized with the EAAC1 glutamatergic transporter but not with the GAD67 GABAergic marker. Moreover, while the excitatory responses to Fs require both AMPA and NMDA receptors, the inhibitory responses rely instead on GABA channels. Taken together, our results indicate that two functionally and partly segregated LHb neuronal ensembles encode Fs in an opposite fashion. This highlights the neuronal complexity in the LHb for processing aversive external stimuli.

Punishment-Predictive Cues Guide Avoidance through Potentiation of Hypothalamus-to-Habenula Synapses.
Throughout life, individuals learn to predict a punishment via its association with sensory stimuli. This process ultimately prompts goal-directed actions to prevent the danger, a behavior defined as avoidance. Neurons in the lateral habenula (LHb) respond to aversive events as well as to environmental cues predicting them, supporting LHb contribution to cue-punishment association. However, whether synaptic adaptations at discrete habenular circuits underlie such associative learning to instruct avoidance remains elusive. Here, we find that, in mice, contingent association of an auditory cue (tone) with a punishment (foot shock) progressively causes cue-driven LHb neuronal excitation during avoidance learning. This process is concomitant with the strengthening of LHb AMPA receptor-mediated neurotransmission. Such a phenomenon occludes long-term potentiation and occurs specifically at hypothalamus-to-habenula synapses. Silencing hypothalamic-to-habenulainputs or optically inactivating postsynaptic AMPA receptors within the LHb disrupts avoidance learning. Altogether, synaptic strengthening at a discrete habenular circuit transforms neutral stimuli into salient punishment-predictive cues to guide avoidance.

Inhibition of N-acylethanolamine acid amidase reduces nicotine-induced dopamine activation and reward.
Tobacco smoke is the leading preventable cause of death in the world and treatments aimed to increase success rate in smoking cessation by reducing nicotine dependence are sought. Activation of peroxisome proliferator-activated receptor-alpha (PPARα) by synthetic or endogenous agonists was shown to suppress nicotine-induced activation of mesolimbic dopamine system, one of the major neurobiological substrates of nicotine dependence, and nicotine-seeking behavior in rats and monkeys. An alternative indirect way to activate PPARα is inhibition of N-acylethanolamine acid amidase (NAAA), one of the major hydrolyzing enzyme for its endogenous agonists palmitoylethanolamide (PEA) and oleoylethanolamide (OEA). We synthetized a novel specific brain permeable NAAA inhibitor, AM11095. We administered AM11095 to rats and carried out

brain lipid analysis, a functional observational battery (FOB) to assess toxicity, in vivo electrophysiological recording from dopamine cells in the ventral tegmental area, brain microdialysis in the nucleus accumbens shell and behavioral experiments to assess its effect on nicotine -induced conditioned place preference (CPP). AM11095 (5 and 25 mg/kg, i.p.) was devoid of neurotoxic and behavioral effects and did not affect motor behavior and coordination. This NAAA inhibitor (5 mg/kg i.p.) increased OEA and PEA levels in the hippocampus and cortex, prevented nicotine-induced activation of mesolimbic dopamine neurons in the ventral tegmental area, nicotine-induced elevation of dopamine levels in the nucleus accumbens shell and decreased the expression of nicotine CPP. Our results indicate that NAAA inhibitors represent a new class of pharmacological tools to modulate brain PEA/PPARα signalling and show potential in the treatment of nicotine dependence.

FUNCTIONAL AND MOLECULAR ANALYSES OF NG2 GLIA IN THE CEREBELLUM

POSTER SESSION 03 - SECTION: ASTROCYTES AND MICROGLIA

Dario Tascio[1], Nehal Gebril[1], Gerald Seifert[1], Frank Kirchhoff[2], Ronald Jabs[1], Christian Henneberger[1], Christian Steinhäuser[1]

Aims. Grey matter NG2 glia constitute a heterogeneous glial population whose functions remain incompletely understood. In the hippocampus, Schaffer collaterals activate AMPA receptors (AMPARs) in NG2 glia, giving rise to small post-synaptic currents (PSCs). Cerebellar climbing fibers can also form synapses with NG2 glia, producing much larger PSCs. We aim to assess mechanisms underlying these regional differences and better understand the role of NG2 glia AMPARs in influencing the activity of neuronal networks. **Methods.** Combined patch-clamp and RT-PCR analyses allowed for determining properties and functions of AMPARs expressed by cerebellar NG2 glia, and comparing them with their hippocampal counterpart. Field potential recordings (fEPSPs) were conducted in slices from mice with inducible deletion of AMPARs GluA1-4 in NG2 glia (GluAflox). **Results.** RT-PCR data suggested selective expression of the auxiliary AMPAR subunit TARP-γ2 in cerebellar NG2 glia, which is required for translocation of Ca^{2+}-permeable (CP) AMPARs to the plasma membrane. Comparing excitatory PSCs in NG2 glia of both regions while applying CP-AMPARs antagonists revealed a higher expression of those receptors in the cerebellum. fEPSPs recordings in slices from GluAflox mice unraveled impaired long term potentiation (LTP) in both regions. **Conclusions.** These findings help explaining divergent properties of NG2 glia AMPARs in the hippocampus and cerebellum. Currently, we are investigating whether the impaired plasticity in GluAflox mice can be rescued pharmacologically, to identify potential mechanisms by which NG2 glia influence neuronal networks. Auxiliary Subunits Control Function and Subcellular Distribution of AMPA Receptor Complexes in NG2 Glia of the Developing Hippocampus.
Synaptic and axonal glutamatergic signaling to NG2 glia in white matter is critical for the cells' differentiation and activity dependent myelination. However, in gray matter the impact of neuron-to-NG2 glia signaling is still elusive, because most of these cells keep their non-myelinating phenotype throughout live. Early in postnatal development, hippocampal NG2 glia express AMPA receptors with a significant Ca permeability allowing for plasticity of the neuron-glia synapses, but whether this property changes by adulthood is not known. Moreover, it is unclear whether NG2 glia express auxiliary transmembrane AMPA receptor related proteins (TARPs), which modify AMPA receptor properties, including their Ca permeability. Through combined molecular and functional analyses, here we show that hippocampal NG2 glia abundantly express TARPs γ4, γ7, and γ8 as well as cornichon (CNIH)-2. TARP γ8 undergoes profound downregulation during development. Receptors of adult NG2 glia showed an increased sensitivity to blockers of Ca permeable AMPA receptors, but this increase mainly concerned receptors located close to the soma. Evoked synaptic currents of NG2 glia were also sensitive to blockers of Ca permeable AMPA receptors. The presence of AMPA receptors with varying Ca permeability during postnatal maturation may be important for the cells' ability to sense and respond to local glutamatergic activity and for regulating process motility, differentiation, and proliferation.

Neurons are polarized cells, which build functional networks of communication, through synapses. These are specialized junctions between neurons and their formation is mediated by cell adhesion proteins. Among those, Neurexins are widely recognized as key proteins for synapse organization and loss-off-function mutations are associated with neurodevelopmental disorders as autism or schizophrenia. Three coding genes and extensive alternative splicing generate Neurexin proteins with various binding motifs, a flexibility which may determine synapse specification. A comprehensive understanding of the underlying molecular mechanisms is however largely missing. Our aim is to unravel the molecular composition of Neurexin networks in the brain by using unbiased quantitative proteomic approaches. Here we show results from targeted proteomics, combining affinity isolation of endogenous Neurexin complexes from mouse brain with high-resolution quantitative mass spectrometry. The identified interactome of Neurexin 1-3 contains members of different classes of secreted, adhesion or integral membrane proteins. This includes known binding partners (such as Cerebellin, Neuroligin and LRRTM proteins), but also quite a number of proteins that lack any annotation of primary function(s) and relation to synaptic physiology. We present in detail the common protein building blocks of Neurexins at the pre-synapse, the repertoire of ligands and trans-synaptic bridges and the differences among the isoforms. Furthermore, the impact of heparan sulfate modifications on the interactome will be shown. Together, we provide insights into the complex molecular environment of Neurexins in the brain and therefore open a possibility for future targeted analysis of molecular mechanisms involved in synapse formation, maintenance and function.

Several studies emphasize the major role of astrocytic intracellular calcium signaling in brain homeostasis and physiology. Among membrane ion Ca^{2+} channels, transient receptor potential channels (TRP), called TRPA1 and TRPV4 are of interest of astrocytic Ca^{2+} signaling. Azobenzene (Azo) is a molecule that can be switched from *trans* to *cis* configuration by light stimuli. Recent evidence indicated that Azo-derived molecular photoswitches can modulate the functionality of neurons. However, it is unknown whether Azo also specifically affects astrocytes' functions. **AIMS** Novel tools to modulate astrocytic Ca^{2+} signaling might be relevant to elucidate the mechanisms underpinning astrocytic role in information processing and in pathologies. Here, we investigate the effect of Azo in primary cultured astrocytes, heterologous expression systems and brain slices. **METHODS** Ca^{2+} imaging technique. **RESULTS** We found that photostimulation of Azo elicits Ca^{2+} signalling in astrocytes in a dose-dependent manner. Pharmacological analyses revealed that extracellular Ca^{2+} influx, intracellular Ca^{2+} release and the function of TRPV4, TRPA1 are critical for the Azo-induced Ca^{2+} signal. Experiments in heterologous expression confirmed that TRPA1 and TRPV4 are activated by Azo. We used a set of Azo derivatives to describe mechanisms beyond the observed effect. The results were confirmed also in brain slices from GFAP-eGFP mice, clearly defining a Ca^{2+}response induced by Azo photostimulation in rodent brain astrocytes. **CONCLUSIONS** Collectively the results demonstrated that the photoswitching of Azo could represent a powerful tool to trigger and modulate TRP Ca^{2+} signalling in astrocytes, thereby opening a new perspective to study astrocytes' role in brain function and dysfunction.

Glycogen is predominantly stored in astrocytes in the brain, and glycogen metabolism has been implicated in synaptic plasticity and memory. Nonetheless, cellular glycogen changes have not been visualized in live animal's brain. Here we attempted to label glycogen clusters by expressing a fluorescent protein-fused glycogen-binding protein. We expressed such a glycogen-tag probe in astrocytes of the mouse somatosensory cortex using an adeno-associated viral vector. *In vivo* two-photon microscopy through a cranial window showed a punctate distribution in astrocytic processes resembling glycogen immunohistochemistry and was distinct from the cytosolic morphology by GFP expression. Systemic administration of 20% glucose resulted in significant increases of fluorescence in the soma. Attenuating neuronal activity by Gi-DREADD also resulted in fluorescent signal increases in somas and processes after an hour. Methionine sulfoximime (LMSO, i.p. 50 mg/kg, a subconvulsive low dosage), a known reagent to increase brain glycogen content, increased fluorescence signals in somas and processes after one hour. Since cAMP elevation induces glycogen breakdown, we co-expressed Gs-DREADD and the glycogen-binding fluorescent protein. However, we found that fluorescence signal distribution was no longer punctate even before Gs-DREADD activation by CNO. Instead, the fluorescence signal had a cytosolic appearance, which is possibly due to a constitutive activation of Gs-DREADD. This first-generation glycogen probe appears to indicate glycogen localization in astrocytes. Future studies shall address glycogen dynamics in distinct brain states and during disease development.

S100B is a calcium-binding protein mainly concentrated in astrocytes. Its levels in biological fluids are recognized as a reliable, even predictive, biomarker of active neural distress. Mounting evidence now points to S100B as a Damage-Associated Molecular Pattern protein which, when released at high concentration, triggers tissue reaction to damage in various neural disorders (1). In particular, the inhibitor of S100B activity pentamidine has been shown to ameliorate clinical scores and neuropathologic-biomolecular parameters in the relapsing-remitting experimental autoimmune encephalomyelitis (EAE) mouse model of multiple sclerosis (MS) (2). Also arundic acid (AA), a known inhibitor of astrocytic S100B synthesis, in the chronic EAE,, which is another mouse model of MS usually studied. by the daily evaluation of clinical scores and neuropathologic-molecular analysis, induced lower severity compared to the vehicle-treated mice, particularly in the early phase of disease onset. A significant reduction of astrocytosis, demyelination, immune infiltrates, proinflammatory cytokines expression and enzymatic oxidative reactivity in the AA-treated group was also observed, indicating the participation of S100B in processes leading to the activated neuroinflammatory phenotype, reasonably as an astrocytic activity. The active participation of astrocytes in S100B-induced MS processes is currently studied. This scenario supports the perspective that S100B may be regarded as a therapeutic target for MS, as for different neural disorders appearing to share some common pathogenic features, reasonably attributable to neuroinflammation (1). Aims: Understanding the mechanisms of myeloid cells-specific responses during neurodegenerative pathologies is vital to promote regenerative processes. IRF5, a transcription factor highly involved in innate immunity, drives microglia/macrophage towards a pro-inflammatory state and has been associated to multiple sclerosis (MS) susceptibility. On this basis, we assessed the specific role of IRF5 in the development of MS pathogenesis. Methods and results: We analyzed the role of Irf5 in autoimmune inflammation. *Irf5*$^{-/-}$ showed exacerbated damage in the chronic phase of experimental autoimmune encephalomyelitis (EAE) mice and an excess of myelin debris in microglia/macrophages. To specifically analyze the role of Irf5 in remyelination, we induced lesions in the spinal cord of WT and *Irf5*$^{-/-}$ mice by lysolecithin injection. Interestingly, *Irf5*$^{-/-}$ animals showed larger lesions and an impairment in oligodendrocyte migration into the core of the lesion, probably as a result of extracellular matrix alterations. Moreover, *knock-out* mice animals showed a higher accumulation of myelin debris as well as an aberrant aggregation and accumulation of lipids into lipid droplets, both in the EAE and the LPC-demyelinating lesions. Transcriptomic and lipidomic analysis of WT and *Irf5*$^{-/-}$ microglia evidence a role of this transcription factor in myelin metabolism and cholesterol homeostasis. Indeed, *Irf5*$^{-/-}$ microglia showed increased accumulation of cholesterol esters and formation of cholesterol crystals. Conclusion: We demonstrated that the pro-inflammatory transcription factor Irf5 modulates lipid metabolism, mechanistic link that could be crucial for myelin regeneration in MS.

VAGUS NERVE STIMULATION REDUCES DISEASE IN RODENT MODEL OF MULTIPLE SCLEROSIS

POSTER SESSION 03 - SECTION: MULTIPLE SCLEROSIS: BIOMARKERS, PATHOGENESIS AND THERAPIES

Chandramohan Natarajan, Manojkumar Gunasekaran, David Chernoff, Yaakov Levine
SetPoint Medical, Research, Valencia, United States of America

Background: Despite multiple approved therapies for treating multiple sclerosis (MS), there remains a need for new therapeutic options. Vagus nerve stimulation (VNS) can activate neuro-immune reflexes that attenuate inflammation, increase T_{reg} populations, and is neuroprotective in the central nervous system (Immunol Rev 2012; 248(1):188). We hypothesized that VNS would be ameliorative in an experimental autoimmune encephalomyelitis (EAE) model of MS. **Aims**: To explore the effect of cervical VNS on disease severity in a standard rodent model of MS. **Methods**: VNS devices (SetPoint Medical, CA) were fully implanted in 6-week-old female Lewis rats. Following recovery, EAE was induced with myelin basic protein (0.1 mg/rat) and complete Freund's adjuvant (Hooke Laboratories, CT). Conscious rats were treated with VNS (1mA, 10 Hz, 60 second train, TID) from 7 days post-immunization (DPI), the day prior to the typical onset of clinical symptoms, through 21 DPI. Clinical scores were recorded daily in a treatment-blinded manner (0-5 scale). **Results** Cervical VNS decreased disease severity compared to the sham treatment. Maximum clinical score was significantly reduced in the VNS group (mean±SEM: 3.4±0.1 vs. 2.4±0.3, $p<0.005$) as were the number of symptomatic days (7.9±0.2 vs. 6.3±0.3, $p <0.0001$). Total AUC of clinical score vs. DPI was also significantly reduced (30%, $p <0.01$). **Conclusions**: These data indicate that daily cervical VNS reduced disease severity in a rat model of semi-established EAE, comparable to treatment with 3mg/kg/day teriflunomide. To further investigate the underlying mechanisms of these neuroprotective effects, glial and immunocyte targets are being investigated.

Aim. MicroRNAs (miRs) have come up as pleiotropic determinants in the CNS-immune system crosstalk. We aim at investigating their role in the course of multiple sclerosis (MS) especially linked to the inflammatory synaptopathy, a crucial hallmark of the disease. **Methods.** We screened, by qPCR and Bio-plex system, 24 selected miRs and 27 inflammation-related proteins circulating cerebrospinal fluid (CSF) in a large cohort of MS patients, and we correlated them with clinical, cognitive and transcranial magnetic stimulation parameters assessed at the diagnosis (T0) and after follow-up periods (Tf). Multiple statistical and bioinformatics analyses were confirmed by preclinical studies in MOG_{35-55} EAE model and transgenic mice. **Results.** We identified let-7b-5p and miR-142-3p as two main miRs with opposite functions in neuroinflammation and MS prognosis. Let-7b-5p is a potential protective factor for MS course, with anti-inflammatory and neuroprotective properties from the earliest stages of the disease. Moreover, CSF let-7b-5p levels are reduced in progressive MS and negatively correlate with disease severity at both T0 and Tf. On the contrary, miR-142-3p emerged as an adverse biomarker of the synaptopathy-driven disease progression and a promising tool for identifying personalized therapies. Indeed, we demonstrated in MS and in EAE that miR-142-3p is an essential effector of IL-1ß-induced synaptic alterations and low miR-142-3p levels associate with a more effective response to dimethyl fumarate, an established MS treatment. **Conclusions.** Our results lay the basis for an important advance in MS diagnosis and prognosis related to synaptopathy-driven detrimental outcomes, with possible implication in the therapeutic decision-making strategy.

miR-142-3p Is a Key Regulator of IL-1β-Dependent Synaptopathy in Neuroinflammation.
MicroRNAs (miRNA) play an important role in post-transcriptional gene regulation of several physiological and pathological processes. In multiple sclerosis (MS), a chronic inflammatory and degenerative disease of the CNS, and in its mouse model, the experimental autoimmune encephalomyelitis (EAE), miRNA dysregulation has been mainly related to immune system dysfunction and white matter (WM) pathology. However, little is known about their role in gray matter pathology. Here, we explored miRNA involvement in the inflammation-driven alterations of synaptic structure and function, collectively known as synaptopathy, a neuropathological process contributing to excitotoxic neurodegeneration in MS/EAE. Particularly, we observed that miR-142-3p is increased in the CSF of patients with active MS and in EAE brains. We propose miR-142-3p as a molecular mediator of the IL-1β-dependent downregulation of the glial glutamate-aspartate transporter (GLAST), which causes an enhancement of the glutamatergic transmission in the EAE cerebellum. The synaptic abnormalities mediated by IL-1β and the clinical and neuropathological manifestations of EAE disappeared in miR-142 knock-out mice. Furthermore, we observed that in vivo miR-142-3p inhibition, either by a preventive and local treatment or by a therapeutic and systemic strategy, abolished IL-1β- and GLAST-dependent synaptopathy in EAE wild-type mice. Consistently, miR-142-3p was responsible for the glutamatergic synaptic alterations caused by CSF of patients with MS, and CSF levels of miR-142-3p correlated with prospective MS disease progression. Our findings highlight miR-142-3p as key molecular player in IL-1β-mediated synaptic dysfunction, possibly leading to excitotoxic damage in both EAE and MS diseases. Inhibition of miR-142-3p could be neuroprotective in MS.

microRNAs Modulate Spatial Memory in the Hippocampus and in the Ventral Striatum in a Region-Specific Manner.
MicroRNAs are endogenous, noncoding RNAs crucial for the post-transcriptional regulation of gene expression. Their role in spatial memory formation, however, is poorly explored. In this study, we analyzed learning-induced microRNA expression in the hippocampus and in the ventral striatum. Among miRNAs specifically downregulated by spatial training, we focused on the hippocampus-specific miR-324-5p and the ventral striatum-specific miR-24. In vivo overexpression of the two miRNAs demonstrated that miR-324-5p is able to impair memory if administered in the hippocampus but not in the ventral striatum, while the opposite is true for miR-24. Overall, these findings demonstrate a causal relationship between miRNA expression changes and spatial memory formation. Furthermore, they provide support for a regional dissociation in the post-transcriptional processes underlying spatial memory in the two brain structures analyzed.

Siponimod (BAF312) prevents synaptic neurodegeneration in experimental multiple sclerosis.
Data from multiple sclerosis (MS) and the MS rodent model, experimental autoimmune encephalomyelitis (EAE), highlighted an inflammation-dependent synaptopathy at the basis of the neurodegenerative damage causing irreversible disability in these disorders. This synaptopathy is characterized by an imbalance between glutamatergic and GABAergic transmission and has been proposed to be a potential therapeutic target. Siponimod (BAF312), a selective sphingosine 1-phosphate1,5 receptor modulator, is currently under investigation in a clinical trial in secondary progressive MS patients. We investigated whether siponimod, in addition to its peripheral immune modulation, may exert direct neuroprotective effects in the central nervous system (CNS) of mice with chronic progressive EAE.

Synaptopathy connects inflammation and neurodegeneration in multiple sclerosis.
Multiple sclerosis (MS) has long been regarded as a chronic inflammatory disease of the white matter that leads to demyelination and eventually to neurodegeneration. In the past decade, several aspects of MS pathogenesis have been challenged, and degenerative changes of the grey matter, which are independent of demyelination, have become a topic of interest. CNS inflammation in MS and experimental autoimmune encephalomyelitis (EAE; a disease model used to study MS in rodents) causes a marked imbalance between GABAergic and glutamatergic transmission, and a loss of synapses, all of which leads to a diffuse 'synaptopathy'. Altered synaptic transmission can occur early in MS and EAE, independently of demyelination and axonal loss, and subsequently causes excitotoxic damage. Inflammation-driven synaptic abnormalities are emerging as a prominent pathogenic mechanism in MS-importantly, they are potentially reversible and, therefore, represent attractive therapeutic targets. In this Review, we focus on the connection between inflammation and synaptopathy in MS and EAE, which sheds light not only on the pathophysiology of MS but also on that of primary neurodegenerative disorders in which inflammatory processes contribute to disease progression.

Acute stress alters amygdala microRNA miR-135a and miR-124 expression: inferences for corticosteroid dependent stress response.
The amygdala is a brain structure considered a key node for the regulation of neuroendocrine stress response. Stress-induced response in amygdala is accomplished through neurotransmitter activation and an alteration of gene expression. MicroRNAs (miRNAs) are important regulators of gene expression in the nervous system and are very well suited effectors of stress response for their ability to reversibly silence specific mRNAs. In order to study how acute stress affects miRNAs expression in amygdala we analyzed the miRNA profile after two hours of mouse restraint, by microarray analysis and reverse transcription real time PCR. We found that miR-135a and miR-124 were negatively regulated. Among in silico predicted targets we identified the mineralocorticoid receptor (MR) as a target of both miR-135a and miR-124. Luciferase experiments and endogenous protein expression analysis upon miRNA upregulation and inhibition allowed us to demonstrate that mir-135a and mir-124 are able to negatively affect the expression of the MR. The increased levels of the amygdala MR protein after two hours of restraint, that we analyzed by western blot, negatively correlate with miR-135a and miR-124 expression. These findings point to a role of miR-135a and miR-124 in acute stress as regulators of the MR, an important effector of early stress response.

Interleukin-1β alters glutamate transmission at purkinje cell synapses in a mouse model of multiple sclerosis.
Cerebellar deficit contributes significantly to disability in multiple sclerosis (MS). Several clinical and experimental studies have investigated the pathophysiology of cerebellar dysfunction in this neuroinflammatory disorder, but the cellular and molecular mechanisms are still unclear. In experimental autoimmune encephalomyelitis (EAE), a mouse model of MS, proinflammatory cytokines, together with a degeneration of inhibitory neurons, contribute to impair GABAergic transmission at Purkinje cells (PCs). Here, we investigated glutamatergic transmission to gain insight into the pathophysiology of cerebellar dysfunction in EAE. Electrophysiological recordings from PCs showed increased duration of spontaneous excitatory postsynaptic currents (EPSCs) during the symptomatic phase of EAE, suggesting an alteration of glutamate uptake played by Bergmann glia. We indeed observed an impaired functioning of the glutamate-aspartate transporter/excitatory amino acid transporter 1 (GLAST/EAAT1) in EAE cerebellum caused by protein downregulation and in correlation with prominent astroglia activation. We have also demonstrated that the proinflammatory cytokine interleukin-1β (IL-1β), released by a subset of activated microglia/macrophages and infiltrating lymphocytes, was involved directly in such synaptic alteration. In fact, brief incubation of IL-1β in normal cerebellar slices replicated EAE modifications through a rapid GLAST/EAAT1 downregulation, whereas incubation of an IL-1 receptor antagonist (IL-1ra) in EAE slices reduced spontaneous EPSC alterations. Finally, EAE mice treated with intracerebroventricular IL-1ra showed normal glutamatergic and GABAergic transmissions, along with GLAST/EAAT1 normalization, milder inflammation, and reduced motor deficits. These results highlight the crucial role played by the proinflammatory IL-1β in triggering molecular and synaptic events involved in neurodegenerative processes that characterize neuroinflammatory diseases such as MS.

The microRNA let-7b-5p Is Negatively Associated with Inflammation and Disease Severity in Multiple Sclerosis.
The identification of microRNAs in biological fluids for diagnosis and prognosis is receiving great attention in the field of multiple sclerosis (MS) research but it is still in its infancy. In the present study, we observed in a large sample of MS patients that let-7b-5p levels in the cerebrospinal fluid (CSF) were highly correlated with a number of microRNAs implicated in MS, as well as with a variety of inflammation-related protein factors, showing specific expression patterns coherent with let-7b-5p-mediated regulation. Additionally, we found that the CSF let-7b-5p levels were significantly reduced in patients with the progressive MS compared to patients with relapsing-remitting MS and were negatively correlated with characteristic hallmark processes of the two phases of the disease. Indeed, in the non-progressive phase, let-7b-5p inversely associated with both central and peripheral inflammation; whereas, in progressive MS, the CSF levels of let-7b-5p negatively correlated with clinical disability at disease onset and after a follow-up period. Overall, our results uncovered, by the means of a multidisciplinary approach and multiple statistical analyses, a new possible pleiotropic action of let-7b-5p in MS, with potential utility as a biomarker of MS course.

MiR-142-3p regulates synaptopathy-driven disease progression in multiple sclerosis.
We recently proposed miR-142-3p as a molecular player in inflammatory synaptopathy, a new pathogenic hallmark of multiple sclerosis (MS) and of its mouse model experimental autoimmune encephalomyelitis (EAE), that leads to neuronal loss independently of demyelination. MiR-142-3p seems to be unique among potential biomarker candidates in MS, since it is an inflammatory miRNA playing a dual role in the immune and central nervous systems. Here, we aimed to verify the impact of miR-142-3p circulating in the cerebrospinal fluid (CSF) of MS patients on clinical parameters, neuronal excitability and its potential interaction with disease modifying therapies (DMTs).

Peripheral T cells from multiple sclerosis patients trigger synaptotoxic alterations in central neurons.
The crucial step in the pathogenic events that lead to the development and the progression of multiple sclerosis (MS) is the infiltration of autoreactive T cells in the brain. Data from experimental autoimmune encephalomyelitis (EAE) mice indicate that, together with microglia, T cells are responsible for the enhancement of the glutamatergic transmission in central

neurons, contributing to glutamate-mediated excitotoxicity, a pathological hallmark of both EAE and MS brains. Here, we addressed the synaptic role of T cells taken from MS patients.

Stress induces region specific alterations in microRNAs expression in mice.
Several studies have demonstrated that exposure to both acute and chronic aversive stimuli can affect neural activity in different brain areas. In particular it has been shown that stressful events can induce not only short-term changes in neural transmission and gene regulation, but also long-term changes that can lead to structural modification. In this study we investigated, in CD1 mice, the effects of single or repeated exposures to restraint stress (2h for 1 or 5 consecutive days) in the frontal cortex on a crucial class of gene expression regulators, the microRNAs (miRs).First we performed a microarray profiling on RNA extracted from the frontal cortex of mice exposed to acute or repeated restraint stress. The results indicated a prominent increase in the expression levels of different miRs after acute stress while only minor changes were observed after repeated restraint. The Northern blot analysis on selected miRs confirmed an increase after acute restraint for let-7a, miR-9 and miR 26-a/b. Finally, Northern blot analysis of the selected miRs on RNA extracted from the hippocampus of stressed mice demonstrated that such changes were region specific, as no differences were observed in the hippocampus. These data suggest that control of mRNA translation through miRs is an additional mechanism by which stressful events regulates protein expression in the frontal cortex.

Multiple Sclerosis (MS) is a chronic autoimmune neurologic disease that affects the central nervous system and produces a progressive irreversible demyelination with severe immunologic, inflammatory and neurodegenerative consequences. Alterations in the noradrenergic system have been described in MS patients and animal models. Moreover, the lesion of Locus Coeruleus (LC) noradrenergic neurons worsen the symptomatology of a MS animal model. Additionally, evidence reported beneficial effects using several experimental approaches to increase noradrenaline availability. Therefore, we hypothesize that chronic activation of LC noradrenergic neurons improves the symptomatology of an experimental autoimmune encephalomyelitis (EAE) model. Hence, designer receptor exclusively activated by designer drugs (DREADD) was bilaterally administered into the LC of transgenic C57BL/6(TH:cre) female mice. Immunization with myelin oligodendrocyte glycoprotein peptide$_{35–55}$ was used as an EAE model and oral Clozapine N-oxide (DREADD ligand) was administered to activate LC neurons since the onset or the peak of motor symptomatology. Chronic LC activation reduced the motor deficit and sickness behavior in both treatments. However, only treating since the onset of motor symptomatology reduced the anxiety and improved motor activity in EAE animals. Furthermore, both treatments reduced demyelination, glial activation and perivascular infiltration in the spinal cord (SC) of EAE animals. Interestingly, treatments improved the reduced dopamine beta-hydroxylase expression we demonstrated in the SC of EAE mice. However, the treatments effect on these processes was lower in prefrontal and motor cortices. These results support the role of noradrenergic system in MS development and highlight it as a potential target to alleviate its severe clinical course.

Pain and depression comorbidity causes asymmetric plasticity in the locus coeruleus neurons.
There is strong comorbidity between chronic pain and depression, although the neural circuits and mechanisms underlying this association remain unclear. By combining immunohistochemistry, tracing studies and western blotting, with the use of different DREADDS (designer receptor exclusively activated by designer drugs) and behavioural approaches in a rat model of neuropathic pain (chronic constriction injury), we explore how this comorbidity arises. To this end, we evaluated the time-dependent plasticity of noradrenergic locus coeruleus neurons relative to the site of injury: ipsilateral (LCipsi) or contralateral (LCcontra) locus coeruleus at three different time points: short (2 days), mid (7 days) and long term (30-35 days from nerve injury). Nerve injury led to sensorial hypersensitivity from the onset of injury, whereas depressive-like behaviour was only evident following long-term pain. Global chemogenetic blockade of the LCipsi system alone increased short-term pain sensitivity while the blockade of the LCipsi or LCcontra relieved pain-induced depression. The asymmetric contribution of locus coeruleus modules was also evident as neuropathy develops. Hence, chemogenetic blockade of the LCipsi→spinal cord projection, increased pain-related behaviours in the short term. However, this lateralized circuit is not universal as the bilateral chemogenetic inactivation of the locus coeruleus-rostral anterior cingulate cortex pathway or the intra-rostral anterior cingulate cortex antagonism of alpha1- and alpha2-adrenoreceptors reversed long-term pain-induced depression. Furthermore, chemogenetic locus coeruleus to spinal cord activation, mainly through LCipsi, reduced sensorial hypersensitivity irrespective of the time post-injury. Our results indicate that asymmetric activation of specific locus coeruleus modules promotes early restorative analgesia, as well as late depressive-like behaviour in chronic pain and depression comorbidity.

The Role of the Locus Coeruleus in Pain and Associated Stress-Related Disorders.
The locus coeruleus (LC)-noradrenergic system is the main source of noradrenaline in the central nervous system and is involved intensively in modulating pain and stress-related disorders (e.g., major depressive disorder and anxiety) and in their comorbidity. However, the mechanisms involving the LC that underlie these effects have not been fully elucidated, in part owing to the technical difficulties inherent in exploring such a tiny nucleus. However, novel research tools are now available that have helped redefine the LC system, moving away from the traditional view of LC as a homogeneous structure that exerts a uniform influence on neural activity. Indeed, innovative techniques such as DREADDs (designer receptors exclusively activated by designer drugs) and optogenetics have demonstrated the functional heterogeneity of LC, and novel magnetic resonance imaging applications combined with pupillometry have opened the way to evaluate LC activity in vivo. This review aims to bring together the data available on the efferent activity of the LC-noradrenergic system in relation to pain and its comorbidity with anxiodepressive disorders. Acute pain triggers a robust LC stress response, producing spinal cord-mediated endogenous analgesia while promoting aversion, vigilance, and threat detection through its ascending efferents. However, this protective biological system fails in chronic pain, and LC activity produces pain facilitation, anxiety, increased aversive memory, and behavioral despair, acting at the medulla, prefrontal cortex, and amygdala levels. Thus, the activation/deactivation of specific LC projections contributes to different behavioral outcomes in the shift from acute to chronic pain.

Nerve injury induces transient locus coeruleus activation over time: role of the locus coeruleus-dorsal reticular nucleus pathway.
The transition from acute to chronic pain results in maladaptive brain remodeling, as characterized by sensorial hypersensitivity and the ensuing appearance of emotional disorders. Using the chronic constriction injury of the sciatic nerve as a model of neuropathic pain in male Sprague-Dawley rats, we identified time-dependent plasticity of locus coeruleus (LC) neurons related to the site of injury, ipsilateral (LCipsi) or contralateral (LCcontra) to the lesion, hypothesizing that the LC→dorsal reticular nucleus (DRt) pathway is involved in the pathological nociception associated with chronic pain. LCipsi inactivation with lidocaine increased cold allodynia 2 days after nerve injury but not later. However, similar blockade of LCcontra reduced cold allodynia 7 and 30 days after inducing neuropathy but not earlier. Furthermore, lidocaine blockade of the LCipsi or LCcontra reversed pain-induced depression 30 days after neuropathy. Long-term pain enhances phosphorylated cAMP-response element binding protein expression in the DRtcontra but not in the DRtipsi. Moreover, inactivation of the LCcontra→DRtcontra pathway using dual viral-mediated gene transfer of designer receptor exclusively activated by designer drugs produced consistent analgesia in evoked and spontaneous pain 30 days postinjury. This analgesia was similar to that produced by spinal activation of α2-adrenoreceptors. Furthermore, chemogenetic inactivation of the LCcontra→DRtcontra pathway induced depressive-like behaviour in naïve animals, but it did not modify long-term pain-induced depression. Overall, nerve damage activates the LCipsi, which temporally dampens the neuropathic phenotype. However, the ensuing activation of a LCcontra→DRtcontra facilitatory pain projection contributes to chronic pain, whereas global bilateral LC activation contributes to associated depressive-like phenotype.

Pain in neuropsychiatry: Insights from animal models.
Pain is the most common symptom reported in clinical practice, meaning that it is associated with many pathologies as either the origin or a consequence of other illnesses. Furthermore, pain is a complex emotional and sensorial experience, as the correspondence between pain and body damage varies considerably. While these issues are widely acknowledged in clinical pain research, until recently they have not been extensively considered when exploring animal models, important tools for understanding pain pathophysiology. Interestingly, chronic pain is currently considered a risk factor to suffer psychiatric disorders, mainly stress-related disorders like anxiety and depression. Conversely, pain appears to be altered in many psychiatric disorders, such as depression, anxiety and schizophrenia. Thus, pain and psychiatric disorders have been linked in epidemiological and clinical terms, although the neurobiological mechanisms involved in this pathological bidirectional relationship remain unclear. Here we review the evidence obtained from animal models about the co-morbidity of pain and psychiatric disorders, placing special emphasis on the different dimensions of pain.

The onset of treatment with the antidepressant desipramine is critical for the emotional consequences of neuropathic pain.
Neuropathic pain is a chronic condition that is challenging to treat. It often produces considerable physical disability and emotional distress. Patients with neuropathic pain often experience depression and anxiety both of which are known to be temporally correlated with noradrenergic dysfunction in the locus coeruleus (LC) as pain becomes chronic. Antidepressants are the first-line drug therapy for neuropathic pain, and the LC represents a potential target for such therapy. In this study, we evaluated the efficacy of the tricyclic antidepressant desipramine (DMI, a noradrenaline reuptake inhibitor) in preventing or relieving the noradrenergic impairment induced by neuropathic pain. The treatment started before or after the onset of the anxiodepressive phenotype ("early or late treatment") in adult rats subjected to chronic sciatic constriction. Electrophysiological and western blotting assays showed LC dysfunction (increased bursting activity, alpha2-adrenoceptor sensitivity, tyrosine hydroxylase, and noradrenaline transporter expression) in chronic constriction injury at long term. These noradrenergic changes were concomitant to the progression of anxiety and despair-like features. Desipramine induced efficient analgesia, and it counteracted the despair-like behavior in chronic constriction injury-DMI animals, reducing the burst rate and tyrosine hydroxylase expression. Surprisingly, "early" DMI treatment did not modify pain-induced anxiety, and it dampened pain aversion, although these phenomena were abolished when the treatment commenced after noradrenaline impairment had been established. Hence, DMI seems to produce different outcomes depending when the treatment commences, indicating that the balance between the benefits and adverse effects of DMI therapy may shift as neuropathy progresses.

Deep brain stimulation electrode insertion and depression: Patterns of activity and modulation by analgesics.
An initial antidepressant effect when using deep brain stimulation (DBS) of the subcallosal area of the cingulate cortex (Cg25) to treat resistant depression that could be the result of electrode insertion has been described. We previously showed that electrode insertion into the infralimbic cortex (ILC; the Cg25 rodent correlate) provokes a temporally limited antidepressant-like effect that is counteracted by non-steroidal anti-inflammatory drugs, such as those routinely used for pain relief.

Effect of Deep Brain Stimulation of the ventromedial prefrontal cortex on the noradrenergic system in rats.
Deep Brain Stimulation (DBS) of the subgenual cingulate cortex (SCC) is a promising therapeutic alternative to treat resistant major depressive disorder. In preclinical studies, DBS of the ventromedial prefrontal cortex (vmPFC, the rodent SCC correlate) provokes an antidepressant-like effect, along with changes in noradrenaline levels at the site of stimulation. Hence, DBS appears to activate the noradrenergic-locus coeruleus (LC) system.

HCN2 ion channels play a central role in inflammatory and neuropathic pain.
The rate of action potential firing in nociceptors is a major determinant of the intensity of pain. Possible modulators of action potential firing include the HCN ion channels, which generate an inward current, I(h), after hyperpolarization of the membrane. We found that genetic deletion of HCN2 removed the cyclic adenosine monophosphate (cAMP)-sensitive component of I(h) and abolished action potential firing caused by an elevation of cAMP in nociceptors. Mice in which HCN2 was specifically deleted in nociceptors expressing Na(V)1.8 had normal pain thresholds, but inflammation did not cause hyperalgesia to heat stimuli. After a nerve lesion, these mice showed no neuropathic pain in response to thermal or mechanical stimuli. Neuropathic pain is therefore initiated by HCN2-driven action potential firing in Na(V)1.8-expressing nociceptors.

Osteopontin as a biomarker has been used for the diagnosis of diseases as well as therapeutic targets. The biological role of osteopontin remain to be evaluated in an animal model of autoimmune central nervous system diseases. The present study was aimed to evaluate the involvement of OPN in the eyes of experimental autoimmune uveitis (EAU) and experimental autoimmune encephalomyelitis (EAE) models. EAU model was developed by immunization of interphotoreceptor retinoid-binding protein in Lewis rats, while EAE was developed by immunization of MOG peptides in C57BL mice. In EAU, OPN level has been found to be significantly upregulated in the serum and eyes of EAU afftected rats on day 9 post-immunization. The level of CD44, a ligand of OPN, was increased in the ciliary body in EAU rats. Furthermore, OPN was also detected in the ciliary body and activated microglia/macrophages in the EAU retina. The results of EAE were largely matched with those of EAU cases. These results suggest that OPN is significantly increased in the eyes of both EAE mice and EAU rats, and that it may be useful as an early biomarker of ocular autoimmune diseases. Funding: This study was supported by the National Research Foundation of Korea, No. NRF-2019R1A2C1087753.

The increasing number of available treatments for multiple sclerosis (MS) highlights the need for biomarkers for individualized medicine. Fingolimod is a disease-modifying treatment that acts as a sphingosine-1-phosphate receptor modulator. It promotes the immunosuppressive activity of Myeloid-Derived Suppressor Cells (MDSCs), a cell type which can be used as biomarker of disease severity and of the degree of demyelination and axonal damage extent in MS. In the present study, we interrogate whether the abundance of peripheral MDSCs could be a useful biomarker of Fingolimod efficacy. For this purpose, blood immune cells were analyzed at disease onset of the MS model, experimental autoimmune encephalomyelitis (EAE), in an individualized manner. Fingolimod treated animals presented a milder EAE course with a less demyelination and axonal damage. However, few animals that did not respond to Fingolimod were invariably associated with a lower number of MDSCs prior to treatment initiation. Remarkably, higher MDSC abundance also revealed to be an important parameter to distinguish EAE mice prone to higher Fingolimod efficacy. Cox regression analysis showed that Fingolimod effectiveness was related to MDSC abundance and independent of other clinical or immunological variables. Lastly, MDSCs were quantified in peripheral blood mononuclear cells from MS patients at baseline and after 6 and 12 months of Fingolimod treatment. Our preliminary data showed that a higher MDSC abundance at baseline seemed to be related with lower disease activity at 12 months of follow-up. In sum, our data indicate that MDSCs may be good biomarkers for Fingolimod responsiveness and treatment efficacy in MS.

Multiple sclerosis is currently considered as the most common cause of disability in the young adults. This autoimmune, demyelinating and neurodegenerative pathology of the central nervous system (CNS) classically progress from a relapsing-remitting form in which a spontaneous regeneration of the lost myelin (also called remyelination) occurs, towards a progressive form. The latter is characterized by remyelination failure and the subsequent onset of irreversible neurological disabilities related to axonal and neuronal damage and loss (Thompson et al, 2018). The male hormones or androgens have been well-studied in animal models of CNS demyelination (Hussain et al, 2013 ; Bielecki et al, 2016 ; Laouarem et al, 2021). Their neuroprotective, anti-inflammatory and remyelinating properties have been mainly shown in male animals. However, females also produce these hormones nevertheless at much lower levels than males. The aim of the present work was to investigate if androgens display specific activities in females compared to males. In this purpose, we used different models of CNS demyelination and analyzed the brain and spinal cord from the demyelinated animals by using specific immunostainings as well as fluorescence-activated cell sorting of the peripheral immune cells. Our data indicate the repairing properties of androgens in the female tissues including neuroprotective, remyelinating and anti-inflammatory effects. They also show the regulation of peripheral immune cells in both the lymphoid organs and neural tissue. The male hormones thus contribute to CNS regeneration in females with nevertheless several specific effects compared to those previously characterized in males.

Myeloid-derived suppressor cells (MDSCs) are immature myeloid cells with a regulatory role in multiple sclerosis (MS). Our group has recently described the presence of MDSCs in the CNS of MS patients, being mainly circumscribed to areas with a high inflammatory activity. Interestingly, the abundance of MDSCs in the peripheral blood at the onset of the symptoms in the MS model experimental autoimmune encephalomyelitis is inversely correlated with clinical course severity and tissue damage extent, pointing to MDSCs as feasible bioindicators of disease progression. We investigate whether functional differences of MDSCs are involved in the severity of MS in both human samples and the EAE model. In the CNS from MS patients, the higher abundance of MDSCs in active lesions was related to a lower density of T lymphocytes. Moreover, the apoptotic T cell density increased in MS patients with milder clinical courses. After the identification of two groups of mice with different clinical course based on the clustering analysis of clinical and immunological variables at EAE onset, we corroborated that the differences in the abundance of MDSCs in both groups were not only numerical, but also functional showing different immunosuppressive activity. RNAseq analysis of MDSCs from mild EAE mice pointing to a notable MDSC immunosuppressive phenotype in less severe EAE mice. Our results suggest that disease severity is related not only to MDSC abundance but also to a better immunoregulatory function, suggesting that the modulation of MDSCs should be a promising strategy to control the disease progression in MS.

TLR4 pathway impairs synaptic number and cerebrovascular functions through astrocyte activation following traumatic brain injury.
Activation of astrocytes contributes to synaptic remodelling, tissue repair and neuronal survival following traumatic brain injury (TBI). The mechanisms by which these cells interact to resident/infiltrated inflammatory cells to rewire neuronal networks and repair brain functions remain poorly understood. Here, we explored how TLR4-induced astrocyte activation modified synapses and cerebrovascular integrity following TBI.

Myeloid-derived suppressor cells support remyelination in a murine model of multiple sclerosis by promoting oligodendrocyte precursor cell survival, proliferation, and differentiation.
The most frequent variant of multiple sclerosis (MS) is the relapsing-remitting form, characterized by symptomatic phases followed by periods of total/partial recovery. Hence, it is possible that these patients can benefit from endogenous agents that control the inflammatory process and favor spontaneous remyelination. In this context, there is increasing interest in the role of myeloid-derived suppressor cells (MDSCs) during the clinical course of experimental autoimmune encephalomyelitis (EAE). MDSCs speed up infiltrated T-cell anergy and apoptosis. In different animal models of MS, a milder disease course is related to higher presence/density of MDSCs in the periphery, and smaller demyelinated lesions in the central nervous system (CNS). These observations lead us to wonder whether MDSCs might not only exert an anti-inflammatory effect but might also have direct influence on oligodendrocyte precursor cells (OPCs) and remyelination. In the present work, we reveal for the first time the relationship between OPCs and MDSCs in EAE, relationship that is guided by the distance from the

inflammatory core. We describe the effects of MDSCs on survival, proliferation, as well as potent promoters of OPC differentiation toward mature phenotypes. We show for the first time that osteopontin is remarkably present in the analyzed secretome of MDSCs. The ablation of this cue from MDSCs-secretome demonstrates that osteopontin is the main MDSC effector on these oligodendroglial cells. These data highlight a crucial pathogenic interaction between innate immunity and the CNS, opening ways to develop MDSC- and/or osteopontin-based therapies to promote effective myelin preservation and repair in MS patients.

Tissue plasminogen activator worsens experimental autoimmune encephalomyelitis by complementary actions on lymphoid and myeloid cell responses.
Tissue plasminogen activator (tPA) is a serine protease involved in fibrinolysis. It is released by endothelial cells, but also expressed by neurons and glial cells in the central nervous system (CNS). Interestingly, this enzyme also contributes to pathological processes in the CNS such as neuroinflammation by activating microglia and increasing blood-brain barrier permeability. Nevertheless, its role in the control of adaptive and innate immune response remains poorly understood.

Neuroendothelial NMDA receptors as therapeutic targets in experimental autoimmune encephalomyelitis.
Multiple sclerosis is among the most common causes of neurological disability in young adults. Here we provide the preclinical proof of concept of the benefit of a novel strategy of treatment for multiple sclerosis targeting neuroendothelial N-methyl-D-aspartate glutamate receptors. We designed a monoclonal antibody against N-methyl-D-aspartate receptors, which targets a regulatory site of the GluN1 subunit of N-methyl-D-aspartate receptor sensitive to the protease tissue plasminogen activator. This antibody reverted the effect of tissue plasminogen activator on N-methyl-D-aspartate receptor function without affecting basal N-methyl-D-aspartate receptor activity ($n = 21$, $P < 0.01$). This antibody bound N-methyl-D-aspartate receptors on the luminal surface of neurovascular endothelium in human tissues and in mouse, at the vicinity of tight junctions of the blood-spinal cord barrier. Noteworthy, it reduced human leucocyte transmigration in an in vitro model of the blood-brain barrier ($n = 12$, $P < 0.05$). When injected during the effector phase of MOG-induced experimental autoimmune encephalomyelitis ($n = 24$), it blocked the progression of neurological impairments, reducing cumulative clinical score ($P < 0.001$) and mean peak score ($P < 0.001$). This effect was observed in wild-type animals but not in tissue plasminogen activator knock-out animals ($n = 10$). This therapeutic effect was associated to a preservation of the blood-spinal cord barrier ($n = 6$, $P < 0.001$), leading to reduced leucocyte infiltration ($n = 6$, $P < 0.001$). Overall, this study unveils a critical function of endothelial N-methyl-D-aspartate receptor in multiple sclerosis, and highlights the therapeutic potential of strategies targeting the protease-regulated site of N-methyl-D-aspartate receptor.

Myeloid derived suppressor cells in inflammatory conditions of the central nervous system.
The knowledge of the immune system elements and their relationship with other tissues, organs and systems are key approximations for the resolution of many immune-related disorders. The control of the immune response and/or its modulation from the pro-inflammatory to the anti-inflammatory response is being deeply studied in the field. In the last years, the study of myeloid-derived suppressor cells (MDSCs), a group of immature myeloid cells with a high suppressive activity on T cells has been extensively addressed in cancer. In contrast, their role in neuroimmune diseases is far from being totally understood. In this review, we will summarize data about MDSCs coming from the study of neuroinflammatory diseases in general and their potential role in multiple sclerosis, in order to introduce the putative use of this extraordinary promising cell type for future cell-based therapies. This article is part of a Special Issue entitled: Neuro Inflammation edited by Helga E. de Vries and Markus Schwaninger.

The synthetic retinoid Am80 delays recovery in a model of multiple sclerosis by modulating myeloid-derived suppressor cell fate and viability.
Relapsing-remitting multiple sclerosis (RR-MS) is an inflammatory and demyelinating disease of the central nervous system (CNS). It is characterized by relapsing phases with ongoing neurological affectation that are followed by a remitting period in which inflammatory events are controlled and the patients partially recover. Experimental Autoimmune Encephalomyelitis (EAE) is the animal model most often used to study the inflammatory component of MS. Several cell types are involved in controlling the immune response in EAE and immature myeloid-derived suppressor cells (MDSCs) have emerged as

important actors in the immunomodulation that occurs in EAE due to their ability to suppress inflammatory responses by inducing T cell apoptosis. In this study, we assessed whether MDSC differentiation may have consequences on the clinical course of EAE by treating mice around the peak of the clinical course EAE with the MDSC-differentiating agent Am80, an analogue of retinoid acid. Am80 administration abrogates the immunomodulation that occurs in EAE mice through different MDSC-related mechanisms: i) induction of MDSC apoptosis; ii) polarization of MDSCs to mature subsets of myeloid cells (dendritic cells/macrophages/neutrophils); and iii) altering their immunosuppressor phenotype. Consequently, T cell density increases and their viability is promoted, delaying the animal's recovery. Therefore, our data point to MDSC behaviour as a crucial factor in facilitating the transition from the relapsing to the remission phase in EAE, which should be considered for future immune-related therapies for MS.

The effect of glia-glia interactions on oligodendrocyte precursor cell biology during development and in demyelinating diseases.
Oligodendrocyte precursor cells (OPCs) originate in specific areas of the developing central nervous system (CNS). Once generated, they migrate towards their destinations where they differentiate into mature oligodendrocytes. In the adult, 5-8% of all cells in the CNS are OPCs, cells that retain the capacity to proliferate, migrate, and differentiate into oligodendrocytes. Indeed, these endogenous OPCs react to damage in demyelinating diseases, like multiple sclerosis (MS), representing a key element in spontaneous remyelination. In the present work, we review the specific interactions between OPCs and other glial cells (astrocytes, microglia) during CNS development and in the pathological scenario of MS. We focus on: (i) the role of astrocytes in maintaining the homeostasis and spatial distribution of different secreted cues that determine OPC proliferation, migration, and differentiation during CNS development; (ii) the role of microglia and astrocytes in the redistribution of iron, which is crucial for myelin synthesis during CNS development and for myelin repair in MS; (iii) how microglia secrete different molecules, e.g., growth factors, that favor the recruitment of OPCs in acute phases of MS lesions; and (iv) how astrocytes modify the extracellular matrix in MS lesions, affecting the ability of OPCs to attempt spontaneous remyelination. Together, these issues demonstrate how both astroglia and microglia influence OPCs in physiological and pathological situations, reinforcing the concept that both development and neural repair are complex and global phenomena. Understanding the molecular and cellular mechanisms that control OPC survival, proliferation, migration, and differentiation during development, as well as in the mature CNS, may open new opportunities in the search for reparative therapies in demyelinating diseases like MS.

Megalin mediates the influence of sonic hedgehog on oligodendrocyte precursor cell migration and proliferation during development.
Oligodendrocyte precursor cells (OPCs) of the optic nerve are generated in the preoptic area, from where they migrate to colonize it entirely. Sonic hedgehog (Shh) induces the proliferation of these cells as well as influencing their migration, acting through its canonical receptor (Ptc-1). However, the multiligand receptor megalin (or LRP-2) is also involved in Shh-induced OPC proliferation and migration, and thus, we have evaluated the relevance of this interaction. During the stages at which Shh influences OPC development, we found megalin to be selectively expressed by optic nerve astrocytes, whereas Ptc-1 and Gli1 were found in OPCs. Indeed, this pattern of expression paralleled the rostral-caudal expression of the three Shh-related molecules during the time course of plp-dm20(+) -OPC colonization. The blockage of megalin partially abolished OPC chemoattraction and fully impaired Shh-induced proliferation. Using in vitro co-cultures of dissociated optic nerve cells, we demonstrated that Shh was internalized by astrocytes via megalin, and sufficient Shh was subsequently released to produce the biological effects on OPCs observed in the nerve. Together, these data indicate that at least part of the influence of Shh on OPCs is mediated by megalin during optic nerve development, and that astrocytes expressing megalin transiently capture Shh to present it to OPCs and/or to control the gradient of this molecule during development.

Myeloid-derived suppressor cells limit the inflammation by promoting T lymphocyte apoptosis in the spinal cord of a murine model of multiple sclerosis.
Multiple Sclerosis (MS) is a demyelinating/inflammatory disease of the central nervous system. Relapsing-remitting MS is characterized by a relapsing phase with clinical symptoms and the production of inflammatory cell infiltrates, and a period of remission during which patients recover partially. Myeloid-derived suppressor cells (MDSCs) are immature cells capable of suppressing the inflammatory response through Arginase-I (Arg-I) activity, among other mechanisms. Here, we have identified Arg-I(+) -MDSCs in the spinal cord during experimental autoimmune encephalomyelitis (EAE), cells that were largely restricted to the demyelinating plaque and that always exhibited the characteristic MDSC surface markers Arg-

I/CD11b/Gr-1/M-CSF1R. The presence and density of Arg-I(+) -cells, and the proportion of apoptotic but not proliferative T cells, were correlated with the EAE time course: peaked in parallel with the clinical score, decreased significantly during the remitting phase and completely disappeared during the chronic phase. Spinal cord-isolated MDSCs of EAE animals augmented the cell death when co-cultured with stimulated control splenic CD3 T cells. These data point to an important role for MDSCs in limiting inflammatory damage in MS, favoring the relative recovery in the remitting phase of the disease. Thus, the MDSC population should be considered as a potential therapeutic target to accelerate the recovery of MS patients.
Brain Pathol, 2011; 21

FGF-2 and Anosmin-1 are selectively expressed in different types of multiple sclerosis lesions.
Multiple sclerosis is a demyelinating disease that affects ≈ 2,000,000 people worldwide. In the advanced stages of the disease, endogenous oligodendrocyte precursors cannot colonize the lesions or differentiate into myelinating oligodendrocytes. During development, both FGF-2 and Anosmin-1 participate in oligodendrocyte precursor cell migration, acting via the FGF receptor 1 (FGFR1). Hence, we performed a histopathological and molecular analysis of these developmental modulators in postmortem tissue blocks from multiple sclerosis patients. Accordingly, we demonstrate that the distribution of FGF-2 and Anosmin-1 varies between the different types of multiple sclerosis lesions: FGF-2 is expressed only within active lesions and in the periplaque of chronic lesions, whereas Anosmin-1 is upregulated within chronic lesions and is totally absent in active lesions. We show that the endogenous oligodendrocyte precursor cells recruited toward chronic-active lesions express FGFR1, possibly in response to the FGF-2 produced by microglial cells in the periplaque. Also in human tissue, FGF-2 is upregulated in perivascular astrocytes in regions of the normal-appearing gray matter, where the integrity of the blood-brain barrier is compromised. In culture, FGF-2 and Anosmin-1 influence adult mouse oligodendrocyte precursor cell migration in the same manner as at embryonic stages, providing an explanation for the histopathological observations: FGF-2 attracts/enhances its migration, which is hindered by Anosmin-1. We propose that FGF-2 and Anosmin-1 are markers for the histopathological type and the level of inflammation of multiple sclerosis lesions, and that they may serve as novel pharmacogenetic targets to design future therapies that favor effective remyelination and protect the blood-brain barrier.

OLFACTORY DYSFUNCTION AND PRONOUNCED GLIOSIS IN THE OLFACTORY BULB PRECEDE MOTOR IMPAIRMENT IN THE RAT MODEL OF MULTIPLE SCLEROSIS

POSTER SESSION 03 - SECTION: MULTIPLE SCLEROSIS: BIOMARKERS, PATHOGENESIS AND THERAPIES

Andjela Stekic
University of Belgrade. Faculty of Biology, Department For General Physiology And Biophysics, Belgrade, Serbia

Background: Olfactory dysfunction is a common symptom in several neurodegenerative disorders, including Parkinson's and Alzheimer's disease, which appear decades before motor disability and cognitive decline. Clinical studies have shown that a certain percentage of multiple sclerosis (MS) patients manifest reduced olfaction in the prodromal phase of the disease. The underlying mechanism of olfactory dysfunction and the changes in the olfactory pathway may be central to understanding the autoimmune disease onset and progression. **Aim**: The objective of this study was to examine the occurrence of olfactory dysfunction and dynamics of neuroinflammatory activation that may underlie the sensory deterioration in experimental autoimmune encephalomyelitis (EAE), a rat model of MS. **Methods**: Two-month-old male *Dark agouti* rats were used in the study. Animals were tested for olfactory latency by Buried food test before and after the induction of EAE until motor symptoms began to interfere with the test performance. EAE was induced by injection of encephalitogenic emulsion (rat spinal cord homogenate in a complete Freund's adjuvant). Animals were sacrificed in the paralytic stage of the disease and olfactory bulbs (OB) were bilaterally dissected and processed for immunohistochemistry. **Results**: The first signs of olfactory dysfunction appeared at 2-dpi and exhibited a relapsing-remitting-like dynamic, while motor disabilities first began at 7-dpi. Immunohistochemical analysis demonstrated prominent gliosis in OB, reflected as massively increased GFAP and Iba1 immunoreactivity. **Conclusion:** Olfactory dysfunction and associated reactive gliosis precede the onset of neurological disabilities in EAE and may be used as an early diagnostic tool and/or marker of disease progression.

Downregulation of CD73/AR-Mediated Adenosine Signaling as a Potential Mechanism of Neuroprotective Effects of Theta-Burst Transcranial Magnetic Stimulation in Acute Experimental Autoimmune Encephalomyelitis.
Multiple sclerosis (MS) is a chronic neurodegenerative disease caused by autoimmune-mediated inflammation in the central nervous system. Purinergic signaling is critically involved in MS-associated neuroinflammation and its most widely applied animal model-experimental autoimmune encephalomyelitis (EAE). A promising but poorly understood approach in the treatment of MS is repetitive transcranial magnetic stimulation. In the present study, we aimed to investigate the effect of continuous theta-burst stimulation (CTBS), applied over frontal cranial bone, on the adenosine-mediated signaling system in EAE, particularly on CD73/AR/AR in the context of neuroinflammatory activation of glial cells. EAE was induced in two-month-old female DA rats and in the disease peak treated with CTBS protocol for ten consecutive days. Lumbosacral spinal cord was analyzed immunohistochemically for adenosine-mediated signaling components and pro- and anti-inflammatory factors. We found downregulated IL-1β and NF- κB- and upregulated IL-10 pointing towards a reduction in the neuroinflammatory process in EAE animals after CTBS treatment. Furthermore, CTBS attenuated EAE-induced glial eN/CD73 expression and activity, while inducing a shift in AR expression from glia to neurons, contrary to EAE, where tight coupling of eN/CD73 and AR on glial cells is observed. Finally, increased glial AR expression following CTBS supports anti-inflammatory adenosine actions and potentially contributes to the overall neuroprotective effect observed in EAE animals after CTBS treatment.

EPENDYMA: A NEW TARGET FOR AUTOANTIBODIES FROM NEUROMYELITIS OPTICA PATIENTS?

POSTER SESSION 03 - SECTION: MULTIPLE SCLEROSIS: BIOMARKERS, PATHOGENESIS AND THERAPIES

Maxime Bigotte, Anne Ruiz, Aseel El-Hajj, Pascale Giraudon, Gael Malleret, Paul Salin, Romain Marignier
Université Claude Bernard Lyon 1, Centre De Recherche En Neurosciences De Lyon, Bron, France

Background: Ependyma maintains crucial functions such as the regulation of cerebrospinal fluid (CSF) circulation by synchronous ciliary beating, the monitoring of molecular exchanges between CSF and parenchyma and the regulation of neural stem cells (NSCs) proliferation and survival present in the subventricular zone (SVZ). Neuromyelitis Optica (NMO) is a severe neurological disease associated with autoantibodies (NMO-IgG), directed against aquaporin 4 (AQP4). NMO-IgG are known to trigger astrocyte dysfunction leading to demyelination and axonal loss. Interestingly, ependymal cells also express AQP4 and evidences of ependymal alteration are reported in NMO. **Aims:** To evaluate morphological changes and dysfunctions of ependyma induced by NMO-IgG. **Methods:** NMO-IgG were purified from AQP4 antibodies positive patients' plasma. IgG from healthy donors (CTRL-IgG) and non-treated conditions were used as controls. Primary ependymal cell cultures and cultured wholemount dissections ("en-face" view of the entire ependyma) from adult rat lateral ventricular were exposed to NMO-IgG or control conditions. Immunolabeling and ependymal flow assay with fluorescent microbeads were used to evaluate morphological and functional changes. **Results:** We showed that NMO-IgG: 1) induced agglomeration of AQP4 and the gap junction connexin-43 at the lateral membrane of ependymocyte, and increased cell size; 2) induced planar apical depolarization of cilia tufts and altered the speed of beads injected on the surface of wholemounts; 3) activated the subventricular NSCs by increasing the number of proliferating cells and the number of quiescent NSCs processes contacting the CSF. **Conclusions:** NMO-IgG directly induce alterations of ependymal cells' functions and suggest an involvement of ependyma in NMO physiopathology.

Patients suffering from relapsing remitting form of multiple sclerosis go through successive episodes of demyelination/remyelination with sensory-motor loss followed by functional recovery. Cognitive impact of such episodes is rarely addressed, although 40-60% of MS patients suffer from cognitive impairment. Yet, growing amount of studies suggest that myelin alteration is a common feature of psychiatric disorders and neurodegenerative diseases such as Alzheimer's disease (AD). In this project, we address in mouse models the link between myelin alteration and cognitive deficits by evaluating the long-term effects of a transient demyelination at the cognitive, histological, ultrastructural and electrophysiological levels. Mice fed with cuprizone for 5 weeks undergo massive demyelination, followed by spontaneous remyelination. While sensory-motor and cognitive deficits have largely been studied during the demyelination/remyelination process, few studies have questioned the possible long-term effects. We followed up cognitive performances of mice at late time points when remyelination is supposed to be complete, and evidenced persistent signs of anxiety, together with working memory and flexibility deficits. We hypothesize that although gross myelin quantification shows efficient remyelination, subtle alterations of the myelin pattern in the cortex and/or in the hippocampus may underlie network dysfunction. To test this hypothesis, we are starting to perform electrophysiological recordings and ultrastructural analyses with optical and electronic microscopy in the medial prefrontal-hippocampus network of remyelinated mice. To further address the role of myelin in cognitive deficits observed in neurodegenerative diseases, we also study AD pathogenesis and evaluate weather myelin dysfunction may underlie or contribute to AD development.

PROTEOMIC ALTERATION AND MORPHOLOGICAL CHANGES OF SIBLING NG2 GLIAL CELLS IN RESPONSE TO TWO EXPERIMENTAL MODELS OF MULTIPLE SCLEROSIS

POSTER SESSION 03 - SECTION: MULTIPLE SCLEROSIS: BIOMARKERS, PATHOGENESIS AND THERAPIES

Sonsoles Barriola[1], Lina Delgado-García[2], Ignacio Iñigo-Marco[3], Joaquín Fernández-Irigoyen[3], Enrique Santamaría[3], Laura López-Mascaraque[1]

Multiple sclerosis (MS) is an autoimmune and neurodegenerative disorder of the central nervous system (CNS). The variability in the MS pathophysiology makes difficult its study, although the use of animal models gives a more holistic comprehension of this disease. Here we used two murine experimental models, the autoimmune encephalomyelitis (EAE) and the toxin-induced demyelination by cuprizone (CPZ). Those models reflect different MS pathophysiological mechanisms to respectively simulate the relapsing-remitting and the primary progressive MS forms in human. NG2-glia, also referred as oligodendrocyte precursor cells (OPC), are of great interest in demyelinating diseases due to their remyelination potential. Here, we investigate the morphological differential response, to CPZ and EAE cortical brain lesions, of clonally related NG2-glia using an *in vivo* genetic multicolor lineage-tracing tool, StarTrack, along with a single-cell morphometric cluster analysis. Data from the morphometric analysis allowed us to unravel different NG2-glia cell clusters categorized by morphological parameters related, not only to their ontogenic origin, but also to their changes due to the different demyelinating scenarios. In addition, to address the differential altered neural pathways, we compared the proteomic profile of EAE brains (at the peak stage of acute EAE), and CPZ brains (during the acute phase) in both somatosensory cortex and spinal cord. Our analysis revealed altered proteins in both regions and MS murine models.

Background: CSPGs are key components of the extracellular matrix involved in forming a glial scar around injuries in the central nervous system (CNS). An injury in the CNS causes astrocytes to produce CSPGs in excess, which prevents spontaneous remyelination, facilitated by the interactions between CSPGs and their receptors from the protein tyrosine phosphatase receptor (PTPRS,F) and Nogo receptor families (NgR1,3). **Aim:** The objective of this investigation was to study the potential regenerative effect created by the blockage of the interaction of CSPGs and their inhibitory receptors by a proliferation inducing ligand from the TNF superfamily (APRIL, TNFSF13), a natural ligand of CSPGs recently identified in the laboratory. **Methods:** Competitive ELISA was performed to test the effect of APRIL on the interaction between CSPGs and their receptors PTPRS and NgR1. To see the functional effect of these interactions, *in vitro* neurite outgrowth assays were performed, by culturing neurons on CSPG coated surfaces with a subsequent rescue condition using APRIL. These were followed by an *ex vivo* myelination assay, carried out with chemically demyelinated organotypic cerebellar tissues, to observe the effect of APRIL on remyelination. **Results:** Binding of APRIL to various CSPGs impaired their interactions with PTPRS and NgR1. APRIL also restored the neurite outgrowth suppressed by CSPGs *in vitro,* and showed a marked increase of remyelination in the *ex vivo* demyelinated cerebellar slices. **Conclusion:** CSPG antagonism by APRIL shows great promise in terms of neuroregeneration. Our future investigations will explore the possibility to translate this trait of APRIL's to Multiple Sclerosis.

PLASMA CONCENTRATION OF IFNα2, MCP-3, IL-6 AND IL-8 IS DIFFERENTIALLY DECREASED IN NON-ACTIVE PRIMARY PROGRESSIVE MULTIPLE SCLEROSIS

POSTER SESSION 03 - SECTION: MULTIPLE SCLEROSIS: BIOMARKERS, PATHOGENESIS AND THERAPIES

Albert Miguela-Benavides[1], Imma Gómez[1], María Muñoz-San Martín[1], Marina González-Del Río[1,2], Gary Álvarez-Bravo[1,2], René Robles-Cedeño[1,2,3], Ana Quiroga-Varela[1], Lluís Ramió-Torrentà[1,2,3]

AIMS: Disease presentation in multiple sclerosis (MS) is heterogeneous, making diagnosis sometimes challenging. Descriptors such as activity and progression have been applied to relapsing-remitting (RRMS) and primary progressive (PPMS) phenotypes. PPMS can also be further characterized as non-active or active according to the ongoing disease process. However, biomarkers that facilitate distinction of MS phenotypes and prediction of the disease course might improve patient care. We aim to identify differential patterns in biomarkers of inflammation and oxidative stress in cerebrospinal fluid (CSF) and blood which could be used to distinguish between these two MS phenotypes. METHODS: Plasma and cell-free CSF from RRMS, PPMS, and control individuals were collected. Eight pro-inflammatory cytokines were assessed in plasma using a Milliplex multiplex assay. CSF levels of two biomarkers for oxidative stress, H_2O_2 and 8-iso-prostaglandin-F2α, were measured by luminometry and ELISA respectively. RESULTS: In plasma, IFNα2 and MCP-3 levels were decreased in non-active PPMS and controls compared to RRMS. IL-8 concentration was significantly lower in non-active PPMS compared to RRMS while IL-6 levels were reduced in non-active PPMS compared to active PPMS. H_2O_2 concentration was higher in non-active PPMS CSF than in RRMS. No differences between groups have been observed in 8-iso-prostaglandin-F2α levels in CSF. CONCLUSIONS: Our results suggest that IFNα2, MCP-3, IL-6, and IL-8 concentration in plasma and H_2O_2 concentration in CSF could be a helpful tool to distinguish between active and non-active PPMS. These results may contribute, after a validation process, to change our treatment approach for people diagnosed with this debilitating disease.

In recent years, dietary supplementations are attracting the attention of researchers to support therapy and ameliorate life quality in patients suffering from multiple sclerosis (MS). Among foods, pomegranate recently gained huge popularity as a nutraceutical source, thanks to its high content in bioactive compounds, such as ellagic acid (EA). However, the efficacy of pomegranate extracts is questioned because of the low solubility of this component. To increase its bioavailability, a new formulation of a pomegranate-peel extract (PEm) has been proposed. The extract was administered to mice suffering from the experimental autoimmune encephalomyelitis (EAE), and its potential health properties were investigated and compared to those elicited by a formulation containing EA (EAm).
Control and EAE mice were chronically administered with EAm and PEm (50mg/kg) dissolved in the drinking water for 14 days starting from the onset of the clinical signs (11 d.p.i). Then, animals were sacrificed, and the spinal cords were collected for immunohistochemical and western blot analyses.
The treatment with both EAm and PEm elicted a significant amelioration of the clinical symptoms as well as a reduction of microgliosis, astrocytosis, and lymphocyte infiltration in the spinal cord of EAE mice since western blot and immunohistochemical studies unveiled a reduction of CD45, GFAP, and Iba1 immunopositivity.
These findings support the potential use of both EAm and PEm as a dietary supplement and therapeutic support in MS patients.

Aim. Chronic inflammation promoted by nutritional overload contributes to Multiple Sclerosis (MS) susceptibility and disease severity. In MS and in its mouse model experimental autoimmune encephalomyelitis (EAE) inflammatory molecules and downstream mechanisms cause 'synaptopathy', a reversible synaptic dysfunction that can cause excitotoxic damage and neuronal death. We aim at further understanding the relationship of nutritional overload with neuroinflammation and synaptic damage participating in EAE and MS course.
Methods. We explored the impact of high fat diet (HFD) compared to standard diet (SD) in EAE and control mice (n=25 for each experimental group) by monitoring clinical score and by performing behavioural, electrophysiological and molecular experiments. A clinical retrospective study on MS patients was performed to support our preclinical observations.
Results. HFD caused significant increase of both striatal excitatory transmission and neuroinflammation in control mice. HFD obesity prompted a worsen EAE clinical deficits by increasing clinical score and weight loss dependent on EAE induction. Interestingly, during the acute phase of the disease the HFD exacerbated the EAE striatal synaptopathy, strongly increasing the duration and the frequency of glutamatergic currents. In parallel, the striatal neuroinflammatory status of EAE mice fed with HFD was significantly enhanced compared to EAE mice fed with SD. Finally, statistical analyses in MS patients showed that an altered lipid profile correlates with disease severity and cerebrospinal fluid glutamate levels in MS patients.
Conclusions. Our results indicate that HFD strongly contributes to the pathophysiology of EAE/MS by enhancing neuroinflammation and glutamate-mediated synaptopathy, both reversible mechanisms that control MS severity.

Emerging Role of Extracellular Vesicles in the Pathophysiology of Multiple Sclerosis.
Extracellular vesicles (EVs) represent a new reality for many physiological and pathological functions as an alternative mode of intercellular communication. This is due to their capacity to interact with distant recipient cells, usually involving delivery of the EVs contents into the target cells. Intensive investigation has targeted the role of EVs in different pathological conditions, including multiple sclerosis (MS). MS is a chronic inflammatory and neurodegenerative disease of the nervous system, one of the main causes of neurological disability in young adults. The fine interplay between the immune and nervous systems is profoundly altered in this disease, and EVs seems to have a relevant impact on MS pathogenesis. Here, we provide an overview of both clinical and preclinical studies showing that EVs released from blood-brain barrier (BBB) endothelial cells, platelets, leukocytes, myeloid cells, astrocytes, and oligodendrocytes are involved in the pathogenesis of MS and of its rodent model experimental autoimmune encephalomyelitis (EAE). Most of the information points to an impact of EVs on BBB damage, on spreading pro-inflammatory signals, and altering neuronal functions, but EVs reparative function of brain damage deserves attention. Finally, we will describe recent advances about EVs as potential therapeutic targets and tools for

therapeutic intervention in MS.

Re-Examining the Role of TNF in MS Pathogenesis and Therapy.
Multiple sclerosis (MS) is a common neurological disorder of putative autoimmune origin. Clinical and experimental studies delineate abnormal expression of specific cytokines over the course of the disease. One major cytokine that has been shown to play a pivotal role in MS is tumor necrosis factor (TNF). TNF is a pleiotropic cytokine regulating many physiological and pathological functions of both the immune system and the central nervous system (CNS). Convincing evidence from studies in human and experimental MS have demonstrated the involvement of TNF in various pathological hallmarks of MS, including immune dysregulation, demyelination, synaptopathy and neuroinflammation. However, due to the complexity of TNF signaling, which includes two-ligands (soluble and transmembrane TNF) and two receptors, namely TNF receptor type-1 (TNFR1) and type-2 (TNFR2), and due to its cell- and context-differential expression, targeting the TNF system in MS is an ongoing challenge. This review summarizes the evidence on the pathophysiological role of TNF in MS and in different MS animal models, with a special focus on pharmacological treatment aimed at controlling the dysregulated TNF signaling in this neurological disorder.

Inflammation-Associated Synaptic Alterations as Shared Threads in Depression and Multiple Sclerosis.
In the past years, several theories have been advanced to explain the pathogenesis of Major Depressive Disorder (MDD), a neuropsychiatric disease that causes disability in general population. Several theories have been proposed to define the MDD pathophysiology such as the classic "monoamine-theory" or the "glutamate hypothesis." All these theories have been recently integrated by evidence highlighting inflammation as a pivotal player in developing depressive symptoms. Proinflammatory cytokines have been indeed claimed to contribute to stress-induced mood disturbances and to major depression, indicating a widespread role of classical mediators of inflammation in emotional control. Moreover, during systemic inflammatory diseases, peripherally released cytokines circulate in the blood, reach the brain and cause anxiety, anhedonia, social withdrawal, fatigue, and sleep disturbances. Accordingly, chronic inflammatory disorders, such as the inflammatory autoimmune disease multiple sclerosis (MS), have been associated to higher risk of MDD, in comparison with overall population. Importantly, in both MS patients and in its experimental mouse model, Experimental Autoimmune Encephalomyelitis (EAE), the notion that depressive symptoms are reactive epiphenomenon to the MS pathology has been recently challenged by the evidence of their early manifestation, even before the onset of the disease. Furthermore, in association to such mood disturbance, inflammatory-dependent synaptic dysfunctions in several areas of MS/EAE brain have been observed independently of brain lesions and demyelination. This evidence suggests that a fine interplay between the immune and nervous systems can have a huge impact on several neurological functions, including depressive symptoms, in different pathological conditions. The aim of the present review is to shed light on common traits between MDD and MS, by looking at inflammatory-dependent synaptic alterations associated with depression in both diseases.

MiR-142-3p regulates synaptopathy-driven disease progression in multiple sclerosis.
We recently proposed miR-142-3p as a molecular player in inflammatory synaptopathy, a new pathogenic hallmark of multiple sclerosis (MS) and of its mouse model experimental autoimmune encephalomyelitis (EAE), that leads to neuronal loss independently of demyelination. MiR-142-3p seems to be unique among potential biomarker candidates in MS, since it is an inflammatory miRNA playing a dual role in the immune and central nervous systems. Here, we aimed to verify the impact of miR-142-3p circulating in the cerebrospinal fluid (CSF) of MS patients on clinical parameters, neuronal excitability and its potential interaction with disease modifying therapies (DMTs).

Exercise protects from hippocampal inflammation and neurodegeneration in experimental autoimmune encephalomyelitis.
Exercise is increasingly recommended as a supportive therapy for people with Multiple Sclerosis (pwMS). While clinical research has still not disclosed the real benefits of exercise on MS disease, animal studies suggest a substantial beneficial

effect on motor disability and pathological hallmarks such as central and peripheral dysregulated immune response. The hippocampus, a core area for memory formation and learning, is a brain region involved in MS pathophysiology. Human and rodent studies suggest that the hippocampus is highly sensitive to the effects of exercise, the impact of which on MS hippocampal damage is still elusive. Here we addressed the effects of chronic voluntary exercise on hippocampal function and damage in experimental autoimmune encephalomyelitis (EAE), animal model of MS. Mice were housed in standard or wheel-equipped cages starting from the day of immunization and throughout the disease course. Although running activity was reduced during the symptomatic phase, exercise significantly ameliorated motor disability. Exercise improved cognition that was assessed through the novel object recognition test and the nest building in presymptomatic and acute stages of the disease, respectively. In the acute phase exercise was shown to prevent EAE-induced synaptic plasticity abnormalities in the CA1 area, by promoting the survival of parvalbumin-positive (PV+) interneurons and by attenuating inflammation. Indeed, exercise significantly reduced microgliosis in the CA1 area, the expression of tumour necrosis factor (TNF) in microglia and, to a lesser extent, the hippocampal level of interleukin 1 beta (IL-1β), previously shown to contribute to aberrant synaptic plasticity in the EAE hippocampus. Notably, exercise exerted a precocious and long-lasting mitigating effect on microgliosis that preceded its neuroprotective action, likely underlying the improved cognitive function observed in both presymptomatic and acute phase EAE mice. Overall, these data provide evidence that regular exercise improves cognitive function and synaptic and neuronal pathology that typically affect EAE/MS brains.

The microRNA let-7b-5p Is Negatively Associated with Inflammation and Disease Severity in Multiple Sclerosis.
The identification of microRNAs in biological fluids for diagnosis and prognosis is receiving great attention in the field of multiple sclerosis (MS) research but it is still in its infancy. In the present study, we observed in a large sample of MS patients that let-7b-5p levels in the cerebrospinal fluid (CSF) were highly correlated with a number of microRNAs implicated in MS, as well as with a variety of inflammation-related protein factors, showing specific expression patterns coherent with let-7b-5p-mediated regulation. Additionally, we found that the CSF let-7b-5p levels were significantly reduced in patients with the progressive MS compared to patients with relapsing-remitting MS and were negatively correlated with characteristic hallmark processes of the two phases of the disease. Indeed, in the non-progressive phase, let-7b-5p inversely associated with both central and peripheral inflammation; whereas, in progressive MS, the CSF levels of let-7b-5p negatively correlated with clinical disability at disease onset and after a follow-up period. Overall, our results uncovered, by the means of a multidisciplinary approach and multiple statistical analyses, a new possible pleiotropic action of let-7b-5p in MS, with potential utility as a biomarker of MS course.

Central Modulation of Selective Sphingosine-1-Phosphate Receptor 1 Ameliorates Experimental Multiple Sclerosis.
Future treatments of multiple sclerosis (MS), a chronic autoimmune neurodegenerative disease of the central nervous system (CNS), aim for simultaneous early targeting of peripheral immune function and neuroinflammation. Sphingosine-1-phosphate (S1P) receptor modulators are among the most promising drugs with both "immunological" and "non-immunological" actions. Selective S1P receptor modulators have been recently approved for MS and shown clinical efficacy in its mouse model, the experimental autoimmune encephalomyelitis (EAE). Here, we investigated the anti-inflammatory/neuroprotective effects of ozanimod (RPC1063), a S1P modulator recently approved in the United States for the treatment of MS, by performing ex vivo studies in EAE brain. Electrophysiological experiments, supported by molecular and immunofluorescence analysis, revealed that ozanimod was able to dampen the EAE glutamatergic synaptic alterations, through attenuation of local inflammatory response driven by activated microglia and infiltrating T cells, the main CNS-cellular players of EAE synaptopathy. Electrophysiological studies with selective S1P (AUY954) and S1P (A971432) agonists suggested that S1P modulation is the main driver of the anti-excitotoxic activity mediated by ozanimod. Accordingly, in vivo intra-cerebroventricular treatment of EAE mice with AUY954 ameliorated clinical disability. Altogether these results strengthened the relevance of S1P agonists as immunomodulatory and neuroprotective drugs for MS therapy.

CXCR2 increases in ALS cortical neurons and its inhibition prevents motor neuron degeneration in vitro and improves neuromuscular function in SOD1G93A mice.
Amyotrophic Lateral Sclerosis (ALS) is a progressive neurodegenerative disease characterized by depletion of motor neurons

(MNs), for which effective medical treatments are still required. Previous transcriptomic analysis revealed the up-regulation of C-X-C motif chemokine receptor 2 (CXCR2)-mRNA in a subset of sporadic ALS patients and SOD1G93A mice. Here, we confirmed the increase of CXCR2 in human ALS cortex, and showed that CXCR2 is mainly localized in cell bodies and axons of cortical neurons. We also investigated the effects of reparixin, an allosteric inhibitor of CXCR2, in degenerating human iPSC-derived MNs and SOD1G93A mice. In vitro, reparixin rescued MNs from apoptotic cell death, preserving neuronal morphology, mitochondrial membrane potential and cytoplasmic membrane integrity, whereas in vivo it improved neuromuscular function of SOD1G93A mice. Altogether, these data suggest a role for CXCR2 in ALS pathology and support its pharmacological inhibition as a candidate therapeutic strategy against ALS at least in a specific subgroup of patients. ASSESSMENT OF IL-38 LEVELS IN MULTIPLE SCLEROSIS

POSTER SESSION 03 - SECTION: MULTIPLE SCLEROSIS: BIOMARKERS, PATHOGENESIS AND THERAPIES

Néstor López González[1], Andrea Vera Barrón[2], Jose Martínez Rodríguez[2], Rubèn López Vales[1]
[1]Universitat Autònoma de Barcelona, Departament De Biologia Cel·lular, Fisiologia I Immunologia, Institut De Neurociències De La Uab, Bellaterra, Barcelona, Spain, [2]Hospital del Mar Medical Research Institute, Neurology Department, Barcelona, Spain

Multiple Sclerosis (MS) is chronic inflammatory disease of the central nervous system with an increasing prevalence last years. Interleukin 38 (IL-38) is the most recently discovered cytokine of the IL-1 family with reported anti-inflammatory effects. However, little is known about the changes in IL-38 expression in MS. **Aims** In this work we aimed to investigate the changes in IL-38 levels in serum samples from MS patients, as well as, in the spinal cord of experimental autoimmune encephalomyelitis mice, a murine model of MS **Methods** Human Serum samples of patients with MS and healthy individuals were collected and IL-38 levels were quantified by ELISA. Spinal cords from EAE mice were harvested at different stages of the disease and IL-38 levels were assessed by QPCR. **Results** Despite IL-38 has potent anti-inflammatory actions, the protein levels of this cytokine were not increased in MS patients. Similarly, IL-38 transcripts were not detected in the spinal cord of EAE mice at the onset and peak of the disease. However, we observed that IL-38 mRNA levels were induced in the spinal cord of EAE mice at the remission phase of the disease, coinciding with the attenuation of the neuroinflammatory response. **Conclusions** These results suggest that IL-38 could be involved in attenuating inflammation in EAE mice, and that the induction of this cytokine is defective in MS patients.

APTAMERS TO REMYELINATE MULTIPLE SCLEROSIS: EFFECTS OF APTOLL© TREATMENT IN PRECLINICAL MODELS AND DETECTION OF MECHANISMS IN HUMAN SAMPLES

POSTER SESSION 03 - SECTION: MULTIPLE SCLEROSIS: BIOMARKERS, PATHOGENESIS AND THERAPIES

Fernando De Castro[1], Beatriz Fernández-Gómez[1], Miguel Marchena[2], Inês Tocha[1], Paula Gómez-Martín[1], David Piñeiro[3], Macarena Hernández[3]
[1]Consejo Superior de Investigaciones Científicas-CSIC, Instituto Cajal-csic, Madrid, Spain, [2]Universidad Europea de Madrid, Medicina, Villaviciosa de Odón (Madrid), Spain, [3]AptaTargets, S.L., R&d, Madrid, Spain

Multiple sclerosis (MS) is a neurodegenerative, autoimmune and chronic disease of the central nervous system (CNS) and the second cause of neurological disability in young adults. The main histopathogenic feature is the patched death of oligodendrocytes and the subsequent loss of myelin, both in the white and in the grey matters. Demyelination is mainly accepted to derive from autoimmune-triggered inflammation, where the Toll-like receptor 4 (TLR4) plays a crucial role. ApTOLL© has been developed with aptamer technology to antagonize TLR4. The molecular nature and mechanism of action of this single chain DNA aptamer represents a novel strategy to treat diseases with an important inflammatory component, such as MS. In our present research, we have determined the optimal dose for the in vivo use of ApTOLL© to treat murine Experimental Autoimmune Encephalitis (0.91 mg/kg). Clinical score was significantly lower in ApTOLL©-treated animals, where myelin and axons were better preserved, too. Furthermore, this molecule seems to directly promote the proliferation of oligodendrocytes precursors cells (OPCs) and its differentiation towards myelin-forming phenotypes. Finally, we have determined the presence of TLR4 in different cell types from human tissue of MS patients and controls. Altogether, our data point to ApTOLL© as an innovative candidate to be incorporated to the pharmaceutical arsenal to treat MS as (re)myelinating and neuroprotector.

Multiple Sclerosis (MS) is a neurodegenerative disease, characterized by the loss of myelin, a specialized oligodendrocytes (OL)-derived membrane. At early stages, demyelinated lesions are characterized by the presence of OLs precursor cells (OPCs), reactive astrocytes and proinflammatory microglia (‘M1-like’ phenotype). One intervention that has shown promising results in the treatment of peripheral and central inflammation is the electrical stimulation of vagus nerve (VNS). In murine models of neuroinflammation the evidence indicates that VNS reduces proinflammatory cytokines, as well as microglia and macrophages infiltration, promoting the anti-inflammatory phenotype of microglia (‘M2-like’). However, the effect of VNS in MS-animal models have not been systematically studied. Our aim was to study the effect of *in vivo* VNS in the neuroinflammation and the progression of demyelination/remyelination in a murine MS model. We induced our MS model with focal stereotaxic injections of lysolecithin (LPC) in C57BL/6 mice (PN45). Mice were treated with VNS after 7-to-9 days post injection, when the peak of OPCs in the lesion is reached. Afterwards, brain tissue was analyzed by immunostaining of myelin, glial and neuronal markers, as well as cytokines expression. Interestingly, we observed an increase in the myelinated area, a reduction in the population of astrocytes and M1-like microglia, along with changes in the TGFß-1 levels in the VNS treated group. Our preliminary results suggest that VNS improves remyelination by reducing the proinflammatory environment in demyelinating MS-like lesions. *Funded by fondecyt#1210940 to FCO, VRAID-DUIA #210-2021 to RV*

IN VIVO IMAGING OF OLIGODENDROCYTE INJURY IN AN NMO MOUSE MODEL

POSTER SESSION 03 - SECTION: MULTIPLE SCLEROSIS: BIOMARKERS, PATHOGENESIS AND THERAPIES

Selin Kenet[1,2], Marina Herwerth[1,3,4], Jeffrey Bennett[5], Bernhard Hemmer[4,6], Thomas Misgeld[1,6,7]
[1]Technical University of Munich, Institute Of Neuronal Cell Biology, Munich, Germany, [2]Ludwig-Maximilians University, Graduate School Of Systemic Neurosciences, Planegg-Martinsried, Germany, [3]University of Zurich, Institute Of Pharmacology And Toxicology, Zurich, Switzerland, [4]Technical University of Munich, Klinikum Rechts Der Isar, Department Of Neurology, Munich, Germany, [5]University of Colorado School of Medicine, Department Of Neurology And Ophthalmology, Aurora, United States of America, [6]Munich Cluster for Systems Neurology, (synergy), Munich, Germany, [7]German Center for Neurodegenerative Diseases, (dzne), Munich, Germany

Neuromyelitis optica (NMO) is an autoimmune disease predominantly affecting spinal cord and optic nerve. The majority of NMO patients have serum antibodies (IgG) against the water channel aquaporin4 (AQP4), which is expressed on astrocytes in the CNS. Despite this primary astrocytic target, demyelination is prominent in AQP4-IgG+-NMO. However, how NMO pathology spreads beyond astrocytes remains elusive. We investigated early signs of oligodendrocyte damage in a mouse model of acute NMO induced by spinal application of patient-derived AQP4-IgG and human complement followed by in vivo imaging. Morphological assessment and calcium imaging of astrocytes and oligodendrocytes revealed the relative time-course of injury: Within an hour of AQP4-IgG application, astrocytes showed a global calcium rise and membrane rupture confirmed by uptake of a cell-impermeable dye and cellular fragmentation. Concurrent to astrocytic calcium rise, oligodendrocyte processes also showed calcium overload, which however reached the soma comparatively later. In contrast to pervasive lytic death of astrocytes, only some oligodendrocytes were lost at later time points. While dye exclusion experiments negated overt membrane rupture, expression of the MAC-inhibitor protein CD59 on oligodendrocytes protected these cells after AQP4-IgG-mediated astrocyte injury. These results imply that oligodendrocyte pathology in NMO is not driven by the loss of astrocytes per se, but rather evolves from MAC-dependent ‘bystander’ targeting of oligodendrocytes as suggested by prior in vitro and fixed tissue observations. Our dynamic observations suggest that despite the similar starting point of injury, executive phase might differ and activate distinct cell death pathways in the two major glial target cells of NMO.

[1]Atlas Antibodies AB, Research And Development, Bromma, Sweden, [2]Redoxis, Research And Development, Lund, Sweden

Animal models allow for greater understanding of underlying mechanisms of CNS disorders. Highly validated specific antibodies further enable generation of high-quality results, also in translational research. The aim of the present study was to validate an antibody panel developed by Atlas Antibodies using Experimental Autoimmune Encephalomyelitis (EAE) rat models of multiple sclerosis (MS). Forty-nine antibodies developed against human epitopes, including markers for neurons, astrocytes, oligodendrocytes, and microglia were evaluated in IHC experiments using human and rodent tissues. Normal human tissues were obtained from a commercial biobank (Asterand®, BioIVT, West Sussex, UK). EAE rodent tissues were provided by Redoxis (Redoxis, Sweden). Tissue sections were stained using a standard IHC protocol with DAB visualization. Multiplexed immunofluorescence IHC was performed with selected number of antibodies. All 49 antibodies showed expected staining in human tissues. 26 antibodies (59%) displayed expected immunoreactivity in normal rat brain. These antibodies were further validated in EAE models (SCH- and MOG-induced), including multiplexed IHC-IF analysis to confirm cell type specificity. Both SCH and MOG groups displayed decreased expression of MBP, indicative of demyelination/loss of myelinated axons. Increased number of P2RX7+ reactive astrocytes was observed in both SCH and MOG, especially in the areas of demyelination. CRYAB expression was increased in SCH- and decreased in MOG within areas of demyelination. Fewer GPR17+ cells were detected in SCH respect normal brain, while a greater numbers in MOG, indicating oligodendrocyte aberration. The data confirm the usability of EAE rat model and the antibody panel for studying the underlying cellular mechanisms of MS.

EXPLORING THE MECHANISM OF ACTION OF THE NOVEL REMYELINATION THERAPY NEFIRACETAM

POSTER SESSION 03 - SECTION: MULTIPLE SCLEROSIS: BIOMARKERS, PATHOGENESIS AND THERAPIES

Lisa Mcdonnell[1], Elaine Keogh[1], Mark Pickering[2], Keith Murphy[1]
[1]Conway Institute, University College Dublin, Dublin, Ireland, [2]School of Medicine, University College Dublin, Dublin, Ireland

Aims: Multiple sclerosis (MS) is a neurodegenerative disorder involving immune-mediated damage to myelin. Initially, damage is repaired through the activation of a repair process called remyelination. However, as MS progresses, remyelination fails leaving axons vulnerable to damage. Loss of chronically demyelinated axons causes a decline in neuronal activity, resulting in progressive disability. Current therapies target the immune component of MS but do not address the remyelination deficits underlying progression. Thus, there is a need for therapies which encourage remyelination to improve treatment outcomes. We have found that nefiracetam accelerates remyelination; our aim is to elucidate its mechanism of action. **Methods:** C57/Bl6j mice were fed a cuprizone diet for 6 weeks to induce a demyelinating insult. Mice were given daily injections of 15mg/kg nefiracetam for 3 days from day 38. Corpus callosum and cortical tissue samples were taken for molecular analysis. Primary oligodendrocyte precursor cells (OPCs) derived from neonatal rodent cortices were used to study the direct effect of nefiracetam on OPCs. **Results:** Omics-based analyses of the tissue identified several signalling pathways which may be central to nefiracetam's therapeutic effect. The data also highlights genes and pathways which are regulated in response to the model in these brain regions. The *in vitro* studies on OPCs revealed that nefiracetam directly modulates a key phase of the remyelination process. In particular, the data implicates the regulation of glutamate signalling in nefiracetam's remyelinating action. **Conclusion:** We have identified a novel remyelination therapy which has the potential to be used in the treatment of MS.

The onset and progression of neurological disorders have been recently linked to neutrophils. The neutrophil-to-lymphocyte ratio has been proposed as a clinical marker both for ischemic stroke and Multiple Sclerosis (MS). It is known that CD66b+ neutrophils can exert either a pro-inflammatory or an anti-inflammatory function, but their role in Multiple Sclerosis is still unclear. Khorooshi R, and colleagues stated that a subgroup of neutrophils might have a protective function in the first phases of EAE (Experimental Autoimmune Encephalitis). Moreover, the PD-1 axis seems to have a key role in this population and its functions. Our group recently observed a group of neutrophils expressing PD-1 ligand 2 (CD273) both in patients with an active form of MS and in mice with EAE. We characterized CD273+ neutrophils and performed functional studies on both human and murine neutrophils. We also confirmed that CD273+ neutrophils release EVs and tested whether they could exert an immunosuppressive function. Finally, we validated the role of CD273+ neutrophils in the murine model of EAE. We speculate that CD273 might identify a novel subpopulation of regulatory neutrophils in MS patients, paving the way for innovative approaches in terms of diagnosis, cell therapies, or new drug delivery tools through vesicles.

ROSTRAL-TO-CAUDAL INCREASE IN METABOLIC ACTIVITY OF CULTURED EX VIVO SLICES OF NEONATAL RAT BRAIN

POSTER SESSION 03 - SECTION: MULTIPLE SCLEROSIS: BIOMARKERS, PATHOGENESIS AND THERAPIES

Małgorzata Dąbrowska[1], Jill Mcmahon[1], Bertrand Huard[2], Una Fitzgerald[1]

Ex vivo organotypic slice models are optimum for investigation of cell types in their natural 3D orientation, as well as maintaining endogenous signalling pathways and cell:cell interactions. Here, we examined metabolic activity in slice cultures from different anatomical areas of the cortex. Sequential coronal slices (12-13) were dissected, along the rostral-caudal axis, from each of four neonatal rats (P 10/11) and cultured in Millicell Culture Plate Inserts (0.4µm pore size). Slices were maintained in serum-free medium for 7 days and metabolic activity was determined by daily testing of supernatant with alamarBlue™ reagent (biological replicates). This approach showed a pattern: the metabolic activity of slices dropped over time, with a slight recovery on the 4th day. The impact of anatomical location, as well as the presence of connected subcortical regions, on slice metabolic activity was determined. Results from the average viability over the 7 days of sampling indicate that the more caudal slices (Bregma point -1,10mm to -3,50mm) had 29.6% higher metabolic activity than rostral regions ($p<0,001$, $n=50$). Additionally, slices with cortex alone showed 38.5% lower metabolic activity than those with all connections between structures intact ($p<0,001$, $n=26$). When those connections got interrupted, a 25.5% ($p<0,02$, $n=20$) drop-in metabolic activity was observed. This finding emphasises the importance of tracking the anatomical origin and connectivity between regions, when designing and executing cortex-focused ex vivo experiments. We recommend use of caudal region slices, connected with all structures within the slice, as an optimal platform for mimicking cortical physiology under control and diseased conditions.

Molecular autopsy and subsequent functional analysis reveal de novo DSG2 mutation as cause of sudden death.
Sudden cardiac death (SCD) is a common cause of death in young adults. In up to 80% of cases a genetic cause is suspected. Next-generation sequencing of candidate genes can reveal the cause of SCD, provide prognostic management, and facilitate pre-symptomatic testing and prevention in relatives. Here we present a proband who experienced SCD in his sleep for which molecular autopsy was performed. We performed a post-mortem genetic analysis of a 49-year-old male who died during sleep after competitive kayaking, using a Cardiomyopathy and Primary Arrhythmia next-generation sequencing panel, each containing 51 candidate genes. Autopsy was not performed. Genetic testing of the proband resulted in missense variants in KCNQ1 (c.1449C > A; p.(Asn483Lys)) and DSG2 (c.2979G > T; p.(Gln993His)), both absent from the gnomAD database. Familial segregation analysis showed de novo occurrence of the DSG2 variant and presence of the KCNQ1 variant in the proband's mother and daughter. KCNQ1 p.(Asn483Lys) was predicted to be pathogenic by MutationTaster. However, none of the KCNQ1 variant carrying family members showed long QTc on ECG or Holter. We further functionally analysed this variant using patch-clamp in a heterologous expression system (Chinese Hamster Ovary (CHO) cells) expressing the KCNQ1 mutant in combination with KCNE1 wild type protein and showed no significant changes in electrophysiological function of Kv7.1. Based on the above evidence, we concluded that the DSG2 p.(Gln993His) variant is the most likely cause of SCD in the presented case, and that there is insufficient evidence that the identified KCNQ1 p.(Asn483Lys) variant would confer risk for SCD in his mother and daughter. Fortunately, the DSG2 variant was not inherited by the proband's two children. This case report indicates the added value of molecular autopsy and the importance of subsequent functional study of variants to inform patients and family members about the risk of variants they might carry.

White matter disorders of the CNS such as MS, lead to failure of nerve conduction and long-lasting neurological disabilities affecting a variety of sensory and motor systems including vision. While most disease-modifying therapies target the immune and inflammatory response, the promotion of remyelination has become a new therapeutic avenue, to prevent neuronal degeneration and promote recovery. Most of these strategies are developed in short-lived rodent models of demyelination, which spontaneously repair and do not reflect the size, organization, and biology of the human CNS. Thus, well-defined non-human primate models are required to efficiently advance therapeutic approaches for patients. Here, we followed the consequence of long-term toxin-induced demyelination of the macaque optic nerve on remyelination and axon preservation, as well as its impact on visual functions. Findings from oculo-motor behavior, ophthalmic examination, electrophysiology, and retinal imaging indicate visual impairment involving the optic nerve and retina. These visual dysfunctions fully correlated at the anatomical level, with sustained optic nerve demyelination, axonal degeneration, and alterations of the inner retinal layers. This non-human primate model of chronic optic nerve demyelination associated with axonal degeneration and visual dysfunction, recapitulates several key features of MS lesions and should be instrumental in providing the missing link to translate emerging repair pro-myelinating/neuroprotective therapies to the clinic for myelin disorders such as MS.

THE PREVALENCE AND TOPOGRAPHY OF DEMYELINATION AND INFLAMMATORY ACTIVITY IN THE MULTIPLE SCLEROSIS SPINAL CORD

POSTER SESSION 03 - SECTION: MULTIPLE SCLEROSIS: BIOMARKERS, PATHOGENESIS AND THERAPIES

Alex Waldman[1,2,3], Cecilia Catania[1], Marco Pisa[1], Mark Jenkinson[4], Gabriele De Luca[1]
[1]University of Oxford, Neurodegeneration And Inflammation Research Group, Academic Unit Of Neuropathology, Nuffield Department Of Clinical Neurosciences, Oxford, United Kingdom, [2]National Institutes of Health, Molecular Development Of The Immune System Section, Laboratory Of Immune System Biology, National Institute Of Allergy And Infectious Diseases, Bethesda, United States of America, [3]Emory University, Md/phd Program, Atlanta, United States of America, [4]University of Oxford, Wellcome Centre For Integrative Neuroimaging, Oxford Centre For Functional Mri Of The Brain, Nuffield Department Of Clinical Neurosciences, Oxford, United Kingdom

Background: The demyelinated lesion is a cardinal feature of progressive multiple sclerosis (MS) pathology that commonly affects the spinal cord. The study of lesion topography in the spinal cord and the extent of inflammation may provide important clues about disease pathogenesis. Aims: We aimed to characterise the prevalence and distribution of demyelination in the progressive MS spinal cord. Methods: Immunohistochemistry was used to detect demyelination (proteolipid protein) and classify its inflammatory activity (CD68) in the cervical, thoracic, and lumbar spinal cord of 119 MS cases. Lesions were standardised onto anatomical templates before mixed models and permutation-based cluster analysis were used to identify patterns in the prevalence and topography of demyelination. Results: Spinal cord lesions were observed in 76.5% of cases. When stratified by histological classification, inflammatory activity was a common feature observed in 87.9% of cases. Lesions consistently affected the dorsal columns, lateral corticospinal tracts, and central canal. Interestingly, the subpial surface was commonly spared. However, when present, subpial demyelination only affected a limited circumference (less than 15%). The presence of lesions also exhibited a strong relationship with clinical disease milestones. Conclusions: Our findings demonstrate that 1) inflammatory spinal cord lesions are an unappreciated feature of progressive MS pathology, 2) white matter tracts and the central canal are common lesion predilection sites, 3) subpial sparing is a salient feature of spinal cord lesional pathology which argues against an outside-in gradient of spinal cord demyelination in MS, and 4) spinal cord demyelination is a substrate underpinning a more aggressive disease course.

CONTRIBUTION OF MUSCLE-INTRINSIC TOXICITY OF ALS-MUTANT FUS TO MOTOR NEURON DEGENERATION

POSTER SESSION 03 - SECTION: AMYOTROPHIC LATERAL SCLEROSIS

Anne Regina Wienand[1], Luc Dupuis[2], Erik Storkebaum[1]
[1]Donders Institute - Radboud University, Molecular Neurobiology, Nijmegen, Netherlands, [2]University of Strasbourg, Inserm 1118, Strasbourg, France

Amyotrophic lateral sclerosis (ALS) is the most frequent adult-onset motor neurodegenerative disease characterized by relatively selective degeneration of upper and lower motor neurons. Nevertheless, non-cell autonomous contributions of cell types other than motor neurons have been implicated in ALS pathogenesis. However, whether skeletal muscles also contribute to motor neuron degeneration is quite controversial. We gained evidence that skeletal muscles contribute to neuromuscular junction pathology in ALS caused by heterozygous mutations in the gene encoding the RNA-binding protein FUS. FUS-ALS accounts for the majority of the most aggressive forms of ALS with juvenile onset and rapid disease progression. In FUS-ALS patients, mutations are commonly clustered in the nuclear localization signal (NLS). The $Fus^{\Delta NLS/+}$ mouse expresses a truncated FUS protein lacking the NLS, which leads to FUS-ALS symptoms from 10 months of age onward. Newborn $Fus^{\Delta NLS/\Delta NLS}$ mice and patient iPSC-derived motor neuron-myotube co-cultures showed impaired maturation of neuromuscular junctions, which was attributable to toxicity of ALS-mutant FUS in motor neurons, but also skeletal muscle/myotubes. These findings raise the question whether skeletal muscle intrinsic toxicity of ALS-mutant FUS is an active contributor to motor neuron degeneration and motor deficits in adult $Fus^{\Delta NLS/+}$ mice. We tackle this question by genetically manipulating ALS-mutant FUS specifically in skeletal muscle of $Fus^{\Delta NLS}$ mice. We assess the neuromuscular function of these mice in a longitudinal motor behavior study and by histological and molecular analyses. Our study indicates that the skeletal muscle may constitute a novel therapeutic target for FUS-ALS.

tRNA overexpression rescues peripheral neuropathy caused by mutations in tRNA synthetase.
Heterozygous mutations in six transfer RNA (tRNA) synthetase genes cause Charcot-Marie-Tooth (CMT) peripheral neuropathy. CMT mutant tRNA synthetases inhibit protein synthesis by an unknown mechanism. We found that CMT mutant glycyl-tRNA synthetases bound tRNA but failed to release it, resulting in tRNA sequestration. This sequestration potentially depleted the cellular tRNA pool, leading to insufficient glycyl-tRNA supply to the ribosome. Accordingly, we found ribosome stalling at glycine codons and activation of the integrated stress response (ISR) in affected motor neurons. Moreover, transgenic overexpression of tRNA rescued protein synthesis, peripheral neuropathy, and ISR activation in and mouse CMT disease type 2D (CMT2D) models. Conversely, inactivation of the ribosome rescue factor GTPBP2 exacerbated peripheral neuropathy. Our findings suggest a molecular mechanism for CMT2D, and elevating tRNA levels may thus have therapeutic potential.

V. (DZNE), Department Of Neuroinflammation, Bonn, Germany

Frontotemporal dementia (FTD) and Amyotrophic lateral sclerosis (ALS) are two neurodegenerative diseases of a common clinical, genetic and neuropathological spectrum but common biological pathways leading to these two diseases remain elusive. In this study, we show that TDP-43, the most common form of aggregated protein in ALS and FTD, activates microglial NLRP3 inflammasome pathway through recognition by TLR receptors and its endocytosis. By stimulating C9orf72-/- and GrnR493X/R493X deficient murine microglia with TDP-43, we were able to show that these cells were hyperreactive to this stimulus. This effect was reproducible using monocyte-derived-microglia-like cells obtained from FTD patients with C9ORF72 and GRN mutations. Our data highlight for the first time a similar dysregulation by mutations in the two main genes responsible for TDP-43 proteinopathy and causing, respectively, FTD and FTD/ALS. It points to neuroinflammation and microglia endolysosomal dynamics as key players in FTD and ALS and open new avenues for therapeutic developement in these diseases.

ROLE OF METABOLISM IN PATHOLOGICAL AGGREGATION OF TDP-43 AND ITS DOWN-STREAM TOXICITY

POSTER SESSION 03 - SECTION: AMYOTROPHIC LATERAL SCLEROSIS

Ismail Gbadamosi, Ali Jawaid
Nencki Institute of Experimental Biology, Translational Research In Neuropsychiatric Disorders, Warsaw, Poland

Background: Amyotrophic lateral sclerosis (ALS) and frontotemporal lobar degeneration (FTLD) are two fatal neurodegenerative disorders with considerable molecular overlap. Cytoplasmic aggregation of transactive response DNA binding protein of 43 kDa (TDP-43) in neurons and glia is a consistent feature of the majority of ALS and FTLD cases. Certain metabolic conditions that are conventionally considered risk factors for cardiovascular and cerebrovascular diseases; such as type-2 diabetes mellitus, high body mass index, and dyslipidaemia are intriguingly associated with delayed onset, slower disease progression, and/or longer survival in both ALS and FTLD. **Aims:** This study aims to investigate the molecular mechanisms underlying the disease-modifying effects of metabolic disorders in ALS and FTLD with a particular focus on the role of TDP-43 in the regulation of neuronal metabolism. **Results:** Our preliminary investigations performed in NSC-34 mouse motor neuron-like cells reveals a regulatory role of TDP-43 in neuronal glucose metabolism. Notably, TDP-43 knock-down alters expression of key rate-limiting enzymes involved in glycolysis and the citric acid cycle. At the functional level, these changes correlate with increased utilization of glucose by the NSC-34 cells and over-reliance on anaerobic respiration. Furthermore, TDP-43 depletion renders NSC-34 cells more vulnerable to the effects of glucose depletion. **Conclusion:** Our current findings underscore an interplay between TDP-43 and neuronal glucose metabolism that may have important implications for neuronal survival under conditions of metabolic stress. Our current focus is on validating the findings via modelling TDP-43 aggregation in NSC -34 cells and identifying the underlying molecular cascade. **Keywords:** TDP-43, metabolism, neurodegeneration, ALS, FTLD

Hippocampal Degeneration and Behavioral Impairment During Alzheimer-Like Pathogenesis Involves Glutamate Excitotoxicity.
The hallmarks of Alzheimer's disease (AD) pathology include senile plaques accumulation and neurofibrillary tangles, which is thought to underlie synaptic failure. Recent evidence however supports that synaptic failure in AD may instead be instigated by enhanced N-methyl-D-aspartate (NMDA) activity, via a reciprocal relationship between soluble amyloid-β (Aβ) accumulation and increased glutamate agonist. While previous studies have shown Aβ-mediated alterations to the glutamatergic system during AD, the underlying etiology of excitotoxic glutamate-induced changes has not been explored. Here, we investigated the acute effects of stereotaxic dentate gyrus (DG) glutamate injection on behavior and molecular expression of specific proteins and neurochemicals modulating hippocampal functions. Dependence of glutamate-mediated effects on NMDA receptor (NMDAR) hyperactivation was tested using NMDARs antagonist memantine. DG of Wistar rats (12-weeks-old) were bilaterally microinjected with glutamate (500 mM) with or without daily intraperitoneal (i.p.) memantine injection (20 mg/kg) for 14 days, while controls received either intrahippocampal/i.p. PBS or i.p. memantine. Behavioral characterization in open field and Y-maze revealed that glutamate evoked anxiogenic responses and perturbed spatial memory were inhibited by memantine. In glutamate-treated rats, increased NO expression was accompanied by marked reduction in profiles of glutathione-s-transferase and glutathione peroxidase. Similarly, glutamate-mediated increase in acetylcholinesterase expression corroborated downregulation of synaptophysin and PSD-95, coupled with initiation of reactive astrogliosis (GFAP). While neurofilament immunolocalization/immunoexpression was unperturbed, we found

glutamate-mediated reduction in neurogenic markers Ki67 and PCNA immunoexpression, with a decrease in NR2B protein expression, whereas mGluR1 remains unchanged. In addition, increased expression of apoptotic regulatory proteins p53 and Bax was seen in glutamate infused rats, corroborating chromatolytic degeneration of granule neurons in the DG. Interestingly, memantine abrogated most of the degenerative changes associated with glutamate excitotoxicity in this study. Taken together, our findings causally link acute glutamate dyshomeostasis in the DG with development of AD-related behavioral impairment and molecular neurodegeneration.

Ameliorative effects of on cuprizone-induced memory decline in rat model of multiple sclerosis.
Cuprizone is a neurotoxin with copper-chelating ability used in animal model of multiple sclerosis in which oxidative stress has been documented as one of the cascade in the pathogenesis. is a phytomedicinal plant with antioxidant and neuroprotective properties. This study aimed at evaluating the ameliorative capability of in cuprizone-induced behavioral and histopathological alterations in the prefrontal cortex and hippocampus of Wistar rats. Four groups of rats were treated with normal saline, cuprizone, and a combination of and cuprizone, for five weeks. The rats were subjected to Morris water maze and Y-maze to assess long and short-term memory respectively. The animals were sacrificed, and brain tissues were removed for histochemical and enzyme lysate immunosorbent assay for catalase, superoxide dismutase, and nitric oxide. Cuprizone significantly induced oxidative and nitrosative stress coupled with memory decline and cortico-hippocampal neuronal deficits; however, administration of significantly reversed the neuropathological deficits induced by cuprizone.

Moringa oleifera phytochemicals protect the brain against experimental nicotine-induced neurobehavioral disturbances and cerebellar degeneration.
Nicotine is a neuro-stimulant that has been implicated in the pathophysiology of many brain diseases. The need to prevent or alleviate the resulting dysfunction is therefore paramount, which has also given way to the use of medicinal plants in the management of brain conditions. This study was designed to determine the histomorphological and neurobehavioural changes in the cerebellum of Wistar rats following nicotine insult and how such injuries respond to Moringa intervention. Twenty-four adult male Wistar rats were divided into 4 groups. Group A and B were orally treated with normal saline and Moringa oleifera respectively for twenty-eight days; Group C was treated with nicotine while group D was treated orally with Moringa oleifera and intraperitoneally with nicotine for twenty-eight days. Animals were subjected to the open field test on the last day of treatment. 24 h after last day treatment, the animals were anesthetized and perfusion fixation was carried out. The cerebellum was excised and post-fixed in 4% paraformaldehyde and thereafter put through routine histological procedures. Results revealed cytoarchitectural distortion and extreme chromatolysis in neuronal cells of the cerebellar cortical layers in the nicotine-treated group. The Purkinje cells of the cerebellum of animals in this group were degenerated. There were also reduced locomotor activities in the group. Moringa was able to prevent the chromatolysis, distortion of the cerebellar cortical cells and neurobehavioural deficit. Our result suggests that Moringa oleifera could prevent nicotine-induced cerebellar injury in Wistar rats, with the possibility of ameliorating the clinical features presented in associated cerebellar pathology.

Ascorbic acid ameliorates behavioural deficits and neuropathological alterations in rat model of Alzheimer's disease.
Exploring the links between neural pathobiology and behavioural deficits in Alzheimer's disease (AD), and investigating substances with known therapeutic advantages over subcellular mechanisms underlying these dysfunctions could advance the development of potent therapeutic molecules for AD treatment. Here we investigated the efficacy of ascorbic acid (AA) in reversing aluminium chloride (AlCl)-induced behavioural deficits and neurotoxic cascades within prefrontal cortex (PFC) and hippocampus of rats. A group of rats administered oral AlCl (100mg/kg) daily for 15days showed degenerative changes characterised by significant weight loss, reduced exploratory/working memory, frontal-dependent motor deficits, cognitive decline, memory dysfunction and anxiety during behavioural assessments compared to control. Subsequent analysis showed that oxidative impairment-indicated by depleted superoxide dismutase and lipid peroxidation (related to glutathione-S-transferase activity), cholinergic deficits seen by increased neural acetylcholinesterase (AChE) expression and elevated lactate dehydrogenase underlie behavioural alterations. Furthermore, evidences of proteolysis were seen by reduced Nissl

profiles in neuronal axons and dendrites which correspond to apoptotic changes observed in H&E staining of PFC and hippocampal sections. Interestingly, AA (100mg/kg daily for 15days) significantly attenuated behavioural deficits in rats through inhibition of molecular and cellular stressor proteins activated by AlCl Our results showed that the primary mechanisms underlying AA therapeutic advantages relates closely with its abilities to scavenge free radicals, prevent membrane lipid peroxidation, modulate neuronal bioenergetics, act as AChE inhibitor and through its anti-proteolytic properties. These findings suggest that supplementing endogenous AA capacity through its pharmacological intake may inhibit progression of AD-related neurodegenerative processes and behavioural alterations.

FUNCTIONAL ROLE OF AMYOTROPHIC LATERAL SCLEROSIS-ASSOCIATED OPTINEURIN VARIANT IN SH-SY5Y NEURONAL CELLS

POSTER SESSION 03 - SECTION: AMYOTROPHIC LATERAL SCLEROSIS

Dibyakanti Mishra
Indian Institute of Technology Delhi (IIT Delhi), Kusuma School Of Biological Sciences (ksbs), New Delhi, India

Aim: To study the cell death mechanisms in SH-SY5Y neuronal cells expressing wild-type and mutant optineurin protein (OPTN) associated with Amyotrophic Lateral Sclerosis (ALS) and carry out a comparative functional analysis to understand its relative participation in apoptosis, autophagy, necroptosis and inflammation. **Methods:** We performed sanger sequencing for confirming the mutation, MTT assay to measure the cell viability, real-time PCR to measure the mRNA expression, immunoblotting to check the protein expression, Confocal microscopy to check the localisation of all optineurin linked proteins, and pulldown assay to check all binding partners of optineurin. **Results:** The mutation identified in Indian patients is novel and occurs in the ubiquitin-binding domain of OPTN. From immunoblotting, RT-PCR, and confocal microscopy data, we observed that this mutant altered mRNA and protein expression of miR9, REST, CoREST, BDNF, RIPK1, RIPK3 and MLKL in SH-SY5Y neuronal cells. A time-course MTT assay showed an increase in the death of SH-SY5Y cells harbouring the mutant OPTN. **Conclusion:** We found that OPTN mutant causes a notable increase in cell death and is most likely pathogenic. From our study, we observed that this variant of optineurin causes severe cell damage via apoptosis and necroptosis in SH-SY5Y neuronal cells. Our results show that the optineurin novel mutant affects miR9 and BDNF mediated apoptosis, and RIPK1 and MLKL mediated necroptosis in SH-SY5Y cells. ***Corresponding Author:** Prof. James Gomes, Kusuma School of Biological Sciences, Indian Institute of Technology Delhi, New Delhi, India **Acknowledgements:** Indian Institute of Technology Delhi for the infrastructure facility, scholarship and funding.

Identification and characterization of novel and rare susceptible variants in Indian amyotrophic lateral sclerosis patients.
Rare missense variants play a crucial role in amyotrophic lateral sclerosis (ALS) pathophysiology. We report rare/novel missense variants from 154 Indian ALS patients, identified through targeted sequencing of 25 ALS-associated genes. As pathogenic variants could explain only a small percentage of ALS pathophysiology in our cohort, we investigated the frequency of tolerated and benign novel/rare variants, which could be potentially ALS susceptible. These variants were identified in 5.36% (8/149) of sporadic ALS (sALS) cases; with one novel variant each in ERBB4, SETX, DCTN1, and MATR3; four rare variants, one each in PON2 and ANG and two different rare variants in SETX. Identified variants were either absent or present at extremely rare frequencies (MAF < 0.01) in large population databases and were absent in 50 healthy controls sequenced through Sanger method. Furthermore, an oligogenic basis of ALS was observed in three sALS, with co-occurrence of intermediate-length repeat expansions in ATXN2 and a rare/novel variant in DCTN1 and SETX genes. Additionally, molecular dynamics and biochemical functional analysis of an angiogenin variant (R21G) identified from our cohort demonstrated loss of ribonucleolytic and nuclear translocation activities. Our findings suggest that rare variants could be potentially pathogenic and functional studies are warranted to decisively establish the pathogenic mechanisms associated with them.

Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease, which is characterized by motor neuron degeneration in the central nervous system. Wobbler mice (WR) show similar symptoms and cellular defects as ALS patients and therefore can be used to study ALS *in vivo*. One of these impairments that is commonly seen in ALS is the production of increased levels of reactive oxygen species (ROS). Under pathological conditions increased ROS level and impairments in the cell defense mechanisms can be detrimental, and lead to cell death. In this study, we aim to investigate the underlying mechanisms for increased ROS levels in the WR spinal cord. We demonstrated increased ROS levels in the WR primary motor neurons by using live cell imaging with dihydroethidium *ex vivo*. Additionally, we have shown elevated levels of DNA damage response proteins, 53BP1 and γH2AX, in WR by qPCR and IF analyses. Furthermore, several ROS detoxification molecules were evaluated, of all, glutathione peroxidase 4 was found to be upregulated in WR by qPCR and WB analyses. Concordantly, WR showed reduced total glutathione, in addition to reduced ratio of glutathione-to-glutathione disulfide. Lastly, primary motor neurons were treated with several ROS scavenger molecules and stained for γH2AX to compare the DNA damage. All used ROS scavenger molecules decreased the number of γH2AX spots in WR. Overall, this study suggests that there is an increased ROS production, impairment in the antioxidant system, and DNA damage in the spinal cord tissue of WR.

Little Helpers or Mean Rogue-Role of Microglia in Animal Models of Amyotrophic Lateral Sclerosis.
Amyotrophic lateral sclerosis (ALS) is one of the most common neurodegenerative diseases, causing degeneration of both upper and lower motor neurons in the central nervous system (CNS). ALS patients suffer from hyperreflexia, spasticity, paralysis and muscle atrophy and typically die due to respiratory failure 1-5 years after disease onset. In addition to the degeneration of motor neurons on the cellular level, ALS has been associated with neuroinflammation, such as microgliosis. Microglial activation in ALS can either be protective or degenerative to the neurons. Among others, mutations in superoxide dismutase 1 (SOD1), chromosome 9 open reading frame 72 (C9Orf72), transactive response DNA binding protein (TDP) 43 and vacuolar protein sorting-associated protein 54 (VPS54) genes have been associated with ALS. Here, we describe the dual role and functionality of microglia in four different in vivo ALS models and search for the lowest common denominator with respect to the role of microglia in the highly heterogeneous disease of ALS.

Increased ROS-Dependent Fission of Mitochondria Causes Abnormal Morphology of the Cell Powerhouses in a Murine Model of Amyotrophic Lateral Sclerosis.
Amyotrophic lateral sclerosis (ALS) is the most common motor neuron disease in humans and remains to have a fatal prognosis. Recent studies in animal models and human ALS patients indicate that increased reactive oxygen species (ROS) play an important role in the pathogenesis. Considering previous studies revealing the influence of ROS on mitochondrial physiology, our attention was focused on mitochondria in the murine ALS model, wobbler mouse. The aim of this study was to investigate morphological differences between wild-type and wobbler mitochondria with aid of superresolution structured illumination fluorescence microscopy, TEM, and TEM tomography. To get an insight into mitochondrial dynamics, expression

studies of corresponding proteins were performed. Here, we found significantly smaller and degenerated mitochondria in wobbler motor neurons at a stable stage of the disease. Our data suggest a ROS-regulated, Ox-CaMKII-dependent Drp1 activation leading to disrupted fission-fusion balance, resulting in fragmented mitochondria. These changes are associated with numerous impairments, resulting in an overall self-reinforcing decline of motor neurons. In summary, our study provides common pathomechanisms with other ALS models and human ALS cases confirming mitochondria and related dysfunctions as a therapeutic target for the treatment of ALS.

INVESTIGATION OF THE FUNCTIONAL INTERACTION BETWEEN TDP-43 AND SMN IN THE GENETIC ZEBRAFISH MODEL OF SMA AND IN PATIENT DERIVED MOTOR NEURONS.

POSTER SESSION 03 - SECTION: AMYOTROPHIC LATERAL SCLEROSIS

Elena Pasho, Aixin Li, Sorana Ciura, Edor Kabashi
Institut Imagine, Translational Research For Neurological Disorders Laboratory, Paris, France

The two most prominent motor neuron diseases, **Spinal Muscular Atrophy (SMA)** and **Amyotrophic Lateral Sclerosis (ALS)**, are both linked to defects in RNA-processing factors. SMA, currently the most common genetic cause of infant mortality, results from the loss of function of the **survival motor neuron** (**SMN***)* protein, an essential factor in the assembly of spliceosomes in the nuclear bodies gems and Cajal Bodies. For ALS, an adult onset fatal motor neuron degeneration, the RNA-binding protein **TDP-43** is found in cytoplasmic aggregates of affected regions, representing the pathological hallmark of the disease. TDP-43 and SMN have convergent functions, with both ALS and SMA sharing disrupted spliceosome assembly and perturbed RNA metabolism. In this study we investigate the functional interaction between TDP-43 and SMN in the genetic zebrafish model of SMA and in patient-derived motor neurons. We show that knock-down of the zebrafish orthologue of SMN causes locomotor defects accompanied by spinal motor neuron axonopathy in zebrafish larvae. Overexpression of human TDP-43 significantly improves these features, while a TPD-43 construct bearing the ALS-linked mutation G93A is unable to ameliorate the SMN knock-down phenotype. To test this effect in patient derived cells, we have differentiated motor neurons from SMA patient iPSCs. Motor neurons were analysed with the live cell imaging and analysis system Incucyte, observing an early phenotype consisting of reduced neurite extension in SMA mutant vs. control motor neurons. Currently, this screenable assay is used to further determine the functional interaction between TDP-43 and SMN in a patient-relevant context.

Aims: Amyotrophic Lateral Sclerosis (ALS) is an incurable progressive motor neuron disease. Two pharmaceutical drugs, Riluzole® and Edaravone®, are available for treatment but exhibit very modest effects on average. Hence, the search for novel, therapeutic alternatives is necessary. One hallmark of ALS is the presence of toxic cytoplasmic aggregates of the protein TDP-43 in ≥97% of patients, rendering this protein a major therapeutic target. Thus, the aim of our study is to develop biotherapeutics targeting TDP-43. **Methods/Results:** Using phage display to screen a library of single-chain variable fragments (scFv) against purified, human, wild-type TDP-43, we identified 4 clones exhibiting TDP-43-specific affinity. Their overexpression/colocalization with TDP-43 and safety in HEK293T cells were confirmed via immunofluorescence and MTT reduction, respectively. Surface plasmon resonance (SPR) suggested high affinity for TDP-43, reflected by a K_D of 5.59 nM. Immunoblots of lysates of co-transfected cells revealed that the scFv decreased the expression and aggregation of TDP-43. Moreover, *in silico* binding prediction revealed relevant, potential binding sites that are known to have roles in the aggregation of TDP-43. We have recently succeeded in conjugating the scFv candidates to PEG-SPION complexes to facilitate their vectorization through the blood-brain-barrier for pre-clinical trials. **Conclusion:** Overall, our results confirm the binding of our scFv's to TDP-43 and suggest a potential role in counteracting TDP-43 pathology. We will further evaluate their effect on processes altered by TDP-43 proteinopathy including energy metabolism, RNA metabolism, and cell viability in ALS patient-derived fibroblasts and a mouse TDP-43 model.

Amyotrophic lateral sclerosis (ALS) is a progressive and fatal neurodegenerative disease characterized by the motor neurons death. The aggregation of misfolded proteins such as SOD1 or TDP-43 is the pathological hallmark of ALS and has been associated with neuroinflammation and ultimately, cellular degeneration. P2X4 receptor (P2X4), a non-selective cationic ATP-gated channel is involved in various diseases such as chronic pain and neurodegenerative diseases including ALS. In this study, we observed a surface upregulation of P2X4 in peripheral macrophages of SOD1G93A ALS mouse model (SOD1) at presymptomatic stages and within microglial spinal cord during disease progression. We demonstrated that this pathological increase of surface P2X4 density is due to the interference of misfolded mutant SOD1 or TDP-43 proteins with P2X4 endocytosis machinery. To address the role of P2X4 in ALS pathogenesis, we generate double transgenic SOD1 mice expressing either internalization-defective P2X4mCherryIN knock-in gene (SOD1:P2X4KI) or lacking the P2X4 gene (SOD1:P2X4KO). Our results showed that the absence of P2X4 improves motor performances and survival of SOD1 mice. Interestingly, increased P2X4 surface density has also a positive impact on ALS, a paradoxical output that may be the result of complex time and cell-dependent roles of P2X4. We are currently developing new transgenic mice expressing conditional either knock-in non-internalized P2X4 (cP2X4KI) or knock-out (cP2X4KO) selectively in macrophage/microglia or neurons to unravel the cell-specific function of P2X4 in ALS pathogenesis of SOD1 mice. Overall, this work will determine whether manipulating P2X4 is a promising therapeutic strategy for fighting against ALS.

Aims: Amyotrophic lateral sclerosis (ALS) exists on a pathogenetic disease spectrum with frontotemporal dementia (FTD), with patients sometimes experiencing elements of both conditions (ALS-FTSD). For mutations associated with ALS-FTSD, such as the C9orf72 hexanucleotide repeat expansion, the factors influencing where an individual may lie on this spectrum require further characterisation. As such, our study aimed to investigate molecular signatures underlying heterogeneity in C9orf72-associated disease. Methods: Using digital pathology analysis and random forest modelling we have previously shown that microglial staining is predictive of C9orf72-ALS disease status, and that microglial activation is elevated in the language region (BA39) for language-impaired cases. Here we used NanoString molecular barcoding with a panel of 770 neuroinflammatory genes to interrogate this dysregulation at the level of gene expression. Validation was performed using BaseScope(TM) *in situ* hybridisation and immunohistochemistry. Results: We identified 21 top hits for dysregulated neuroinflammatory genes in the motor cortex, with enrichment of microglial and inflammatory response gene sets in disease. Our analyses also revealed two distinct C9orf72-ALS subtypes, with inflammatory signatures that segregate with glial TDP-43 burden and language impairment. Conclusions: These data imply that distinct molecular signatures can be detected within well curated and deeply clinically phenotyped cohorts that could hold promise for future targeted therapies.

BODY COMPLEXION AND CIRCULATING LIPIDS IN THE RISK OF FRONTOTEMPORAL DEMENTIA AND AMYOTROPHIC LATERAL SCLEROSIS

POSTER SESSION 03 - SECTION: AMYOTROPHIC LATERAL SCLEROSIS

Luis Carlos Fernandez Beltran[1], Juan Miguel Godoy Corchuelo[1], Noelia Esteban-García[1], Jose L Ayala[2], Jordi A. Matias[1], Silvia Corrochano[1]
[1]Hospital Clínico San Carlos, Neurological Disorders Group, Madrid, Spain, [2]Universidad Complutense de Madrid, Statistical Department, Madrid, Spain

Frontotemporal dementia (FTD) and Amyotrophic lateral sclerosis (ALS) are neurodegenerative diseases that seems to be the two ends of a spectrum due to clinical and genetic overlap. Nearly 50% of FTD and 98% of all ALS patients have histopathological TDP-43 aggregates. In this work we aim to evaluate whether different body lipid metabolic traits are causally associated with the risk of FTD TDP43 subtype, and compare it to their causal role in the risk of ALS, and identify genetic variants shared between these two TDP-43 related disorders in relation to lipid metabolic traits. Two-sample mendelian randomization analyses (2SMR) were performed to evaluate the causal association of 9 body complexion and 9 circulating lipids traits with the risk of FTD TDP-43 subtype, and the risk of ALS. The inverse-variance weighted method (IVW) was the primary analysis followed by secondary sensitive analyses. Genetically increased trunk predicted mass and fat-free mass were suggestively associated with the risk of FTD TDP-43 subtype. We corroborated that genetically predicted high levels of LDL cholesterol are causally associated with higher risk of ALS, and found suggestive causal associations with other circulating fatty acids. This work provides evidence that body complexion and circulating lipids traits impact differentially on the risk of FTD TDP-43 subtype and ALS, advocating for new and specific interventional approaches in the control of body lipid metabolism for FTD and ALS.

A Transcriptomic Meta-Analysis Shows Lipid Metabolism Dysregulation as an Early Pathological Mechanism in the Spinal Cord of SOD1 Mice.
Amyotrophic lateral sclerosis (ALS) is a multifactorial and complex fatal degenerative disorder. A number of pathological mechanisms that lead to motor neuron death have been identified, although there are many unknowns in the disease aetiology of ALS. Alterations in lipid metabolism are well documented in the progression of ALS, both at the systemic level and in the spinal cord of mouse models and ALS patients. The origin of these lipid alterations remains unclear. This study aims to identify early lipid metabolic pathways altered before systemic metabolic symptoms in the spinal cord of mouse models of ALS. To do this, we performed a transcriptomic analysis of the spinal cord of mice at an early disease stage, followed by a robust transcriptomic meta-analysis using publicly available RNA-seq data from the spinal cord of SOD1 mice at early and late symptomatic disease stages. The meta-analyses identified few lipid metabolic pathways dysregulated early that were exacerbated at symptomatic stages; mainly cholesterol biosynthesis, ceramide catabolism, and eicosanoid synthesis pathways. We present an insight into the pathological mechanisms in ALS, confirming that lipid metabolic alterations are transcriptionally dysregulated and are central to ALS aetiology, opening new options for the treatment of these devastating conditions.

LIPIDS AS A NOVEL BIOMARKER FOR AMYOTROPHIC LATERAL SCLEROSIS - EVIDENCE FROM THE SOD1 MOUSE.

POSTER SESSION 03 - SECTION: AMYOTROPHIC LATERAL SCLEROSIS

Sophia Luikinga[1], Vinod Narayana[2], Vic Lin[1], Bradley Turner[1]
[1]The Florey Institute of Neuroscience and Mental Health, Motor Neurone Disease Laboratory, Parkville, Australia, [2]University of Melbourne, Metabolomics Australia, Parkville, Australia

Diagnosis of Amyotrophic lateral sclerosis (ALS) can be a lengthy process, mainly due to the lack of accurate biomarkers that are easily accessible. To date, blood-based biomarkers lack specificity and are unable to distinguish MND from other neurodegenerative disorders. It has increasingly been acknowledged that lipid metabolism plays a crucial role in ALS. Therefore, the aim of this study is to discover novel biomarkers that are specific to ALS, based on the blood lipidome of mutant SOD1 mice. We performed targeted lipidomic analysis on plasma of $SOD1^{G93A}$ and wildtype littermates at metabolomics Australia. Analysis was conducted pre-symptomatically at postnatal day (P) 60, symptomatic – P90 and end stage ~P150. Further, we treated a separate group of mice with ambroxol, an inhibitor of a key enzyme in the glycosphingolipid pathway and a novel candidate for treating MND symptoms. Treatment started at P60 and blood was collected at P90 and end stage. We discovered a distinct lipid dysregulation found in the blood of $SOD1^{G93A}$ mice compared to their wildtype littermates at P60. Next, we sought how lipids change with disease progression. Here, we compared targeted lipidomics of P60, P90 and ~P150 $SOD1^{G93A}$ mice. We found that lipids have a dynamic abundance, changing with disease progression. Lastly, we show that ambroxol can significantly restructure lipid composition, possibly explaining extension in lifespan of mutant SOD1 mice. Together, we are the first to show that blood lipids have a strong potential to function as reliable biomarkers, which may improve diagnostic interval in ALS.

Ferroptosis mediates selective motor neuron death in amyotrophic lateral sclerosis.
Amyotrophic lateral sclerosis (ALS) is caused by selective degeneration of motor neurons in the brain and spinal cord; however, the primary cell death pathway(s) mediating motor neuron demise remain elusive. We recently established that necroptosis, an inflammatory form of regulated cell death, was dispensable for motor neuron death in a mouse model of ALS, implicating other forms of cell death. Here, we confirm these findings in ALS patients, showing a lack of expression of key necroptotic effector proteins in spinal cords. Rather, we uncover evidence for ferroptosis, a recently discovered iron-dependent form of regulated cell death, in ALS. Depletion of glutathione peroxidase 4 (GPX4), an anti-oxidant enzyme and central repressor of ferroptosis, occurred in post-mortem spinal cords of both sporadic and familial ALS patients. GPX4 depletion was also an early and universal feature of spinal cords and brains of transgenic mutant superoxide dismutase 1 (SOD1), TDP-43 and C9orf72 mouse models of ALS. GPX4 depletion and ferroptosis were linked to impaired NRF2 signalling and dysregulation of glutathione synthesis and iron-binding proteins. Novel BAC transgenic mice overexpressing human GPX4 exhibited high GPX4 expression localised to spinal motor neurons. Human GPX4 overexpression in SOD1 mice significantly delayed disease onset, improved locomotor function and prolonged lifespan, which was attributed to attenuated lipid peroxidation and motor neuron preservation. Our study discovers a new role for ferroptosis in mediating motor neuron death in ALS, supporting the use of anti-ferroptotic therapeutic strategies, such as GPX4 pathway induction and upregulation, for ALS treatment.

Developmental perspectives on methamphetamine abuse: Exploring adolescent vulnerabilities on brain and behavior.
Most people that experience illicit drugs do so for the first time during adolescence, and methamphetamine (meth) is no exception. Therefore, research into the effects of meth should highlight the adolescent period. Despite this, the vast majority of current literature has mainly focused on meth exposure during adulthood. In this review, we first describe existing literature that compares the behavioral effects of meth where exposure occurs in adolescence compared to adulthood. Given that there

are actually very few such studies, we also look at what is known about neural effects of meth in the adult brain, and relate these to normal neural development occurring during the adolescent period to establish how meth may target maturing regions and related neurochemistry. What emerges overall is that adolescents appear to be more vulnerable to the rewarding and reinforcing effects of meth, and that meth indeed has effects on areas that are in flux during adolescence. However, there is some evidence for a paradoxical resistance to the neurotoxic effects during this period. We highlight the need for further age-related research to better understand, treat, and prevent meth use disorders and addiction in general.

Stimulation of mTOR-independent autophagy and mitophagy by rilmenidine exacerbates the phenotype of transgenic TDP-43 mice.
Autophagy, which mediates the delivery of cytoplasmic substrates to the lysosome for degradation, is essential for maintaining proper cell homeostasis in physiology, ageing, and disease. There is increasing evidence that autophagy is defective in neurodegenerative disorders, including motor neurons affected in amyotrophic lateral sclerosis (ALS). Restoring impaired autophagy in motor neurons may therefore represent a rational approach for ALS. Here, we demonstrate autophagy impairment in spinal cords of mice expressing mutant TDP-43 or co-expressing TDP-43 transgenes. The clinically approved anti-hypertensive drug rilmenidine was used to stimulate mTOR-independent autophagy in double transgenic TDP-43 mice to alleviate impaired autophagy. Although rilmenidine treatment induced robust autophagy in spinal cords, this exacerbated the phenotype of TDP-43 mice, shown by truncated lifespan, accelerated motor neuron loss, and pronounced nuclear TDP-43 clearance. Importantly, rilmenidine significantly promoted mitophagy in spinal cords TDP-43 mice, evidenced by reduced mitochondrial markers and load in spinal motor neurons. These results suggest that autophagy induction accelerates the phenotype of this TDP-43 mouse model of ALS, most likely through excessive mitochondrial clearance in motor neurons. These findings also emphasise the importance of balancing autophagy stimulation with the potential negative consequences of hyperactive mitophagy in ALS and other neurodegenerative diseases.

Extinction and drug-induced reinstatement of cocaine seeking following self-administration or conditioned place preference in adolescent and adult rats.
Adolescence marks a particularly vulnerable period to developing substance use disorders, and people who start using drugs in adolescence are more likely to relapse. A limited number of studies have investigated age difference in relapse following re-exposure to the drug after a period of abstinence. Using a cocaine self-administration paradigm, we showed no age difference in acquisition or extinction of self-administration. Interestingly, adolescent rats displayed impaired cocaine-primed reinstatement of cocaine seeking. Using the same dose as that self-administered in the first experiment, we then investigated age differences in acquisition and extinction of conditioned place preference, as well as locomotor sensitization. While there were no differences in locomotor activity or acquisition of preference, adolescents failed to extinguish their preference, even when the number of extinction sessions was doubled from what adults received. Taken together, these results suggest that while cocaine has similar rewarding and reinforcing effects regardless of age, adolescents may attribute stronger salience to the drug-associated context. In addition, re-exposure to cocaine itself may not be a strong relapse trigger in adolescence. Overall, these findings suggest that we should focus more on alleviating drug-context salience compared to re-exposure to substance in order to reduce relapse of drug seeking in adolescents.

Effects of Methamphetamine Exposure on Fear Learning and Memory in Adult and Adolescent Rats.
Methamphetamine (meth) use is often comorbid with anxiety disorders, with both conditions predominant during adolescence. Conditioned fear extinction is the most widely used model to study the fear learning and regulation that are relevant for anxiety disorders. The present study investigates how meth binge injections or meth self-administration affect subsequent fear conditioning, extinction and retrieval in adult and adolescent rats. In experiment 1, postnatal day 35 (P35-adolescent) and P70 (adult) rats were intraperitoneally injected with increasing doses of meth across 9 days. At P50 or P85, they underwent fear conditioning followed by extinction and test. In experiments 2a-c, P35 or P70 rats self-administered meth for 11 days then received fear conditioning at P50 or P85, followed by extinction and test. We observed that meth binge exposure caused a significant disruption of extinction retrieval in adult but not adolescent rats. Interestingly, meth self-administration in adolescence or adulthood disrupted acquisition of conditioned freezing in adulthood. Meth self-administration in adolescence did not affect conditioned freezing in adolescence. These results suggest that intraperitoneal injections of high doses of meth and meth self-administration have dissociated effects on fear conditioning and extinction during adulthood, while adolescent fear conditioning and extinction are unaffected.

Aripiprazole Facilitates Extinction of Conditioned Fear in Adolescent Rats.
Anxiety disorders are the most common type of mental disorder during adolescence, which is at least partly due to the resistance to extinction exhibited at this age. The dopaminergic system is known to be dysregulated during adolescence; therefore, we aimed to facilitate extinction in adolescent rats using the dopamine receptor 2 partial agonist aripiprazole (Abilify™), and examine the behavioral and neural outcomes. Adolescent rats were conditioned to fear a tone. The next day, rats received extinction 30 min after a systemic injection of either 5 mg/kg aripiprazole or vehicle, and then were tested the following day. For the immunohistochemistry experiment, naïve and "no extinction" conditions were added and rats were perfused either on the extinction day or test day. To assess the activation of neurons receiving dopaminergic input, c-Fos, and dopamine- and cAMP-regulated neuronal phosphoprotein (DARPP-32) labeled neurons were quantified in the amygdala and the medial prefrontal cortex (mPFC). Systemic treatment with aripiprazole at the time of extinction significantly reduced freezing at test the next day. This effect was not observed in rats that were fear conditioned but did not receive any extinction. Aripiprazole's facilitation of extinction was accompanied by increased activation of neurons in the mPFC. Taken together, aripiprazole represents a novel pharmacological adjunct to exposure therapy worthy of further examination. The effect of aripiprazole is related to enhanced activation of mPFC neurons receiving dopaminergic innervation.

Chronic voluntary alcohol consumption causes persistent cognitive deficits and cortical cell loss in a rodent model.
Chronic alcohol use is associated with cognitive decline that impedes behavioral change during rehabilitation. Despite this, addiction therapy does not address cognitive deficits, and there is poor understanding regarding the mechanisms that underlie this decline. We established a rodent model of chronic voluntary alcohol use to measure ensuing cognitive effects and underlying pathology. Rats had intermittent access to alcohol or an isocaloric solution in their home cage under voluntary 2-bottle choice conditions. In Experiments 1 and 2 cognition was assessed using operant touchscreen chambers. We examined performance in a visual discrimination and reversal task (Experiment 1), and a 5-choice serial reaction time task (Experiment 2). For Experiment 3, rats were perfused immediately after cessation of alcohol access period, and volume, cell density and microglial populations were assessed in the prefrontal cortex and striatum. Volume was assessed using the Cavalieri probe, while cell and microglial counts were estimated using unbiased stereology with an optical fractionator. Alcohol-exposed and control rats showed comparable acquisition of pairwise discrimination; however, performance was impaired when contingencies were reversed indicating reduced behavioral flexibility. When tested in a 5-choice serial reaction time task alcohol-exposed rats showed increased compulsivity and increased attentional bias towards a reward associated cue. Consistent with these changes, we observed decreased cell density in the prefrontal cortex. These findings confirm a detrimental effect of chronic alcohol and establish a model of alcohol-induced cognitive decline following long-term voluntary intake that may be used for future intervention studies.

Extinction of conditioned cues attenuates incubation of cocaine craving in adolescent and adult rats.
Relapse to drug use is often precipitated by exposure to drug associated cues that evoke craving. Cue-induced drug craving has been observed in both animals and humans to increase over the first few weeks of abstinence and remain high over extended periods, a phenomenon known as 'incubation of craving'. As adolescence represents a period of vulnerability to developing drug addiction, potentially due to persistent reactivity to drug associated cues, we first compared incubation of cocaine craving in adolescent and adult rats. Adolescent (P35) and adult (P70) rats were trained to lever press to obtain intravenous cocaine, with each drug delivery accompanied by a light cue that served as the conditioned stimulus (CS). Following acquisition of stable responding, rats were tested for cue-induced cocaine-seeking after either 1 or 30days of abstinence. Additional groups of rats were also tested after 30days of abstinence, however these rats were subjected to a cue extinction session 1week into the abstinence period. Rats were injected with aripiprazole, a dopamine 2 receptor (D2R)-like partial agonist, or vehicle, 30min prior to cue extinction. We found that adolescent and adult rats acquired and maintained a similar level of cocaine self-administration, and rats of both ages exhibited a higher level of cue-induced cocaine-seeking if they were tested after 30days of abstinence compared to 1day. Incubation of cocaine craving was significantly reduced to 1day levels in both adults and adolescents that received cue extinction training. Administration of aripiprazole prior to cue extinction did not further reduce cue-induced drug-seeking. These results indicate that cue extinction training during abstinence may effectively reduce cue-induced relapse at a time when cue-induced drug craving is usually high.

Extinction of a cocaine-taking context that protects against drug-primed reinstatement is dependent on the metabotropic

glutamate 5 receptor.
We investigated the effects of extinguishing action-reward versus context-reward associations on drug-primed reinstatement, and the potential role of the metabotropic glutamate 5 receptor (mGlu5) in these different types of extinction in rats that self-administer cocaine. We observed that daily context extinction (non-reinforced exposures to the cocaine-taking context with retracted levers) was just as effective as daily lever extinction in reducing cocaine-primed reinstatement compared with passive abstinence. Additionally, systemic injections of the mGlu5 negative allosteric modulator MTEP (3-[(2-methyl-1,3-thiazol-4-yl)ethynyl]-pyridine) following each extinction session significantly impaired the ability of context extinction to reduce cocaine-primed reinstatement, without affecting reinstatement after lever extinction or passive abstinence.

Endoglin haplo-insufficiency modifies the inflammatory response in irradiated mouse hearts without affecting structural and mircovascular changes.
It is now widely recognized that radiotherapy of thoracic and chest wall tumors increases the long-term risk of cardiovascular damage although the underlying mechanisms are not fully elucidated. There is increasing evidence that microvascular damage is involved. Endoglin, an accessory receptor for TGF-β1, is highly expressed in damaged endothelial cells and may play a crucial role in cell proliferation and revascularization of damaged heart tissue. We have therefore specifically examined the role of endoglin in microvascular damage and repair in the irradiated heart.

THE MOTONEURONAL RECEPTOROME IN ALS REVEALS ADRENERGIC ENTRY POINTS TO MODULATE MN EXCITABILITY AND FIRING

POSTER SESSION 03 - SECTION: AMYOTROPHIC LATERAL SCLEROSIS

Guillaume Caron[1], Stefano Antonucci[2], Marcin Bączyk[3], Daniel Zytnicki[1], Francesco Roselli[2,4]
[1]Université de Paris, Sppin - Umr8003, Paris, France, [2]Ulm University, Department Of Neurology, Ulm, Germany, [3]Poznań University of Physical Education, Department Of Neurobiology, Poznań, Poland, [4]Ulm University, German Center For Neurodegenerative Diseases, Ulm, Germany

Modulation of motoneuron (MN) excitability and synaptic excitation constitutes an important entry point to affect MN degeneration in several MN diseases. We have previously demonstrated that chemogenetic interventions on excitability and PKA signaling exert beneficial effects on synaptic integrity and disease burden in ALS MN. To achieve a similar upregulation of PKA signaling and MN firing through natural receptor, we explored the PKA-coupled motoneuronal receptorome in ALS. Among the receptors prioritized by screening available databases (Allen Spinal Cord Atlans, GPCR database), adenosinergic, histaminergic, cholinergic and several peptidergic receptors are downregulated in G93A SOD1 mice, whereas beta-1 adrenergic receptor is distinctively upregulated and the expression of dopaminergic D5 and beta-2 and beta-3 adrenergic receptors are preserved. Importantly, in vivo intracellular recordings of MN in G93A SOD1 mice show that acute activation of Dopaminergic D5 and beta2/3 adrenergic receptors by selective agonists increase MN excitability, through a decreased recruitment current for D5 agonist, and through an increased gain of the frequency-current relationship for beta2/3 agonists, indicating a role for D5 and beta2/3 receptors in the regulation of MN excitability in ALS. In addition, intracellular iontophoretic injection of cAMP-sP increases the gain of the frequency-current relationship, suggesting that beta2/3 receptors increase MN excitability through the PKA pathway. The ALS MN receptorome is nevertheless highly dynamic and all studied receptors are downregulated in advanced stages of disease. Our data show that MN display extensive entry points for modulation of their electrophysiological properties, which can be accessed with small molecules with translational potential.

ASSESSING THE ROLE OF CORTICAL NETWORK DYSFUNCTION IN AMYOTROPHIC LATERAL SCLEROSIS THROUGH CHEMOGENETIC SILENCING OF THE CORTICOSPINAL NEURONS

POSTER SESSION 03 - SECTION: AMYOTROPHIC LATERAL SCLEROSIS

Tando Maduna, Geoffrey Stuart-Lopez, Johan Gilet, Mike Araujo Duarte, Caroline Rouaux
Centre de Recherche en Biomédecine de Strasbourg, Inserm U1118, Strasbourg, France

Amyotrophic lateral sclerosis (ALS) arises from the combined degeneration of both corticospinal neurons (CSNs) and motorneurons (MNs). Transcranial magnetic stimulation studies revealed that ALS patients display early cortical hyperexcitability, while various ALS mouse models display altered excitability of cortical excitatory neurons, including CSNs and inhibitory interneurons, from development to adulthood. “Designer Receptors Exclusively Activated by Designer Drugs” (DREADD)-mediated inhibition of Parvalbumin-positive cortical interneurons was demonstrated as beneficial in a mouse model of ALS, while DREADD-mediated activation of CSNs was deleterious to MNs in wildtype mice. We recently demonstrated that in the context of ALS, CSNs are toxic to their downstream targets. Thus, we hypothesize that this toxicity may result from their adaptation to their hyperexcitable environment leading to their aberrant neuronal activity and deleterious impacts on their spinal targets. To test this hypothesis, we aimed to evaluate the consequences of CSN silencing on disease onset and progression in a mouse model of ALS. We crossed Sod1G86R mice with CrymCreERT2 mice that selectively express Cre in layer V cortical neurons, for selective expression of the hM4Di DREADD silencing receptor, or control reporter gene upon AAV injection in the motor cortex. Four groups were generated (Sod1G86R or control, injected either with hM4Di or control), chronically treated with Clozapine-N-Oxide (CNO), the DREADD ligand, in drinking water from the pre-symptomatic ages of 30 or 60 days and are currently under evaluation using adapted clinical and motor tests. The study intends to evaluate whether cortical hyperexcitability could represent a new therapeutic target in ALS.

Neuropeptides shaping the central nervous system development: Spatiotemporal actions of VIP and PACAP through complementary signaling pathways.
Pituitary adenylate cyclase-activating polypeptide (PACAP) and vasoactive intestinal peptide (VIP) are neuropeptides with wide, complementary, and overlapping distributions in the central and peripheral nervous systems, where they exert important regulatory roles in many physiological processes. VIP and PACAP display a large range of biological cellular targets and functions in the adult nervous system including regulation of neurotransmission and neuroendocrine secretion and neuroprotective and neuroimmune responses. As the main focus of the present review, VIP and PACAP also have been long implicated in nervous system development and maturation through their interaction with the seven transmembrane domain G protein-coupled receptors, PAC1, VPAC1, and VPAC2, initiating multiple signaling pathways. Compared with PAC1, which solely binds PACAP with very high affinity, VPACs exhibit high affinities for both VIP and PACAP but differ from each other because of their pharmacological profile for both natural accessory peptides and synthetic or chimeric molecules, with agonistic and antagonistic properties. Complementary to initial pharmacological studies, transgenic animals lacking these neuropeptides or their receptors have been used to further characterize the neuroanatomical, electrophysiological, and behavioral roles of PACAP and VIP in the developing central nervous system. In this review, we recapitulate the critical steps and processes guiding/driving neurodevelopment in vertebrates and superimposing the potential contribution of PACAP and VIP receptors on the given timeline. We also describe how alterations in VIP/PACAP signaling may contribute to both (neuro)developmental and adult pathologies and suggest that tuning of VIP/PACAP signaling in a spatiotemporal manner may represent a novel avenue for preventive therapies of neurological and psychiatric disorders. © 2016 Wiley Periodicals, Inc.

Unveiling the Impact of Morphine on Tamoxifen Metabolism in Mice .
Tamoxifen is used to treat breast cancer and cancer recurrences. After administration, tamoxifen is converted into two more potent antitumor compounds, 4OH-tamoxifen and endoxifen by the CYP3A4/5 and 2D6 enzymes in human. These active

compounds are inactivated by the same UDP-glucuronosyltransferase isoforms as those involved in the metabolism of morphine. Importantly, cancer-associated pain can be treated with morphine, and the common metabolic pathway of morphine and tamoxifen suggests potential clinically relevant interactions. Mouse liver microsomes were used to determine the impact of morphine on 4OH-tamoxifen metabolism . For experiments, female mice were first injected with tamoxifen alone and then with tamoxifen and morphine. Blood was collected, and LC-MS/MS was used to quantify tamoxifen, 4OH-tamoxifen, N-desmethyltamoxifen, endoxifen, 4OH-tamoxifen-glucuronide, and endoxifen-glucuronide. , we found increased values for the production of 4OH-tamoxifen-glucuronide in the presence of morphine, suggesting an inhibitory effect on 4OH-tamoxifen glucuronidation. Conversely, morphine treatment decreased 4OH-tamoxifen levels in the blood while dramatically increasing the formation of inactive metabolites 4OH-tamoxifen-glucuronide and endoxifen-glucuronide. Our findings emphasize the need for caution when extrapolating results from metabolic assays to drug metabolism interactions. Importantly, morphine strongly impacts tamoxifen metabolism in mice. It suggests that tamoxifen efficiency could be reduced when both drugs are co-administered in a clinical setting, e.g., to relieve pain in breast cancer patients. Further studies are needed to assess the potential for tamoxifen-morphine metabolic interactions in humans.

Mu opioid receptor in microglia contributes to morphine analgesic tolerance, hyperalgesia, and withdrawal in mice.
A major challenge in medicine is developing potent pain therapies without the adverse effects of opiates. Neuroinflammation and in particular microglial activation have been shown to contribute to these effects. However, the implication of the microglial mu opioid receptor (MOR) is not known. We developed a novel conditional knockout (cKO) mouse line, wherein MOR is deleted in microglia. Morphine analgesic tolerance was delayed in both sexes in cKO mice in the hot plate assay. Opioid-induced hyperalgesia (OIH) as measured in the tail immersion assay was abolished in male cKO mice, and physical dependence to morphine as assessed by naloxone-induced withdrawal was attenuated in female cKO mice. Our results show a sex-dependent contribution of microglial MOR in morphine analgesic tolerance, OIH, and physical dependence. In conclusion, our data suggest that blockade of microglial MOR could represent a therapeutic target for opiate analgesia without the opiate adverse effects.

Lithium reverses mechanical allodynia through a mu opioid-dependent mechanism.
Background Lithium is widely used to treat bipolar disorders and displays mood stabilizing properties. In addition, lithium relieves painful cluster headaches and has a strong analgesic effect in neuropathic pain rat models. Objectives To investigate the analgesic effect of lithium on the cuff model of neuropathic pain. Methods We used behavioral and pharmacological approaches to study the analgesic effect of a single injection of lithium in wild-type and mu opioid receptor (MOR) null cuffed neuropathic mice. Mass spectrometry and enzyme-linked immunosorbent assay allowed to measure the levels of endogenous MOR agonist beta-endorphin as well as monoamines in brain and plasma samples 4 h after lithium administration. Results A single injection of lithium chloride (100 mg/kg, ip) alleviated mechanical allodynia for 24 h, and this effect was absent in MOR null neuropathic mice. Biochemical analyses highlight a significant increase in beta-endorphin levels by 30% in the brain of lithium-treated mice compared to controls. No variation of beta-endorphin was detected in the blood. Conclusions Together, our results provide evidence that lithium induces a long-lasting analgesia in neuropathic mice presumably through elevated brain levels of beta-endorphin and the activation of MORs.

Microglia Express Mu Opioid Receptor: Insights From Transcriptomics and Fluorescent Reporter Mice.
Microglia activation contributes to chronic pain and to the adverse effects of opiate use such as analgesic tolerance and opioid-induced hyperalgesia. Both mu opioid receptor (MOR) encoded by gene and toll like receptor 4 (TLR4) have been reported to mediate these morphine effects and a current question is whether microglia express the Oprm1 transcript and MOR protein. The aim of this study was to characterize -MOR expression in naive murine and human microglia, combining transcriptomics datasets previously published by other groups with our own imaging study using the Cx3cr1-eGFP-MOR-mCherry reporter mouse line. We analyzed microglial expression obtained from transcriptomics datasets, focusing on studies from adult wild-type animals and adult post-mortem human cerebral cortex. , as well as co-regulated gene sets were examined. The expression of MOR in microglia was also investigated using our novel fluorescent Cx3cr1-eGFP-MOR-mcherry reporter mouse line. We determined whether CX3cR1-eGFP positive microglial cells expressed MOR-mCherry protein by imaging various brain areas including the Frontal Cortex, Nucleus Accumbens, Ventral Tegmental Area, Central Amygdala, and Periaqueductal Gray matter, as well as spinal cord. expression was found in all 12 microglia datasets from mouse whole brain, in 7 out of 8 from cerebral cortex, 3 out of 4 from hippocampus, 1 out of 1 from striatum, and 4 out of 5

from mouse or rat spinal cord. was expressed in 16 out of 17 microglia transcriptomes from human cerebral cortex. In Cx3cr1-eGFP-MOR-mCherry mice, the percentage of MOR-positive microglial cells ranged between 35.4 and 51.6% in the different brain areas, and between 36.8 and 42.4% in the spinal cord. The comparative analysis of the microglia transcriptomes indicates that transcripts are expressed in microglia. The investigation of Cx3cr1-eGFP-MOR-mCherry mice also shows microglial expression of MOR proteinin the brain and spine. These results corroborate functional studies showing the actions of MOR agonists on microglia and suppression of these effects by MOR-selective antagonists or MOR knockdown.

Stable isotope-labelled morphine to study in vivo central and peripheral morphine glucuronidation and brain transport in tolerant mice.
Chronic administration of medication can significantly affect metabolic enzymes leading to physiological adaptations. Morphine metabolism in the liver has been extensively studied following acute morphine treatment, but such metabolic processes in the CNS are poorly characterized. Long-term morphine treatment is limited by the development of tolerance, resulting in a decrease of its analgesic effect. Whether or not morphine analgesic tolerance affects in vivo brain morphine metabolism and blood-brain barrier (BBB) permeability remains a major question. Here, we have attempted to characterize the in vivo metabolism and BBB permeability of morphine after long-term treatment, at both central and peripheral levels.

ALS is a neurodegenerative disease characterized by the progressive loss of motor neurons and premature death. Given their central role in the disease, major focus has been directed to motor neuron intrinsic properties as a cause for degeneration. However, our previous data demonstrated that V1 inhibitory interneurons degenerate and lose their connectivity to vulnerable motor neurons, possibly playing a role in disease initiation. V1 interneurons are a heterogeneous population which can be identified by specific marker co-expression. Using *in situ* multiplexing techniques, we have performed a comprehensive study on the expression of several markers in the $SOD1^{G93A}$ mouse model with the aim to elucidate the contribution of specific interneuron subpopulations to ALS pathology. We first validated the expression of 24 interneuron markers, typically described at embryonic stages, in adult mouse tissue by *in situ* sequencing. Then, we quantified transcript expression by RNAscope HiPlexUp, an *in situ* hybridization quantitative technique allowing for co-detection of multiple transcripts, at three different timepoints. Our data show downregulation of different V1 interneuron clade-defining transcription factors starting at early stages of disease (from day 63) and preceding motor neuron degeneration. Notable is the early dysregulation of V1 Renshaw cells, defined by Calbindin 1. Additionally, we investigated other interneuron populations. Here, we describe substantial downregulation of the Chx10 transcription factor, marker for the excitatory V2a interneuron subpopulation, at later stages (from day 112). Overall, our study evidences a pronounced dysregulation of interneuron motor networks throughout ALS progression and identifies several potential sources for non-autonomous motor neuron degeneration.

Locomotor deficits in a mouse model of ALS are paralleled by loss of V1-interneuron connections onto fast motor neurons.
ALS is characterized by progressive inability to execute movements. Motor neurons innervating fast-twitch muscle-fibers preferentially degenerate. The reason for this differential vulnerability and its consequences on motor output is not known. Here, we uncover that fast motor neurons receive stronger inhibitory synaptic inputs than slow motor neurons, and disease progression in the SOD1 mouse model leads to specific loss of inhibitory synapses onto fast motor neurons. Inhibitory V1 interneurons show similar innervation pattern and loss of synapses. Moreover, from postnatal day 63, there is a loss of V1 interneurons in the SOD1 mouse. The V1 interneuron degeneration appears before motor neuron death and is paralleled by the development of a specific locomotor deficit affecting speed and limb coordination. This distinct ALS-induced locomotor deficit is phenocopied in wild-type mice but not in SOD1 mice after appearing of the locomotor phenotype when V1 spinal interneurons are silenced. Our study identifies a potential source of non-autonomous motor neuronal vulnerability in ALS and links ALS-induced changes in locomotor phenotype to inhibitory V1-interneurons.

The protective effect of Angiotensin AT2-receptor stimulation in Neuromyelitis optica spectrum disorder is independent of astrocyte-derived BDNF.
Neuromyelitis optica spectrum disorder (NMOSD) is an antibody-mediated autoimmune inflammatory disease of the central nervous system (CNS), resulting in primary astrocytopathy. We have previously shown that Angiotensin AT2-receptor (AT2R) stimulation with the specific agonist Compound 21 (C21) attenuated NMOSD-like pathology. Recent studies have proposed that the mechanism behind protective effects of AT2R includes induction of brain derived neurotrophic factor (BDNF).

Astrocytes are a major cellular source of BDNF. In this study we used mice with conditional BDNF deficiency in astrocytes (GfapF) to examine the involvement of astrocyte-derived BDNF in NMOSD-like pathology and in mediating the protective effect of AT2R stimulation.

DEFINING THE FUNCTIONAL ROLE OF TBK1 USING A NOVEL ZEBRAFISH MODEL OF AMYOTROPHIC LATERAL SCLEROSIS (ALS).

POSTER SESSION 03 - SECTION: AMYOTROPHIC LATERAL SCLEROSIS

Gregoire Haouy[1], Hortense De Calbiac[1], Marion Rosello[2], Filippo Del Bene[2], Sorana Ciura[3], Edor Kabashi[3]
[1]Institut Imagine, Laboratoire De Recherche Translationnelle Sur Les Maladies Neurologiques, Paris, France, [2]Institut de la Vision, Department Of Development, Paris, France, [3]Institut Imagine, Translational Research For Neurological Disorders Laboratory, Paris, France

ALS is a progressive neurodegenerative disorder affecting motor neurons that leads to muscle paralysis and denervation of the respiratory muscle through the degeneration of cortical and spinal motor neurons. In 2015, mutations leading to haploinsufficiency of TBK1 were first described in ALS patients. Tightly linked to both autophagy and inflammation, two impaired cellular pathways in ALS, it has become of major interest to understand TBK1 functional role in the pathogenesis. Therefore, we utilized zebrafish, an optimal vertebrate model to study ALS related genes, including Tbk1. To analyze the mechanisms underlying *TBK1* deletion in motor neurons degeneration, we designed and characterized novel *tbk1* KO and KD zebrafish models. We observed a decrease in the locomotor ability associated with tbk1 loss of function and we correlated it to a decrease in the number of spinal motor neurons. The KO model is also characterized by a high lethality early in development. To elucidate pathways that could be responsible for motor neuron degeneration and early lethality, we have performed age-dependent metabolic profiles in these models. We demonstrate that tbk1 loss of function leads to an increase production of antioxidant molecules followed by dysregulation in the NAD metabolism. These two profiles suggest a harmful oxidative stress followed by a decrease in the NAD pool; two hallmarks of the pathogenesis observed in ALS patients attesting the validity of our model to study this disease. Finally, we are in the process of targeting these dysregulated pathways using prioritized compounds to identify novel therapeutic strategies for ALS.

Aims: Frontotemporal dementia (FTD) characterizes by progressive degeneration of frontal and temporal lobes which results in cognitive, behavioral, and language dysfunction. Almost half of the FTD patients present toxic, cytoplasmic aggregates of the ribonucleoprotein TDP-43 as a consequence, among others, of its post-translational hyperphosphorylation. Given that CK-1δ and TTBK1 kinases have been involved in TDP-43 phosphorylation, we hypothesize that their pharmacological inhibition could be beneficial against TDP-43-based FTD. **Methods**: Presymptomatic CaMKII-TDP-43 transgenic mice (at post-natal day (PND) 45) were chronically treated with IGS2.7 (CK-1δ inhibitor), VNG1.47 (TTBK1 inhibitor) or vehicle for 45 days. Novel object recognition (NOR) test was performed at PND60 and PND90. Animals were euthanized at PND90, and brain hemispheres were processed for immunohistochemistry and biochemical analysis. **Results:** As early as PND60, CaMKII-TDP-43 transgenic mice treated with IGS2.7 or VNG1.47 showed higher discrimination index in the NOR test than CaMKII-TDP-43 mice treated with vehicle. This finding was also observed at PND90. At biochemical level, both inhibitors decreased TDP-43 phosphorylation in the prefrontal cortex (PFC) and the hippocampus compared to non-treated CaMKII-TDP-43 transgenic mice. These benefits were accompanied, at histological level, by neuronal preservation in the PFC and the hippocampus, as well as by reduced astrogliosis in the PFC and a subtle attenuation in hippocampal microgliosis. **Conclusion:** Our data suggest that inhibition of TDP-43 phosphorylation could be a beneficial disease-modifying strategy to tackle FTD with TDP-43 proteinopathy and propose CK-1δ and TTBK1 as promising targets.

TDP-43 Modulation by Tau-Tubulin Kinase 1 Inhibitors: A New Avenue for Future Amyotrophic Lateral Sclerosis Therapy.
Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease without any effective treatment. Protein TDP-43 is a pathological hallmark of ALS in both sporadic and familiar patients. Post-translational modifications of TDP-43 promote its aggregation in the cytoplasm. Tau-Tubulin kinase (TTBK1) phosphorylates TDP-43 in cellular and animal models; thus, TTBK1 inhibitors emerge as a promising therapeutic strategy for ALS. The design, synthesis, biological evaluation, kinase-ligand complex structure determination, and molecular modeling studies confirmed novel pyrrolopyrimidine derivatives as valuable inhibitors for further development. Moreover, compound revealed good brain penetration and was able to reduce TDP-43 phosphorylation not only in cell cultures but also in the spinal cord of transgenic TDP-43 mice. A shift to M2 anti-inflammatory microglia was also demonstrated . Both these activities led to motor neuron preservation in mice, proposing pyrrolopyrimidine as a valuable lead compound for future ALS therapy.

Preclinical Investigation in Neuroprotective Effects of the GPR55 Ligand VCE-006.1 in Experimental Models of Parkinson's Disease and Amyotrophic Lateral Sclerosis.
Cannabinoids act as pleiotropic compounds exerting, among others, a broad-spectrum of neuroprotective effects. These effects have been investigated in the last years in different preclinical models of neurodegeneration, with the cannabinoid type-1 (CB) and type-2 (CB) receptors concentrating an important part of this research. However, the issue has also been extended to additional targets that are also active for cannabinoids, such as the orphan G-protein receptor 55 (GPR55). In the present study, we investigated the neuroprotective potential of VCE-006.1, a chromenopyrazole derivative with biased orthosteric and positive allosteric modulator activity at GPR55, in murine models of two neurodegenerative diseases. First, we

proved that VCE-006.1 alone could induce ERK1/2 activation and calcium mobilization, as well as increase cAMP response but only in the presence of lysophosphatidyl inositol. Next, we investigated this compound administered chronically in two neurotoxin-based models of Parkinson's disease (PD), as well as in some cell-based models. VCE-006.1 was active in reversing the motor defects caused by 6-hydroxydopamine (6-OHDA) in the pole and the cylinder rearing tests, as well as the losses in tyrosine hydroxylase-containing neurons and the elevated glial reactivity detected in the substantia nigra. Similar cytoprotective effects were found in vitro in SH-SY5Y cells exposed to 6-OHDA. We also investigated VCE-006.1 in LPS-lesioned mice with similar beneficial effects, except against glial reactivity and associated inflammatory events, which remained unaltered, a fact confirmed in BV2 cells treated with LPS and VCE-006.1. We also analyzed GPR55 in these in vivo models with no changes in its gene expression, although GPR55 was down-regulated in BV2 cells treated with LPS, which may explain the lack of efficacy of VCE-006.1 in such an assay. Furthermore, we investigated VCE-006.1 in two genetic models of amyotrophic lateral sclerosis (ALS), mutant SOD1, or TDP-43 transgenic mice. Neither the neurological decline nor the deteriorated rotarod performance were prevented with this compound, and the same happened with the elevated microglial and astroglial reactivities, albeit modest spinal motor neuron preservation was achieved in both models. We also analyzed GPR55 in these in vivo models and found no changes in both TDP-43 transgenic and mSOD1 mice. Therefore, our findings support the view that targeting the GPR55 may afford neuroprotection in experimental PD, but not in ALS, thus stressing the specificities for the development of cannabinoid-based therapies in the different neurodegenerative disorders.

Tideglusib, a Non-ATP Competitive Inhibitor of GSK-3β as a Drug Candidate for the Treatment of Amyotrophic Lateral Sclerosis.

Amyotrophic Lateral Sclerosis (ALS) is the most common degenerative motor neuron disease in adults. About 97% of ALS patients present TDP-43 aggregates with post-translational modifications, such as hyperphosphorylation, in the cytoplasm of affected cells. GSK-3β is one of the protein kinases involved in TDP-43 phosphorylation. Up-regulation of its expression and activity is reported on spinal cord and cortex tissues of ALS patients. Here, we propose the repurposing of Tideglusib, an in-house non-ATP competitive GSK-3β inhibitor that is currently in clinical trials for autism and myotonic dystrophy, as a promising therapeutic strategy for ALS. With this aim we have evaluated the efficacy of Tideglusib in different experimental ALS models both in vitro and in vivo. Moreover, we observed that GSK-3β activity is increased in lymphoblasts from sporadic ALS patients, with a simultaneous increase in TDP-43 phosphorylation and cytosolic TDP-43 accumulation. Treatment with Tideglusib decreased not only phospho-TDP-43 levels but also recovered its nuclear localization in ALS lymphoblasts and in a human TDP-43 neuroblastoma model. Additionally, we found that chronic oral treatment with Tideglusib is able to reduce the increased TDP-43 phosphorylation in the spinal cord of Prp-hTDP-43 mouse model. Therefore, we consider Tideglusib as a promising drug candidate for ALS, being proposed to start a clinical trial phase II by the end of the year.

Targeting the CB receptor and other endocannabinoid elements to delay disease progression in amyotrophic lateral sclerosis.

Cannabinoids form a singular group of plant-derived compounds, endogenous lipids and synthetic derivatives with multiple therapeutic effects exerted by targeting different elements of the endocannabinoid system. One of their therapeutic applications is the preservation of neuronal integrity exerted by attenuating the multiple neurotoxic events that kill neurons in neurodegenerative disorders. In this review, we will address the potential of cannabinoids as neuroprotective agents in amyotrophic lateral sclerosis (ALS), a devastating neurodegenerative disorder characterized by muscle denervation, atrophy and paralysis, and progressive deterioration in upper and/or lower motor neurons. The emphasis will be paid on the cannabinoid type 2 (CB) receptor, whose activation limits glial reactivity, but the potential of additional endocannabinoid-related targets will be also addressed. The evidence accumulated so far at the preclinical level supports the need to soon move towards the patients and initiate clinical trials to confirm the potential of cannabinoid-based medicines as disease modifiers in ALS. Neuroprotection with the cannabigerol quinone derivative VCE-003.2 and its analogs CBGA-Q and CBGA-Q-Salt in Parkinson's disease using 6-hydroxydopamine-lesioned mice.

The quinone derivative of the non-psychotropic cannabinoid cannabigerol (CBG), so-called VCE-003.2, has been recently investigated for its neuroprotective properties in inflammatory models of Parkinson's disease (PD) in mice. Such potential

derives from its activity at the peroxisome proliferator-activated receptor-γ (PPAR-γ). In the present study, we investigated the neuroprotective properties of VCE-003.2 against the parkinsonian neurotoxin 6-hydroxydopamine (6-OHDA), in comparison with two new CBG-related derivatives, the cannabigerolic acid quinone (CBGA-Q) and its sodium salt CBGA-Q-Salt, which, similarly to VCE-003.2, were found to be active at the PPAR-γ receptor, but not at the cannabinoid CB and CB receptors. First, we investigated their cytoprotective properties in vitro by analyzing cell survival in cultured SH-SY5Y cells exposed to 6-OHDA. We found an important cytoprotective effect of VCE-003.2 at a concentration of 20 μM, which was not reversed by the blockade of PPAR-γ receptors with GW9662, supporting its activity at an alternative site (non-sensitive to classic antagonists) in this receptor. We also found CBGA-Q and CBGA-Q-Salt being cytoprotective in this cell assay, but their effects were completely eliminated by GW9662, thus indicating that they are active at the canonical site in the PPAR-γ receptor. Then, we moved to in vivo testing using mice unilaterally lesioned with 6-OHDA. Our data confirmed that VCE-003.2 administered orally (20 mg/kg) preserved tyrosine hydroxylase (TH)-positive nigral neurons against 6-OHDA-induced damage, whereas it completely attenuated the astroglial (GFAP) and microglial (CD68) reactivity found in the substantia nigra of lesioned mice. Such neuroprotective effects caused an important recovery in the motor deficiencies displayed by 6-OHDA-lesioned mice in the pole test and the cylinder rearing test. We also investigated CBGA-Q, given orally (20 mg/kg) or intraperitoneally (10 mg/kg, i.p.), having similar benefits compared to VCE-003.2 against the loss of TH-positive nigral neurons, glial reactivity and motor defects caused by 6-OHDA. Lastly, the sodium salt of CBGA-Q, given orally (40 mg/kg) to 6-OHDA-lesioned mice, also showed benefits at behavioral and histopathological levels, but to a lower extent compared to the other two compounds. In contrast, when given i.p., CBGA-Q-Salt (10 mg/kg) was poorly active. We also analyzed the concentrations of dopamine and its metabolite DOPAC in the striatum of 6-OHDA-lesioned mice after the treatment with the different compounds, but recovery in the contents of both dopamine and DOPAC was only found after the treatment with VCE-003.2. In summary, our data confirmed the neuroprotective potential of VCE-003.2 in 6-OHDA-lesioned mice, which adds to its previous activity found in an inflammatory model of PD (LPS-lesioned mice). Additional phytocannabinoid derivatives, CBGA-Q and CBGA-Q-Salt, also afforded neuroprotection in 6-OHDA-lesioned mice, but their effects were lower compared to VCE-003.2, in particular in the case of CBGA-Q-Salt. In vitro studies confirmed the relevance of PPAR-γ receptors for these effects.

Targeting nuclear protein TDP-43 by cell division cycle kinase 7 inhibitors: A new therapeutic approach for amyotrophic lateral sclerosis.

Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease with no known cure. Aggregates of the nuclear protein TDP-43 have been recognized as a hallmark of proteinopathy in both familial and sporadic cases of ALS. Post-translational modifications of this protein, include hyperphosphorylation, cause disruption of TDP-43 homeostasis and as a consequence, promotion of its neurotoxicity. Among the kinases involved in these changes, cell division cycle kinase 7 (CDC7) plays an important role by directly phosphorylating TDP-43. In the present manuscript the discovery, synthesis, and optimization of a new family of selective and ATP-competitive CDC7 inhibitors based on 6-mercaptopurine scaffold are described. Moreover, we demonstrate the ability of these inhibitors to reduce TDP-43 phosphorylation in both cell cultures and transgenic animal models such as C. elegans and Prp-hTDP43 (A315T) mice. Altogether, the compounds described here may be useful as versatile tools to explore the role of CDC7 in TDP-43 phosphorylation and also as new drug candidates for the future development of ALS therapies.

Δ -Tetrahydrocannabinolic acid alleviates collagen-induced arthritis: Role of PPARγ and CB receptors.

Δ -Tetrahydrocannabinolic acid (Δ -THCA-A), the precursor of Δ -THC, is a non-psychotropic phytocannabinoid that shows PPARγ agonist activity. Here, we investigated the ability of Δ -THCA-A to modulate the classic cannabinoid CB and CB receptors and evaluated its anti-arthritis activity in vitro and in vivo.

Neuronal activity plays a crucial role in motoneurons vulnerability in amyotrophic lateral sclerosis (ALS). Enhanced motoneurons excitability has been shown to promote neuroprotection while reduced excitability has been shown to accelerate disease progression. However, the molecular basis of neuronal activity impact in ALS has not been identified yet. In this study, the impact of the activity-dependent transcription factor Serum Response Factor (SRF) was investigated in vivo and in vitro. Conditional motoneuron-selective SRF ablation in the context of the SOD1(G93A) ALS mouse model caused an early disease onset as revealed by anticipated start of body weight loss, earlier appearance of advanced clinical stages and faster decline in grip-strength. However, overall survival was not affected, indicating a major role of SRF only for some motoneuron subpopulations. At P50, loss of SRF in motoneurons caused a more pronounced neuromuscular junctions' denervation and expanded neuroinflammatory response. Increased vulnerability of motoneurons corresponded to fewer Beclin+ inclusions in histology and reduced induction of autophagy genes assessed in laser-microdissected motoneurons. We complemented these studies assessing autophagy genes induction in HEK cells expressing the C9-Orf72-associated polyGA polypeptide: the overexpression of SRF resulted in a decreased burden of polyGA inclusions. Live-imaging microscopy with the autophagy sensor P62-GFP-RFP revealed a faster autophagy flux upon overexpression of SRF compared to an inactive SRF mutant protein. Thus, in vitro data further confirmed a role of SRF in the transcriptional regulation of cellular proteostasis. In conclusion, a novel link between neuronal activity, synaptic input and autophagy imbalance was provided in this project.

AIMS: Amyotrophic Lateral Sclerosis (ALS) is a non-cell-autonomous neurodegenerative disease. One major cause of motor neuron degeneration is glutamate-mediated excitotoxicity, and metabotropic glutamate receptor type 5 (mGluR5) seems highly involved. Here, we investigated the *in-vitro* effects of the negative mGluR5 allosteric modulator 2-chloro-4-((2,5-dimethyl-1-(4-(trifluoromethoxy)phenyl)-1H-imidazol-4-yl)ethynyl)pyridine (CTEP) exposure on the phenotype of inducible neural progenitor cell (iNPC)-derived astrocytes from ALS patients and healthy donors. **METHODS**: iNPCs were directly converted from human skin fibroblasts of C9orf72 and SOD1^{A4V} ALS patients and healthy individuals. After differentiation, i-astrocytes were treated with 100nM CTEP or vehicle for three days and then used for western blot (WB), immunofluorescence (IF) and enzymatic assays. **RESULTS:** CTEP reduced the expression of mGluR5 and the reactive astrocyte markers GFAP, S100-beta, and C3 in C9orf72 and SOD1^{A4V} i-astrocytes, as detected by WB and IF. CTEP also reduced the expression of NLRP3 and increase the expression of Nrf2, two markers of inflammation and oxidative stress response, respectively. We tested the activity of glucose-6-phosphate dehydrogenase, glutathione reductase, glutathione peroxidase and catalase, four enzymes associated with antioxidant cellular defenses, which were higher in C9orf72 and SOD1^{A4V} iNPC-derived i-astrocytes than in controls. CTEP reduced the enzyme activity, suggesting amelioration of the redox state. Accordingly, CTEP-treated ALS i-astrocytes showed a reduced lipid peroxidation compared to untreated cells. We detected no functional alterations in CTEP-treated i-astrocytes from healthy donors. **CONCLUSIONS:** These results suggest that mGluR5 modulation by CTEP positively impacts on the i-astrocyte reactive phenotype of ALS patients, expanding *in-vitro* and *in-vivo* results previously obtained with SOD1^{G93A} mouse astrocytes.

Nearly 30 Years of Animal Models to Study Amyotrophic Lateral Sclerosis: A Historical Overview and Future Perspectives.
Amyotrophic lateral sclerosis (ALS) is a fatal, multigenic, multifactorial, and non-cell autonomous neurodegenerative disease characterized by upper and lower motor neuron loss. Several genetic mutations lead to ALS development and many emerging gene mutations have been discovered in recent years. Over the decades since 1990, several animal models have been generated to study ALS pathology including both vertebrates and invertebrates such as yeast, worms, flies, zebrafish, mice, rats, guinea pigs, dogs, and non-human primates. Although these models show different peculiarities, they are all useful and complementary to dissect the pathological mechanisms at the basis of motor neuron degeneration and ALS progression, thus contributing to the development of new promising therapeutics. In this review, we describe the up to date and available ALS genetic animal models, classified by the different genetic mutations and divided per species, pointing out their features in modeling, the onset and progression of the pathology, as well as their specific pathological hallmarks. Moreover, we highlight similarities, differences, advantages, and limitations, aimed at helping the researcher to select the most appropriate experimental animal model, when designing a preclinical ALS study.

The Role of Endoplasmic Reticulum in the Differential Endurance against Redox Stress in Cortical and Spinal Astrocytes from the Newborn SOD1 Mouse Model of Amyotrophic Lateral Sclerosis.
Recent studies reported that the uptake of [18F]-fluorodeoxyglucose (FDG) is increased in the spinal cord (SC) and

decreased in the motor cortex (MC) of patients with ALS, suggesting that the disease might differently affect the two nervous districts with different time sequence or with different mechanisms. Here we show that MC and SC astrocytes harvested from newborn B6SJL-Tg (SOD1) 1Gur mice could play different roles in the pathogenesis of the disease. Spectrophotometric and cytofluorimetric analyses showed an increase in redox stress, a decrease in antioxidant capacity and a relative mitochondria respiratory uncoupling in MC SOD1 astrocytes. By contrast, SC mutated cells showed a higher endurance against oxidative damage, through the increase in antioxidant defense, and a preserved respiratory function. FDG uptake reproduced the metabolic response observed in ALS patients: SOD1 mutation caused a selective enhancement in tracer retention only in mutated SC astrocytes, matching the activity of the reticular pentose phosphate pathway and, thus, of hexose-6P dehydrogenase. Finally, both MC and SC mutated astrocytes were characterized by an impressive ultrastructural enlargement of the endoplasmic reticulum (ER) and impairment in ER-mitochondria networking, more evident in mutated MC than in SC cells. Thus, SOD1 mutation differently impaired MC and SC astrocyte biology in a very early stage of life.

Blocking glutamate mGlu receptors with the negative allosteric modulator CTEP improves disease course in SOD1 mouse model of amyotrophic lateral sclerosis.
The pathogenesis of amyotrophic lateral sclerosis (ALS) is not fully clarified, although excessive glutamate (Glu) transmission and the downstream cytotoxic cascades are major mechanisms for motor neuron death. Two metabotropic glutamate receptors (mGlu and mGlu) are overexpressed in ALS and regulate cellular disease processes. Expression and function of mGlu receptors are altered at early symptomatic stages in the SOD1 mouse model of ALS and knockdown of mGlu5 receptors in SOD1 mice improved disease progression.

Mechanisms underlying the predictive power of high skeletal muscle uptake of FDG in amyotrophic lateral sclerosis.
We recently reported that enhanced [18F]-fluorodeoxyglucose (FDG) uptake in skeletal muscles predicts disease aggressiveness in patients with amyotrophic lateral sclerosis (ALS). The present experimental study aimed to assess whether this predictive potential reflects the link between FDG uptake and redox stress that has been previously reported in different tissues and disease models.

Enhanced Function and Overexpression of Metabotropic Glutamate Receptors 1 and 5 in the Spinal Cord of the SOD1 Mouse Model of Amyotrophic Lateral Sclerosis during Disease Progression.
Glutamate (Glu)-mediated excitotoxicity is a major cause of amyotrophic lateral sclerosis (ALS) and our previous work highlighted that abnormal Glu release may represent a leading mechanism for excessive synaptic Glu. We demonstrated that group I metabotropic Glu receptors (mGluR1, mGluR5) produced abnormal Glu release in SOD1 mouse spinal cord at a late disease stage (120 days). Here, we studied this phenomenon in pre-symptomatic (30 and 60 days) and early-symptomatic (90 days) SOD1 mice. The mGluR1/5 agonist ()-3,5-Dihydroxyphenylglycine (3,5-DHPG) concentration dependently stimulated the release of [H]d-Aspartate ([H]d-Asp), which was comparable in 30- and 60-day-old wild type mice and SOD1 mice. At variance, [H]d-Asp release was significantly augmented in 90-day-old SOD1 mice and both mGluR1 and mGluR5 were involved. The 3,5-DHPG-induced [H]d-Asp release was exocytotic, being of vesicular origin and mediated by intra-terminal Ca release. mGluR1 and mGluR5 expression was increased in Glu spinal cord axon terminals of 90-day-old SOD1 mice, but not in the whole axon terminal population. Interestingly, mGluR1 and mGluR5 were significantly augmented in total spinal cord tissue already at 60 days. Thus, function and expression of group I mGluRs are enhanced in the early-symptomatic SOD1 mouse spinal cord, possibly participating in excessive Glu transmission and supporting their implication in ALS. Please define all abbreviations the first time they appear in the abstract, the main text, and the first figure or table caption.

Altered glucose catabolism in the presynaptic and perisynaptic compartments of SOD1 mouse spinal cord and motor cortex indicates that mitochondria are the site of bioenergetic imbalance in ALS.
Amyotrophic lateral sclerosis is an adult-onset neurodegenerative disease that develops because of motor neuron death. Several mechanisms occur supporting neurodegeneration, including mitochondrial dysfunction. Recently, we demonstrated that the synaptosomes from the spinal cord of SOD1 mice, an in vitro model of presynapses, displayed impaired

mitochondrial metabolism at early pre-symptomatic stages of the disease, whereas perisynaptic astrocyte particles, or gliosomes, were characterized by mild energy impairment only at symptomatic stages. This work aimed to understand whether mitochondrial impairment is a consequence of upstream metabolic damage. We analyzed the critical pathways involved in glucose catabolism at presynaptic and perisynaptic compartments. Spinal cord and motor cortex synaptosomes from SOD1 mice displayed high activity of hexokinase and phosphofructokinase, key glycolysis enzymes, and of citrate synthase and malate dehydrogenase, key Krebs cycle enzymes, but did not display high lactate dehydrogenase activity, the key enzyme in lactate fermentation. This enhancement was evident in the spinal cord from the early stages of the disease and in the motor cortex at only symptomatic stages. Conversely, an increase in glycolysis and lactate fermentation activity, but not Krebs cycle activity, was observed in gliosomes from the spinal cord and motor cortex of SOD1 mice although only at the symptomatic stages of the disease. The cited enzymatic activities were enhanced in spinal cord and motor cortex homogenates, paralleling the time-course of the effect observed in synaptosomes and gliosomes. The observed metabolic modifications might be considered an attempt to restore altered energetic balance and indicate that mitochondria represent the ultimate site of bioenergetic impairment.

In-vivo genetic ablation of metabotropic glutamate receptor type 5 slows down disease progression in the SOD1 mouse model of amyotrophic lateral sclerosis.
Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease due to motor neuron (MN) loss. The mechanisms causing selective MN death are largely unknown, thus prejudicing successful pharmacological treatments. Major causes of MN damage are effects downstream of the abnormal glutamate (Glu) neurotransmission. Group I metabotropic Glu receptors (mGluR1, mGluR5) actively contribute to the excitotoxicity in ALS and represent druggable molecular targets. We previously demonstrated that halving mGluR1 or mGluR5 expression in the widely studied SOD1 mouse model of ALS had a positive impact on disease onset, clinical progression and survival, as well as on cellular and biochemical parameters altered in ALS. Whereas these effects were similar in female and male mGluR1 heterozygous SOD1mice, only male mGluR5 heterozygous SOD1 mice showed improved motor skills during disease progression. To further validate the role of Group I mGluRs in ALS, we generated in this study mGluR1 or mGluR5 null mice expressing the SOD1 mutation (SOD1Grm1 or SOD1Grm5, respectively). SOD1Grm1 mice showed early and progressive motor impairments and died even before SOD1 mice, while SOD1Grm5 mice exhibited delayed disease onset, longer survival, and ameliorated motor skills than SOD1 mice. No difference between female and male SOD1Grm5 mice were observed. These effects were associated with enhanced MN preservation and decreased astrocytic and microglial activation. Our results strongly support the assumption that constitutively lowering of mGluR5 expression has a positive impact in mice with ALS by counteracting the abnormal Glu transmission and this could be a potentially effective pharmacological target in ALS.

Aims. Amyotrophic lateral sclerosis (ALS) is a non-cell-autonomous neurodegenerative disease involving oligodendrocyte (OL) damage. We reported that the function of the GPR17 receptor, involved in oligodendrocyte precursor cell (OPC) maturation, is altered in the SOD1^{G93A} mouse model of ALS. Interestingly, primary cultured SOD1^{G93A} OPCs displayed differentiation defects compared to wild-type cells, which were significantly restored by *in vitro* exposure to the already marketed non-selective GPR17 antagonist montelukast (MTK). Here we translated the *in-vitro* data to *in-vivo* studies assessing the effects of the MTK treatment in SOD1^{G93A} mice. **Methods.** MTK (10 or 30 mg/kg/day; gavage) was chronically administered to SOD1^{G93A} mice from day 90 of life until death. Vehicle-treated SOD1^{G93A} mice were used as controls. We evaluated survival probability and body weight loss; motor functions by Rotarod, beam balance, gait, and extension reflex tests. Immunohistochemistry (IHC) was performed to assess oligodendrocyte and microglia markers. **Results.** MTK (10 mg/kg/day) neither increased survival probability nor ameliorated disease progression. Accordingly, IHC did not highlight MTK-induced modifications of OL differentiation and microglia activation state. On the contrary, 30 mg/kg/day MTK ameliorated survival probability and delayed weight loss in SOD1^{G93A} female but not male mice. Motor abilities also improved in MTK-treated SOD1^{G93A} female mice only. IHC is currently ongoing to evaluate the MTK treatment impact on OL dysfunction, neuroinflammation, and MN degeneration. **Conclusion.** Our results suggest that *in-vivo* targeting GPR17 by the antagonist MTK gender-dependently improves ALS progression and highlights GPR17 as a novel promising pharmacological target. EARLY REVERSIBLE STRUCTURAL AND FUNCTIONAL IMPAIRMENTS OF EXCITATORY SYNAPSES ON ALS MOTONEURONS

POSTER SESSION 03 - SECTION: AMYOTROPHIC LATERAL SCLEROSIS

Excessive excitation is hypothesized to cause motoneuron (MN) degeneration in amyotrophic lateral sclerosis (ALS), but actual proof of hyperexcitation in vivo is missing: how are synaptic inputs to MN affected by the disease, and are they increased or decreased? We demonstrate, by in vivo intracellular MN electrophysiology, that, contrary to expectations, excitatory post-synaptic potentials evoked by electrical or mechanical stimulation of Ia sensory fibers are reduced in MNs of adult presymptomatic mutSOD1 mice. This synaptic impairment correlates with disrupted postsynaptic clustering of Homer1b, Shank, and GluR4 subunits. Moreover, this impairment has a deep impact on the whole MN biology since mechanically-induced Ia inputs translate in a reduced phosphorylation of the CREB transcription factor in MNs. Interestingly, a similar functional impairment is observed in synapses on MN originating from the brainstem descending medial longitudinal fasciculus, indicating a widespread phenomenon. Restoration of excitatory synapses can be achieved by activation of the cAMP/PKA pathway, by either intracellular injection of cAMP or DREADD-Gs stimulation. Furthermore, we reveal, through independent control of signaling and excitability in MN allowed by multiplexed DREADD/PSAM chemogenetics, that PKA-induced restoration of synapses triggers an excitation-dependent decrease in misfolded SOD1 burden and autophagy overload. In turn, increased MN excitability contributes to restoring synaptic structures. Thus, the decrease of excitation to MN is an early but reversible event in ALS. Failure of the postsynaptic site, rather than hyperexcitation, drives disease pathobiochemistry at this stage of the disease evolution. Aims Amyotrophic Lateral Sclerosis (ALS) is a non-cell-autonomous neurodegenerative disease, and astrocytes play a crucial role in motor neuron (MN) damage, possibly trough paracrine mechanisms mediated by secretion of soluble factors or extracellular vesicles (EVs). Here, we compared the characteristics of EVs secreted by spinal cord astrocytes from $SOD1^{G93A}$ mice, a model of ALS, and WT mice. **Methods** Astrocytes were cultured (20 DIV) from the spinal cord of 120-day-old $SOD1^{G93A}$ and WT mice. EVs were isolated by the nickel-based isolation (NBI) procedure from the astrocyte supernatant. MNs were purified by a gradient from the spinal cord of E13,5 WT mouse embryos, cultured, and counted for viability from day 8 and for 14 days after seeding. EV-RNA was extracted using the Single Cell RNA extraction kit (Norgen-Biotek) and analyzed by RNA sequencing. **Results** We obtained more astrocytes from $SOD1^{G93A}$ mice ($6.37x10^5$/spinal cord) than from WT mice ($1.61x10^5$/spinal cord). Moreover, $SOD1^{G93A}$ astrocytes secreted more EVs ($6,73x10^5$ EV/cell) than WT astrocytes ($1,78x10^6$ EV/cell). We did not detect differences in EV size or Z potential. We now completed the EV RNA collection and sequencing to define the RNA and microRNA repertoire of $SOD1^{G93A}$ and WT astrocyte-derived EVs. Bioinformatic analysis is ongoing. Finally, we measured MN viability as a functional readout, which appeared significantly reduced when exposing MNs to EV from $SOD1^{G93A}$ astrocytes. **Conclusions** Our results indicate that $SOD1^{G93A}$ astrocytes influence MN viability in ALS through EV secretion and suggest that EVs play a key role in spreading their neurotoxic properties.

Nearly 30 Years of Animal Models to Study Amyotrophic Lateral Sclerosis: A Historical Overview and Future Perspectives.
Amyotrophic lateral sclerosis (ALS) is a fatal, multigenic, multifactorial, and non-cell autonomous neurodegenerative disease characterized by upper and lower motor neuron loss. Several genetic mutations lead to ALS development and many emerging gene mutations have been discovered in recent years. Over the decades since 1990, several animal models have been generated to study ALS pathology including both vertebrates and invertebrates such as yeast, worms, flies, zebrafish, mice, rats, guinea pigs, dogs, and non-human primates. Although these models show different peculiarities, they are all useful and complementary to dissect the pathological mechanisms at the basis of motor neuron degeneration and ALS progression, thus contributing to the development of new promising therapeutics. In this review, we describe the up to date and available ALS genetic animal models, classified by the different genetic mutations and divided per species, pointing out their features in modeling, the onset and progression of the pathology, as well as their specific pathological hallmarks. Moreover, we highlight similarities, differences, advantages, and limitations, aimed at helping the researcher to select the most appropriate experimental animal model, when designing a preclinical ALS study.

The Role of Endoplasmic Reticulum in the Differential Endurance against Redox Stress in Cortical and Spinal Astrocytes from the Newborn SOD1 Mouse Model of Amyotrophic Lateral Sclerosis.
Recent studies reported that the uptake of [18F]-fluorodeoxyglucose (FDG) is increased in the spinal cord (SC) and decreased in the motor cortex (MC) of patients with ALS, suggesting that the disease might differently affect the two nervous districts with different time sequence or with different mechanisms. Here we show that MC and SC astrocytes harvested from newborn B6SJL-Tg (SOD1) 1Gur mice could play different roles in the pathogenesis of the disease. Spectrophotometric and

cytofluorimetric analyses showed an increase in redox stress, a decrease in antioxidant capacity and a relative mitochondria respiratory uncoupling in MC SOD1 astrocytes. By contrast, SC mutated cells showed a higher endurance against oxidative damage, through the increase in antioxidant defense, and a preserved respiratory function. FDG uptake reproduced the metabolic response observed in ALS patients: SOD1 mutation caused a selective enhancement in tracer retention only in mutated SC astrocytes, matching the activity of the reticular pentose phosphate pathway and, thus, of hexose-6P dehydrogenase. Finally, both MC and SC mutated astrocytes were characterized by an impressive ultrastructural enlargement of the endoplasmic reticulum (ER) and impairment in ER-mitochondria networking, more evident in mutated MC than in SC cells. Thus, SOD1 mutation differently impaired MC and SC astrocyte biology in a very early stage of life.

Blocking glutamate mGlu receptors with the negative allosteric modulator CTEP improves disease course in SOD1 mouse model of amyotrophic lateral sclerosis.

The pathogenesis of amyotrophic lateral sclerosis (ALS) is not fully clarified, although excessive glutamate (Glu) transmission and the downstream cytotoxic cascades are major mechanisms for motor neuron death. Two metabotropic glutamate receptors (mGlu and mGlu) are overexpressed in ALS and regulate cellular disease processes. Expression and function of mGlu receptors are altered at early symptomatic stages in the SOD1 mouse model of ALS and knockdown of mGlu5 receptors in SOD1 mice improved disease progression.

DECREASED NORADRENALINE LEVELS CONTRIBUTE TO CORTICAL HYPEREXCITABILITY IN MOUSE MODELS OF AMYOTROPHIC LATERAL SCLEROSIS

POSTER SESSION 03 - SECTION: AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic lateral sclerosis (ALS), the most common adult-onset motor neuron disease, relies on the detection of the combined degeneration of upper motor neurons in the cerebral cortex, and lower motor neurons in the brain stem and spinal cord. Cortical hyperexcitability was demonstrated in ALS patients using paired-pulse transcranial magnetic stimulation (ppTMS). Cortical hyperexcitability precedes motoneuron signs, is detrimental to motoneuron function, and negatively correlates with patients' survival. This earliness could make cortical hyperexcitability a powerful feature to promote early diagnosis of ALS. To unravel the dynamics of cortical network impairment in ALS mouse models, we used electrocorticography (ECoG) and analyses of phase-amplitude frequency coupling (PAC), a specific pattern of oscillatory activity corresponding to the modulation of the amplitude of a fast oscillation (gamma) by the phase of a slow oscillation (theta), as a proxi for cortical excitation/inhibition imbalance. We demonstrate that Sod1G86R and FusΔNLS mouse models of ALS present early and constant alteration of cortical network functions, and propose EEG and PAC analyses as an alternative to ppTMS in ALS patients. To gain insights into the molecular and cellular origins of this cortical dysfunction, we analysed the cortical levels of different neurotransmitters and unravelled decreased noradrenaline levels, common to Sod1G86R and FusΔNLS mice. Experimental cortical noradrenaline depletion was sufficient to significantly decrease PAC in WT animals, while noradrenaline supplementation was sufficient to significantly improved PAC in ALS mouse models. Together, the data pave the way to the development of new diagnostic and therapeutic approaches targeting cortical network dysfunction in ALS.

Sacco", Milan, Italy, [4]University of Turin, Department Of Veterinary Science,, Turin, Italy, [5]Avantea, S.r.l., Cremona, Italy

Two goals of Amyotrophic Lateral Sclerosis (ALS) research are: a) validation of new experimental models b) identification of diagnostic biomarkers to speed up the diagnosis. Extracellular vesicles (EVs) and their content may be reliable clinical biomarkers for ALS, as they have been used for the diagnosis and prognosis of various diseases. In this context, we developed a hSOD1G93A transgenic swine characterized by a reproducible preclinical and clinical phase to clarify certain ALS etiopathogenetic aspects. Therefore, this study aimed at evaluating of miRNA into EVs isolated from hSOD1G93A transgenic swine plasma, in preclinical and clinical phase. EVs were isolated from plasma of hSOD1G93A and wild type pigs by a modified precipitation method. EVs were characterized by Nanosight, flow cytometry and Western blotting. miRNAs were sequenced on a NextSeq 500/550. Phenotype characterization confirmed that the majority of EVs were exosomes expressing the typical exosome markers (CD63, TSG101, Flotillin 1, Alix). As regard miRNA analysis, few miRNAs were deregulated in transgenic swine, representing a specific expression pattern in the model. Also, an evident up-regulation of miR-206 was observed. This miRNA is involved in the proper formation and regeneration of the mature neuromuscular junction. Interestingly, its increased exosomal expression was also detected comparing hSOD1G93A samples at clinical phase with their corresponding preclinical samples. Nonetheless, miR-206 was up-regulated in homozygous transgenic swine compared to heterozygous ones. In conclusion, these data show that in the swine model, biomarkers already associated to ALS are expressed and that miRNAs may be used as monitoring tools for disease severity.

Increasing evidence support that neuroinflammation has a key role in the pathobiological processes of ALS. Immunoglobulins from ALS patients showed anti-motoneuronal properties and their presence resulted in increased proinflammatory factors in the spinal cord of mice after intraperitoneal injection. Furthermore, these autoantibodies can bind and modify the function of calcium channels, which leads to disturbance in the calcium homeostasis and eventually neuronal loss. Utilizing these degenerative effects, blood sera from ALS patients without known genetic alterations or with identified mutations were injected into Balb/c mice to create an immune-based experimental motoneuron (MN) degeneration model. Previously we demonstrated increased calcium content in the axon terminals but the effect of such treatment in the perikaryon reminded unknown. Similarly to the axon terminals, significant increase in the calcium level of the MN cell bodies accompanied with remarkable motor neuronal loss was observed in the ALS serum treated group compared to the untreated and the healthy serum treated groups. Interestingly, we found that mice treated with ALS sera from patients with C9ORF72 mutation showed the most prominent elevation in the calcium level also the most robust motoneuronal loss. Expectation-Maximization cluster analysis based on the correlation of calcium elevation and motoneuronal loss is capable of separating controls and ALS patients, furthermore, C9ORF72 mutation sorted into a more progressive subgroup. Since this mutation has a significant role in numerous immune-mediated processes, in the future, we would like to examine these events which might lead to novel therapeutic targets for ALS.

Passive Transfer of Blood Sera from ALS Patients with Identified Mutations Results in Elevated Motoneuronal Calcium Level and Loss of Motor Neurons in the Spinal Cord of Mice.
Previously, we demonstrated the degeneration of axon terminals in mice after repeated injections of blood sera from amyotrophic lateral sclerosis (ALS) patients with identified mutations. However, whether a similar treatment affects the cell body of motor neurons (MNs) remained unresolved. Sera from healthy individuals or ALS patients with a mutation in different ALS-related genes were intraperitoneally injected into ten-week-old male Balb/c mice (= 3/serum) for two days. Afterward, the perikaryal calcium level was measured using electron microscopy. Furthermore, the optical disector method was used to evaluate the number of lumbar MNs. The cytoplasmic calcium level of the lumbar MNs of the ALS-serum-treated mice, compared to untreated and healthy-serum-treated controls, was significantly elevated. While injections of the healthy serum did not reduce the number of MNs compared to the untreated control group, ALS sera induced a remarkable loss of MNs. Similarly to the distant motor axon terminals, the injection of blood sera of ALS patients has a rapid degenerative effect on MNs. Analogously, the magnitude of the evoked changes was specific to the type of mutation; furthermore, the degeneration was most pronounced in the group treated with sera from ALS patients with a mutation in the gene.
