Parvalbumin interneurons (PVI) represent only 1 to 2% of the neuronal population of the striatum, a cerebral structure involved in the execution of cognitive and motor processes. Despite their low numbers, PVI receive many afferences ranging from associative to motor areas of the cortex allowing for a fast and powerful inhibition of the striatal networks. Recent studies suggested the implication of striatal PVI in cognitive processes and decision-making in particular (Gage et al., 2010; Martiros et al., 2018). In this project, we are interested in the role of striatal PVI in information processing during decision-making. Over this process, one need to accumulate evidence before taking action. We hypothesize that striatal PVI could have a crucial role in inhibiting striatal processing, thus delaying choice execution while accumulating more information to optimize choice, especially during difficult decision. To address this question, we developed a novel decision-making task implemented in innovative custom-built automatized operant chambers, which allow for collecting thousands of trials over several weeks. We could contrast the animals performance depending on the levels of choice-difficulty while recording striatal PVI activity using fiber-photometry. Our behavioural results showed the more difficult the choice, the longer the decision duration, validating the task. Preliminary neurophysiological recordings showed an increase of PVI activity when the mouse was exposed to the stimulus; suggesting the implication of PVI in the decision-making process.

UNCERTAINTY-RELATED INTER-SUBJECT VARIABILITY IN HUMAN CHOICES DURING SEQUENTIAL DECISION-MAKING

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Alexander Paunov[1], Dalin Guo[2], Maëva L'Hôtellier[1], Angela Yu*[2], Florent Meyniel*[1]
[1]INSERM-CEA-University Paris Saclay, Cognitive Neuroimaging Unit, Neurospin Center, Gif/Yvette, France, [2]University of California San Diego, Cognitive Science, San Diego, United States of America

Aim. Humans often need to make choices in changing and uncertain environments. Previous studies found considerable between-subject variability in information-seeking and uncertainty-attitude, but its origin is unclear since typical experimental designs confound learning and decision-making. Here, we present a novel bandit task that dissociates reward and different forms of uncertainty during learning and decision making. **Methods.** Our task addresses two key challenges. First, reward and uncertainty are often inversely related because more rewarding options are sampled more frequently. We introduce forced choices to better decorrelate them. Second, we distinguish different forms of uncertainty, expected and unexpected, and dissociate them through intermittent changes in reward levels and noise. To explore the neural substrate of choice variability, we test subjects across two sessions (behavioral and fMRI) with two repeated sets of reward sequences. We use a Bayesian model for the learning process. **Results.** Our results show that expected reward is a major and consistent driver of choices across subjects. In contrast, the effect of uncertainty is smaller and variable across subjects in both direction (uncertainty-seeking or avoidance) and magnitude, but stable across sessions and reward sequences. In preliminary fMRI results, we localize effects of reward and uncertainty to previously reported neural substrates in subcortical regions and frontoparietal cortical networks. **Conclusion.** Our results contribute to a computational understanding of the roles of uncertainty in learning and choice. Our next steps are to map the behavioral variability in uncertainty-related choices to neuromodulatory and cortical brain correlates and to stable individual differences in psychological profiles.

SLEEP DEPRIVATION INCREASES PERFORMANCE IN LARVAL ZEBRAFISH DECISION MAKING

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Hanna Zwaka[1], Paula Pflitsch[1], Kumaresh Krishnan[1], Nadine Oury[1], Declan Lyons[2], Armin Bahl[3], Jason Rihel[2], Florian Engert[1]
[1]Harvard, Mcb, Cambridge, United States of America, [2]UCL, Bioscience, London, United Kingdom, [3]University Konstanz, Neurobiology, Konstanz, Germany

Humans and most animals need sleep to function well. Lack of sleep has a multitude of effects on the body including a decrease of cognitive and physical performance. Zebrafish are a popular model to study sleep. Here we set out to investigate the effects of sleep deprivation on simple behavior and cognition in larval zebrafish. We show that in zebrafish larvae sleep deprivation downregulates bouting the day after sleep deprivation but does not compromise visual-motor integration. In contrast to expectation, sleep-deprived larvae that are faced with a random-dot motion discrimination task perform better than a well-rested control. Previous work has demonstrated that zebrafish larvae accumulate motion evidence over time and their resulting decision can be explained with a bounded leaky integrator model. We hypothesize that the reduced bouting gives them more time to integrate the random-dot-motion and hence leads to an increased performance. The change in bouting frequency, however, leads to a decrease in exploratory behavior. Finally, we artificially reduce bouting in zebrafish larvae using the drug melatonin and show that the decrease bouting in fact leads to an increased performance.

Memory enhancement by ferulic acid ester across species.
Cognitive impairments can be devastating for quality of life, and thus, preventing or counteracting them is of great value. To this end, the present study exploits the potential of the plant and identifies the constituent ferulic acid eicosyl ester [icosyl-(2)-3-(4-hydroxy-3-methoxyphenyl)-prop-2-enoate (FAE-20)] as a memory enhancer. We show that food supplementation with dried root material from dose-dependently improves odor-taste reward associative memory scores in larval and prevents the age-related decline of this appetitive memory in adult flies. Task-relevant sensorimotor faculties remain unaltered. From a parallel approach, a list of candidate compounds has been derived, including -derived FAE-20. Here, we show that both -derived FAE-20 and synthetic FAE-20 are effective as memory enhancers in larval . Synthetic FAE-20 also partially compensates for age-related memory decline in adult flies, as well as genetically induced early-onset loss of memory function in young flies. Furthermore, it increases excitability in mouse hippocampal CA1 neurons, leads to more stable context-shock aversive associative memory in young adult (3-month-old) mice, and increases memory scores in old (>2-year-old) mice. Given these effects, and given the utility of -the plant from which we discovered FAE-20-as a memory enhancer, these results may hold potential for clinical applications.

Learning and Its Neural Correlates in a Virtual Environment for Honeybees.
The search for neural correlates of operant and observational learning requires a combination of two (experimental) conditions that are very difficult to combine: stable recording from high order neurons and free movement of the animal in a rather natural environment. We developed a virtual environment (VE) that simulates a simplified 3D world for honeybees walking stationary on an air-supported spherical treadmill. We show that honeybees perceive the stimuli in the VE as meaningful by transferring learned information from free flight to the virtual world. In search for neural correlates of learning in the VE, mushroom body extrinsic neurons were recorded over days during learning. We found changes in the neural activity specific to the rewarded and unrewarded visual stimuli. Our results suggest an involvement of the mushroom body extrinsic neurons in operant learning in the honeybee ().

The Circuitry of Olfactory Projection Neurons in the Brain of the Honeybee, .
In the honeybee brain, two prominent tracts - the medial and the lateral antennal lobe tract - project from the primary olfactory center, the antennal lobes (ALs), to the central brain, the mushroom bodies (MBs), and the protocerebral lobe (PL). Intracellularly stained uniglomerular projection neurons were reconstructed, registered to the 3D honeybee standard brain atlas, and then used to derive the spatial properties and quantitative morphology of the neurons of both tracts. We evaluated putative synaptic contacts of projection neurons (PNs) using confocal microscopy. Analysis of the patterns of axon terminals revealed a domain-like innervation within the MB lip neuropil. PNs of the lateral tract arborized more sparsely within the lips and exhibited fewer synaptic boutons, while medial tract neurons occupied broader regions in the MB calyces and the PL. Our data show that uPNs from the medial and lateral tract innervate both the core and the cortex of the ipsilateral MB lip but differ in their innervation patterns in these regions. In the mushroombody neuropil collar we found evidence for ALT boutons suggesting the collar as a multi modal input site including olfactory input similar to lip and basal ring. In addition, our data support the conclusion drawn in previous studies that reciprocal synapses exist between PNs, octopaminergic-, and GABAergic cells in the MB calyces. For the first time, we found evidence for connections between both tracts within the AL.

Neural Organization of A3 Mushroom Body Extrinsic Neurons in the Honeybee Brain.
In the insect brain, the mushroom body is a higher order brain area that is key to memory formation and sensory processing. Mushroom body (MB) extrinsic neurons leaving the output region of the MB, the lobes and the peduncle, are thought to be especially important in these processes. In the honeybee brain, a distinct class of MB extrinsic neurons, A3 neurons, are implicated in playing a role in learning. Their MB arborisations are either restricted to the lobes and the peduncle, here called A3 lobe connecting neurons, or they provide feedback information from the lobes to the input region of the MB, the calyces, here called A3 feedback neurons. In this study, we analyzed the morphology of individual A3 lobe connecting and feedback neurons using confocal imaging. A3 feedback neurons were previously assumed to innervate each lip compartment homogenously. We demonstrate here that A3 feedback neurons do not innervate whole subcompartments, but rather innervate zones of varying sizes in the MB lip, collar, and basal ring. We describe for the first time the anatomical details of A3 lobe connecting neurons and show that their connection pattern in the lobes resemble those of A3 feedback cells. Previous studies showed that A3 feedback neurons mostly connect zones of the vertical lobe that receive input from Kenyon cells of distinct calycal subcompartments with the corresponding subcompartments of the calyces. We can show that this also applies to the neck of the peduncle and the medial lobe, where both types of A3 neurons arborize only in corresponding zones in the calycal subcompartments. Some A3 lobe connecting neurons however connect multiple vertical lobe areas. Contrarily, in the medial lobe, the A3 neurons only innervate one division. We found evidence for both input and output areas in the vertical lobe. Thus, A3 neurons are more diverse than previously thought. The understanding of their detailed anatomy might enable us to derive circuit models for learning and memory and test physiological data.

Context odor presentation during sleep enhances memory in honeybees.
Sleep plays an important role in stabilizing new memory traces after learning [1-3]. Here we investigate whether sleep's role in memory processing is similar in evolutionarily distant species and demonstrate that a context trigger during deep-sleep phases improves memory in invertebrates, as it does in humans. We show that in honeybees (Apis mellifera), exposure to an odor during deep sleep that has been present during learning improves memory performance the following day. Presentation of the context odor during wake phases or novel odors during sleep does not enhance memory. In humans, memory consolidation can be triggered by presentation of a context odor during slow-wave sleep that had been present during learning [3-5]. Our results reveal that deep-sleep phases in honeybees have the potential to prompt memory consolidation, just as they do in humans. This study provides strong evidence for a conserved role of sleep-and how it affects memory processes-from insects to mammals.

Neural Correlates of Odor Learning in the Presynaptic Microglomerular Circuitry in the Honeybee Mushroom Body Calyx.
The mushroom body (MB) in insects is known as a major center for associative learning and memory, although exact locations for the correlating memory traces remain to be elucidated. Here, we asked whether presynaptic boutons of olfactory projection neurons (PNs) in the main input site of the MB undergo neuronal plasticity during classical odor-reward conditioning and correlate with the conditioned behavior. We simultaneously measured Ca responses in the boutons and conditioned behavioral responses to learned odors in honeybees. We found that the absolute amount of the neural change for the rewarded but not for the unrewarded odor was correlated with the behavioral learning rate across individuals. The temporal profile of the induced changes matched with odor response dynamics of the MB-associated inhibitory neurons,

suggestive of activity modulation of boutons by this neural class. We hypothesize the circuit-specific neural plasticity relates to the learned value of the stimulus and underlies the conditioned behavior of the bees.

In vitro cultured lung cancer cells are not suitable for animal-based breath biomarker detection.
In vitro cultured lung cancer cell lines were investigated regarding the possible identification of volatile organic compounds as potential biomarkers. Gas samples from the headspace of pure culture medium and from the cultures of human lung adenocarcinoma cell lines A549 and Lu7466 were exposed to polypropylene fleece in order to absorb odour components. Sniffer dogs were trained with loaded fleeces of both cell lines, and honey bees were trained with fleeces exposed to A549. Afterwards, their ability to distinguish between cell-free culture medium odour and lung cancer cell odour was tested. Neither bees nor dogs were able to discriminate between odours from the cancer cell cultures and the pure culture medium. Solid phase micro extraction followed by gas chromatography with mass selective detection produced profiles of volatiles from the headspace offered to the animals. The profiles from the cell lines were largely similar; distinct differences were based on the decrease of volatile culture medium components due to the cells' metabolic activity. In summary, cultured lung cancer cell lines do not produce any biomarkers recognizable by animals or gas chromatographic analysis.

INVOLVEMENT OF SEROTONINERGIC PROJECTIONS TO THE DORSAL STRIATUM IN BEHAVIOURAL SWITCHING UNDER UNCERTAINTY

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Yann Pelloux, Celia Rais, Marielena Veggi, Luca Nava, Alice Gino, Raffaella Tonini
Istituto Italiano di Tecnologia, Neuromodulation Of Cortical And Subcortical Circuits, Genova, Italy

In adaptive decision-making processes, behavioural switching is made based on past outcomes (positive or negative). While the neuromodulator serotonin (5-HT) has been shown to affect specific domains relevant for behavioral switching, such as patience for future rewards, impulse control and active persistence, little is known about the underlying circuit substrates. Here we investigated the involvement of dorsal raphe serotoninergic projections to the posterior dorsomedial and dorsolateral striatum ($DRN_{5\text{-}HT} \rightarrow$ pDMS and $DRN_{5\text{-}HT} \rightarrow$ DLS) in a probabilistic discrimination task, which critically requires the use of previous experience to maximize reinforcement. We trained mice to either clockwise or anticlockwise wheel turning for reward and shaped their preference by contrasting the probability of reinforcement upon the different options. We established probabilistic discrimination to be sensitive to uncertainty (evoked by tempering reward signalling) and to DRN optogenetic inhibition. By using fiber photometry during task, we found that population activity of non-dissected $DRN_{5\text{-}HT}$ neurons was differently related to time-locked reward consumption from DRN_{5HT} neurons projecting to the pDMS or DLS. Furthermore, the activity of $DRN_{5\text{-}HT} \rightarrow$ DLS neurons differed from that of their terminals, with the latter only increasing at reward collection, which is at the time of behavioural evaluation. Accordingly, optogenetic inhibition of DRN_{5HT}-→ DLS projections at wheel turning, or in-vivo 5-HT4R antagonism in the DLS before task, affected behavioural switching. Altogether, these results suggests that serotonergic transmission in the DLS is locally regulated to shape behavioural switching; the contribution of different striatal neuron subpopulations is currently under investigation.

SYSTEMATIC COMPARISON OF RISKY CHOICE PREFERENCE REVERSALS IN HUMAN AND MONKEY

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Leo Chi U Seak, Simone Ferrari-Toniolo, Wolfram Schultz
University of Cambridge, Department Of Physiology, Development And Neuroscience, CAMBRIDGE, United Kingdom

Monkeys have been used to study the neuronal mechanism of risky decision-making for more than a decade. Although some previous studies tried to compare the decision-making of humans and monkeys, these studies did not investigate the consistency of risk preference across these two primate species. We here designed a task allowing direct comparison of the two species' behaviour in a systematic way. We used a well-defined economic test for choice consistency, based on the independence axiom of expected utility theory. We measured the similarity in human's and monkey's stochastic choice behaviour in terms of violations of the independence axiom. More specifically, we tested whether adding a common gamble to two gamble options will change the preference of the subject (across 34 sessions and 26 sessions for two monkeys respectively). With this task, we found that monkeys exhibited preference reversal patterns similar to humans, except that our monkeys are more risk-taking than humans. Moreover, our machine learning models built with monkey data predicted human behaviour and vice versa, supporting the general preference reversal consistency across primates. These data suggest that (1) monkeys have similar risky choice behaviour to humans; (2) monkeys would be a good model organism to study decision-making under risk and the neuronal mechanism behind it, given that precise single-cell electrophysiology can be done in monkeys.

INVESTIGATING THE ROLE OF INHIBITORY CONTROL IN SCIENCE LEARNING USING EEG

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Lorie-Marlène Brault Foisy[1], Yannick Skelling[2], Patrice Potvin[2], Jérémie Blanchette Sarrasin[2], Hugo Lapierre[2], Steve Masson[2], Patrick Charland[2]
[1]Université du Québec à Montréal, Didactique, MONTRÉAL, Canada, [2]Université du Québec à Montréal, Didactique, Montreal, Canada

An extensive research literature reveals that students hold misconceptions about various scientific phenomena. These misconceptions can interfere with the learning of scientific concepts and therefore make formal instruction more difficult. An example of such common misconception could be to believe that bigger objects sink more, that one wire is sufficient to light a bulb, and many more. Furthermore, it has been shown that those misconceptions do not only interfere during learning; they also persist after being given formal instruction. Recent neuroimaging and reaction time studies show that inhibitory control (IC) mechanisms are involved in understanding basic science concepts many scientific domains (e.g. Brault Foisy et al., 2015). The present research investigates the well-documented misconception in biology that “moving things are alive” that is known to interfere with the conceptual learning of what is considered alive or not. Electroencephalography (EEG) measures were selected for this study, as they allow for the detection of brain signal variations over short time frames in ecologically valid tasks. Twenty-eight undergraduate students solved a classification task in which they had to select between two images which one represented a living thing, while their EEG signals were recorded. Results show that ERP signals differ at N200 and LPP locations between counter-intuitive stimuli (for which IC is presumably required) and intuitive ones (counter-intuitive>intuitive). These locations are commonly involved in distinct cognitive processes associated to IC (Zhu et al., 2019). These results will be discussed as well as methodological considerations regarding the use of EEG to address science learning.

PHARMACOLOGICAL STIMULATION OF THE SEROTONIN RECEPTOR 7 RESCUES FEAR GENERALIZATION IN A PTSD MOUSE MODEL CARRYING A TRUNCATED FORM OF MECP2

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Livia Di Crescenzo[1], Livia Cosentino[1], Chiara Urbinati[1], Enza Lacivita[2], Marcello Leopoldo[2], Bianca De Filippis[1]
[1]Istituto Superiore di Sanità, Center For Behavioural Sciences And Mental Health, Rome, Italy, [2]University of Bari, Department Of Pharmacy, Drug Sciences, Bari, Italy

Post-traumatic stress disorder (PTSD) is a chronic mental disorder occurring after trauma exposure, characterized by invalidating symptoms, that are often resistant to current interventions. The serotonin receptor 7 (5-HT7R) is involved in the endocrine and behavioural responses undertaken to cope with stress, and controls brain structural changes related to memory processes. Although these functions are relevant in PTSD neurobiology, the role of 5-HT7R in PTSD has not been investigated yet. **Aims**: we sought to evaluate the effects of 5-HT7R pharmacological stimulation on PTSD-like behavioural alterations in a mouse model of trauma vulnerability, carrying a truncated form of the X-linked epigenetic regulator methyl-CpG binding protein 2 (MeCP2). **Methods**: mutant males (MeCP2-308) and wild-type (wt) controls were systemically treated with the 5-HT7R agonist LP-211 for 7 days (0.25 mg/kg/day), starting 24 hours after the trauma (2x 3s, 0.8 mA unescapable footshocks). Mice were tested for cued and contextual fear memory recall (Day 1 and 7 of treatment) and for avoidance of trauma-related stimuli (Day 6). **Results**: Trauma-exposed MeCP2-308 mice performed freezing when exposed to a novel, non-threatening context, suggesting that they generalized fear to neutral stimuli. Consistently, traumatized mutants exhibited fear regardless of the presence of trauma-related stimuli in the avoidance task. LP-211 treatment rescued both aberrant behaviours. **Conclusions:** Present data provide novel evidence of a potential involvement of 5-HT7R in PTSD vulnerability, suggesting a role for 5-HT7R in counteracting fear generalization, a maladaptive memory-related process typically observed in patients with PTSD. Further studies are needed to clarify the mechanisms involved.

TRANSCRIPTOMICS ANALYSIS FOR THE PRISMO STUDY: EXPRESSION PROFILES IN SUSCEPTIBLE VERSUS RESILIENT INDIVIDUALS IN A PROSPECTIVE PTSD COHORT.

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Ghazi Al Jowf
Maastricht University, Dept. Of Neuroscience, Maastricht, Netherlands

Aim: Post-traumatic Stress Disorder (PTSD) symptoms consist of, among others, re-experiencing traumatic experiences, avoidance of stimuli that remind of this traumatic experience, aggression, and sleep problems, leading to a strong adverse effect on patients' daily functioning. Epigenetic mechanisms, such as DNA methylation, have been proposed to underlie the relationship between exposure to traumatic stress and the susceptibility to develop PTSD. **Method:** Analysis of blood transcriptomics and DNA methylation profiles in relation to the development of PTSD symptoms in a prospective military cohort study (PRISMO). A subset (total n=96) of three similarly sized subgroups (susceptible, resilient, and control) of study participants was pre-selected based on the level of traumatic stress exposure and the presence of PTSD symptoms. **Result:** Transcriptomics data have been pre-processed and statistically analysed to compare susceptible to resilient profiles 6 months after return from deployment. Our preliminary findings suggest that there are 397 genes that are significantly differentially expressed in those who are susceptible to developing PTSD. Including control group (non-trauma exposed) expression levels, the changed genes have been further categorised into response classes, *e.g.*, being in- or decreased, or rather lacking in- or decrease in susceptible versus resilient individuals after trauma exposure. **Conclusion:** Genes in several response classes have been identified. Follow-up analyses, including pathway and Gene Ontology mapping, will be conducted to further biologically characterise these observed classes. Furthermore, differential expression results will be aligned with the epigenomics data we have collected previously, and the profiles correlated with the findings of our earlier published study.

SEX-SPECIFIC CONDITIONED CONTEXT AVERSION IN OUTBRED MICE AS A MODEL OF ANTICIPATORY NAUSEA IN HUMANS

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Çınar Furkan Ilhan[1], Ayşe Seza Şahin[1], Gonzalo Urcelay[2], Sezen Kışlal[1]
[1]Middle East Technical University, Psychology, Ankara, Turkey, [2]University of Nottingham, Psychology, Nottingham, United Kingdom

Aim: Anticipatory nausea and vomiting (ANV), which results from classical conditioning, develops mostly in female patients undergoing chemotherapy. Preclinical studies have shown that the administration of an illness-inducing agent in the presence of novel contextual cues can cause conditioned context aversion (CCA) in rodents as an animal model of ANV. This study investigated sex-specific development of CCA in mice after a single context-illness pairing. **Methods:** Twelve-week-old CD1 outbred mice were assigned to either the experimental (n = 15 for male, n = 14 for female) or control groups (n = 15 for male, n = 13 for female). A distinctive context consisting of tactile, auditory, and visual cues was paired with an intraperitoneal injection of illness-inducing lithium chloride (LiCl; 6 mEq/kg) in the experimental groups and sodium chloride (NaCl; 0.9%) in the control groups. To investigate the long-term retention of CCA, we conducted retention tests (20 minutes) measuring water intake in the trained context at three-day intervals. An independent sample t-test was used to measure the sex-specific significant differences between the experimental and control groups. **Results:** Both sexes acquired CCA learning after a single conditioning trial ($p < .001$). Retention of the CCA (decreased water intake) lasted 12 and 24 days for males and females, respectively (Figure 1,2). **Conclusion:** Female mice showed longer and more robust retention than male mice, similar to clinical findings showing sex differences among cancer patients. The results indicate the importance of using the CD1 outbred strain of mice as an animal model of
ANV.

FKBP51 IN GLUTAMATERGIC FOREBRAIN NEURONS MEDIATES BENEFICIAL EFFECTS OF MODERATE EARLY LIFE ADVERSITY ON HIPPOCAMPAL STRUCTURE AND FUNCTION.

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Lotte Van Doeselaar[1], Huanqing Yang[1], Shiladitya Mitra[1], Joeri Bordes[1], Clara Engelhardt[1], Lea Brix[1], Benoit Boulet[2], Tibor Stark[2], Juan Pablo Lopez[3], Jan Deussing[4], Michael Czisch[2], Danusa Menegaz[5], Matthias Eder[5], Mathias Schmidt[1]
[1]Max Planck Institute of Psychiatry, Neurobiology Of Stress Resilience, München, Germany, [2]Max Planck Institute of Psychiatry, Core Unit Neuroimaging, Muenchen, Germany, [3]Max Planck Institute of Psychiatry, Stress Neurobiology And Neurogenetics, München, Germany, [4]Max Planck Institute of Psychiatry, Stress Neurogenetics, München, Germany, [5]Max Planck Institute of Psychiatry, Core Unit Electrophysiology, Muenchen, Germany

Exposure to stressors in early in life can be a risk factor for later psychopathologies, but may also enhance stress resilience, dependent on the genetic background and later life conditions of an individual. The chaperone FKBP51 has been implicated in mediating such effects, but the underlying mechanism are still largely unclear. Furthermore, recent research has highlighted the differential responses to stress between sexes. This study investigates whether early-life stress (ELS) exposure can enhance cognitive performance in adulthood and if FKBP51 plays a role in this process. Mice with a conditional deletion of FKBP51 in forebrain glutamatergic neurons (FKBP51^{Nex}) or wild-type (WT) litter mates were either subjected to ELS in the form of limited nesting and bedding material or left undisturbed. Cognitive testing in adulthood at 5 - 7 months of age revealed that predominantly in female offspring ELS resulted in an improved cognitive performance specifically under high-stress conditions, and this effect was absent in FKBP51^{Nex} mice. Subsequent structural MRI revealed genotype or ELS-induced volumetric changes. Additionally, RNA bulk sequencing revealed interesting differences in expression profiles within the hippocampi of female mice, whereas field potential recordings in CA1 slices of a separate cohort of female FKBP51^{Nex} and WT mice exposed contrasting LTP induction profiles in response to a corticosterone application. Taken together, our results show that moderate exposure to early life adversity can enhance resilience in a sex-dependent manner by improving cognitive performance under high stress conditions as a result of molecular, functional and structural changes.

CANNABIDIOL PREVENTS COGNITIVE DEFICITS INDUCED BY ACUTE STRESS IN SERINE RACEMASE MUTANT MICE.

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Igor Rangel[1], Melissa De Souza[1], Mariana Medeiros[1], Luciana Romão[1], Rogerio Panizzutti[2]
[1]Federal University of Rio de Janeiro, Biomedical Sciences Institute, Rio de Janeiro, Brazil, [2]Federal University of Rio de Janeiro, Psychiatry Institute, Rio de Janeiro, Brazil

Introduction: Genetic variations in serine racemase (SRR), enzyme that forms D-serine endogenously, are associated to schizophrenia, and mice with mutations that inactivate SRR resemble cognitive aspects of schizophrenia. Acute stress decreases D-serine levels in pre-frontal cortex causing deficit in recognition memory. The endocannabinoid system modulates the stress response and evidence suggest that cannabidiol (CBD) may remediate cognitive deficits in animal models. However, we don't know whether CBD is able to prevents the memory deficit induced by acute stress in a schizophrenia mice model. Aim: To investigate the effects of CBD on memory deficits induced by acute stress on serine racemase mutant mice (SRR-/-). Methods: C57Bl/6 (WT) and SRR-/- male mice between 2 – 6 months old were exposed to acute restrained stress. CBD 5mg/kg was orally administrated 3h before acute stress. Animals were exposed to acute stress immediately after training trial of Novel Object Recognition task (NOR). The retention test occurred 24h after training. Results: Stressed animals showed higher levels of serum corticosterone than non-stressed animals. Acute stress reduced the performance at NOR in both WT and SRR-/- mice. CBD reduced performance at NOR test and failed to protect against the impairments in recognition memory induced by acute stress in WT mice. Interestingly, in SRR-/- mice CBD prevented the deficits in NOR induced by stress. Conclusion: CBD harmed recognition memory in WT mice, but prevented the induction of deficit by acute stress in serine racemase mutant mice.

ACUTE INSULIN ADMINISTRATION ENHANCES CONTEXTUAL FEAR MEMORY INDEPENDENTLY OF ADRENALINE, THROUGH INCREASED HIPPOCAMPUS BDNF EXPRESSION

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Ana Oliveira[1,2], Rafaela Seixas[1,2], Francisca Pereira[1,2], Raquel Martinho[1,2], Paula Serrão[2,3], Mónica Moreira-Rodrigues[1,2]
[1]Institute of Biomedical Sciences Abel Salazar, University of Porto (ICBAS/UP), Laboratory Of Physiology, Department Of Immuno-physiology And Pharmacology, Porto, Portugal, [2]University of Porto (UP), Center For Drug Discovery And Innovative Medicines, University Of Porto (medinup), Porto, Portugal, [3]Faculty of Medicine, University of Porto (FMUP), Department Of Biomedicine, Porto, Portugal

Increased adrenaline and consequently hyperglycemia are effective in contextual fear memory enhancement[1]. Subsequently, hyperglycemia leads to insulin release which facilitates spatial memory-related and passive-avoidance tasks[2,3]. This physiological loop makes it difficult to distinguish the actions of both hormones in contextual fear memory. We aim to determine how insulin affects contextual fear memory in an adrenaline deficient mouse (phenylethanolamine-*N*-methyltransferase knock-out, Pnmt-KO) model. Wild type (WT) and Pnmt-KO (129x1/SvJ) mice were exposed to a fear conditioning protocol. On day 1, mice were exposed to 3-foot shocks (2 s, 0.6 mA) followed by contextual reminder exposure on day 2. Insulin (2 U/kg; i.p.) or vehicle (0.9% NaCl) were administered before training and context. Freezing percentage, tissues/plasma catecholamines, and *Bdnf* mRNA expression were evaluated. $P<0.05$ represents a significant difference. Insulin-treated WT mice have increased freezing behaviour and catecholamines in plasma when compared with vehicle-treated WT mice. Insulin-treated Pnmt-KO mice presented an increased freezing behaviour when compared with vehicle-treated Pnmt-KO mice, with no plasma catecholamines changes. Furthermore, they presented increased hippocampus *Bdnf* gene expression. In conclusion, insulin administration appears to strengthen contextual fear memory in a mice model with/without endogenous adrenaline. This memory enhancement could be related to the increased expression of *Bdnf* in the hippocampus of insulin-treated mice which can possibly lead to central molecular changes that promote contextual fear memory formation and strengthening. Epinephrine Released During Traumatic Events May Strengthen Contextual Fear Memory Through Increased Hippocampus mRNA Expression of Transcription Factors.
Epinephrine (EPI) strengthens contextual fear memories by acting on peripheral β-adrenoceptors. Phenylethanolamine--methyltransferase-knockout (Pnmt-KO) mice are EPI-deficient mice and have reduced contextual fear learning. Our aim was to evaluate the molecular mechanisms by which peripheral EPI strengthens contextual fear memory and if a β-adrenoceptor antagonist can erase contextual fear memories. Pnmt-KO and wild-type (WT) mice were submitted to fear conditioning (FC) procedure after treatment with EPI, norepinephrine (NE), EPI plus ICI 118,551 (selective β-adrenoceptor antagonist), ICI 118,551 or vehicle (NaCl 0.9%). Catecholamines were separated and quantified by high performance liquid chromatography-electrochemical detection (HPLC-ED). Blood glucose was measured by coulometry. Real-time polymerase chain reaction (qPCR) was used to evaluate mRNA expression of nuclear receptor 4a1 (), and in hippocampus samples. In WT mice, plasma EPI concentration was significantly higher after fear acquisition (FA) compared with mice without the test. NE did not increase in plasma after FA and did not strengthen contextual fear memory, contrary to EPI. Freezing induced by EPI was blocked by ICI 118,551 in Pnmt-KO mice. In WT mice, ICI 118,551 blocked blood glucose release into the bloodstream after FA and decreased contextual fear memory. , and mRNA expression decreased in Pnmt-KO mice compared with WT mice after FC procedure. In Pnmt-KO mice, EPI induced an increase in mRNA expression of compared to vehicle. In conclusion, EPI increases in plasma after an aversive experience, possibly improving long-term and old memories, by acting on peripheral β-adrenoceptors. Glucose could be the mediator of peripheral EPI in the central nervous system, inducing the expression of transcription factor genes involved in consolidation of contextual fear memories.

Epinephrine May Contribute to the Persistence of Traumatic Memories in a Post-traumatic Stress Disorder Animal Model.
The importance of catecholamines in post-traumatic stress disorder (PTSD) still needs to be explored. We aimed to evaluate epinephrine's (EPI) causal role and molecular mechanism for the persistence of PTSD traumatic memories. Wild-type (WT) and EPI-deficient mice (phenylethanolamine--methyltransferase-knockout mice, Pnmt-KO) were induced with PTSD and behavioral tests were performed. Some Pnmt-KO mice were administered with EPI or vehicle. Catecholamines were quantified by HPLC-ED. , , and mRNA expression were evaluated by real-time PCR in hippocampus samples. It was observed an increase in EPI and freezing behavior, and a decrease in open arm entries in the elevated plus-maze test and time spent in the light in the light-dark test in WT mice in the PTSD-induction group compared to control. After induction of PTSD, Pnmt-KO mice showed a decrease in freezing, as well as an increase in open arm entries and transitions between compartments compared to WT. After PTSD induction, Pnmt-KO mice administered with EPI showed an increase in freezing compared with the vehicle. On day 0 of PTSD induction, it was observed an increase in mRNA expression of and genes in the hippocampus of WT mice compared to control, contrary to Pnmt-KO mice. In conclusion, our data suggest that EPI may be involved in the persistence of traumatic memories in PTSD, possibly through enhancement of the expression of and genes in the hippocampus. Peripheral administration of EPI restored contextual traumatic memories in Pnmt-KO mice, which suggests a causal role for EPI. The persistence of contextual traumatic memories may contribute to anxiety-like behavior and resistance of traumatic memory extinction in this PTSD mice model.

Sotalol Treatment may Interfere With Retrieval, Expression, and/or Reconsolidation Processes Thus Disrupting Traumatic Memories in a Post-Traumatic Stress Disorder Mice Model.
The processes by which fear memory is encoded, consolidated, and re-consolidated are extremely complex and appear to require the release of stress hormones, especially adrenaline (AD). AD improves contextual fear memory, acting specifically on peripheral β2-adrenoceptors. Propranolol (peripheral and central β-adrenoceptor antagonist) treatment was shown to prevent post-traumatic stress disorder (PTSD) development and reduce its symptoms. However, propranolol has several side effects. Thus, we aimed to evaluate if sotalol (a peripheral β-adrenoceptor antagonist) treatment interferes with retrieval, expression, and/or reconsolidation of traumatic memories in a validated mice model that mimics the signs/symptoms of PTSD, thus intending to decrease them. Female mice were induced with PTSD following an established protocol. Sotalol (2.0 mg/kg) or vehicle were administered on days 2, 7, and 14. The percentage of freezing was calculated, and behavioral tests were carried out. Catecholamines in plasma were quantified by HPLC with electrochemical detection. Quantitative real-time polymerase chain reaction (qPCR) was used to evaluate mRNA expression of NR4A family genes in hippocampus. Following the submission of the animals to the same aversive context on days 2, 7, and 14, sotalol-treated mice exhibited significant less freezing behavior. In the elevated plus-maze test, the time spent and number of entries in the open arms, and total arm entries were increased in sotalol-treated mice. Also, the light-dark transition test revealed higher time spent, number of transitions to the light, and total number of transitions in sotalol-treated mice. Moreover, plasma AD was significantly decreased in sotalol-treated mice. On day 14, sotalol-treated mice exhibited a decrease in mRNA expression of in the hippocampus. In conclusion, in PTSD mice model, sotalol appears to decrease traumatic memories and anxiety-like behavior, probably due to a decrease in peripheral adrenergic activity, which influences traumatic memories. The effects of sotalol upon re-exposure to the traumatic context may be consistent with interference in the retrieval, expression, and/or reconsolidation processes of contextual traumatic memory, resulting in a long-term reduction of PTSD symptoms and signs. The decreased mRNA expression in the hippocampal formation may be crucial for these mice to develop diminished traumatic contextual memories after sotalol therapy in PTSD.

Treatment With Nepicastat Decreases Contextual Traumatic Memories Persistence in Post-traumatic Stress Disorder.
Post-traumatic stress disorder (PTSD) is a common anxiety mental disorder and can be manifested after exposure to a real or perceived life-threatening event. Increased noradrenaline and adrenaline in plasma and urine have been documented in PTSD. Dopamine-β-hydroxylase (DBH) catalyzes the conversion of dopamine to noradrenaline and consequently, DBH inhibition reduces catecholamines. Our aim was to evaluate if nepicastat treatment decreases PTSD signs in an animal model. Wild-type (129x1/SvJ) female mice were submitted to PTSD induction protocol. DBH-inhibitor nepicastat (30 mg/kg) or vehicle (0.2% HPMC) were administered once daily since day 0 until day 7 or 12. The percentage of freezing was calculated on days 0, 1, 2, and 7, and behavioral tests were performed. Quantification of nepicastat in plasma and DBH activity in the adrenal gland was evaluated. Catecholamines were quantified by HPLC with electrochemical detection. mRNA expression of and in hippocampus was evaluated by qPCR.Mice in the PTSD-group and treated with nepicastat showed a decrease in freezing, and an increase in the time spent and entries in open arms in elevated plus maze test. In mice treated with

nepicastat, adrenal gland DBH activity was decreased, and catecholamines were also decreased in plasma and tissues. On day 7, in mice treated with nepicastat, there was an increase of and mRNA expression in the hippocampus.In conclusion, DBH inhibitor nepicastat has an effect consistent with a decrease in the persistence of traumatic memories and anxiety-like behavior in this PTSD mice model. The disruption of traumatic memories through interference with the formation, consolidation, retrieval, and/or expression processes may be important to decrease PTSD symptoms and signs. The increase in and mRNA expression in the hippocampus may be important to develop a weaker traumatic contextual memory after nepicastat treatment.

Neuroinflammation has been classified as a trigger of behavioral alterations and cognitive impairments. Given the role of metainflammation during aging, the way to regulate it may be an effective strategy to influence cognitive functions. We have studied the mechanisms of insulin signaling and metaflammation in the brain in Wild-type mice and NLRP3 KO mice. Aim: to assess NLRP3 inflammasome contribution to anxiety, acquisition of fear responses, hippocampal neurogenesis and brain insulin resistance. Methods: Behavioral, immunohistochemical and electrophysiological approaches were used. Results: NLRP3 KO mice demonstrate anxious behavior and deterioration in learning and memory; impairment of adult neurogenesis; reduction and altered morphology of astrocytes. We have found the hyperexcitability in basolateral amygdala; impaired activation in axons of pyramidal cells of CA1 zone in NLRP3 KO mice; and impaired synaptic transduction in pyramidal cells mediated by an embarrassment of neurotransmitter release from presynaptic site in CA3 zone. It was revealed that NLRP3 inflammasomes are required for insulin-dependent glucose transport in the brain and memory consolidation. Conclusions: The study has demonstrated the novel findings that basal level of NLRP3 inflammasome in the brain of young mice is required for conditioning-induced plasticity in the ventral hippocampus and the basolateral amygdala. The deletion of NLRP3 impair synaptic transduction and caused anxiety-like behavior and labored fear learning, suggesting that low grade inflammation, mediated by NLRP3 expression, play a key role in memory consolidation. This work was supported by a grant from the President of the Russian Federation for State support of young Russian scientists - MD-2368.2022.3.

NLRP3 deficiency-induced hippocampal dysfunction and anxiety-like behavior in mice.
Neuroinflammation has been classified as a trigger of behavioral alterations and cognitive impairments in many neurological conditions, including Alzheimer's disease, major depression, anxiety and others. Regardless of the cause of neuroinflammation, key molecules, which sense neuropathological conditions, are intracellular multiprotein signaling inflammasomes. Increasing evidence shows that the inflammatory response, mediated by activated nucleotide-binding oligomerization domain-, leucine-rich repeat- and pyrin domain-containing 3 (NLRP3) inflammasomes, is associated with the onset and progression of a wide range of diseases of the CNS. However, whether the NLRP3 inflammasome in the CNS is involved in the learning, development of anxiety and adult neurogenesis remains elusive. Therefore, the present study was designed to assess NLRP3 inflammasome contribution in anxiety and reveal its potential involvement in the experimental acquisition of fear responses and hippocampal neurogenesis. Behavioral, immunohistochemical and electrophysiological alterations were measured to evaluate role of neuroinflammation in the limbic system of mice. In this study, we describe interrelated neurophysiological mechanisms, which culminate in absence of NLRP3 inflammasome in young 4 months mice. These include the following: anxious behavior and deterioration in learning and memory of fear conditioning; impairment of adult neurogenesis; reduction and altered morphology of astrocytes in the brain; hyperexcitability in basolateral amygdala (BLA); impaired activation in axons of pyramidal cells of CA1 hippocampal zone in NLRP3 KO mice particularly via the Schaffer collateral pathway; and impaired synaptic transduction in pyramidal cells mediated by an embarrassment of neurotransmitter release from presynaptic site in CA3 hippocampal zone. The present study has demonstrated the novel findings that basal level of NLRP3 inflammasome in the brain of young mice is required for conditioning-induced plasticity in the ventral hippocampus and the basolateral amygdala. The deletion of NLRP3 impair synaptic transduction and caused anxiety-like behavior and labored fear learning, suggesting that low grade inflammation, mediated by NLRP3 expression, play a key role in memory consolidation.

NLRP3 Inflammasome Blocking as a Potential Treatment of Central Insulin Resistance in Early-Stage Alzheimer's Disease.
Alzheimer's disease (AD) is a devastating neurodegenerative disorder. In recent years, attention of researchers has increasingly been focused on studying the role of brain insulin resistance (BIR) in the AD pathogenesis. Neuroinflammation makes a significant contribution to the BIR due to the activation of NLRP3 inflammasome. This study was devoted to the understanding of the potential therapeutic roles of the NLRP3 inflammasome in neurodegeneration occurring concomitant with BIR and its contribution to the progression of emotional disorders.

Inflamm-Aging and Brain Insulin Resistance: New Insights and Role of Life-style Strategies on Cognitive and Social Determinants in Aging and Neurodegeneration.
Over the past decades, the human life span has dramatically increased, and therefore, a steady increase in diseases associated with age (such as Alzheimer's disease and Parkinson's disease) is expected. In these neurodegenerative diseases, there is a cognitive decline and memory loss, which accompany increased systemic inflammation, the inflamm-aging, and the insulin resistance. Despite numerous studies of age-related pathologies, data on the contribution of brain insulin resistance and innate immunity components to aging are insufficient. Recently, much research has been focused on the consequences of nutrients and adiposity- and nutrient-related signals in brain aging and cognitive decline. Moreover, given the role of metainflammation in neurodegeneration, lifestyle interventions such as calorie restriction may be an effective way to break the vicious cycle of metainflammation and have a role in social behavior. The various effects of calorie restriction on metainflammation, insulin resistance, and neurodegeneration have been described. Less attention has been paid to the social determinants of aging and the possible mechanism by which calorie restriction might influence social behavior. The purpose of this review is to discuss current knowledge in the interdisciplinary field of geroscience-immunosenescence, inflamm-aging, and metainflammation-which makes a significant contribution to aging. A substantial part of the review is devoted to frontiers in the brain insulin resistance in relation to neuroinflammation. In addition, we summarize new data on potential mechanisms of calorie restriction that influence as a lifestyle intervention on the social brain. This knowledge can be used to initiate successful aging and slow the onset of neurodegenerative diseases.

Expression of NLRP3 Inflammasomes in Neurogenic Niche Contributes to the Effect of Spatial Learning in Physiological Conditions but Not in Alzheimer's Type Neurodegeneration.
A common feature of neurodegenerative disorders, in particular Alzheimer's disease (AD), is a chronic neuroinflammation associated with aberrant neuroplasticity. Development of neuroinflammation affects efficacy of stem and progenitor cells proliferation, differentiation, migration, and integration of newborn cells into neural circuitry. However, precise mechanisms of neurogenesis alterations in neuroinflammation are not clear yet. It is well established that expression of NLRP3 inflammasomes in glial cells marks neuroinflammatory events, but less is known about contribution of NLRP3 to deregulation of neurogenesis within neurogenic niches and whether neural stem cells (NSCs), neural progenitor cells (NPCs) or immature neuroblasts may express inflammasomes in (patho)physiological conditions. Thus, we studied alterations of neurogenesis in rats with the AD model (intra-hippocampal injection of Aβ1-42). We found that in Aβ-affected brain, number of CD133+ cells was elevated after spatial training in the Morris water maze. The number of PSA-NCAM+ neuroblasts diminished by Aβ injection was completely restored by subsequent spatial learning. Spatial training leads to elevated expression of NLRP3 inflammasomes in the SGZ (subgranular zones): CD133+ and PSA-NCAM+ cells started to express NLRP3 in sham-operated, but not AD rats. Taken together, our data suggest that expression of NLRP3 inflammasomes in CD133+ and PSA-NCAM+ cells may contribute to stimulation of adult neurogenesis in physiological conditions, whereas Alzheimer's type neurodegeneration abolishes stimuli-induced overexpression of NLRP3 within the SGZ neurogenic niche.

CD157 and Brain Immune System in (Patho)physiological Conditions: Focus on Brain Plasticity.
Ectoenzyme and receptor BST-1/CD157 has been considered as a key molecule involved in the regulation of functional activity of cells in various tissues and organs. It is commonly accepted that CD157 catalyzes NAD+ hydrolysis and acts as a component of integrin adhesion receptor complex. Such properties are important for the regulatory role of CD157 in neuronal and glial cells: in addition to recently discovered role in the regulation of emotions, motor functions, and social behavior, CD157 might serve as an important component of innate immune reactions in the central nervous system. Activation of innate immune system in the brain occurs in response to infectious agents as well as in brain injury and neurodegeneration. As an

example, in microglial cells, association of CD157 with CD11b/CD18 complex drives reactive gliosis and neuroinflammation evident in brain ischemia, chronic neurodegeneration, and aging. There are various non-substrate ligands of CD157 belonging to the family of extracellular matrix proteins (fibronectin, collagen I, finbrinogen, and laminin) whose activity is required for controlling cell adhesion and migration. Therefore, CD157 could control structural and functional integrity of the blood-brain barrier and barriergenesis. On the other hand, contribution of CD157 to the regulation of brain development is rather possible since in the embryonic brain, CD157 expression is very high, whereas in the adult brain, CD157 is expressed on neural stem cells and, presumably, is involved in the neurogenesis. Besides, CD157 could mediate astrocytes' action on neural stem and progenitor cells within neurogenic niches. In this review we will summarize how CD157 may affect brain plasticity acting as a molecule at the crossroad of neurogenesis, cerebral angiogenesis, and immune regulation.

Excitation/inhibition imbalance and impaired neurogenesis in neurodevelopmental and neurodegenerative disorders.
The excitation/inhibition (E/I) balance controls the synaptic inputs to prevent the inappropriate responses of neurons to input strength, and is required to restore the initial pattern of network activity. Various neurotransmitters affect synaptic plasticity within neural networks via the modulation of neuronal E/I balance in the developing and adult brain. Less is known about the role of E/I balance in the control of the development of the neural stem and progenitor cells in the course of neurogenesis and gliogenesis. Recent findings suggest that neural stem and progenitor cells appear to be the target for the action of GABA within the neurogenic or oligovascular niches. The same might be true for the role of neuropeptides (i.e. oxytocin) in neurogenic niches. This review covers current understanding of the role of E/I balance in the regulation of neuroplasticity associated with social behavior in normal brain, and in neurodevelopmental and neurodegenerative diseases. Further studies are required to decipher the GABA-mediated regulation of postnatal neurogenesis and synaptic integration of newly-born neurons as a potential target for the treatment of brain diseases.

Vascular RAGE transports oxytocin into the brain to elicit its maternal bonding behaviour in mice.
Oxytocin sets the stage for childbirth by initiating uterine contractions, lactation and maternal bonding behaviours. Mice lacking secreted oxcytocin (,) or its receptor ( ) fail to nurture. Normal maternal behaviour is restored by peripheral oxcytocin replacement in and , but not mice, implying that circulating oxcytocin crosses the blood-brain barrier. Exogenous oxcytocin also has behavioural effects in humans. However, circulating polypeptides are typically excluded from the brain. We show that oxcytocin is transported into the brain by receptor for advanced glycation end-products (RAGE) on brain capillary endothelial cells. The increases in oxcytocin in the brain which follow exogenous administration are lost in male mice lacking RAGE, and behaviours characteristic to abnormalities in oxcytocin signalling are recapitulated in mice, including deficits in maternal bonding and hyperactivity. Our findings show that RAGE-mediated transport is critical to the behavioural actions of oxcytocin associated with parenting and social bonding.

Oxytocin and excitation/inhibition balance in social recognition.
Social recognition is the sensitive domains of complex behavior critical for identification, interpretation and storage of socially meaningful information. Social recognition develops throughout childhood and adolescent, and is affected in a wide variety of psychiatric disorders. Recently, new data appeared on the molecular mechanisms of these processes, particularly, the excitatory-inhibitory (E/I) ratio which is modified during development, and then E/I balance is established in the adult brain. While E/I imbalance has been proposed as a mechanism for schizophrenia, it also seems to be the common mechanism in autism spectrum disorder (ASD). In addition, there is a strong suggestion that the oxytocinergic system is related to GABA-mediated E/I control in the context of brain socialization. In this review, we attempt to summarize the underpinning molecular mechanisms of E/I balance and its imbalance, and related biomarkers in the brain in healthiness and pathology. In addition, because there are increasing interest on oxytocin in the social neuroscience field, we will pay intensive attention to the role of oxytocin in maintaining E/I balance from the viewpoint of its effects on improving social impairment in psychiatric diseases, especially in ASD.

Neurobiological Aspects of Face Recognition: The Role of Oxytocin.

Face recognition is an important index in the formation of social cognition and neurodevelopment in humans. Changes in face perception and memory are connected with altered sociability, which is a symptom of numerous brain conditions including autism spectrum disorder (ASD). Various brain regions and neuropeptides are implicated in face processing. The neuropeptide oxytocin (OT) plays an important role in various social behaviors, including face and emotion recognition. Nasal OT administration is a promising new therapy that can address social cognition deficits in individuals with ASD. New instrumental neurotechnologies enable the assessment of brain region activation during specific social tasks and therapies, and can characterize the involvement of genes and peptides in impaired neurodevelopment. The present review sought to discuss some of the mechanisms of the face distinguishing process, the ability of OT to modulate social cognition, as well as new perspectives and technologies for research and rehabilitation of face recognition.

[Early changes in hyppocampal neurogenesis induced by soluble Ab1-42 oligomers].
Alzheimer's disease is characterized by the loss of neurons, the accumulation of intracellular neurofibrillary tangles and extracellular amyloid plaques in the brain. However, there are contradicting data on differences in neurogenesis at the onset of the disease or before the formation of amyloid plaques. As awareness of the importance of the pre-symptom phase in neurodegenerative diseases grows in the context of early diagnosis and pathogenesis, we analyzed the critical periods of adult hippocampal neurogenesis at an early stage under the action of soluble Ab1-42 beta-amyloid. The proliferation, migration and neuronal cells survival were evaluated in mice with an injection of soluble amyloid beta-oligomers. It was found that the injection of Ab1-42 oligomers causes a decrease in cell proliferation in the mouse hippocampus. Despite the preservation of the neuroblast pool in animals after beta-amyloid injection, the process of radial migration is disrupted, and an increase in apoptosis in the neurogenic niche was revealed. Thus, our results demonstrate damage of neurogenesis critical stages: the progenitor cells, neuroblast migration, the integration of immature neurons, and the survival of neurons under application of soluble beta-amyloid oligomers. The obtained data indicate decline in proliferation rate in the subgranular zone, that is accompanied by ectopic differentiation and disturbed migration, producing, apparently, abnormal neurons that have lower survival rates. That could lead to a decrease in mature neurons numbers and the number of cells in the granular layer of the dentate gyrus.

CONTRIBUTION OF ADULT HIPPOCAMPAL NEUROGENESIS TO PRENATAL STRESS-INDUCED VULNERABILITY TO PTSD-LIKE MEMORY

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Mohamed-Lyès Kaci[1], Chloé Bouarab[1], Fanny Farrugia[2], Djoher Nora Abrous[1], Aline Desmedt[1], Muriel Koehl[1]
[1]INSERM U1215 - Univ. Bordeaux, Neurocentre Magendie, Bordeaux, France, [2]Inserm U1215 - Univ. Bordeaux, Neurocentre Magendie, Bordeaux, France

Life events in childhood, experienced as early as during *in utero* life, play a pivotal role in shaping adult behavior, and studies have shown that exposure to prenatal stress (PS) could constitute a developmental risk factor for psychiatric disorders, with behavioral features reminiscent to those of post-traumatic stress disorder (PTSD). One of the cardinal feature of PTSD is a paradoxical pattern of memory with both emotional hypermnesia and contextual amnesia. Furthermore, it has recently been proposed that alteration in contextual pattern separation, which depends on adult hippocampal neurogenesis, could contribute to this abnormal memory profile. Altogether, this led us to examine the impact of PS in mice in a fear paradigm allowing to evidence PTSD-associated memory disturbances, and to analyze the contribution of adult neurogenesis in the PS-induced phenotype. We used optogenetics to target and activate 6-weeks old newborn neurons when mice were exposed to the fear paradigm. We then measured the effects of this stimulation on freezing behavior when mice were re-exposed to the fear conditioning context or to a neutral context. We report that PS mice exhibit a PTSD-like aberrant memory profile, while control mice develop a normal fear memory. Activating adult-born neurons prevents this PTSD-like memory in PS mice while it has no effect in control mice. In conclusion these results indicate that PS alters trauma contextualization, hence increasing the risk of developing PTSD-like memory disturbances, and that acting on adult-born neurons activity could help restoring a normal memory profile.

REPEATED STRESS IN THE EARLY ADOLESCENT PERIOD: ARE CB1 RECEPTORS MEDIATING STRESS-REACTIVITY IN A SEX-SPECIFIC MANNER?

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Emmanuelle Person, Alexandre Savard, Helene Plamondon
University of Ottawa, School Of Psychology, Ottawa, Canada

The importance of adolescent living experiences in shaping ensuing social and cognitive responses has been reported, although mechanisms remained to be determined. This study examined the effects of a heterotypic stress in prepubescent rats on social behaviours, memory and corticosterone levels, and possible mediation of stress outcomes by cannabinoid CB1 receptor antagonism. Sixty-four (N = 32 per sex) male and female rats were randomly assigned to a stress or a no-stress condition. Rats in the stress condition underwent a 10-day heterotypic stress paradigm alternating between a restrain stressor and a modified forced swim between postnatal day (PND) 30 and PND39. On PND42 and PND44, half of the rats received a dose of cannabinoid 1 receptor (CB1) antagonist AM251 (1mg/kg) before behavioural testing on the social interaction and social preference test (SIT), and the Y-Maze passive avoidance test (YMPAT), respectively. Blood droplets were collected via tail puncture at 5 different timepoints (PND30, PND35, PND39, PND42, PND46) to assess sex-related time-related changes in circulatory levels of corticosterone prior, during and post stress exposure experiment. Corticosterone (CORT) ELISA immunoassays indicated that while male rats habituated to stress exposure, females showed heightened secretion compared to males from baseline and CORT secretion remained elevated throughout assessments days. CB1 antagonism using AM251 failed to influence CORT levels. Analysis of the impact of pre-testing blockade of CB1 receptors in the SIT and the YMPAT is pending. Our findings are consistent with increased CORT secretion reported in females, and further suggest sex-specific differences in habituation to stress exposure.

Animals have developed complex physical and behavioural systems in response to chemosensory stimuli. The ability to detect, sort and respond to those signals might be critical for their survival, as it reveals key information about the environment. In rodents, chemical cues are detected by the olfactory and vomeronasal systems, responsible respectively, for the detection of volatile and non-volatile molecules. The vomeronasal organ of mice can detect both attractive sexual pheromones and cues from sick conspecifics, thus avoiding social interaction with them, reducing the risk of infection. In this work, we studied whether signals from sick males can counteract the attraction elicited by male pheromones present in urine. We also tested whether attractive or aversive responses are mediated by volatile molecules or require direct contact with male-derived stimuli. Using a model of infection based on the immune response to lipopolysaccharides (LPS) we performed two-choice preference tests in female subjects confronting soiled bedding from female, healthy male and LPS-treated males. Our results reveal that female mice show preference for either LPS-treated or healthy male-soiled bedding when presented against female-soiled bedding, both in volatile and contact-allowing tests. However, females showed no preference when presented with LPS-infected vs. healthy male bedding. We concluded that the LPS treatment is not robust enough to elicit aversive behaviour in females. Therefore, we suggest employing pathogenic infection models when seeking aversive behaviour. Funded by the Spanish Ministry of Science and Innovation-FEDER (PID2019-108562GB-I00). VARIABILITY IN ESCAPE BEHAVIOUR IS CONSERVED ACROSS SPECIES AND EXPLAINED BY AN ACTIVE INFERENCE PROCESS

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Rory Bufacchi[1], Marie Hebert[2], Tom Hagley[3], Dario Campagner[4], Tiago Branco[5], Giorgio Vallortigara[6], Isaac Bianco[3], Gian Domenico Iannetti[7]

Animals must effectively escape from sudden threats to ensure survival. Despite this strong selective pressure, in many species an individual's escape trajectories are quite variable, sometimes even driving prey in the direction of a predator. This seemingly random trial-by-trial variability has been interpreted as a strategy to prevent predators from predicting escape behaviour, thereby improving population fitness. However, an overarching formal explanation of this variability is missing. Here we investigated escape behaviour evoked by looming visual stimuli in four phylogenetically distant organisms (fish, chicks, mice and humans). We discovered that a large part of the trial-to-trial variability in escapes is not random, but predictable from sensory and behavioural state variables. Specifically, we found that in all species 1) early escapes are more frequently directed towards the threat; 2) escapes are more frequently directed in the direction of gaze. In addition, fish and chicks' propensity to escape is higher when gaze direction and threat position overlap. Using an active inference framework, we demonstrate that these observations can be explained *respectively* by independent, competing drives aiming to 1) reduce sensory uncertainty, and 2) pursue existing movement goals, all the while additionally avoiding threats. The inclusion of new-borns (fish larvae and chicks) and a precocial species (chicks) suggests that these principles are mostly innate. In sum, we show that a large part of the seemingly random variability in escape behaviour is in fact predictable and propose that it is a consequence of the interplay between perceptual and motor goals.

An Action Field Theory of Peripersonal Space.
Predominant conceptual frameworks often describe peripersonal space (PPS) as a single, distance-based, in-or-out zone within which stimuli elicit enhanced neural and behavioural responses. Here we argue that this intuitive framework is contradicted by neurophysiological and behavioural data. First, PPS-related measures are not binary, but graded with proximity. Second, they are strongly influenced by factors other than proximity, such as walking, tool use, stimulus valence, and social cues. Third, many different PPS-related responses exist, and each can be used to describe a different space. Here, we reconceptualise PPS as a set of graded fields describing behavioural relevance of actions aiming to create or avoid contact between objects and the body. This reconceptualisation incorporates PPS into mainstream theories of action selection and behaviour.

Movement vigor: Frameworks, exceptions, and nomenclature.
Shadmehr and Ahmed cogently argue that vigor of appetitive movements is positively correlated with their value, and that value can therefore be inferred by measuring vigor. Here, we highlight three points to consider when interpreting this account: (1) The correlation between vigor and value is not obligatory, (2) the vigor effect also arises in frameworks other than optimal foraging, and (3) the term vigor can be misinterpreted, thereby affecting rigor.

Ultralow-frequency neural entrainment to pain.
Nervous systems exploit regularities in the sensory environment to predict sensory input, adjust behavior, and thereby

maximize fitness. Entrainment of neural oscillations allows retaining temporal regularities of sensory information, a prerequisite for prediction. Entrainment has been extensively described at the frequencies of periodic inputs most commonly present in visual and auditory landscapes (e.g., >0.5 Hz). An open question is whether neural entrainment also occurs for regularities at much longer timescales. Here, we exploited the fact that the temporal dynamics of thermal stimuli in natural environment can unfold very slowly. We show that ultralow-frequency neural oscillations preserved a long-lasting trace of sensory information through neural entrainment to periodic thermo-nociceptive input as low as 0.1 Hz. Importantly, revealing the functional significance of this phenomenon, both power and phase of the entrainment predicted individual pain sensitivity. In contrast, periodic auditory input at the same ultralow frequency did not entrain ultralow-frequency oscillations. These results demonstrate that a functionally significant neural entrainment can occur at temporal scales far longer than those commonly explored. The non-supramodal nature of our results suggests that ultralow-frequency entrainment might be tuned to the temporal scale of the statistical regularities characteristic of different sensory modalities.

Gravitational cues modulate the shape of defensive peripersonal space.
The potential damage caused by an environmental threat increases with proximity to the body, so animals perform more effective and stronger defensive responses when threatening stimuli occur nearby the body, in a region termed the defensive peripersonal space (DPPS) [1,2]. We recently characterized the fine-grained geometry of the face's DPPS by recording the enhancement of the blink reflex elicited by electrical stimulation of the median nerve (hand-blink reflex, HBR), when the hand is closer to the face [3]. The resulting DPPS has the shape of a bubble, elongated asymmetrically along the rostro-caudal axis, extending further above eye-level [4]. We hypothesized that this vertical asymmetry is determined by gravitational cues: the probability that a threat will hit the body is higher when it comes from above. By systematically altering body posture, we show that the extent of DPPS asymmetry is defined in an earth-centred coordinate frame. This observation suggests the brain takes gravitational cues to automatically update threat value in an adaptive mechanism that accounts for the simple fact that objects fall down.

The effect of salient stimuli on neural oscillations, isometric force, and their coupling.
Survival in a suddenly-changing environment requires animals not only to detect salient stimuli, but also to promptly respond to them by initiating or revising ongoing motor processes. We recently discovered that the large vertex brain potentials elicited by sudden supramodal stimuli are strongly coupled with a multiphasic modulation of isometric force, a phenomenon that we named cortico-muscular resonance (CMR). Here, we extend our investigation of the CMR to the time-frequency domain. We show that (i) both somatosensory and auditory stimuli evoke a number of phase-locked and non-phase-locked modulations of EEG spectral power. Remarkably, (ii) some of these phase-locked and non-phase-locked modulations are also present in the Force spectral power. Finally, (iii) EEG and Force time-frequency responses are correlated in two distinct regions of the power spectrum. An early, low-frequency region (~4 Hz) reflects the previously-described coupling between the phase-locked EEG vertex potential and force modulations. A late, higher-frequency region (beta-band, ~20 Hz) reflects a second coupling between the non-phase-locked increase of power observed in both EEG and Force. In both time-frequency regions, coupling was maximal over the sensorimotor cortex contralateral to the hand exerting the force, suggesting an effect of the stimuli on the tonic corticospinal drive. Thus, stimulus-induced CMR occurs across at least two different types of cortical activities, whose functional significance in relation to the motor system should be investigated further. We propose that these different types of corticomuscular coupling are important to alter motor behaviour in response to salient environmental events.

Saliency Detection as a Reactive Process: Unexpected Sensory Events Evoke Corticomuscular Coupling.
Survival in a fast-changing environment requires animals not only to detect unexpected sensory events, but also to react. In humans, these salient sensory events generate large electrocortical responses, which have been traditionally interpreted within the sensory domain. Here we describe a basic physiological mechanism coupling saliency-related cortical responses

with motor output. In four experiments conducted on 70 healthy participants, we show that salient substartle sensory stimuli modulate isometric force exertion by human participants, and that this modulation is tightly coupled with electrocortical activity elicited by the same stimuli. We obtained four main results. First, the force modulation follows a complex triphasic pattern consisting of alternating decreases and increases of force, time-locked to stimulus onset. Second, this modulation occurs regardless of the sensory modality of the eliciting stimulus. Third, the magnitude of the force modulation is predicted by the amplitude of the electrocortical activity elicited by the same stimuli. Fourth, both neural and motor effects are not reflexive but depend on contextual factors. Together, these results indicate that sudden environmental stimuli have an immediate effect on motor processing, through a tight corticomuscular coupling. These observations suggest that saliency detection is not merely perceptive but reactive, preparing the animal for subsequent appropriate actions. Salient events occurring in the environment, regardless of their modalities, elicit large electrical brain responses, dominated by a widespread "vertex" negative-positive potential. This response is the largest synchronization of neural activity that can be recorded from a healthy human being. Current interpretations assume that this vertex potential reflects sensory processes. Contrary to this general assumption, we show that the vertex potential is strongly coupled with a modulation of muscular activity that follows the same pattern. Both the vertex potential and its motor effects are not reflexive but strongly depend on contextual factors. These results reconceptualize the significance of these evoked electrocortical responses, suggesting that saliency detection is not merely perceptive but reactive, preparing the animal for subsequent appropriate actions.

Brain Responses to Surprising Stimulus Offsets: Phenomenology and Functional Significance.
Abrupt increases of sensory input (onsets) likely reflect the occurrence of novel events or objects in the environment, potentially requiring immediate behavioral responses. Accordingly, onsets elicit a transient and widespread modulation of ongoing electrocortical activity: the Vertex Potential (VP), which is likely related to the optimisation of rapid behavioral responses. In contrast, the functional significance of the brain response elicited by abrupt decreases of sensory input (offsets) is more elusive, and a detailed comparison of onset and offset VPs is lacking. In four experiments conducted on 44 humans, we observed that onset and offset VPs share several phenomenological and functional properties: they (1) have highly similar scalp topographies across time, (2) are both largely comprised of supramodal neural activity, (3) are both highly sensitive to surprise and (4) co-occur with similar modulations of ongoing motor output. These results demonstrate that the onset and offset VPs largely reflect the activity of a common supramodal brain network, likely consequent to the activation of the extralemniscal sensory system which runs in parallel with core sensory pathways. The transient activation of this system has clear implications in optimizing the behavioral responses to surprising environmental changes.

Local spatial analysis: an easy-to-use adaptive spatial EEG filter.
Spatial EEG filters are widely used to isolate event-related potential (ERP) components. The most commonly used spatial filters (e.g., the average reference and the surface Laplacian) are "stationary." Stationary filters are conceptually simple, easy to use, and fast to compute, but all assume that the EEG signal does not change across sensors and time. Given that ERPs are intrinsically nonstationary, applying stationary filters can lead to misinterpretations of the measured neural activity. In contrast, "adaptive" spatial filters (e.g., independent component analysis, ICA; and principal component analysis, PCA) infer their weights directly from the spatial properties of the data. They are, thus, not affected by the shortcomings of stationary filters. The issue with adaptive filters is that understanding how they work and how to interpret their output require advanced statistical and physiological knowledge. Here, we describe a novel, easy-to-use, and conceptually simple adaptive filter (local spatial analysis, LSA) for highlighting local components masked by large widespread activity. This approach exploits the statistical information stored in the trial-by-trial variability of stimulus-evoked neural activity to estimate the spatial filter parameters adaptively at each time point. Using both simulated data and real ERPs elicited by stimuli of four different sensory modalities (audition, vision, touch, and pain), we show that this method outperforms widely used stationary filters and allows to identify novel ERP components masked by large widespread activity. Implementation of the LSA filter in MATLAB is freely available to download. EEG spatial filtering is important for exploring brain function. Two classes of filters are commonly used: stationary and adaptive. Stationary filters are simple to use but wrongly assume that stimulus-evoked EEG responses (ERPs) are stationary. Adaptive filters do not make this assumption but require solid statistical and physiological knowledge. Bridging this gap, we present local spatial analysis (LSA), an adaptive, yet computationally simple, spatial filter based on linear regression that separates local and widespread brain activity (https://www.iannettilab.net/lsa.html or https://github.com/rorybufacchi/LSA-filter).

INTEGRATED CARDIO-BEHAVIOURAL DEFENSIVE STATES

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Jérémy Signoret-Genest, Nina Schukraft, Sara Reis, Dennis Segebarth, Philip Tovote
University Hospital Würzburg, Institute Of Clinical Neurobiology, Wuerzburg, Germany

Fear and anxiety are brain states that evolved to mediate defensive responses to threat. While it is clear that the defence reaction includes multiple interacting behavioural, autonomic and endocrine adjustments, their integrative nature is poorly understood. In particular, under seemingly identical threat conditions, both deceleration (bradycardia) as well as acceleration (tachycardia) of heart rate (HR) have been reported, hampering consensus on the relevance and meaning of cardiac changes for the integrated defence reaction. By identifying stereotypical behavioural and HR dynamic associations at different timescales and under various conditions, we here define cardio-behavioural, rapid “microstates” and “macrostates”, characterized by slower dynamics. Interestingly, both micro-and macrostates reflect context-dependent threat levels, but we also found that macrostate dynamics can critically affect the expression of the most elemental cardio-behavioural elements (i.e. microstates), encompassing the most common readout for fear, i.e. the freezing response. In turn, optogenetics experiments designed accordingly revealed how integrated cardio-behavioural micro- and macrostates are mediated by specific circuit elements in the midbrain periaqueductal grey. Our work puts forth a framework for systematic integration of cardiac and behavioural readouts that presents the basis for a better understanding of complex neural defensive states and their associated systemic functions.

NEUROBIOLOGICAL CONSEQUENCES OF THE ADOLESCENT EXPOSURE TO THE SYNTHETIC CANNABINOID JWH-018 IN MALE AND FEMALE MICE

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Cristina Izquierdo-Luengo, Marc Ten-Blanco, Maria Ponce-Renilla, Inmaculada Pereda-Perez, Fernando Berrendero
Universidad Francisco de Vitoria, Faculty Of Experimental Sciences, Pozuelo de Alarcón, Spain

Spice/K2 herbal mixtures containing synthetic cannabinoids such as JWH-018, have been marketed as marijuana surrogates. Early abuse of cannabinoids has been related to the development of psychiatric disorders in adulthood as adolescence is a critical period for the maturation of the central nervous system. This study aims to analyze the short and long-term effects of the exposure to JWH-018 during adolescence, on aversive emotional memory, anxiety, and psychotic-like behaviours. Mice were treated from postnatal day 35 to 49 with increasing doses of JWH-018. Short and long-term effects were analyzed 5 and 20 days, respectively, after the end of the treatment. Adolescent treated males, but not females, showed significant anxiety-like behaviour 5 days after treatment. This effect was not maintained at long-term in males. However, JWH-018 administration induced a clear anxiogenic tendency in females. Fear extinction was not modified neither in males nor in females both in short and long-term. Males, but not females, chronically exposed to JWH-018, showed a reduction in pre-pulse inhibition of startle reflex in short and long-term suggesting the development of a psychotic-like behaviour. Alterations in the expression of parvalbumin-containing neurons and perineuronal nets have been associated to changes in the plasticity and maturation of the prefrontal cortex. Therefore, immunohistochemical studies are also being carried out in JWH-018 exposed mice to analyze the expression of these neuronal features in this brain area. To conclude, the exposure to JWH-018 during adolescence leads to the appearance of different behavioural alterations which could be dependent on gender.

EFFECTS OF A NOVEL POSITIVE NMDA RECEPTOR MODULATOR IN A MOUSE MODEL OF IMPAIRED FEAR EXTINCTION

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Eva Maria Fritz[1], Crystle Kelly[2], Katherine Leaderbrand[2], Amanda Barth[2], Harald Murck[2], Nicolas Singewald[1]
[1]University of Innsbruck, Pharmacology & Toxicology, Innsbruck, Austria, [2]Aptinyx Inc., Aptinyx Inc., Evanston, United States of America

Aims: Approved treatments for PTSD, such as antidepressants or cognitive behavioral therapy (CBT), leave many patients with an unsatisfying clinical outcome to control their symptoms. The search for more effective drugs and augmentation strategies for CBT to improve the quality of life of these patients poses a great challenge for preclinical and clinical research. This subgroup of treatment-resistant individuals is closely modeled by the 129S1/SvImJ (S1) inbred mouse strain, which exhibits impaired fear extinction and anxiety-like behaviors. The novel, positive N-methyl-D-aspartate (NMDA) receptor modulator NYX-783 has already shown promising results in exploratory clinical studies in PTSD patients, but has not been tested before in a mouse model of deficient fear extinction. **Methods & Results**: In our experiments, acute NYX-783 administration improved fear extinction in extinction-competent C57BL/6J mice, but had no such effect in S1 animals. Here, NYX-783 strengthened fear memories, most likely because no within-session fear extinction was achieved in this test setting. Interestingly, however, in naïve (not fear-conditioned) S1 mice, NYX-783 had an anxiolytic-like effect in the elevated plus maze. **Conclusions**: In summary, our preliminary data suggest that NYX-783 may acutely reduce anxiety and serve as a powerful cognitive enhancer for emotional memories acquired during drug action, regardless of their valence. Further experiments are needed to determine mechanism and site(s) of action in the brain, as well as to gain more detailed information on how PTSD patients may benefit best from an individualized therapy regimen that utilizes NYX-783 to provide anxiolysis and selectively enhance fear-inhibitory memories. Supported by Aptinyx.

NEUROCIRCUITRY OF SOCIAL FEAR EXTINCTION. INVOLVEMENT OF THE SEPTAL OXYTOCIN SYSTEM?

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Theresa Süß, Inga Neumann, Rohit Menon
University Regensburg, Department Of Neurobiology, Regensburg, Germany

Social anxiety disorder (SAD), is the second most common anxiety disorder and characterized by fear and avoidance of social situations. Understanding the neuronal mechanisms underlying SAD is of utmost importance to develop new therapeutic strategies. Using the social fear conditioning (SFC) paradigm, we identified oxytocin (OXT) signaling within the lateral septum (LS) as a critical regulator of social fear extinction. The LS is reciprocally connected with various brain regions which control different drive states and motivated responses. Therefore, the LS is thought to serve as an essential converging point, that relays incoming cognitive information to downstream affective regions that then adjust the behavioral output in response to varied environmental stimuli. We were able to show, that OXT receptors (OXTR) are expressed in high levels specifically in the caudal part of the LS (LSc). Infusion of OXT in the LSc facilitates social fear extinction, but the exact signaling mechanisms of OXTR-expressing neurons in the LSc in the context of social fear extinction are still unknown. Using a viral anterograde tracer in combination with an OXTR-Cre mouse line, we were able to identify the medial habenula (MHb) as a downstream target of OXTR-expressing neurons. We now aim to identify the functional role of OXTR-expressing neurons in the LSc within the framework of the SFC paradigm using an in vivo calcium imaging approach. This study may provide a deeper understanding on how septal oxytocin signaling modulates emotional states, and might shed light on the mechanisms that underlie the extinction of social fear.

SEX-SPECIFIC DISRUPTION OF SOCIAL, BUT NOT EMOTIONAL BEHAVIOR AFTER SOCIAL TRAUMA IN ADOLESCENT MICE

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Leopold Kinzel[1], Rohit Menon[1], Valery Grinevich[2], Anna Bludau[1], Inga Neumann[1]
[1]University of Regensburg, Neurobiology & Animal Physiology, Regensburg, Germany, [2]University of Heidelberg, Department Of Neuropeptide Research In Psychiatry, Central Institute Of Mental Health, Mannheim, Germany

The developmental period of adolescence is highly vulnerable towards stress, especially social trauma, leading to a higher susceptibility for mental disorders such as social anxiety disorder (SAD). We aimed to investigate the acute and long-lasting effects of adolescent social trauma on socio-emotional behavior and the underlying neuronal mechanisms. Hence, adolescent male and female mice were exposed to the social fear conditioning (SFC) paradigm, a mouse model of social trauma generating social avoidance as symptom of SAD. Social fear extinction was performed either on the subsequent day or in adulthood. To assess neuronal activation and oxytocin receptor (OXTR) binding, SFC mice were subjected to singular social stimuli in either adolescence or adulthood. We confirmed that SFC generates robust social fear in adolescent male and female mice, without affecting general anxiety- and depressive-like behavior. However, SFC exposure in adolescence lead to social fear persisting into adulthood in male mice only. Analyzing the neuronal activation of mice following a social encounter the day after SFC revealed a sex-dependent activity of the lateral septum (LS). Here, SFC mice showed reduced activation within either the ventral LS in females or the dorsal LS in males. Moreover, we found lower OXTR binding within the ventromedial hypothalamus of adult SFC male mice. In conclusion, we demonstrate higher vulnerability of adolescent SFC male compared to female mice with respect to disruption of social behavior during adulthood. Further, adolescent SFC leads to changes in adolescent neuronal activation and the adult oxytocin system, possible contributing factors for SAD development.

Aims Nicotine has been described as the main component of cigarette, which is responsible for a wide variety of neurochemical and behavioral effects. The aims of the present study were to a) investigate the effects of nicotine intake on behavioral parameters (anxiety-like behavior, motility), as well as activity of acetylcholinesterase's (AChE) isoforms (G1, G4) on specific brain regions of adult male mice and b) evaluate, by patch-clamp recordings, the effect of acute slice perfusion of various concentrations (1-10 mM) of nicotine on inhititory and excitatory inputs on hippocampal CA1 neurons. **Methods** Mice were divided into 3 groups: control, cigarettes' smoke and Tobacco Heating System 2.2 (THS2.2') aerosol exposed groups. The exposure was carried out in a unique smoking device with whole body exposure to smoke. The behavioral analysis was assessed by using the open field test, by which anxiety-like behavior and motility will be addressed. The activity of both G1 and G4 AChE's isoforms was determined by using Ellman's colorimetric method. Whole cell patch-clamp recording of spontaneous GABAergic and Glutamatergic currents was performed in CA1 hippocampal neurons. **Results** Our results show that both the smoke and aerosol exposures affected the anxiety-like behavior and inhibits AChE's isoform activity. Moreover, nicotine increases in a dose dependent way both the amplitude and the frequency of glutammatergic or GABAergic currents, respectively, recorded in CA1 neurons **Conclusion** Nicotine exposure inhibits affects anxiety-like behavior, AChE activity in brain areas and may affect hippocampal function and may decrease its function at least when is somministrated acutely.

HARNESSING THE HETEROGENEITY OF FREEZING RESPONSES IN MICE TO UNDERSTAND BIOLOGICAL BASES OF SPECTRUM OF ANXIETY DISORDERS.

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Irina Kovlyagina[1], Anna Wierczeiko[2,3], Hristo Todorov[4], Susanne Gerber[4], Beat Lutz[1,3]
[1]University Medical Center of the Johannes Gutenberg University Mainz, Institute Of Physiological Chemistry, Mainz, Germany, [2]Institute of Human Genetics, University Medical Center Mainz, Mainz, Germany, [3]Leibniz Institute for Resilience Research, Leibniz Association, Mainz, Germany, [4]University Medical Centre of the Johannes Gutenberg University, Institute Of Human Genetics, Mainz, Germany

Preclinical studies rely on functional patterns of defensive behaviors in rodents as basis for conceptualizing human fear/anxiety. However, very often animal models do not account for the role of inter-individual differences of stimulus perception and processing in shaping the behavioral response. By applying cued fear conditioning paradigm with prolonged retrieval session we confirmed that mice respond to fearful stimuli in an individual manner. Using unsupervised clustering approach, we identified 2 distinct endophenotypes (phasic and sustained responders) in the population of wild-type mice (C57BL6/J). The phenotypes are stable at least through two retrievals in both male and female mice. Interestingly, distribution of phasic/sustained responders is 60/30% for males but 30/60% for females consistent with higher occurrence of anxiety disorders in women compared to men. Also freezing behaviour during retrieval correlated with approach-avoidance behavior in anxiety tests. Transcriptomic analysis of key brain regions in defence circuit of phasic (n=6) and sustained (n=6) female responders revealed substantial differences in transcriptomes of ACC, BLA, CeA, and BNST. At 24h post-conditioning time-point (Retrieval I) the largest transcriptomic changes were detected in CeA (2922 DEGs), followed by ACC (378 DEGs). Functional annotation analysis revealed that DEGs from both regions are enriched for genes involved in inflammatory response. Additionally, extracellular matrix organization pathway was significantly deregulated in CeA. Interestingly, when sequencing was repeated using the same brain regions 28d post-conditioning (Retrieval II) the number of DEGs decreased in all regions except BLA, where it almost doubled (140 vs 253 DEGs).

[1]University of Florence, Dipartimento Di Scienze Della Salute, Florence, Italy, [2]University of Florence, Dept Of Neurosciences, Psychology, Drug Research And Child Health (neurofarba), Florence, Italy, [3]University of Florence, Department Of Health Sciences, Firenze, Italy

Background: Exposure to repeated social stress may cause maladaptive emotional reactions. Histaminergic neurotransmission has a central role in orchestrating specific behavioural responses depending on the homeostatic state of a subject, but it remains to be established if it participates in stress susceptibility and resilience. Aim: The study aims at understanding the full implications of activating or silencing hypothalamic histaminergic neurons in the development of cognitive and behavioural impairments induced by repeated exposures to stressful events. Methods: we used the DREADDs-driven technology injecting HDC-Cre male mice bilaterally into the TMN with excitatory or inhibitory DREADDs to transfect histaminergic neurons. Mice underwent the chronic social defeat (CSD) stress protocol for variable periods of time during which they received clozapine N-oxide i.p. daily. Mice were then tested for social interaction and short-term memory by using the novel object recognition test. Results: Chemogenetic activation of histaminergic neurons during a 10-day CSD protocol improved the social interaction index and memory in the novel object recognition test. On the other hand, chemogenetic inhibition of histaminergic neurons during a 3-day CSD worsened the social interaction index and short-term memory. Conclusions: Our data strongly suggest that the chemogenetic activation of TMN^{HA} neurons confers a pro-resilient phenotype to repeated exposure to stressful events, whereas their inactivation renders the subject more susceptible. Our results pave the way for future studies to deconstruct specific histaminergic neural pathways involved in the observed effects and may open new strategies for the treatment of specific maladaptive behaviours manifested in psychiatric disorders.

Aim: Amphetamine is an indirect dopamine agonist with generally performance enhancing effects, tested here in an appetitive within-subjects inhibitory learning (A+/AX-) procedure (Waite *et al*. 10.1016/j.physbeh.2021.113557). **Methods:** Excitatory training was followed by inhibitory discrimination, summation and retardation test stages. Experiments 2-3 included some variations in the behavioural procedure, e.g. increased inter-trial-interval. D-amphetamine (sub-cutaneous) was administered at inhibitory discrimination and summation in Experiments 1-2 and before summation and retardation tests in Experiment 3. Data were analysed in mixed ANOVAs with between-subjects factors of dose (Experiment 1: 1.5mg/kg, 1mg/kg and saline and Experiments 2-3: 1.0mg/kg, 0.5mg/kg and saline). **Results:** Experiment 1 showed no clear inhibitory discrimination (A+/AX-) across groups, an overall effect of dose because of reduced nose-poking at 1.5mg/kg, but no interaction between dose and discrimination. The expression of inhibitory learning at the retardation test was impaired in animals which acquired the inhibitory discrimination under *d*-amphetamine (1.5mg/kg). Experiment 2 showed overall clear inhibitory discrimination, and nose-poking was generally increased at 0.5mg/kg, but there was no expression of inhibitory learning at the drug-free retardation test. In Experiment 3, the inhibitory discrimination was learned, but there was no expression of inhibitory learning (now under drug) at retardation. In all experiments, the summation test was overall passed by the weak control (C>CX). **Conclusions:** D-amphetamine had dose-dependent effects, though these differed in profile by experiment: 1.5mg/kg reduced and 0.5mg/kg increased nose-poking. Despite these shifts in baseline responding, there were no consistent effects of d-amphetamine on the acquisition of inhibitory discrimination, summation or retardation test performance.

Strain comparisons in inhibitory discrimination learning and novel object recognition procedures.
Strain differences in visual abilities and exploratory tendencies can confound rats' performance in cognitive tests of learning and memory. In the present study we compared the performance of albino Wistar and pigmented Lister Hooded rats in appetitive conditioning and recognition memory procedures, specifically within-subjects inhibitory learning (A+ /AX-) and novel object recognition (NOR) variants. The inhibition task included an excitatory training stage and summation and retardation tests. Difference scores were used to help control for individual variation in baseline nosepoke responding. NOR was tested after a 10 min delay, following 24hr delay and using a recency variant. Discrimination ratios were used to control for individual variation in exploratory activity. In the inhibitory learning procedure, Lister Hooded showed more magazine activity prior to stimulus presentations than Wistar rats but this was a transient effect restricted to day 1 of excitatory training. There was no strain difference in associative learning at the excitatory training stage. The Wistars went on to show some performance advantage at the inhibitory discrimination stage and marginally stronger retardation test performance. In the NOR tasks, there was no significant effect of strain on cognitive performance, but the Wistars showed some advantage in the 10 min delay variant, whereas in the 24hr delay and relative recency NOR variants, the Lister Hooded rats showed some advantage. Overall the results of the present study confirm the suitability of Wistar rats for use in associative learning and basic NOR procedures.

The Role of Vitamin D_3 in the Development and Neuroprotection of Midbrain Dopamine Neurons.
Vitamin D has long been synonymous with bone health. More recently, new health benefits are continually being associated with vitamin D, including a burgeoning field on neuroprotective properties. This has generated a huge explosion of interest in recent years in the potential for vitamin D to be used not only as a therapeutic in neurodegenerative disease, including

Parkinson's disease, but also as biomarkers and for risk association. With an emphasis on Parkinson's disease, this chapter will discuss recent evidence supporting the assertion that vitamin D can be a useful therapeutic agent used as an intervention therapy to be combined with existing treatments; and the case for further development of novel treatments utilizing the potential of vitamin D. In addition, we present novel, previously unpublished evidence showing that in a unilateral model of Parkinson's disease, vitamin D can not only reduce the extent of denervation, but that this is also reflected in functional benefit to the animals. The potential of vitamin D is slowly being realized; in the future, it will be widely associated with far more than just bone health and may even contribute to an elusive treatment of neurodegenerative illness.

SYNAPTIC INTEGRATION IN THE MOUSE MIDBRAIN DURING INSTINCTIVE DEFENSIVE BEHAVIOUR

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Yaara Lefler, Goncalo Ferreira, Yeqing Wang, Tiago Branco
UCL, Sainsbury Wellcome Centre, London, United Kingdom

When faced with threat, animals instinctively react with defensive behaviours, such as escape to a safe place or freezing in a motionless crouching posture. It has recently been shown that activation of neurons in the dorsal periaqueductal gray (dPAG) is the main step for commanding escape initiation. The biophysical and synaptic integration properties in these neurons are therefore critical for controlling escape behaviour but they have not been measured in behaving animals. Here we have investigated how synaptic inputs are integrated during escape initiation and how this process is modulated in conditions that suppress or enhance the likelihood of escape. We have developed a paradigm where awake head-restrained mice navigate between a shelter and a threat zone while exposed to sensory stimuli mimicking approaching predators. Using whole-cell recordings from dPAG neurons we characterized synaptic responses during threat presentation and escape initiation. We found that escape-eliciting stimuli cause depolarizations that are temporally summated across stimuli repetitions and are correlated with escape vigour. Presentation of stimuli that increase escape probability caused sustained depolarization that lasted for several seconds and reduced the amount of synaptic input needed to reach action potential threshold. Conversely, freezing-eliciting stimuli caused hyperpolarization, indicating that escape initiation is actively suppressed by inhibitory input. Our findings suggest that modulating the baseline rate of excitatory and inhibitory synaptic input onto dPAG neurons bidirectionally control the escape initiation threshold. These modulations provide a means for rapid adjustments of escape threshold and may thus be a crucial element supporting survival in dynamic environments.

Most studies on the neural bases of extinction learning dealt with the phenomenon of extinction learning from the perspective of aversive conditioning. However, the neural bases underlying the altered behavioural responses in natural or everyday forms of extinction learning is still controversial. Extinction of appetitive associations is indeed a key to understanding clinical disorders such as abnormal persistent appetite, contextual drug associations and some psychotic symptoms in which failure of extinction may play a major role. Psychosis disorders such as schizophrenia or bipolar disorders affect 3% of the population. These patients present symptoms as delusions and hallucinations that are related to extinction learning (EL) failures. While it is known that psychosis is accompanied by changes in neuronal excitability and synaptic plasticity, the neural circuits modifications associated with the cognitive impairments remain largely unknown In this study, we investigated the extinction and reactivation of a pavlovian conditioned response in the hemizigotic deletion rat model (cacna1c $^{+}/_{-}$). This gene plays an important role in regulating gene expression of L-Type Voltage-Gated Calcium Channels involved in synaptic plasticity and learning, being strongly associated by GWAS with Schizophrenia and Bipolar Disorder. Here, we used fluorescence in situ hybridization of somatic immediate early gene (IEG) expression to scrutinize genotype related brain regional changes at the prefrontal cortex and amygdaloid nuclei in the psychosis model as compared to healthy subjects.

Hippocampal neuropeptide Y receptor blockade improves spatial memory retrieval and modulates limbic brain metabolism.
The neuropeptide Y (NPY) is broadly distributed in the central nervous system (CNS), and it has been related to neuroprotective functions. NPY seems to be an important component to counteract brain damage and cognitive impairment mediated by drugs of abuse and neurodegenerative diseases, and both NPY and its Y receptor (YR) are highly expressed in the hippocampus, critical for learning and memory. We have recently demonstrated its influence on cognitive functions; however, the specific mechanism and involved brain regions where NPY modulates spatial memory by acting on YR remain unclear.

Genetic Depletion of BDNF Impairs Extinction Learning of a Spatial Appetitive Task in the Presence or Absence of the Acquisition Context.
Brain derived neurotropic factor (BDNF) supports neuronal survival, growth, and differentiation and is involved in forms of hippocampus-dependent and independent learning, as well as hippocampus-dependent learning. Extinction learning comprises active inhibition of no-longer relevant learned information, in conjunction with a decreased response of a previously learned behavior. It is highly dependent on context, and evidence exists that it requires hippocampal activation. The participation of BDNF in memory processing is experience-dependent. For example, BDNF has been associated with synaptic plasticity needed for spatial learning, and it is involved in acquisition and extinction learning of fear conditioning. However, little is known about its role in spatial appetitive extinction learning. In this study, we evaluated to what extent BDNF contributes to spatial appetitive extinction learning in the presence (ABA) or absence (AAA) of exposure to the acquisition context. Daily training, of BDNF-mice or their wildtype (WT) littermates, to reach acquisition criterion in a T-maze, resulted in a similar performance outcome. However, extinction learning was delayed in the AAA, and impaired in the ABA-paradigm compared to performance in WT littermates. Trial-by-trial learning analysis indicated differences in the integration of the

context into extinction learning by BDNF-mice compared to WT littermates. Taken together, these results support an important role for BDNF in processes that relate to information updating and retrieval that in turn are crucial for effective extinction learning.

Metaplastic contribution of neuropeptide Y receptors to spatial memory acquisition.
Neuropeptide Y (NPY) is highly abundant in the brain and is released as a co-transmitter with plasticity-related neurotransmitters such as glutamate, GABA and noradrenaline. Functionally, its release is associated with appetite, anxiety, and stress regulation. NPY acting on Y2 receptors (YR), facilitates fear extinction, suggesting a role in associative memory. Here, we explored to what extent NPY action at YR contributes to hippocampus-dependent spatial memory and found that dorsal intrahippocampal receptor antagonism improved spatial reference memory acquired in a water maze in rats, without affecting anxiety levels, or spontaneous motor activity. Water maze training resulted in an increase of YR, but not YR expression in the hippocampus. By contrast, in the prefrontal cortex there was a decrease in YR, and an increase of YR expression. Our results indicate that neuropeptide YR are significantly involved in hippocampus-dependent spatial memory and that receptor expression is dynamically regulated by this learning experience. Effects are consistent with a metaplastic contribution of NPY receptors to cumulative spatial learning.

Functional Compartmentalization of the Contribution of Hippocampal Subfields to Context-Dependent Extinction Learning.
During extinction learning (EL), an individual learns that a previously learned behavior no longer fulfills its original purpose, or is no longer relevant. Recent studies have contradicted earlier theories that EL comprises forgetting, or the inhibition of the previously learned behavior, and indicate that EL comprises new associative learning. This suggests that the hippocampus is involved in this process. Empirical evidence is lacking however. Here, we used fluorescence hybridization of somatic immediate early gene (IEG) expression to scrutinize if the hippocampus processes EL. Rodents engaged in context-dependent EL and were also tested for renewal of (the original behavioral response to) a spatial appetitive task in a T-maze. Whereas distal and proximal CA1 subfields processed both EL and renewal, effects in the proximal CA1 were more robust consistent with a role of this subfield in processing context. The lower blade of the dentate gyrus (DG) and the proximal CA3 subfields were particularly involved in renewal. Responses in the distal and proximal CA3 subfields suggest that this hippocampal subregion may also contribute to the evaluation of the reward outcome. Taken together, our findings provide novel and direct evidence for the involvement of distinct hippocampal subfields in context-dependent EL and renewal.

Spatial memory extinction differentially affects dorsal and ventral hippocampal metabolic activity and associated functional brain networks.
Previous studies showed the involvement of brain regions associated with both spatial learning and associative learning in spatial memory extinction, although the specific role of the dorsal and ventral hippocampus and the extended hippocampal system including the mammillary body in the process is still controversial. The present study aimed to identify the involvement of the dorsal and ventral hippocampus, together with cortical regions, the amygdaloid nuclei, and the mammillary bodies in the extinction of a spatial memory task. To address these issues, quantitative cytochrome c oxidase histochemistry was applied as a metabolic brain mapping method. Rats were trained in a reference memory task using the Morris water maze, followed by an extinction procedure of the previously acquired memory task. Results show that rats learned successfully the spatial memory task as shown by the progressive decrease in measured latencies to reach the escape platform and the results obtained in the probe test. Spatial memory was subsequently extinguished as shown by the descending preference for the previously reinforced location. A control naïve group was added to ensure that brain metabolic changes were specifically related with performance in the spatial memory extinction task. Extinction of the original spatial learning task significantly modified the metabolic activity in the dorsal and ventral hippocampus, the amygdala and the mammillary bodies. Moreover, the ventral hippocampus, the lateral mammillary body and the retrosplenial cortex were differentially recruited in the spatial memory extinction task, as shown by group differences in brain metabolic networks. These findings provide new insights on the brain regions and functional brain networks underlying spatial memory, and specifically spatial memory extinction. © 2016 Wiley Periodicals, Inc.

Brain functional network changes following Prelimbic area inactivation in a spatial memory extinction task.
Several studies suggest a prefrontal cortex involvement during the acquisition and consolidation of spatial memory, suggesting an active modulating role at late stages of acquisition processes. Recently, we have reported that the prelimbic and infralimbic areas of the prefrontal cortex, among other structures, are also specifically involved in the late phases of spatial memory extinction. This study aimed to evaluate whether the inactivation of the prelimbic area of the prefrontal cortex impaired spatial memory extinction. For this purpose, male Wistar rats were implanted bilaterally with cannulae into the prelimbic region of the prefrontal cortex. Animals were trained during 5 consecutive days in a hidden platform task and tested for reference spatial memory immediately after the last training session. One day after completing the training task, bilateral infusion of the GABAA receptor agonist Muscimol was performed before the extinction protocol was carried out. Additionally, cytochrome c oxidase histochemistry was applied to map the metabolic brain activity related to the spatial memory extinction under prelimbic cortex inactivation. Results show that animals acquired the reference memory task in the water maze, and the extinction task was successfully completed without significant impairment. However, analysis of the functional brain networks involved by cytochrome oxidase activity interregional correlations showed changes in brain networks between the group treated with Muscimol as compared to the saline-treated group, supporting the involvement of the mammillary bodies at a the late stage in the memory extinction process.

Functional interactions between dentate gyrus, striatum and anterior thalamic nuclei on spatial memory retrieval.
The standard model of memory system consolidation supports the temporal reorganization of brain circuits underlying long-term memory storage, including interactions between the dorsal hippocampus and extra-hippocampal structures. In addition, several brain regions have been suggested to be involved in the retrieval of spatial memory. In particular, several authors reported a possible role of the ventral portion of the hippocampus together with the thalamus or the striatum in the persistence of this type of memory. Accordingly, the present study aimed to evaluate the contribution of different cortical and subcortical brain regions, and neural networks involved in spatial memory retrieval. For this purpose, we used cytochrome c oxidase quantitative histochemistry as a reliable method to measure brain oxidative metabolism. Animals were trained in a hidden platform task and tested for memory retention immediately after the last training session; one week after completing the task, they were also tested in a memory retrieval probe. Results showed that retrieval of the previously learned task was associated with increased levels of oxidative metabolism in the prefrontal cortex, the dorsal and ventral striatum, the anterodorsal thalamic nucleus and the dentate gyrus of the dorsal and ventral hippocampus. The analysis of functional interactions between brain regions suggest that the dorsal and ventral dentate gyrus could be involved in spatial memory retrieval. In addition, the results highlight the key role of the extended hippocampal system, thalamus and striatum in this process. Our study agrees with previous ones reporting interactions between the dorsal hippocampus and the prefrontal cortex during spatial memory retrieval. Furthermore, novel activation patterns of brain networks involving the aforementioned regions were found. These functional brain networks could underlie spatial memory retrieval evaluated in the Morris water maze task.

Spatial memory extinction: a c-Fos protein mapping study.
While the neuronal basis of spatial memory consolidation has been thoroughly studied, the substrates mediating the process of extinction remain largely unknown. This study aimed to evaluate the functional contribution of selected brain regions during the extinction of a previously acquired spatial memory task in the Morris water maze. For that purpose, we used adult male Wistar rats trained in a spatial reference memory task. Learning-related changes in c-Fos inmunoreactive cells after training were evaluated in cortical and subcortical regions. Results show that removal of the hidden platform in the water maze induced extinction of the previously reinforced escape behavior after 16 trials, without spontaneous recovery 24h later. Extinction was related with significantly higher numbers of c-Fos positive nuclei in amygdala nuclei and prefrontal cortex. On the other hand, the lateral mammillary bodies showed higher number of c-Fos positive cells than the control group. Therefore, in contrast with the results obtained in studies of classical conditioning, we show the involvement of diencephalic structures mediating this kind of learning. In summary, our findings suggest that medial prefrontal cortex, the amygdala complex and diencephalic structures like the lateral mammillary nuclei are relevant for the extinction of spatial memory.

Hippocampal inactivation with TTX impairs long-term spatial memory retrieval and modifies brain metabolic activity.
Functional inactivation techniques enable studying the hippocampal involvement in each phase of spatial memory formation in the rat. In this study, we applied tetrodotoxin unilaterally or bilaterally into the dorsal hippocampus to evaluate the role of

this brain structure in retrieval of memories acquired 28 days before in the Morris water maze. We combined hippocampal inactivation with the assessment of brain metabolism using cytochrome oxidase histochemistry. Several brain regions were considered, including the hippocampus and other related structures. Results showed that both unilateral and bilateral hippocampal inactivation impaired spatial memory retrieval. Hence, whereas subjects with bilateral hippocampal inactivation showed a circular swim pattern at the side walls of the pool, unilateral inactivation favoured swimming in the quadrants adjacent to the target one. Analysis of cytochrome oxidase activity disclosed regional differences according to the degree of hippocampal functional blockade. In comparison to control group, animals with bilateral inactivation showed increased CO activity in CA1 and CA3 areas of the hippocampus during retrieval, while the activity of the dentate gyrus substantially decreased. However, unilateral inactivated animals showed decreased CO activity in Ammon's horn and the dentate gyrus. This study demonstrated that retrieval recruits differentially the hippocampal subregions and the balance between them is altered with hippocampal functional lesions.

INHIBITION OF THE AGE-RELATED METABOLIC RISK FACTOR QUINONE REDUCTASE 2 (QR2) REDUCES BRAIN PATHOLOGIES AND IMPROVES MEMORY OF AGED ALZHEIMER'S DISEASE MODEL MICE

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Nathaniel Gould, Kobi Rosenblum
Haifa University, Neurobiology, Haifa, Israel

The main risk factor for developing neurodegenerative diseases, including Alzheimer's disease (AD), is biological ageing, namely, the prolonged and accumulating metabolic stress within cells, tissues and organs. Finding targetable processes contributing to age-related metabolic stress, that will serve at the same time as a cognitive enhancers, is therefore of major importance. We have recently found that the age-related metabolic risk factor quinone reductase 2 (QR2) functions in the brain. Normally, QR2 acts as a metabolic buffer, downstream of acetylcholine (ACh) or dopamine (DA), depending on brain region and sensory input. Following a salient experience ACh/DA release drive removal of QR2 via micro-RNA-182 (miR-182), which reduces physiological levels of reactive oxygen species (ROS) that QR2 generates within cells. This affects neuronal intrinsic properties, primarily reducing interneuron excitability, thus enabling a transient shift in brain excitation/inhibition balance. The outcome is enhanced memory for salient/important events, which makes them stand out compared to more trivial information, for example - "first time" experiences. However, with age DA/ACh and miR-182 are diminished, while QR2 is overexpressed. This natural process places QR2 as a potentially novel contributor to AD aetiology. We therefore developed novel, selective, non-toxic and orally bioavailable QR2 inhibitors (QR2i), and evaluated their effect on wild-type- as well as aged, AD model mice. We found that mice were able to perform significantly better in a number of memory tasks, while brain pathologies were significantly reduced. QR2i, therefore, represent a novel way to reduce age-related metabolic stress, and a potential AD drug target.

Somatostatin Interneurons of the Insula Mediate QR2-Dependent Novel Taste Memory Enhancement.
Forming long-term memories is crucial for adaptive behavior and survival in changing environments. The molecular consolidation processes which underlie the formation of these long-term memories are dependent on protein synthesis in excitatory and SST-expressing neurons. A centrally important, parallel process to this involves the removal of the memory constraint quinone reductase 2 (QR2), which has been recently shown to enhance memory consolidation for novel experiences in the cortex and hippocampus, via redox modulation. However, it is unknown within which cell type in the cortex removal of QR2 occurs, nor how this affects neuronal function. Here, we use novel taste learning in the mouse anterior insular cortex (aIC) to show that similarly to mRNA translation, QR2 removal occurs in excitatory and SST-expressing neurons. Interestingly, both novel taste and QR2 inhibition reduce excitability specifically within SST, but not excitatory neurons. Furthermore, reducing QR2 expression in SST, but not in PV or excitatory neurons, is sufficient to enhance taste memory. Thus, QR2 mediated intrinsic property changes of SST interneurons in the aIC is a central removable factor to allow novel taste memory formation. This previously unknown involvement of QR2 and SST interneurons in resetting aIC activity hours following learning, describes a molecular mechanism to define cell circuits for novel information. Therefore, the QR2 pathway in SST interneurons provides a fresh new avenue by which to tackle age-related cognitive deficits, while shedding new light onto the functional machinations of long-term memory formation for novel information.

Dopamine-Dependent QR2 Pathway Activation in CA1 Interneurons Enhances Novel Memory Formation.
The formation of memory for a novel experience is a critical cognitive capacity. The ability to form novel memories is sensitive to age-related pathologies and disease, to which prolonged metabolic stress is a major contributing factor. Presently, we describe a dopamine-dependent redox modulation pathway within the hippocampus of male mice that promotes memory consolidation. Namely, following novel information acquisition, quinone reductase 2 (QR2) is suppressed by miRNA-182 (miR-182) in the CA1 region of the hippocampus via dopamine D1 receptor (D1R) activation, a process largely facilitated by locus coeruleus activity. This pathway activation reduces ROS generated by QR2 enzymatic activity, a process that alters the

intrinsic properties of CA1 interneurons 3 h following learning, in a form of oxidative eustress. Interestingly, novel experience decreases QR2 expression predominately in inhibitory interneurons. Additionally, we find that in aged animals this newly described QR2 pathway is chronically under activated, resulting in miR-182 underexpression and QR2 overexpression. This leads to accumulative oxidative stress, which can be seen in CA1 via increased levels of oxidized, inactivated potassium channel Kv2.1, which undergoes disulfide bridge oligomerization. This newly described interneuron-specific molecular pathway lies alongside the known mRNA translation-dependent processes necessary for long-term memory formation, entrained by dopamine in CA1. It is a process crucial for the distinguishing features of novel memory, and points to a promising new target for memory enhancement in aging and age-dependent diseases. One way in which evolution dictates which sensory information will stabilize as an internal representation, relies on information novelty. Dopamine is a central neuromodulator involved in this process in the mammalian hippocampus. Here, we describe for the first time a dopamine D1 receptor-dependent quinone reductase 2 pathway in interneurons. This is a targeted redox event necessary to delineate a novel experience to a robust long-term internal representation. Activation of this pathway alone can explain the effect novelty has on "flashbulb" memories, and it can become dysfunctional with age and diseases, such as Alzheimer's disease.

Muscarinic-Dependent miR-182 and QR2 Expression Regulation in the Anterior Insula Enables Novel Taste Learning.

In a similar manner to other learning paradigms, intact muscarinic acetylcholine receptor (mAChR) neurotransmission or protein synthesis regulation in the anterior insular cortex (aIC) is necessary for appetitive taste learning. Here we describe a parallel local molecular pathway, where GABA receptor control of mAChR activation causes upregulation of miRNA-182 and quinone reductase 2 (QR2) mRNA destabilization in the rodent aIC. Damage to long-term memory by prevention of this process, with the use of mAChR antagonist scopolamine before novel taste learning, can be rescued by local QR2 inhibition, demonstrating that QR2 acts downstream of local muscarinic activation. Furthermore, we prove for the first time the presence of endogenous QR2 cofactors in the brain, establishing QR2 as a functional reductase there. In turn, we show that QR2 activity causes the generation of reactive oxygen species, leading to modulation in Kv2.1 redox state. QR2 expression reduction therefore is a previously unaccounted mode of mAChR-mediated inflammation reduction, and thus adds QR2 to the cadre of redox modulators in the brain. The concomitant reduction in QR2 activity during memory consolidation suggests a complementary mechanism to the well established molecular processes of this phase, by which the cortex gleans important information from general sensory stimuli. This places QR2 as a promising new target to tackle neurodegenerative inflammation and the associated impediment of novel memory formation in diseases such as Alzheimer's disease.

D1 Dopamine Receptor Activation Induces Neuronal eEF2 Pathway-Dependent Protein Synthesis.

Dopamine, alongside other neuromodulators, defines brain and neuronal states, through regulation of global and local mRNA translation. Yet, the signaling pathways underlying the effects of dopamine on mRNA translation and psychiatric disorders are not clear. In order to examine the molecular pathways downstream of dopamine receptors, we used genetic, pharmacologic, biochemical, and imaging methods, and found that activation of dopamine receptor D1 but not D2 leads to rapid dephosphorylation of eEF2 at Thr but not eIF2α in cortical primary neuronal culture in a time-dependent manner. NMDA receptor, mTOR, and ERK pathways are upstream of the D1 receptor-dependent eEF2 dephosphorylation and essential for it. Furthermore, D1 receptor activation resulted in a major reduction in dendritic eEF2 phosphorylation levels. D1-dependent eEF2 dephosphorylation results in an increase of BDNF and synapsin2b expression which was followed by a small yet significant increase in general protein synthesis. These results reveal the role of dopamine D1 receptor in the regulation of eEF2 pathway translation in neurons and present eEF2 as a promising therapeutic target for addiction and depression as well as other psychiatric disorders.

Parvalbumin interneuron inhibition onto anterior insula neurons projecting to the basolateral amygdala drives aversive taste memory retrieval.

Memory retrieval refers to the fundamental ability of organisms to make use of acquired, sometimes inconsistent, information about the world. Although memory acquisition has been studied extensively, the neurobiological mechanisms underlying memory retrieval remain largely unknown. Conditioned taste aversion (CTA) is a robust associative paradigm, through which animals can be trained to express aversion toward innately appetitive tastants. The anterior insula (aIC) is indispensable in the ability of mammals to retrieve associative information regarding tastants that have been previously linked with gastric malaise. Here, we show that CTA memory retrieval promotes cell-type-specific activation in the aIC. Using chemogenetic tools in the aIC, we found that CTA memory acquisition requires activation of excitatory neurons and inhibition of inhibitory neurons, whereas retrieval necessitates activation of both excitatory and inhibitory aIC circuits. CTA memory retrieval at the

aIC activates parvalbumin (PV) interneurons and increases synaptic inhibition onto activated pyramidal neurons projecting to the basolateral amygdala (aIC-BLA). Unlike innately appetitive taste memory retrieval, CTA retrieval increases synaptic inhibition onto aIC-BLA-projecting neurons that is dependent on activity in aIC PV interneurons. PV aIC interneurons coordinate CTA memory retrieval and are necessary for its dominance when conflicting internal representations are encountered over time. The reinstatement of CTA memories following extinction is also dependent on activation of aIC PV interneurons, which increase the frequency of inhibition onto aIC-BLA-projecting neurons. This newly described interaction of PV and a subset of excitatory neurons can explain the coherency of aversive memory retrieval, an evolutionary pre-requisite for animal survival.

Insula to mPFC reciprocal connectivity differentially underlies novel taste neophobic response and learning in mice.
To survive in an ever-changing environment, animals must detect and learn salient information. The anterior insular cortex (aIC) and medial prefrontal cortex (mPFC) are heavily implicated in salience and novelty processing, and specifically, the processing of taste sensory information. Here, we examined the role of aIC-mPFC reciprocal connectivity in novel taste neophobia and memory formation, in mice. Using pERK and neuronal intrinsic properties as markers for neuronal activation, and retrograde AAV (rAAV) constructs for connectivity, we demonstrate a correlation between aIC-mPFC activity and novel taste experience. Furthermore, by expressing inhibitory chemogenetic receptors in these projections, we show that aIC-to-mPFC activity is necessary for both taste neophobia and its attenuation. However, activity within mPFC-to-aIC projections is essential only for the neophobic reaction but not for the learning process. These results provide an insight into the cortical circuitry needed to detect, react to- and learn salient stimuli, a process critically involved in psychiatric disorders.

MITOCHONDRIA, ADULT HIPPOCAMPAL NEUROGENESIS, AND ANXIETY

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Elias Gebara[1], Thomas Larrieu[2], Nicolas Toni[2], Carmen Sandi[1]
[1]Ecole Polytechnique Federale de Lausanne, Brain Mind Institute, Lausanne, Switzerland, [2]Lausanne University Hospital, Department Of Psychiatry, Center For Psychiatric Neurosciences, Prilly, Switzerland

Hippocampal adult neurogenesis involves the generation of new granule neurons in the dentate gyrus and this process has been linked to hippocampal-related behaviors, such as spatial navigation, learning, anxiety, stress regulation, and social cognition. Adult hippocampal neurogenesis is increased by antidepressants, and is required for some of their behavioral effects. However, it remains unclear whether expanding the population of adult-born neurons is sufficient to affect anxiety and depression-related behaviors. Emerging evidence indicates that mitochondria can regulate stem cell fate decisions and are crucial for adult neurogenesis. Nevertheless, the role of both mitochondrial molecular components as well as their functions in adult neurogenesis remains barely understood. In this study, we investigated the molecular underpinnings that link basal anxiety with differences in mitochondrial function in stem cells and newly generated neurons in the dentate gyrus. To this end, we exploited an animal model of natural diversity in anxiety trait and applied different behavioral manipulations (i.e., spontaneous wheel running; chronic stress) to modulate both anxiety and neurogenesis. Our results identify molecules implicated in mitochondrial dynamics as differently expressed in the dentate gyrus of high and low anxious rats. These differences were observed along with variation in mitochondrial respiration. Our findings provide critical information to understand how anxiety affects adult neurogenesis and which factors are important for the regulation of neural stem cell proliferation and the generation of neurons.

THE ROLE OF PREFRONTAL SOMATOSTATIN INTERNEURONS AND NEUROTROPHIN SIGNALING IN STRESS COPING

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Máté Tóth[1], Bendegúz Varga[2], Mano Aliczki[2], Gyula Balla[2], Zoltan K Varga[3], Eva Mikics[2]

Aims. Adequate coping during stressful challenges are essential to adapt, hence, it is regulated by highly conserved brain mechanisms. Alterations of this circuit contribute to the development of affective disorders characterized by shifts towards passive coping (avoidance, inactivity). Accumulating evidence show significant alterations in prefrontal networks with marked changes in somatostatin (SST) interneurons involving altered neurotrophic signaling (Brain-derived neurotrophic factor-BDNF) under these conditions, however causal pathogenetic mechanisms are to be clarified. Methods. We investigated how SST neuron-specific knockout of the tyrosine receptor kinase B (TrkB) receptors alters coping behavior using sst-ires-cre x $TrkB^{flox/flox}$ transgenic male mice (SST-TrkB-CKO). We assessed coping in the Forced swim, Tail suspension, and Back tests. We assessed whole-brain activity using immunohistochemical labeling of c-Fos and other cell-type markers with subsequent quantification of signal counts by an automated method. We also explored major gene expression changes related to TrkB dysfunction using qPCR in order to uncover subcellular mechanisms. Results. We found that TrkB dysfunction of SST neurons resulted in significantly increased active coping indicated by reduced immobility in all tests. We identified complex network alterations involving neuronal populations e.g. in the amygdala, hippocampus and sensory systems. We also describe expression changes of major gene candidates altered by TrkB dysfunction. Conclusions. Altered development of prefrontal SST neurons and their altered neurotrophin signaling pathways significantly modulates coping responses. Accordingly, these subcellular and neuronal network alterations can contribute to the development of affective disorders characterized by dominant passive coping.

FUNCTIONAL DISSOCIATION OF VENTRAL HIPPOCAMPAL INHIBITORY CIRCUITS DURING ANXIETY AND FEAR BEHAVIORS

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Kaizhen Li, Stéphane Ciocchi
Universität Bern, Laboratory Of Systems Neuroscience, Department Of Physiology, Bern, Switzerland

The ability to predict potentially harmful environments and escape from dangerous circumstances is vital for wildlife. Mounting evidence suggests that while the dorsal subdivision of the hippocampus is associated with spatial and episodic memory formation, the ventral hippocampus is mostly involved in emotional behaviors. However, the neural circuits and mechanisms within the ventral hippocampus underlying innate or learned emotional behaviors are poorly understood. In the present work, we investigated whether anxiety and conditioned fear are represented by distinct ventral CA1 (vCA1) neural circuits. By utilizing cell-type-specific expression of calcium indicator GCaMPs and in vivo calcium imaging in freely behaving mice via miniature fluorescence microscope, we monitored the neuronal activity of vCA1 pyramidal cells and three sub-classes of GABAergic interneurons (PV+, VIP+, and SST+) during innate anxiety and conditioned fear behaviors. Our data indicated that vCA1 pyramidal cells and interneurons have distinct activity patterns during anxiety and fear behaviors. Different subpopulations of vCA1 pyramidal cells showed preferential responses to either anxiogenic experiences or fear-conditioned cues. The majority of PV+ interneurons were recruited during anxiety behavior but barely during a cued fear test. By contrast, about half of VIP+ interneurons were involved in conditioned fear learning but not in anxiety behaviors, while SST+ interneurons displayed inhibition during fear learning, suggesting that an inhibitory microcircuit may gate pyramidal cell activity during fear conditioning. Altogether, our data suggested a division of labor among various vCA1 GABAergic interneurons during different forms of emotional behaviors.

Spontaneous calcium transients in the immature adult-born neurons of the olfactory bulb.
Spontaneous neuronal activity and concomitant intracellular Ca signaling are abundant during early perinatal development and are well known for their key role in neuronal proliferation, migration, differentiation and wiring. However, much less is known about the in vivo patterns of spontaneous Ca signaling in immature adult-born cells. Here, by using two-photon Ca imaging, we analyzed spontaneous in vivo Ca signaling in adult-born juxtaglomerular cells of the mouse olfactory bulb over the time period of 5 weeks, from the day of their arrival in the glomerular layer till their stable integration into the preexisting neural network. We show that spontaneous Ca transients are ubiquitously present in adult-born cells right after their arrival, require activation of voltage-gated Na channels and are little sensitive to isoflurane anesthesia. Interestingly, several parameters of this spontaneous activity, such as the area under the curve, the time spent in the active state as well as the fraction of continuously active cells show a bell-shaped dependence on cell's age, all peaking in 3-4 weeks old cells. This data firmly document the in vivo presence of spontaneous Ca signaling during the layer-specific maturation of adult-born neurons in the olfactory bulb and motivate further analyses of the functional role(s) of this activity.

Coupled Proliferation and Apoptosis Maintain the Rapid Turnover of Microglia in the Adult Brain.
Microglia play key roles in brain development, homeostasis, and function, and it is widely assumed that the adult population is long lived and maintained by self-renewal. However, the precise temporal and spatial dynamics of the microglial population are unknown. We show in mice and humans that the turnover of microglia is remarkably fast, allowing the whole population to be renewed several times during a lifetime. The number of microglial cells remains steady from late postnatal stages until aging and is maintained by the spatial and temporal coupling of proliferation and apoptosis, as shown by pulse-chase studies, chronic in vivo imaging of microglia, and the use of mouse models of dysregulated apoptosis. Our results reveal that the microglial population is constantly and rapidly remodeled, expanding our understanding of its role in the maintenance of brain homeostasis.

Long-term in vivo single-cell tracking reveals the switch of migration patterns in adult-born juxtaglomerular cells of the mouse olfactory bulb.
The behavior of adult-born cells can be easily monitored in cell culture or in lower model organisms, but longitudinal observation of individual mammalian adult-born cells in their native microenvironment still proves to be a challenge. Here we have established an approach named optical cell positioning system for long-term in vivo single-cell tracking, which integrates red-green-blue cell labeling with repeated angiography. By combining this approach with in vivo two-photon imaging technique, we characterized the in vivo migration patterns of adult-born neurons in the olfactory bulb. In contrast to the traditional view of mere radial migration of adult-born cells within the bulb, we found that juxtaglomerular cells switch from radial migration to long distance lateral migration upon arrival in their destination layer. This unique long-distance lateral migration has characteristic temporal (stop-and-go) and spatial (migratory, unidirectional or multidirectional) patterns, with a clear cell age-dependent decrease in the migration speed. The active migration of adult-born cells coincides with the time period of initial fate determination and is likely to impact on the integration sites of adult-born cells, their odor responsiveness, as well as their survival rate.

NRAGE is a negative regulator of nerve growth factor-stimulated neurite outgrowth in PC12 cells mediated through TrkA-ERK signaling.
NRAGE, also denominated as MAGE-D1 or Dlxin-1, is firstly identified as a molecule interacting with NGF low affinity receptor p75NTR. It facilitates cell cycle arrest and NGF-dependent neuronal apoptosis. Here we report that NRAGE is downregulated while p75NTR is upregulated during the process of NGF-induced neuronal differentiation of PC12 cells. Knockdown of NRAGE by RNA interference accelerates NGF-mediated neurite outgrowth. In addition, in the NRAGE-suppressed cells, NGF-induced ERK activation is increased and this activation is MEK-dependent. Conversely, NRAGE overexpression significantly represses NGF-induced ERK activation. Further studies revealed that NRAGE downregulates TrkA expression through a post-transcriptional manner and thereby blocks NGF-induced TrkA phosphrylation at tyrosine-490. Altogether, these data indicate for the first time that NRAGE is an endogenous inhibitor for NGF-induced neuronal differentiation of PC12 cells by regulating TrkA-ERK signaling.

AN INTEROCEPTIVE ROLE FOR GLYCINERGIC PERIAQUEDUCTAL GREY CIRCUITS DURING DEFENSIVE STATES

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Sara Reis[1], Jérémy Signoret-Genest[1], Philip Tovote[2,3]
[1]Institute of Clinical Neurobiology, System Neuroscience, Würzburg, Germany, [2]Institute of Clinical Neurobiology, Wuerzburg Neuroscience, Wuerzburg, Germany, [3]Institute of Clinical Neurobiology, Defense Circuits Lab, Würzburg, Germany

Fear and anxiety are defensive states that evolved as adaptive responses to a threat. Inappropriate selection and inability to rapidly switch between defensive states are hallmarks of anxiety-related disorders. Defensive states encompass a multitude of coordinated and integrated responses, such as behavioral and autonomic adaptations, which in turn result in afferent information flow reporting the body's physiological state to the brain. These interoceptive processes are believed to be crucial for regulation of central emotional states. Neuronal circuits of the midbrain periaqueductal grey (PAG) critically contribute to defensive states, however, it remains poorly understood if and how they encode and integrate interoceptive signals as part of a defense reaction. Using in vivo miniscope calcium imaging, we observed activation of glycinergic neurons within the ventrolateral PAG (vlPAG) during the switch between a freezing/bradycardia state to a no-freezing/tachycardia (HR) state, in which HR precedes neuronal activity, suggesting that these neurons receive cardiac interoceptive information. Furthermore, optogenetic manipulation confirmed an involvement of vlPAG glycinergic neurons in regulating macrostate dynamics, in optoactivation caused an increase of HR variability, whereas optoinhibion had the opposite effect. Moreover, trans-synaptic retrograde tracing demonstrated monosynaptic connectivity with cardiac regulatory areas such as nucleus of solitary tract. Anterograde tracing demonstrated that PAG glycinergic neurons project almost exclusively to forebrain regions, suggesting that these neurons might be crucial to report the cardiac state to higher order brain regions. Overall, our data suggest that vlPAG glycinergic neurons contribute to defensive states via regulating cardiac interoception, a process that plays a major role in fear, anxiety and related disorders.

Adenosine A and A receptors differently control synaptic plasticity in the mouse dorsal and ventral hippocampus.
The hippocampus is a brain region involved in processing both memory and emotions, through a preferential involvement of the dorsal hippocampus (DH) and ventral hippocampus (VH), respectively. Adenosine A and A receptors (A R and A R) control both mood and memory, but it is not known if there is a different adenosine modulation of synaptic plasticity along the hippocampal axis. Using adult, C57BL/6 male mice, we show that both A R and A R were more abundant in DH compared with VH. However, recordings of field excitatory postsynaptic potentials at Schaffer collaterals-CA1 pyramidal synapses revealed that A R were equi-effective to inhibit basal excitatory synaptic transmission in DH and VH, but endogenous A R activation was more effective to depress the probability of release in VH. In contrast, the selective A R antagonist (SCH58261, 50 nM) controlled both long-term potentiation (induced by a high frequency stimulation protocol) and long-term depression (induced by a low frequency stimulation protocol) selectively in DH rather than VH, whereas the selective A R antagonist (DPCPX, 100 nM) revealed a similar tonic inhibition of long-term depression in DH and VH. These findings show a different control of synaptic plasticity by the adenosine modulation system in the dorsal and ventral poles of the hippocampus, which may underlie a different efficiency of the adenosine system to control mood and memory.

GLUCOSE-SENSING NEURONS IN THE INSULAR CORTEX MODULATE THE FEAR BALANCE

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Héloïse Policet--Bétend, De Araujo Salgado, Benfredj, Christophe Lamy
University of Geneva, Department Of Anatomy, Geneva, Switzerland

Glucose is the primary energy source for the brain. Its levels are constantly monitored by specialized glucose-sensing neuronal populations that have been described so far mainly in subcortical areas contributing to the regulation of energy homeostasis. The insular cortex (IC) is modulated by blood glucose levels and has been described as an interface between interoception and emotions. The aim of our work was to examine whether glucose-sensing cells are present in IC and, if so, to understand their role in emotional behavior. Monitoring c-Fos expression, we identified a cell population activated by hypoglycemia in the mouse IC. We used a genetic mouse model to target and record those cells in vitro. With this approach we confirmed that they are glucose sensing neurons. Morphological reconstructions showed that they are thick-tufted layer 5 pyramidal cells in the posterior insula. We then devised an intersectional strategy to address those cells in vivo with chemogenetic actuators. With this tool we determined that IC glucose sensing neurons affect fear-like behavior through projection to the central nucleus of the amygdala (CeA). Finally, we identified PKC delta+ neurons of the CeA as downstream connectivity of IC glucose-sensing neurons. Altogether, our data provides the first evidence of the existence of glucose-sensing neurons in the insular cortex and of a neuronal circuit linking directly interoception and emotional behavior.

ENRICHED ENVIRONMENT ATTENUATES ENHANCED TRAIT-ANXIETY AND ASSOCIATED NEURO-INFLAMMATORY DYSBALANCE

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Anupam Sah[1], Mohammad Ebrahimi Daran[1], Sinead Rooney[1], Maria Kharitonova[1], Simone Sartori[1], Bilge Ugursu[2,3], Susanne Wolf[2,3], Nicolas Singewald[1]

Neuroinflammation is discussed to play a role in specific subgroups of different psychiatric disorders. We have previously shown that a mouse model of trait-anxiety (HAB) displays enhanced microglial-density and phagocytic-activity in key regions of anxiety-circuits in comparison to normal anxiety controls (NAB). Using minocycline we provided proof of principle evidence that reducing microglia activation within the dentate gyrus (DG) attenuated enhanced-anxiety in HABs. Besides pharmacological interventions; “positive-stimuli”, which have the advantage of exerting no or negligible side-effects, have been shown to attenuate inflammation in humans. Therefore, in the current study, we investigated whether environmental-enrichment (EE) as a “positive intervention” would be sufficient to modulate inflammation in high anxiety HABs. We now show that EE can also attenuate enhanced-anxiety when presented during adulthood, complimenting our previous observations of such EE effects in early development. Using immunohistochemistry, we found that EE-induced anxiolysis was associated with attenuation of enhanced microglial-density in the DG and medial-prefrontal cortex. Furthermore, EE also reduced phagocytic-activity of microglia within the DG. Hence, successful attenuation of trait-anxiety by EE was associated with normalization of part of the identified neuro-inflammatory imbalances. Together with our previous pharmacological findings, these results indicate that beneficial environmental cues can partly mimic anti-inflammatory effects of minocycline in individuals predisposed to trait-anxiety. Recently, we also found sex differences in microglial-expression, microglial-morphology as well as synaptic-pruning pathways in the DG of HABs compared to NABs and we are currently investigating whether and how these contribute to EE-induced anxiolytic-like effect. STRESS-INDUCED MODULATION OF MEMORY CONSOLIDATION IN THE HIPPOCAMPUS-AMYGDALA NETWORK DURING SLEEP

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Eléonore Pronier[1], Gabrielle Girardeau[2]
[1]Inserm, Sorbonne Université, Institut Du Fer à Moulin, Paris, France, [2]Inserm, Institut Du Fer A Moulin, Paris, France

Aversive memories tend to be more vividly remembered than neutral ones, suggesting a differential consolidation of memories depending on their emotional valence. Stress hormones such as corticosterone (CORT), secreted during threatening events, have been proposed to mediate this selective consolidation. Associating a threat to a particular context requires the hippocampus (HPC), which integrates the spatial context, and the amygdala (BLA) which processes fear. During sleep, the coordinated HPC-BLA representation of an aversive experience is reactivated during hippocampal events called "sharp-wave ripples" (SWRs), potentially sustaining the consolidation of context-threat associations. However, how stress modifies sleep-dependent consolidation mechanisms remains unknown. To tackle this question, we are investigating how stress induced by CORT injections affects the consolidation of contextual fear learning in the HPC-BLA network. Pilot experiments assessing the effects of CORT, without prior learning, on HPC-BLA sleep oscillations show that injecting CORT increases the SWRs rate during subsequent sleep. This could be one of the mechanisms by which stress hormones modulate memory consolidation during sleep.

ADOLESCENT NICOTINE EXPOSURE DISRUPTS ITS ANXIOGENIC PROPERTIES IN ADULTHOOD

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Lauren Reynolds[1], Sophie Fayad[1], Claire Nguyen[1], Thomas Topilko[2], Aylin Gulmez[1], Fabio Marti[3], Nicolas Heck[4], Nicolas Renier[2], Alexandre Mourot[3], Philippe Faure[1]
[1]ESPCI Paris, Plasticité Du Cerveau, Paris, France, [2]Paris Brain Institute, Sorbonne Universite, INSERM, CNRS, Laboratory Of Structural Plasticity, Paris, France, [3]CNRS - ESPCI, Umr8249 - Plasticité Du Cerveau, PARIS, France, [4]Sorbonne Université, Neuroscience Paris Seine, Paris, France

Dopamine (DA) circuity is increasingly considered as a “plasticity system” where its structure and function is shaped by experience during development, creating adaptive behavioral profiles that can endure throughout the lifetime. This plasticity may also demarcate a period of increased vulnerability to environmental insult: adolescent initiation of drug use, in particular, is associated with an increased risk of psychopathologies linked with DA dysfunction. This may be especially true for nicotine, as up to 90% of adult smokers began as adolescents. Nicotine acts on distinct DA pathways to produce both reinforcing and anxiogenic effects: the activation of nucleus accumbens (NAc)-projecting DA neurons produces reinforcement, whereas the simultaneous inhibition of amygdala (AMG)-projecting DA neurons produces anxiety-like behavior. How experience with nicotine in adolescence modulates the anxiogenic effects of later re-exposure is largely unexplored. Remarkably, we found that the anxiogenic response to nicotine injection is abolished in adult mice pre-exposed to nicotine in adolescence, but not those pre-exposed in adulthood. Using iDISCO and ClearMap, we found that adolescent nicotine exposure augments brain-wide activation in response to an acute nicotine injection in adulthood, with notably increased cFos+ neurons in the NAc and AMG. Using single-unit recordings we found that nicotine-induced activation was stronger in adult mice exposed to nicotine in adolescence, nicotine-induced inhibition, however, was unchanged. Together, our results highlight how diverse DA pathways can be impacted by experience in adolescence, and further suggest that developmentally induced “imbalance” of these pathways may alter vulnerability profiles for later DA-dependent psychopathologies.

Aims: Levetiracetam (LEV), which belongs to a new generation of antiepileptic drugs, has been recognized as a relatively safe antiepileptic therapy, according to studies on neurodevelopmental outcomes in children exposed to LEV *in utero*, although some animal studies reported skeletal abnormalities. This study deals with the influence of prenatal exposure to LEV in the doses that cover therapeutic range in humans on gross skeletal structure and anxiety-like behavior in adolescent mice. Methods: Adult 8-weeks old female NMRI mice were randomly divided into four groups and treated subcutaneously during breeding and gestation with saline (control) or LEV in the doses of 158 mg/kg/day (LEV-158), 211 mg/kg/day (LEV-211), or 316 mg/kg/day (LEV-316). After delivery, each female with the progeny was housed separately. Weaning and separation by sex were done on the 20th postnatal day (P20). The elevated plus-maze test was used to assess the anxiety-like behavior in both male and female offspring on P37. Results: Females and males in the LEV-158 and LEV-316 group displayed less anxiety-like behavior compared to the control, while in the LEV-211 group such behavior was not observed. Sex-related differences in anxiety-like behavior were not detected within any LEV group, as well as visible skeletal malformations. Conclusion: The findings in the mouse model suggest that prenatal exposure to LEV could be associated with less anxiety-like behavior in adolescence, paying attention to the U-shaped dose-response and highlighting the behavioral outcomes of small LEV doses. Support: Ministry of Education, Science, and Technological Development of the Republic of Serbia (Contract 451-03-9/2021-14/200007).

THE NEUROMETABOLIC UNDERPINNINGS OF SOCIAL RANK – IS THERE A ROLE FOR ACCUMBAL SIRTUIN 1?

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Silvie Ruigrok[1], Dogukan Ulgen[1], Laia Morato[1], Marie-Isabelle Guillot De Suduiraut[1], Jocelyn Grosse[1], Cristina Cudalbu[2], Carmen Sandi[1]
[1]EPFL, Laboratory Of Behavioural Genetics, Brain Mind Institute, Lausanne, Switzerland, [2]EPFL, Animal Imaging And Technology, Lausanne, Switzerland

Aims: Mental disorders are a major problem in modern society, and social status affects ones' susceptibility to develop such disorders. However, the neural mechanisms whereby social status impacts on mental health is still unclear. The nucleus accumbens (NAc) is a key brain region involved in motivated behaviors, including the establishment of social hierarchies. Our recent work has implicated NAc mitochondrial function as critical underlying mechanism of social status. Sirtuin 1 (SIRT1) is a central regulator of cellular metabolism, and has been related to anxiety-like behaviors. In this project, we asked whether dominant and subordinate individuals differ in their NAc SIRT1 content and whether SIRT1 is causally involved in social status and the NAc metabolic profile. Methods: We first measured SIRT1 protein levels in the NAc of dominant and submissive mice. To study a causal role for SIRT1 in social rank and anxiety, male *Sirt1*^{loxP} mice received a viral injection (AAV2-SYN-eGFP-T2A-iCre-WPRE) in the NAc, resulting in neuron-specific knockdown (KD) of SIRT1. ^{1}H-magnetic resonance spectroscopy was used to study brain metabolite levels *in vivo*. Results: We show that NAc SIRT1 protein levels are lower in subordinate mice. SIRT1 KD affected social but not anxiety-like behavior. Whether SIRT1 KD modulates dominance status and NAc metabolites is currently under investigation. Conclusion: Here, we show that social rank is related to levels of SIRT1 in the NAc, and investigate a causal role for SIRT1 in social rank establishment. This will deepen our understanding of the underpinnings of social rank and the molecular determinants of neurometabolism.

Apolipoprotein E and sex modulate fatty acid metabolism in a prospective observational study of cognitive decline.
Fatty acids play prominent roles in brain function as they participate in structural, metabolic and signaling processes. The homeostasis of fatty acids and related pathways is known to be impaired in cognitive decline and dementia, but the relationship between these metabolic disturbances and common risk factors, namely the ε4 allele of the apolipoprotein E (ApoE-ε4) gene and sex, remains elusive.

Modulation of the Hypothalamic Nutrient Sensing Pathways by Sex and Early-Life Stress.
There are sex differences in metabolic disease risk, and early-life stress (ES) increases the risk to develop such diseases, potentially in a sex-specific manner. It remains to be understood, however, how sex and ES affect such metabolic vulnerability. The hypothalamus regulates food intake and energy expenditure by sensing the organism's energy state via metabolic hormones (leptin, insulin, ghrelin) and nutrients (glucose, fatty acids). Here, we investigated if and how sex and ES alter hypothalamic nutrient sensing short and long-term. ES was induced in mice by limiting the bedding and nesting material from postnatal day (P)2-P9, and the expression of genes critical for hypothalamic nutrient sensing were studied in male and female offspring, both at P9 and in adulthood (P180). At P9, we observed a sex difference in both and expression, while the latter was also increased in ES-exposed animals relative to controls. In adulthood, we found sex differences in , , and expression, whereas ES did not affect the expression of genes involved in hypothalamic nutrient sensing. Thus, we observe a pervasive sex difference in nutrient sensing pathways and a targeted modulation of this pathway by ES early in life. Future research is needed to address if the modulation of these pathways by sex and ES is involved in the differential vulnerability to metabolic diseases.
Front Neurosci, 2021; 15

Adult food choices depend on sex and exposure to early-life stress: Underlying brain circuitry, adipose tissue adaptations and metabolic responses.
Exposure to early-life stress (ES) increases the risk to develop obesity later in life, and these effects may be sex-specific, but it is currently unknown what underlies the ES-induced metabolic vulnerability. We have previously shown that ES leads to a leaner phenotype under standard chow diet conditions, but to increased fat accumulation when exposed to an unhealthy obesogenic diet. However these diets were fed without a choice. An important, yet under investigated, element contributing to the development of obesity in humans is the choice of the food. There is initial evidence that ES leads to altered food choices but a thorough testing on how ES affects the choice of both the fat and sugar component, and if this is similar in males and females, is currently missing. We hypothesized that ES increases the choice for unhealthy foods, while it at the same time also affects the response to such a diet. In a mouse model for ES, in which mice are exposed to limited nesting and bedding material from postnatal day (P)2-P9, we investigated if ES exposure affected i) food choice with a free choice high-fat high-sugar diet (fcHFHS), ii) the response to such a diet, iii) the brain circuits that regulate food intake and food reward and iv) if such ES effects are sex-specific. We show that there are sex differences in food choice under basal circumstances, and that ES increases fat intake in females when exposed to a mild acute stressor. Moreover, ES impacts the physiologic response to the fcHFHS and the brain circuits regulating food intake in sex-specific manner. Our data highlight sex-specific effects of ES on metabolic functioning and food choice.

Effects of early-life stress on peripheral and central mitochondria in male mice across ages.
Exposure to early-life stress (ES) increases the vulnerability to develop metabolic diseases as well as cognitive dysfunction, but the specific biological underpinning of the ES-induced programming is unknown. Metabolic and cognitive disorders are often comorbid, suggesting possible converging underlying pathways. Mitochondrial dysfunction is implicated in both metabolic diseases and cognitive dysfunction and chronic stress impairs mitochondrial functioning. However, if and how mitochondria are impacted by ES and whether they are implicated in the ES-induced programming remains to be determined. ES was applied by providing mice with limited nesting and bedding material from postnatal day (P)2-P9, and metabolic parameters, cognitive functions and multiple aspects of mitochondria biology (i.e. mitochondrial electron transport chain (ETC) complex activity, mitochondrial DNA copy number, expression of genes relevant for mitochondrial function, and the antioxidant capacity) were studied in muscle, hypothalamus and hippocampus at P9 and late adulthood (10-12 months of age). We show that ES altered bodyweight (gain), adiposity and glucose levels at P9, but not in late adulthood. At this age, however, ES exposure led to cognitive impairments. ES affected peripheral and central mitochondria in an age-dependent manner. At P9, both muscle and hypothalamic ETC activity were affected by ES, while in hippocampus, ES altered the expression of genes involved in fission and antioxidant defence. In adulthood, alterations in ETC complex activity were observed in the hypothalamus specifically, whereas in muscle and hippocampus ES affected the expression of genes involved in mitophagy and fission, respectively. Our study demonstrates that ES affects peripheral and central mitochondria biology throughout life, thereby uncovering a converging mechanism that might contribute to the ES-induced vulnerability for both metabolic diseases and cognitive dysfunction, which could serve as a novel target for intervention.

Effects of Early-Life Stress, Postnatal Diet Modulation and Long-Term Western-Style Diet on Peripheral and Central Inflammatory Markers.
Early-life stress (ES) exposure increases the risk of developing obesity. Breastfeeding can markedly decrease this risk, and it is thought that the physical properties of the lipid droplets in human milk contribute to this benefit. A concept infant milk formula (IMF) has been developed that mimics these physical properties of human milk (Nuturis, N-IMF). Previously, we have shown that N-IMF reduces, while ES increases, western-style diet (WSD)-induced fat accumulation in mice. Peripheral and central inflammation are considered to be important for obesity development. We therefore set out to test the effects of ES, Nuturis and WSD on adipose tissue inflammatory gene expression and microglia in the arcuate nucleus of the hypothalamus. ES was induced in mice by limiting the nesting and bedding material from postnatal day (P) 2 to P9. Mice were fed a standard IMF (S-IMF) or N-IMF from P16 to P42, followed by a standard diet (STD) or WSD until P230. ES modulated adipose tissue inflammatory gene expression early in life, while N-IMF had lasting effects into adulthood. Centrally, ES led to a higher microglia density and more amoeboid microglia at P9. In adulthood, WSD increased the number of amoeboid microglia, and while ES exposure increased microglia coverage, Nuturis reduced the numbers of amoeboid microglia upon the WSD challenge. These results highlight the impact of the early environment on central and peripheral inflammatory profiles, which may be key in the vulnerability to develop metabolic derangements later in life.

Reversal of endothelial dysfunction reduces white matter vulnerability in cerebral small vessel disease in rats.
Dementia is a major social and economic problem for our aging population. One of the most common of dementia in the elderly is cerebral small vessel disease (SVD). Magnetic resonance scans of SVD patients typically show white matter abnormalities, but we do not understand the mechanistic pathological link between blood vessels and white matter myelin damage. Hypertension is suggested as the cause of sporadic SVD, but a recent alternative hypothesis invokes dysfunction of the blood-brain barrier as the primary cause. In a rat model of SVD, we show that endothelial cell (EC) dysfunction is the first change in development of the disease. Dysfunctional ECs secrete heat shock protein 90α, which blocks oligodendroglial differentiation, contributing to impaired myelination. Treatment with EC-stabilizing drugs reversed these EC and oligodendroglial pathologies in the rat model. EC and oligodendroglial dysfunction were also observed in humans with early, asymptomatic SVD pathology. We identified a loss-of-function mutation in ATPase11B, which caused the EC dysfunction in the rat SVD model, and a single-nucleotide polymorphism in ATPase11B that was associated with white matter abnormalities in humans with SVD. We show that EC dysfunction is a cause of SVD white matter vulnerability and provide a therapeutic strategy to treat and reverse SVD in the rat model, which may also be of relevance to human SVD.

Early-life stress lastingly alters the neuroinflammatory response to amyloid pathology in an Alzheimer's disease mouse model.
Exposure to stress during the sensitive period of early-life increases the risk to develop cognitive impairments and psychopathology later in life. In addition, early-life stress (ES) exposure, next to genetic causes, has been proposed to modulate the development and progression of Alzheimer's disease (AD), however evidence for this hypothesis is currently lacking. We here tested whether ES modulates progression of AD-related neuropathology and assessed the possible contribution of neuroinflammatory factors in this. We subjected wild-type (WT) and transgenic APP/PS1 mice, as a model for amyloid neuropathology, to chronic ES from postnatal day (P)2 to P9. We next studied how ES exposure affected; 1) amyloid β (Aβ) pathology at an early (4month old) and at a more advanced pathological (10month old) stage, 2) neuroinflammatory mediators immediately after ES exposure as well as in adult WT mice, and 3) the neuroinflammatory response in relation to Aβ neuropathology. ES exposure resulted in a reduction of cell-associated amyloid in 4month old APP/PS1 mice, but in an exacerbation of Aβ plaque load at 10months of age, demonstrating that ES affects Aβ load in the hippocampus in an age-dependent manner. Interestingly, ES modulated various neuroinflammatory mediators in the hippocampus of WT mice as well

as in response to Aβ neuropathology. In WT mice, immediately following ES exposure (P9), Iba1-immunopositive microglia exhibited reduced complexity and hippocampal interleukin (IL)-1β expression was increased. In contrast, microglial Iba1 and CD68 were increased and hippocampal IL-6 expression was decreased at 4months, while these changes resolved by 10months of age. Finally, Aβ neuropathology triggered a neuroinflammatory response in APP/PS1 mice that was altered after ES exposure. APP/PS1 mice exhibited increased CD68 expression at 4months, which was further enhanced by ES, whereas the microglial response to Aβ neuropathology, as measured by Iba1 and CD11b, was less prominent after ES at 10months of age. Finally, the hippocampus appears to be more vulnerable for these ES-induced effects, since ES did not affect Aβ neuropathology and neuroinflammation in the entorhinal cortex of adult ES exposed mice. Overall, our results demonstrate that ES exposure has both immediate and lasting effects on the neuroinflammatory response. In the context of AD, such alterations in neuroinflammation might contribute to aggravated neuropathology in ES exposed mice, hence altering disease progression. This indicates that, at least in a genetic context, ES could aggravate AD pathology.

BLOOD BRAIN BARRIER DIFFERENCES IN THE NUCLEUS ACCUMBENS RELATE TO NATURAL VARIATION IN TRAIT ANXIETY

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Haissa De Castro Abrantes, Camilla Di Giulio, Carmen Sandi
EPFL, Brain Mind Institute, Lausanne, Switzerland

The nucleus accumbens (NAc), a brain region involved in reward and motivation, is implicated in the regulation of anxiety-related behaviors. Astrocytes are powerful modulators of neuronal activity, and their localization around blood vessels is important for brain metabolism. In this study, exploiting natural phenotypic variation in anxiety-like behaviors in outbred Wistar male rats, we aimed at investigating anxiety-related differences in astrocytic and endothelial features in the NAc. We classified animals as high (HA) or low anxious (LA) according to the time spent in the open arms of the elevated plus maze. We assessed astrocyte's morphology using GFAP immunostaining and did not find morphological differences. However, gene expression analyses indicated a significant decrease in the expression levels of Aquaporine 4 (Aqp4) and Claudine 5 (Cldn5) in HA animals. Aqp4 is specifically expressed at the level of astrocytic endfeet around blood vessels. Therefore, we asked whether HA and LA animals show differences in blood brain barrier (BBB) permeability. Using Evan's Blue injections, we observed higher blood vessels' permeability in the NAc of HA animals. Using electron microscopy, we observed a lower number of endfeet processes around blood vessels in the NAc of HA animals. Furthermore, we observed a lower number of contacts between the mitochondria and the endoplasmic reticulum in those endfeets. Therefore, we show differences in the coverage of blood vessels by astrocytic processes, and in the associated BBB permeability, as a function of individuals' anxiety. Our findings suggest that alterations in accumbal astrocytes may contribute to the vulnerability of high anxious individuals.

KISSPEPTIN-13 MAY INDUCE ANXIETY-LIKE BEHAVIOUR VIA MODULATION OF CENTRAL VASOPRESSIN IN RATS

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Krisztina Csabafi, Katalin Ibos, Éva Bodnár, Júlia Szakács, Zsolt Bagosi
University of Szeged, Department Of Pathophysiology, Szeged, Hungary

Aims: Kisspeptin-13 (Kp-13), an endogenous derivative of Kisspeptin, in our previous experiments induced anxiety-like behaviour in rats. In the present experiments, we investigated the possible mechanism of Kp-13's anxiogenic action in adult male Wistar rats. **Methods:** After Kp-13 (2 µg/2 µl) injection intracerebroventricularly (icv) hypothalamic, amygdalar and hippocampal samples were obtained, to measure the relative gene expression of the corticotropin-releasing hormone (CRH) and vasopressin (VP) system via qPCR and the protein level of CRH and VP via ELISA. The behavior of animals, pretreated with CRH or VP receptor antagonists prior to Kp-13, were recorded via elevated plus maze (EPM) and open field (OF) tests. In addition to assess Kp-13 long-term effects, OF test was performed 8 and 24 h after Kp-13 injection. **Results:** Our results showed that Kp-13 upregulated the relative gene expression of VP in amygdala, CRH receptor 1 and VP1b receptors in the hippocampus. VP concentration in the amygdala was elevated. In addition, KISS1R and VP receptor antagonist pretreatment was able to abolish KP-13's anxiogenic effect in behavioral tests, whereas CRH blockage had little effect. Kp-13's anxiogenic effect remained after 24 h. **Conclusion:** KP-13's long-term anxiogenic action might be mediated by central release of the stress responsive VP, rather than CRH. Indeed, increased amygdalar VP expression may alter amygdala processing to induce anxiety and trigger downstream activation of the hypothalamic-pituitary-adrenal axis in rats.

Kisspeptin-8 Induces Anxiety-Like Behavior and Hypolocomotion by Activating the HPA Axis and Increasing GABA Release in the Nucleus Accumbens in Rats.
Kisspeptins (Kp) are RF-amide neuropeptide regulators of the reproductive axis that also influence anxiety, locomotion, and metabolism. We aimed to investigate the effects of intracerebroventricular Kp-8 (an N-terminally truncated octapeptide) treatment in Wistar rats. Elevated plus maze (EPM), computerized open field (OF), and marble burying (MB) tests were performed for the assessment of behavior. Serum LH and corticosterone levels were determined to assess kisspeptin1 receptor (Kiss1r) activation and hypothalamic-pituitary-adrenal axis (HPA) stimulation, respectively. GABA release from the nucleus accumbens (NAc) and dopamine release from the ventral tegmental area (VTA) and NAc were measured via ex vivo superfusion. Kp-8 decreased open arm time and entries in EPM, and also raised corticosterone concentration, pointing to an anxiogenic effect. Moreover, the decrease in arm entries in EPM, the delayed increase in immobility accompanied by reduced ambulatory activity in OF, and the reduction in interactions with marbles show that Kp-8 suppressed exploratory and spontaneous locomotion. The increase in GABA release from the NAc might be in the background of hypolocomotion by inhibiting the VTA-NAc dopaminergic circuitry. As Kp-8 raised LH concentration, it could activate Kiss1r and stimulate the reproductive axis. As Kiss1r is associated with hyperlocomotion, it is more likely that neuropeptide FF receptor activation is involved in the suppression of locomotor activity.

THE “CUFF” MODEL OF SCIATIC NERVE COMPRESSION INDUCES CHRONIC HYPERSENSITIVITY BUT NOT ANXIODEPRESSIVE-LIKE SYMPTOMS IN SPRAGUE-DAWLEY RATS

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

AIMS: About 10-20% of the population is currently suffering from chronic pain. This condition is thus a major cause of disability and disease burden of this century. Although pain syndromes result from different underlying mechanisms, they share common comorbidities such as neurocognitive changes, sleep disturbances and in 50% of the patients suffering from chronic pain, mood alterations leading to anxiety and/or depression. Our aim was to study the mechanism underlying the development of the anxiodepressive-like consequences of chronic pain in a rat model of sciatic nerve compression. METHODS: The “Cuff” model consists in the implantation of a polyethylene tube around the main branch of the right sciatic nerve to induce chronic pain. Calibrated forceps were used to assess the mechanical sensitivity of both hind paws and behavioral tests evaluating anxious- and depressive-like symptoms were done at different time points after the cuff surgery. RESULTS: The sciatic nerve compression induced a chronic mechanical hypersensitivity in male Sprague-Dawley rats, similar to previous results obtained in mice. While this hypersensitivity was accompanied by time-dependent anxiodepressive-like symptoms in the cuffed mice, the rats showed surprisingly neither anxiety nor depression-related behaviors. CONCLUSION: These results suggest that anxiodepressive-like behaviors are not necessarily a consequence of chronic pain, and they provide an interesting model to further investigate the basis of resilience vs susceptibility to this pain comorbidity. AKNOWLEDGEMENTS: This work has been supported by Centre National de la Recherche Scientifique (UPR3212), University of Strasbourg (UPR3212), Agence Nationale de la Recherche (Euridol ANR-17-EURE-0022) and Région Grand Est (ClueDol).

SEEKING COMFORT IN STRESSFUL SITUATIONS: ERP AND ATTACHMENT DIMENSIONS AS PREDICTORS OF CARE OR COMFORT FOOD CHOICE.

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Paolo Enrico[1], Beniamina Mercante[1], Caterina Pozzati[1], Franca Deriu[1], Arcangelo Uccula[2]

Aims: Threatening stimuli induce specific EEG response patterns and, in agreement to the attachment theory, motivate subjects to seek comfort. Both care-seeking and comfort food-seeking behaviour are known strategies of negative emotion regulation, and in this study we investigated in threatening conditions the association of the Late Positive Potential (LPP) response and attachment dimensions in the choice of care/food and its timing (RT). Methods: Fifty-two participants responded to the ECR questionnaire and were subjected to visual stimuli from IAPS, BAPS-Adult and Food-Pics_Extended, during EEG recording. Results: Threatening stimuli increase the choice of care, decrease RT, and increase LPP magnitude in right central-parietal areas (Cpz, Pz, P4), while comfort food choice was reduced, with increased RT. Further, regression analysis show that high increments in LPP magnitude in P4 channel are associated with increased choice of care, while an increase in RT is associated with high LPP increments in Cpz, Pz and P4. When considering the dimensions of attachment, in the threatening conditions, while anxiety is not associated with RT and care choice, avoidance is associated to an increase in care choice and to an increased RT. Conclusions: The specific increment in care choice RT associated with high LPP magnitude in right central-parietal areas, may be explained in terms of an interference of these brain areas in the choice of care, but not of comfort food. Further, we found that the defences of avoidant individuals can be by-passed, and the longer RT may reflect a more articulated elaboration of the choice process.

Background: When foraging for food under threat of predation, animals or humans must be vigilant and switch between behavioural strategies. Understanding how we decide between attending to rewards versus risks may have clinical relevance to understanding disordered responses to threatening stimuli in psychopathology. Methods: To investigate foraging under threat, we designed a task and a cognitive model to explore what information humans consider when choosing freely and continuously among foraging, vigilance, and hiding. We used 7T fMRI to investigate brain activity associated with this task in healthy adults. We additionally collected 400 participants over the internet on the task together with a standard psychiatric questionnaire about real-life anxiety (as well as apathy and compulsivity). Results: We found that real-life anxiety influenced behaviour in our task, leading to threat avoidance. We hypothesised that the ACC will be linked with encoding of action timing and task switching, and that the amygdala and periaqueductal gray will show activity relevant to transitioning from foraging to vigilance. Discussion: We developed a computer-based objective measure mirroring subjective reports related to anxiety. This task could be interesting for clinical collaborations on anxiety disorders or putative novel treatments.

REGION-SPECIFIC CREB FUNCTION REGULATES DISTINCT FORMS OF REGRET ASSOCIATED WITH RESILIENCE VERSUS SUSCEPTIBILITY TO CHRONIC STRESS

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Romain Durand-De Cuttoli, Freddyson Martinez-Rivera, Long Li, Angelica Minier-Toribio, Flurin Cathomas, Leanne Holt, Farzana Yasmin, Salma Elhassa, Sanjana Ahmed, Jasmine Shaikh, Scott Russo, Eric Nestler, Brian Sweis

Regret describes recognizing that alternative actions could have led to better outcomes. This can transform into behavioral consequences, altering subsequent valuations, but remains unclear if regret derives from a generalized computation for mistake appraisal or instead is made up of dissociable action-specific processes. Using a novel neuroeconomic decision-making paradigm, we found mice were differentially sensitive to fundamentally distinct types of missed opportunities following exposure to chronic social defeat stress or manipulations of CREB, a key transcription factor implicated in chronic stress action. Bias to make compensatory decisions after rejecting high-value offers (regret type I) was unique to stress-susceptible mice. Bias following the converse operation, accepting low-value offers (regret type II), was enhanced in stress-resilient and absent in stress-susceptible mice. CREB function in either the medial prefrontal cortex or nucleus accumbens was required to suppress regret type I but differentially affected regret type II. We provide insight into how adaptive versus maladaptive stress-response traits may be related to fundamentally distinct forms of counterfactual thinking and could steer psychotherapy for mood disorders such as depression toward unveiling circuit-specific computations through a careful description of decision narrative.

Chronic nicotine increases midbrain dopamine neuron activity and biases individual strategies towards reduced exploration in mice.
Long-term exposure to nicotine alters brain circuits and induces profound changes in decision-making strategies, affecting behaviors both related and unrelated to drug seeking and consumption. Using an intracranial self-stimulation reward-based foraging task, we investigated in mice the impact of chronic nicotine on midbrain dopamine neuron activity and its consequence on the trade-off between exploitation and exploration. Model-based and archetypal analysis revealed substantial inter-individual variability in decision-making strategies, with mice passively exposed to nicotine shifting toward a more exploitative profile compared to non-exposed animals. We then mimicked the effect of chronic nicotine on the tonic activity of dopamine neurons using optogenetics, and found that photo-stimulated mice adopted a behavioral phenotype similar to that of mice exposed to chronic nicotine. Our results reveal a key role of tonic midbrain dopamine in the exploration/exploitation trade-off and highlight a potential mechanism by which nicotine affects the exploration/exploitation balance and decision-making.

Nicotine inhibits the VTA-to-amygdala dopamine pathway to promote anxiety.
Nicotine stimulates dopamine (DA) neurons of the ventral tegmental area (VTA) to establish and maintain reinforcement. Nicotine also induces anxiety through an as yet unknown circuitry. We found that nicotine injection drives opposite functional responses of two distinct populations of VTA DA neurons with anatomically segregated projections: it activates neurons that project to the nucleus accumbens (NAc), whereas it inhibits neurons that project to the amygdala nuclei (Amg). We further show that nicotine mediates anxiety-like behavior by acting on β2-subunit-containing nicotinic acetylcholine receptors of the VTA. Finally, using optogenetics, we bidirectionally manipulate the VTA-NAc and VTA-Amg pathways to dissociate their

contributions to anxiety-like behavior. We show that inhibition of VTA-Amg DA neurons mediates anxiety-like behavior, while their activation prevents the anxiogenic effects of nicotine. These distinct subpopulations of VTA DA neurons with opposite responses to nicotine may differentially drive the anxiogenic and the reinforcing effects of nicotine.

Orexin signaling in GABAergic lateral habenula neurons modulates aggressive behavior in male mice.
Heightened aggression is characteristic of multiple neuropsychiatric disorders and can have various negative effects on patients, their families and the public. Recent studies in humans and animals have implicated brain reward circuits in aggression and suggest that, in subsets of aggressive individuals, domination of subordinate social targets is reinforcing. In this study, we showed that, in male mice, orexin neurons in the lateral hypothalamus activated a small population of glutamic acid decarboxylase 2 (GAD2)-expressing neurons in the lateral habenula (LHb) via orexin receptor 2 (OxR2) and that activation of these GAD2 neurons promoted male-male aggression and conditioned place preference for aggression-paired contexts. Moreover, LHb GAD2 neurons were inhibitory within the LHb and dampened the activity of the LHb as a whole. These results suggest that the orexin system is important for the regulation of inter-male aggressive behavior and provide the first functional evidence of a local inhibitory circuit within the LHb.

Optofluidic control of rodent learning using cloaked caged glutamate.
Glutamate is the major excitatory neurotransmitter in the brain, and photochemical release of glutamate (or uncaging) is a chemical technique widely used by biologists to interrogate its physiology. A basic prerequisite of these optical probes is bio-inertness before photolysis. However, all caged glutamates are known to have strong antagonism toward receptors of γ-aminobutyric acid, the major inhibitory transmitter. We have developed a caged glutamate probe that is inert toward these receptors at concentrations that are effective for photolysis with violet light. Pharmacological tests in vitro revealed that attachment of a fifth-generation (G5) dendrimer (i.e., cloaking) to the widely used 4-methoxy-7-nitro-indolinyl(MNI)-Glu probe prevented such off-target effects while not changing the photochemical properties of MNI-Glu significantly. G5-MNI-Glu was used with optofluidic delivery to stimulate dopamine neurons of the ventral tegmental area of freely moving mice in a conditioned place-preference protocol so as to mediate Pavlovian conditioning.

Mice adaptively generate choice variability in a deterministic task.
Can decisions be made solely by chance? Can variability be intrinsic to the decision-maker or is it inherited from environmental conditions? To investigate these questions, we designed a deterministic setting in which mice are rewarded for non-repetitive choice sequences, and modeled the experiment using reinforcement learning. We found that mice progressively increased their choice variability. Although an optimal strategy based on sequences learning was theoretically possible and would be more rewarding, animals used a pseudo-random selection which ensures high success rate. This was not the case if the animal is exposed to a uniform probabilistic reward delivery. We also show that mice were blind to changes in the temporal structure of reward delivery once they learned to choose at random. Overall, our results demonstrate that a decision-making process can self-generate variability and randomness, even when the rules governing reward delivery are neither stochastic nor volatile.

Cell-Specific Neuropharmacology.
Neuronal communication involves a multitude of neurotransmitters and an outstanding diversity of receptors and ion channels. Linking the activity of cell surface receptors and ion channels in defined neural circuits to brain states and behaviors has been a key challenge in neuroscience, since cell targeting is not possible with traditional neuropharmacology. We review here recent technologies that enable the effect of drugs to be restricted to specific cell types, thereby allowing acute manipulation of the brain's own proteins with circuit specificity. We highlight the importance of developing cell-specific neuropharmacology strategies for decoding the nervous system with molecular and circuit precision, and for developing future therapeutics with reduced side effects.

A Human Polymorphism in CHRNA5 Is Linked to Relapse to Nicotine Seeking in Transgenic Rats.
Tobacco addiction is a chronic and relapsing disorder with an important genetic component that represents a major public health issue. Meta-analysis of large-scale human genome-wide association studies (GWASs) identified a frequent non-synonymous SNP in the gene coding for the α5 subunit of nicotinic acetylcholine receptors (α5SNP), which significantly increases the risk for tobacco dependence and delays smoking cessation. To dissect the neuronal mechanisms underlying the vulnerability to nicotine addiction in carriers of the α5SNP, we created rats expressing this polymorphism using zinc finger nuclease technology and evaluated their behavior under the intravenous nicotine-self-administration paradigm. The electrophysiological responses of their neurons to nicotine were also evaluated. α5SNP rats self-administered more nicotine at high doses and exhibited higher nicotine-induced reinstatement of nicotine seeking than wild-type rats. Higher reinstatement was associated with altered neuronal activity in several discrete areas that are interconnected, including in the interpeduncular nucleus (IPN), a GABAergic structure that strongly expresses α5-containing nicotinic receptors. The altered reactivity of IPN neurons of α5SNP rats to nicotine was confirmed electrophysiologically. In conclusion, the α5SNP polymorphism is a major risk factor for nicotine intake at high doses and for relapse to nicotine seeking in rats, a dual effect that reflects the human condition. Our results also suggest an important role for the IPN in the higher relapse to nicotine seeking observed in α5SNP rats.

Manipulating midbrain dopamine neurons and reward-related behaviors with light-controllable nicotinic acetylcholine receptors.
Dopamine (DA) neurons of the ventral tegmental area (VTA) integrate cholinergic inputs to regulate key functions such as motivation and goal-directed behaviors. Yet the temporal dynamic range and mechanism of action of acetylcholine (ACh) on the modulation of VTA circuits and reward-related behaviors are not known. Here, we used a chemical-genetic approach for rapid and precise optical manipulation of nicotinic neurotransmission in VTA neurons in living mice. We provide direct evidence that the ACh tone fine-tunes the firing properties of VTA DA neurons through β2-containing (β2*) nicotinic ACh receptors (nAChRs). Furthermore, locally photo-antagonizing these receptors in the VTA was sufficient to reversibly switch nicotine reinforcement on and off. By enabling control of nicotinic transmission in targeted brain circuits, this technology will help unravel the various physiological functions of nAChRs and may assist in the design of novel therapies relevant to neuropsychiatric disorders.

CORTISOL IN CORTISOL LEVELS ACROSS THE LIFESPAN IN COMMON MARMOSETS (CALLITHRIX JACCHUS)

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Kimberley Phillips, Matthew Lopez, Amaya Seidl
Trinity University, Neuroscience, San Antonio, United States of America

Human aging is associated with senescence of the hypothalamic-pituitary-adrenal (HPA) axis, leading to progressive dysregulation characterized by increased cortisol exposure. This key hormone is implicated in the pathogenesis of many age-related diseases. Common marmosets display a wide spectrum of naturally-occurring age-related pathologies that compare similarly to humans, and are increasingly used as translational models of aging and age-related disease. Whether the marmoset HPA axis also shows senescence with increasing age is unknown. We analyzed hair cortisol concentration (HCC) across the lifespan of 50 captive common marmosets via a cross-sectional design. Samples were processed and analyzed for cortisol using enzyme immunoassay. HCC ranged from 1,416 to 15,343 pg/mg. We found significant main effects of age group ($F(4, 39) = 3.46$, $p = 0.016$) and sex ($F(1, 39) = 4.66$, $p = 0.037$), and no interaction effects. Infants had significantly higher levels of HCC compared to all other age groups. Females had higher HCC than males. These results suggest marmosets do not show dysregulation of the HPA axis with increasing age.

ASSESSING THE IMPACT OF HUMAN BODY DISSECTION ON FIRST YEAR UNDERGRADUATE MEDICAL STUDENTS AT BPKIHS.

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Sandip Shah, Sarun Koirala, Laxman Khanal, Presha Baral
B.P. Koirala Institute of Health Sciences, Human Anatomy, Dharan, Nepal

Aims: The present study aimed to assess the stress experienced just after one week of first dissection (IES1) and compare it with impact after 12 weeks (IES2) of first experience by using Impact Event Scale (IES) on first year medical students of B.P. Koirala Institute of Health Sciences, Nepal. **Methods:** Questionnaires for Impact Event Scale (IES) were administered to 100 students attending the cadaveric dissection. The questionnaire provides an overall scale, sub-scales of intrusion and avoidance. The sub-scale scores of 0-8 as a minor reaction;9-19 as a moderate reaction, and a score of 20 or above as a clinically important reaction. The cut-off over all score of 30 on IES indicates a traumatic stress reaction. The results considered significant at the usual 5 per cent level or below. **Results:** The percentage of students having clinically important reaction (a score of 20 or above) after one week of first cadaveric dissection in both sub-scales of Intrusion and Avoidance were 2% and 6% respectively but were found to be reduced to 1% each after 12 weeks. The overall scores indicating traumatic stress reaction was found to be reduced to 2% from 8%. The bivariate correlation analysis between IES 1 and IES 2 was found to have positive correlation with statistical significant level (r_s=0.252;p<0.001). **Conclusion:** The results of present study indicate that the stress related to the human body dissection in medical students reduced significantly after the period of 12 weeks of first cadaveric dissection. **Key words:** dissection; impact Event Scale; intrusion

EFFECT OF RADIATION AND EMOTIONAL STRESS ON BEHAVIOR OF RATS IN THE OPEN FIELD TEST

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Alena Kadukova
Institute of Radiobiology of the National Academy of Sciences of Belarus, Laboratory Of Experimental Biological Models, Gomel, Belarus

Aims: to determine the characteristics of behavioral responses in male and female rats under emotional (immobilization stress) and physical (external irradiation and electromagnetic radiation (EMR)) stress. **Methods:** experiments were carried out on male and female rats (6 months' age). The rats were exposed to the outside of the radiation in a doses of 0.5 and 1.0 Gy (^{137}Cs, 46.2 sGy/min) and prolonged EMR (0.9 GHz for 10 days/8 hours a day). Model of emotional stress were caused by placing the animals in the narrow plastic tubes ("soft" immobilization) for 2 hours per day for 5 days. The animals were examined in the Open Field test (OF) on the next day after last immobilization session. **Results:** emotional stress was resulted in complex degenerative changes of internal organs. It was shown that immobilization leads to inhibition of the horizontal and vertical motor activity in experimental animals in OF test. It was shown that chronic immobilization stress leads to inhibition of the horizontal and vertical motor activity in experimental animals (male and female) in OF test. Thus, the horizontal locomotors activity was reduced by 43.8%; the level of rearing was reduced by 37.6 % (male rats). **Conclusions:** exposure of EMR modifies the level of integrative reaction of CNS rats which were exposed to ionizing radiation in the OF test. It was found that more pronounced negative changes of orientation and exploratory activity and of the levels of emotionality observed in the experimental groups after exposure to ionizing radiation and immobilization.

CHRONIC EXPOSURE TO HIGH FAT DIET AFFECTS THE DOPAMINE MODULATION IN NUCLEUS ACCUMBENS OF ADOLESCENT MALE RATS: IMPLICATIONS IN HEDONIC FOOD INTAKE

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Ramón Sotomayor-Zárate[1], Victoria Collio[1,2], Victoria Velásquez[1,2], Francisco Silva-Olivares[1,2], Wladimir Plaza-Briceño[1,2], Karina Ceballos[1,2], Camila González-Arancibia[1,2], Gonzalo Cruz[1], Jonathan Martínez-Pinto[1], Christian Bonansco[1]
[1]Universidad de Valparaíso, Centro De Neurobiología Y Fisiopatología Integrativa (cenfi), Instituto De Fisiología, Facultad De Ciencias, Valparaiso, Chile, [2]Universidad de Valparaíso, Programa De Doctorado En Ciencias, Mención Neurociencias, Valparaíso, Chile

Obesity is a worldwide health problem, which are caused by an excess of hypercaloric and obesogenic food intake and high palatability, which is increased from puberty. However, the neuronal circuits that regulate hedonic mechanisms of food intake are still poor understanding. **Aim**: To determine the molecular and functional changes of dopaminergic and glutamatergic modulation of nucleus accumbens (NAcc) in male rats exposed to chronic consumption of high fat diet (HFD). **Methods**: Sprague-Dawley male rats were exposed from postnatal day (PND) 21 to 62 to chow or HFD food. Dopamine (DA), DOPAC content and mRNA-DAT levels was measured in NAcc using HPLC-ED and RT-qPCR. DA release and glutamatergic postsynaptic currents properties were assess using voltammetry and patch clamp recordings from the spiny medium neurons (MSN) of NAcc slices obtained after PND 62. In addition, hedonic behavior was measured. **Results**: Our results show that chronic exposure to HFD reduces DOPAC content and DAT levels without affects DA tissue levels. In addition, amphetamine-induced DA release showed a decay time (t) higher than control. In HFD rats, we found a higher number of D_2-type MSN, while amphetamine induced a higher increase of glutamatergic postsynaptic currents in D_2-MSN compared than D_1-MSN. HFD rats showed an increased sucrose intake compared to controls. **Conclusions**: Chronic exposure to HFD reduces DA reuptake due to a decrease in DAT and higher D_2 levels, which could be associated to findings of the glutamatergic modulation from cortical projections. This research was funded by ANID-Chile through FONDECYT Grant Nº 120–0474 and DIUV-CI Grant N°01/2006.

A ROLE FOR NEURONS OF THE MEDIAL DIVISION OF THE CENTRAL AMYGDALA IN APPETITIVE BEHAVIOURS.

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND APPETITIVE LEARNING

Federica Fermani[1], Christian Peters[1], Louise Gaitanos[1], Pilar Alcala Morales[1], Charu Ramakrishnan[2], Karl Deisseroth[2], Rüdiger Klein[1]
[1]Max Planck Institute for Biological Intelligence (in foundation), Department Of Molecules - Signaling - Development, Martinsried, Germany, [2]Stanford University, Department Of Bioengineering, Stanford, United States of America

The central amygdala (CeA) with its lateral (CeL) and medial divisions (CeM) orchestrates a wide range of behaviours, including defensive and appetitive responses. The CeA is composed of GABAergic neuron subpopulations that are marked by expression of neuropeptides, receptors and kinases, and elicit distinct, sometimes opposite behavioural phenotypes. The relative contributions of subpopulations in CeL versus CeM is, however, incompletely understood. Here, we took advantage of an intersectional genetic approach, to investigate how neurons marked by expression of serotonin receptor 2a (Htr2a) or somatostatin (Sst) located in either the CeL or CeM subdivisions regulate feeding, drinking, and promote positive reinforcement. To do so, we generated a novel transgenic mouse line that expresses a Tamoxifen-inducible version of the Flp recombinase (FlpOER) specifically and widely in the CeL, but not in the CeM (Wfs1-FlpOER). Double transgenic mice carrying Wfs1-FlpOER and Htr2a-Cre or Sst-Cre in combination with intersectional viral vectors allowed precise manipulation of CeL cells (positive for both Cre and Flp) versus CeM cells (positive for Cre only). We made the surprising observation that optogenetic activation of the CeM subpopulations mediated appetitive responses. Stimulation of CeM^{Htr2a} and CeM^{Sst} neurons promoted drinking and positive reinforcement behaviour. Stimulation of CeM^{Htr2a}, but not CeM^{Sst}, neurons increased food intake. Photoactivation of the corresponding CeL subpopulations failed to elicit appetitive responses. Ongoing analysis of intra-CeA and long-range projections will provide further insights into the specific roles of CeL and CeM subpopulations in appetitive responses.

Early life stress (ELS) represents a major programming factor in the aetiology of behavioral and mental disorders, as well as in the development of stress resilience. However, the underlying brain mechanisms are still poorly understood. Recent studies revealed evidence for an involvement of the endocannabinoid system as a mediator of vulnerability and resilience. The aim of this study was to test the hypothesis that the endocannabinoid receptor 1 (eCB1R) might play a critical role in this context. Female rats were exposed to ELS using the "neglectful mother" paradigm in which dams had limited access to nesting material from postnatal day 7 to P14. Anxiety-like behavior and gene expression of eCB1R in the prefrontal cortex (PFC) of adult rats were examined. Our results revealed that ELS significantly increased eCB1R expression compared to unstressed controls. We also found that these gene expression changes were mediated by CpG-site specific changes of DNA methylation within or near eCB1R promoter. Behavioral analysis in the same animal cohorts revealed that ELS exposed females exhibit reduced anxiety-like behavior indicated by higher activity and more time spent in the center of an Open Field arena when compared to controls. Taken together we show here that one week of stress exposure at early childhood induces long-term changes of eCB1R gene expression and DNA methylation. We suggest that these ELS-induced changes are associated with the observed behavioral alterations indicating the development of stress resilience.

ENDOCANNABINOID SIGNALLING MODULATES STRESS-INDUCED STEREOTYPIC BEHAVIORS AND HPA AXIS ACTIVATION

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Gavin Petrie
University of Calgary, Hotchkiss Brain Institute, Calgary, Canada

Introduction: Endocannabinoid (eCB) signalling is known to regulate many aspects of the stress response including the hypothalamic-pituitary-adrenal (HPA) axis. A nexus of the HPA axis is a cluster of corticotropin releasing hormone (CRH) producing neurons in the paraventricular nucleus of the hypothalamus (PVN). ECB signalling mediates the glucocorticoid dependent negative feedback mechanism on CRH neurons following stress, suggesting that pharmacological upregulation of this system may dampen stress-induced consequences associated with CRH neuron activity. As such, using an array of cellular, endocrine and behavioral readouts associated with activation of CRH neurons in the PVN, we examined how upregulating eCB signaling ameliorates stress-induced generation of a stress response. **Methods:** Our endpoint measurements of a stress response included the examination of self-directed homecage behaviors (i.e., grooming), activation of CRH neurons in the PVN and corticosterone release. Phyisological readouts were measured using respective immunohistochemical and ELISA approaches. Cannula were implanted for central delivery of eCB enzyme inhibitors prior to foot shock stress. **Results:** Foot shock stress elevated grooming, PVN CRH neuron activation and circulating corticosterone. While FAAH inhibition had no effect, systemic MAGL inhibition ameliorated stress-induced grooming with no influence on HPA measures. Interestingly, preliminary results suggest that intra-PVN MAGL inhibition may ameliorate grooming as well as HPA measures following foot shock stress. **Conclusions:** These data suggest that pharmacological upregulation of 2-AG, specifically in the PVN, can alter the behavioral and HPA response to stress. These results lay the foundation for the development of cannabinoid based therapies targeting symptoms of stress-related disorders.

Endocannabinoids, cannabinoids and the regulation of anxiety.
Cannabis has been used for hundreds of years, with its ability to dampen feelings of anxiety often reported as a primary reason for use. Only recently has the specific role cannabinoids play in anxiety been thoroughly investigated. Here we discuss the body of evidence describing how endocannabinoids and exogenous cannabinoids are capable of regulating the generation and termination of anxiety states. Disruption of the endogenous cannabinoid (eCB) system following genetic manipulation, pharmacological intervention or stress exposure reliably leads to the generation of an anxiety state. On the other hand, upregulation of eCB signaling is capable of alleviating anxiety-like behaviors in multiple paradigms. When considering exogenous cannabinoid administration, cannabinoid receptor 1 (CB1) agonists have a biphasic, dose-dependent effect on anxiety such that low doses are anxiolytic while high doses are anxiogenic, a phenomenon that is evident in both rodent models and humans. Translational studies investigating a loss of function mutation in the gene for fatty acid amide hydrolase, the enzyme responsible for metabolizing AEA, have also shown that AEA signaling regulates anxiety in humans. Taken together, evidence reviewed here has outlined a convincing argument for cannabinoids being powerful regulators of both the manifestation and amelioration of anxiety symptoms, and highlights the therapeutic potential of targeting the eCB system for the development of novel classes of anxiolytics. This article is part of the special issue on 'Cannabinoids'.

Pharmacokinetics and central accumulation of delta-9-tetrahydrocannabinol (THC) and its bioactive metabolites are influenced by route of administration and sex in rats.
Up to a third of North Americans report using cannabis in the prior month, most commonly through inhalation. Animal models that reflect human consumption are critical to study the impact of cannabis on brain and behaviour. Most animal studies to date utilize injection of delta-9-tetrahydrocannabinol (THC; primary psychoactive component of cannabis). THC injections produce markedly different physiological and behavioural effects than inhalation, likely due to distinctive pharmacokinetics. The current study directly examined if administration route (injection versus inhalation) alters metabolism and central accumulation of THC and metabolites over time. Adult male and female Sprague-Dawley rats received either an intraperitoneal injection or a 15-min session of inhaled exposure to THC. Blood and brains were collected at 15, 30, 60, 90 and 240-min post-exposure for analysis of THC and metabolites. Despite achieving comparable peak blood THC concentrations in both groups, our results indicate higher initial brain THC concentration following inhalation, whereas injection resulted in dramatically higher 11-OH-THC concentration, a potent THC metabolite, in blood and brain that increased over time. Our results provide evidence of different pharmacokinetic profiles following inhalation versus injection. Accordingly, administration route should be considered during data interpretation, and translational animal work should strongly consider using inhalation models.

Discovery of a NAPE-PLD inhibitor that modulates emotional behavior in mice.
N-acylethanolamines (NAEs), which include the endocannabinoid anandamide, represent an important family of signaling lipids in the brain. The lack of chemical probes that modulate NAE biosynthesis in living systems hamper the understanding of the biological role of these lipids. Using a high-throughput screen, chemical proteomics and targeted lipidomics, we report here the discovery and characterization of LEI-401 as a CNS-active N-acylphosphatidylethanolamine phospholipase D (NAPE-PLD) inhibitor. LEI-401 reduced NAE levels in neuroblastoma cells and in the brain of freely moving mice, but not in NAPE-PLD KO cells and mice, respectively. LEI-401 activated the hypothalamus-pituitary-adrenal axis and impaired fear extinction, thereby emulating the effect of a cannabinoid CB receptor antagonist, which could be reversed by a fatty acid amide hydrolase inhibitor. Our findings highlight the distinctive role of NAPE-PLD in NAE biosynthesis in the brain and suggest the presence of an endogenous NAE tone controlling emotional behavior.

Nausea-Induced Conditioned Gaping Reactions in Rats Produced by High-Dose Synthetic Cannabinoid, JWH-018.
Cannabinoid hyperemesis syndrome is becoming a more prominently reported side effect of cannabis containing high-dose Δ-tetrahydrocannabinol (THC) and designer cannabinoid drugs such as "Spice." One active ingredient that has been found in "Spice" is 1-pentyl-3-(1-naphthoyl)indole (JWH-018), a synthetic full agonist of the cannabinoid 1 (CB) receptor. In this study, we evaluated the potential of different doses of JWH-018 to produce conditioned gaping in rats, an index of nausea. Rats received 3 daily conditioning trials in which saccharin was paired with JWH-018 (0.0, 0.1, 1, and 3 mg/kg, intraperitoneal [i.p.]). Then the potential of pretreatment with the CB antagonist, rimonabant (SR), to prevent JWH-018-induced conditioned gaping was determined. To begin to understand the potential mechanism underlying JWH-018-induced nausea, serum collected from trunk blood was subjected to a corticosterone (CORT) analysis in rats receiving three daily injections with vehicle (VEH) or JWH-018 (3 mg/kg). At doses of 1 and 3 mg/kg (i.p.), JWH-018 produced nausea-like conditioned gaping reactions. The conditioned gaping produced by 3 mg/kg JWH-018 was reversed by pretreatment with rimonabant, which did not modify gaping on its own. Treatment with JWH-018 elevated serum CORT levels compared to vehicle-treated rats. As we have previously reported with high-dose THC, JWH-018 produced conditioned gaping in rats, reflective of a nausea effect mediated by its action on CB receptors and accompanied by elevated CORT, reflective of hypothalamic-pituitary-adrenal (HPA) activation.

Role of the stress response and the endocannabinoid system in Δ-tetrahydrocannabinol (THC)-induced nausea.
Dysregulation of the endocannabinoid (eCB) system by high doses of Δ-tetrahydrocannabinol (THC) is hypothesized to

generate a dysfunctional hypothalamic-pituitary-adrenal (HPA) axis contributing to cannabinoid hyperemesis syndrome (CHS).
Psychopharmacology (Berl), 2020; 237
33998876: DeVuono MV, La Caprara O, Petrie GN, Limebeer CL, Rock EM, Hill MN, Parker LA
Cannabidiol Interferes with Establishment of Δ-Tetrahydrocannabinol-Induced Nausea Through a 5-HT Mechanism.
Cannabinoid hyperemesis syndrome (CHS) is characterized by intense nausea and vomiting brought on by the use of high-dose Δ-tetrahydrocannabinol (THC), the main psychotropic compound in cannabis. Cannabidiol (CBD), a nonpsychotropic compound found in cannabis, has been shown to interfere with some acute aversive effects of THC. In this study, we evaluated if CBD would interfere with THC-induced nausea through a 5-HT receptor mechanism as it has been shown to interfere with nausea produced by lithium chloride (LiCl). Since CHS has been attributed to a dysregulated stress response, we also evaluated if CBD would interfere with THC-induced increase in corticosterone (CORT). The potential of CBD (5 mg/kg, ip) to suppress THC-induced conditioned gaping (a measure of nausea) was evaluated in rats, as well as the potential of the 5-HT receptor antagonist, WAY-100635 (WAY; 0.1 mg/kg, ip), to reverse the suppression of THC-induced conditioned gaping by CBD. Last, the effect of CBD (5 mg/kg, ip) on THC-induced increase in serum CORT concentration was evaluated. Pretreatment with CBD (5 mg/kg, ip) interfered with the establishment of THC-induced conditioned gaping (=0.007, relative to vehicle [VEH] pretreatment), and this was reversed by pretreatment with 0.1 mg/kg WAY. This dose of WAY had no effect on gaping on its own. THC (10 mg/kg, ip) significantly increased serum CORT compared with VEH-treated rats (=0.04). CBD (5 mg/kg, ip) pretreatment reversed the THC-induced increase in CORT. CBD attenuated THC-induced nausea as well as THC-induced elevation in CORT. The attenuation of THC-induced conditioned gaping by CBD was mediated by its action on 5-HT receptors, similar to that of LiCl-induced nausea.

Vaporized Cannabis Extracts Have Reinforcing Properties and Support Conditioned Drug-Seeking Behavior in Rats.
Recent trends in cannabis legalization have increased the necessity to better understand the effects of cannabis use. Animal models involving traditional cannabinoid self-administration approaches have been notoriously difficult to establish and differences in the drug used and its route of administration have limited the translational value of preclinical studies. To address this challenge in the field, we have developed a novel method of cannabis self-administration using response-contingent delivery of vaporized Δ-tetrahydrocannabinol-rich (CAN) or cannabidiol-rich (CAN) whole-plant cannabis extracts. Male Sprague-Dawley rats were trained to nose-poke for discrete puffs of CAN, CAN, or vehicle (VEH) in daily 1 h sessions. Cannabis vapor reinforcement resulted in strong discrimination between active and inactive operanda. CAN maintained higher response rates under fixed ratio schedules and higher break points under progressive ratio schedules compared with CAN or VEH, and the number of vapor deliveries positively correlated with plasma THC concentrations. Moreover, metabolic phenotyping studies revealed alterations in locomotor activity, energy expenditure, and daily food intake that are consistent with effects in human cannabis users. Furthermore, both cannabis regimens produced ecologically relevant brain concentrations of THC and CBD and CAN administration decreased hippocampal CB1 receptor binding. Removal of CAN reinforcement (but not CAN) resulted in a robust extinction burst and an increase in cue-induced cannabis-seeking behavior relative to VEH. These data indicate that volitional exposure to THC-rich cannabis vapor has bona fide reinforcing properties and collectively support the utility of the vapor self-administration model for the preclinical assessment of volitional cannabis intake and cannabis-seeking behaviors. The evolving legal landscape concerning recreational cannabis use has increased urgency to better understand its effects on the brain and behavior. Animal models are advantageous in this respect; however, current approaches typically used forced injections of synthetic cannabinoids or isolated cannabis constituents that may not capture the complex effects of volitional cannabis consumption. We have developed a novel model of cannabis self-administration using response-contingent delivery of vaporized cannabis extracts containing high concentrations of Δ tetrahydrocannabinol (THC) or cannabidiol. Our data indicate that THC-rich cannabis vapor has reinforcing properties that support stable rates of responding and conditioned drug-seeking behavior. This approach will be valuable for interrogating effects of cannabis and delineating neural mechanisms that give rise to aberrant cannabis-seeking behavior.

Positive allosteric modulation of type 1 cannabinoid receptors reduces spike-and-wave discharges in Genetic Absence Epilepsy Rats from Strasbourg.
Childhood Absence Epilepsy (CAE) accounts for approximately 10% of all pediatric epilepsies. Current treatments for CAE are ineffective in approximately 1/3 of patients and can be associated with severe side effects such as hepatotoxicity. Certain cannabinoids, such as cannabidiol (CBD), have shown promise in the treatment of pediatric epilepsies. However, CBD

remains limited or prohibited in many jurisdictions, and has not been shown to have efficacy in CAE. Modulation of the type 1 cannabinoid receptor (CB1R) may provide more desirable pharmacological treatments. Genetic Absence Epilepsy Rats from Strasbourg (GAERS) model many aspects of CAE, including cortical spike and wave discharges (SWDs). We have recently demonstrated that Δ-tetrahydrocannabinol (THC) increases SWDs in GAERS whereas CBD decreases these events. Here, we characterized aspects of the endocannabinoid system in brain areas relevant to seizures in GAERS and tested whether positive allosteric modulators (PAMs) of CB1R reduced SWDs. Both female and male GAERS had reduced (>50%) expression of CB1R and elevated levels of the endocannabinoid 2-AG in cortex compared to non-epileptic controls (NEC). We then administered the CB1R PAMs GAT211 and GAT229 to GAERS implanted with cortical electrodes. Systemic administration of GAT211 to male GAERS reduced SWDs by 40%. Systemic GAT229 administration reduced SWDs in female and male GAERS. Intracerebral infusion of GAT229 into the cortex of male GAERS reduced SWDs by >60% in a CB1R-dependent manner that was blocked by SR141716A. Together, these experiments identify altered endocannabinoid tone in GAERS and suggest that CB1R PAMs should be explored for treatment of absence seizures.

N-Oleoyl-glycine reduces nicotine reward and withdrawal in mice.

Cigarette smokers with brain damage involving the insular cortex display cessation of tobacco smoking, suggesting that this region may contribute to nicotine addiction. In the present study, we speculated that molecules in the insular cortex that are sensitive to experimental traumatic brain injury (TBI) in mice might provide leads to ameliorate nicotine addiction. Using targeted lipidomics, we found that TBI elicited substantial increases of a largely uncharacterized lipid, N-acyl-glycine, N-oleoyl-glycine (OlGly), in the insular cortex of mice. We then evaluated whether intraperitoneal administration of OlGly would alter withdrawal responses in nicotine-dependent mice as well as the rewarding effects of nicotine, as assessed in the conditioned place preference paradigm (CPP). Systemic administration of OlGly reduced mecamylamine-precipitated withdrawal responses in nicotine-dependent mice and prevented nicotine CPP. However, OlGly did not affect morphine CPP, demonstrating a degree of selectivity. Our respective in vitro and in vivo observations that OlGly activated peroxisome proliferator-activated receptor alpha (PPAR-α) and the PPAR-α antagonist GW6471 prevented the OlGly-induced reduction of nicotine CPP in mice suggests that this lipid acts as a functional PPAR-α agonist to attenuate nicotine reward. These findings raise the possibility that the long chain fatty acid amide OlGly may possess efficacy in treating nicotine addiction.

Introduction: Emerging evidence suggests that enhancing anandamide signaling ameliorates anxiety and depression, although the underlying mechanisms require further investigation. We aimed to determine whether increasing anandamide signaling, using the fatty acid amide hydrolase (FAAH) inhibitor URB597, prevents a stress phenotype via a mechanism involving the Wnt/β-catenin pathway in the medial PFC (mPFC). **Methods:** Rats were exposed to shock and reminders model of PTSD and injected with URB597 (0.4 mg/kg, i.p.). The expression of β-catenin protein levels and the stress markers corticotrophin releasing factor (CRF) and CRF type 1 receptor (CRFr1) were examined 3 weeks after the shock. In a following experiment, rats were taken to stereotaxic surgery in which β-catenin was down-regulated in the mPFC by viral-mediated gene transfer. **Results:** Exposure to shock and reminders induced a depression- and anxiety-like phenotype, upregulated CRF and CRFr1 and downregulated the expression of β-catenin protein levels in the mPFC. URB597 restored the behavioral phenotype and the alterations in CRF, CRFr1 and β-catenin. Importantly, viral downregulation of PFC β-catenin in rats exposed to shock and reminders blocked the therapeutic-like effects of URB597 on the behavioral phenotype and the alterations In CRF and CRFr1 levels. Hence, the therapeutic-like effects of URB597 are mediated via β-catenin in the PFC. **Conclusions:** The findings further support a potential therapeutic role for increasing anandamide signaling in stress-induced depression and anxiety and suggest that the effects of URB597 on stress phenotype are associated with β-catenin function in the PFC.

Cannabinoids as therapeutics for PTSD.
Post-traumatic stress disorder (PTSD) is a complex disorder that involves dysregulation of multiple neurobiological systems. The traumatic stressor plays a causal role in producing psychological dysfunction and the pattern of findings suggests that the hypothalamic-pituitary-adrenal (HPA) axis, which is instrumental for stress adaptation, is critically dysfunctional in PTSD. Given the lack of understanding of the basic mechanisms and underlying pathways that cause the disorder and its heterogeneity, PTSD poses challenges for treatment. Targeting the endocannabinoid (ECB) system to treat mental disorders, and PTSD in particular, has been the focus of research and interest in recent years. The ECB system modulates multiple functions, and drugs enhancing ECB signaling have shown promise as potential therapeutic agents in stress effects and other psychiatric and medical conditions. In this review, we focus on the interaction between the ECB-HPA systems in animal models for PTSD and in patients with PTSD. We summarize evidence supporting the use of cannabinoids in preventing and treating PTSD in preclinical and clinical studies. As the HPA system plays a key role in the mediation of the stress response and the pathophysiology of PTSD, we describe preclinical studies suggesting that enhancing ECB signaling is consistent with decreasing PTSD symptoms and dysfunction of the HPA axis. Overall, we suggest that a pharmacological treatment targeted at one system (e.g., HPA) may not be very effective because of the heterogeneity of the disorder. There are abnormalities across different neurotransmitter systems in the pathophysiology of PTSD and none of these systems function uniformly among all patients with PTSD. Hence, conceptually, enhancing ECB signaling may be a more effective avenue for pharmacological treatment.

Chronic exposure to cannabinoids before an emotional trauma may have negative effects on emotional function.
Chronic direct activation of cannabinoid CB1 receptors (CB1r) may lead to downregulation of CB1r which may in turn result in a depression-like phenotype in certain individuals. We examined the effects of chronic cannabinoid receptor activation before

exposure to an emotional traumatic event on CB1r expression in the basolateral amygdala (BLA) and CA1 and on protracted anxiety- and depression-like behaviors. We used exposure to severe shock and situational reminders (SRs) in an inhibitory apparatus as a model for emotional trauma. Chronic treatment with the CB1/2 receptor agonist WIN55,212-2 (1.2 mg/kg, i.p.) before shock exposure had differential effects on depression- and anxiety-like behavioral measures depending on withdrawal periods. In the 24 hrs withdrawal condition, WIN55,212-2 enhanced fear retrieval and impaired extinction, increased anhedonia and despair, but had a therapeutic effect in the startle test. In the 10 days withdrawal condition, WIN55,212-2 enhanced fear retrieval and impaired extinction without preventing the shock/SR-induced negative effects on anhedonia or startle response, but had a therapeutic effect in the despair test. Chronic treatment with WIN55,212-2 was found to down regulate CB1r protein levels in the BLA in the 10 days withdrawal condition, and to upregulate CB1r protein levels in the 24 hrs condition. In the CA1, rats chronically injected with vehicle or WIN55,212-2 demonstrated downregulation of CB1r protein levels. Chronic exposure to cannabinoids prior to an emotional trauma may have deleterious effects on emotional function suggesting that direct CB1/2 receptor activation may not be an optimal way to manipulate the endocannabinoid system in stressful individuals.

DOSE-DEPENDENT EFFECT OF REPEATED EXPOSURE TO EXTREMELY LOW-FREQUENCY ELECTROMAGNETIC FIELD (ELF-EMF) ON STRESS-RELATED BEHAVIOUR IN RATS

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Angelika Klimek, Maciej Klimiuk, Hanna Kletkiewicz, Justyna Maliszewska, Agnieszka Siejka, Milena Jankowska, Joanna Wyszkowska, Maria Stankiewicz, Justyna Rogalska
Nicolaus Copernicus University, Department Of Animal Physiology And Neurobiology, Toruń, Poland

The ELF-EMF is regarded as a mild stress factor, which has been linked to the development of depression and anxiety in humans and anxiety-like behaviours in animals. Recently we have found the bidirectional effect of ELF-EMF on hypothalamic-pituitary-adrenal axis activity. We hypothesized that there is a safe limit of ELF-EMF intensity to which the organism can adapt and beyond which the behavioural changes can occur. Therefore, the study was aimed at determining the influence of repeated exposure to ELF-EMF 50 Hz of the low and high intensity on stress-related behaviour in rats. Adult male Wistar rats were divided into groups: 1) animals exposed to ELF-EMF of 1 mT, or 2) 7 mT, 3) control animals subjected to the same experimental procedure except for ELF-EMF exposure. Rats were exposed one (E1), two (E2) or three times (E3) for ELF-EMF (each: 7-days, 1 hour per day). After the end of each exposure period, the open-field test was performed. In rats exposed to 1 mT ELF-EMF, the activity was not changed significantly. While in animals exposed to 7 mT ELF-EMF, the activity was increased after E1 and E2, but it reached the control level after E3. We suggest that the stress system response evoked by the low-stress factor - 1 mT EMF - was not strong enough to change the behaviour. However, exposure to 7 mT ELF-EMF can cause the disturbance of stress response determining the increase of sensitivity to subsequent stress and probably the risk of stress-induced disorders.

Aims: Present work used Daun02 inactivation method in c-Fos lacZ transgenic rat in order to evaluate the effect of ventral hippocampus (VH) inactivation on behavioral responses habituation related to repeated chronic stress (CRS). Daun02 is substrate of β-galactosidase that catalyses Daun02 into daunomycin, causing apoptosis and calcium channels blockade. Methods: Guide cannulas were implanted into the VH of c-Fos LacZ transgenic rats. We submitted rats to CRS (2 h/day for 21 days) and studied the effect of vehicle or Daun02 microinjection into the VH on CRS-induced anxiety- (elevated plus maze and open field) and depressive-like (forced swimming test and splash test) responses observed, respectively, 24 and 48h after the last stress session. Results: Preliminary results showed that vehicle group presented a tendency in increase the number of open arms entries when compared to naive group (no stress). Daun02 group did not change the number of entries and the time spent in the open arms when compared to the vehicle. Vehicle group caused no change in time spent in the center of the arena when compared to naive, however Daun02 group showed a tendency of decrease it. Vehicle group showed a tendency in decrease grooming and immobility times when compared to naive. Daun02 group presented a tendency of increase the grooming time when compared to vehicle. Conclusion: Results show that, probably, VH participate in the neural pathway which is involved with behavioral responses observed during CRS. INVESTIGATING THE EFFECTS OF ACUTE THC VAPOUR EXPOSURE ON STRESS REACTIVITY AND FEAR CONDITIONING

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Savannah Lightfoot[1], Andrei Nastase[1], Samantha Baglot[1], Catherine Hume[2], Robert Aukema[1], Ryan Mclaughlin[3], Matthew Hill[2]
[1]University of Calgary, Hotchkiss Brain Institute, Cumming School Of Medicine, Calgary, Canada, [2]University of Calgary, Hotchkiss Brain Institute, Cumming School Of Medicine, Department Of Cell Biology & Anatomy, Calgary, Canada, [3]Washington State University, Department Of Integrative Physiology And Neuroscience, Pullman, United States of America

Management of stress and anxiety in the general population, and management of PTSD symptoms in patients, are often listed as primary motivations behind cannabis use, yet the understanding of how acute exposure to cannabis modulates the neurobehavioral and endocrine response to negatively valanced stimuli is not well characterized. The aims of this study are twofold, to investigate the effects of acute cannabis exposure on stress reactivity and extinction training in a fear conditioning paradigm. Using a highly translational model of THC vapour inhalation, male and female rats were exposed to THC or vehicle for 15 minutes. In study 1, animals were subjected to one of the two vapour exposure conditions followed by exposure to an acute stressor or no stress condition. Blood samples were taken at several time points and plasma corticosterone (CORT) levels were quantified using an ELISA. In study 2, animals underwent fear conditioning, followed by vapour exposure and extinction training and finally extinction retrieval. Both passive (freezing) and active (darting) conditioned responses were quantified. This research has shown that acute THC exposure immediately elevates CORT levels in males but not female rats. It also shows that THC exposure prior to extinction training does not alter fear extinction in males but did impair fear extinction in females. This research suggests that acute exposure to THC vapour has sex-dependent effects on both neuroendocrine and behavioural responses to aversive stimuli.

Pharmacokinetics and central accumulation of delta-9-tetrahydrocannabinol (THC) and its bioactive metabolites are influenced by route of administration and sex in rats.
Up to a third of North Americans report using cannabis in the prior month, most commonly through inhalation. Animal models that reflect human consumption are critical to study the impact of cannabis on brain and behaviour. Most animal studies to date utilize injection of delta-9-tetrahydrocannabinol (THC; primary psychoactive component of cannabis). THC injections produce markedly different physiological and behavioural effects than inhalation, likely due to distinctive pharmacokinetics. The current study directly examined if administration route (injection versus inhalation) alters metabolism and central accumulation of THC and metabolites over time. Adult male and female Sprague-Dawley rats received either an intraperitoneal injection or a 15-min session of inhaled exposure to THC. Blood and brains were collected at 15, 30, 60, 90 and 240-min post-exposure for analysis of THC and metabolites. Despite achieving comparable peak blood THC concentrations in both groups, our results indicate higher initial brain THC concentration following inhalation, whereas injection resulted in dramatically higher 11-OH-THC concentration, a potent THC metabolite, in blood and brain that increased over time. Our results provide evidence of different pharmacokinetic profiles following inhalation versus injection. Accordingly, administration route should be considered during data interpretation, and translational animal work should strongly consider using inhalation models.

Comparison of the Time-Dependent Changes in Immediate Early Gene Labeling and Spine Density Following Abstinence From Contingent or Non-contingent Chocolate Pellet Delivery.
: Incubation of craving is a phenomenon whereby responding for cues associated with a reward increases over extended periods of abstinence. Both contingent and non-contingent behavioral designs have been used to study the incubation of

craving phenomenon with differing results. The present study directly compares behavioral and neural changes following contingent or non-contingent administration of chocolate flavored pellets. : The current study examined whether an incubation of craving response would be observed at the behavioral and neural levels following delays of abstinence from chocolate pellets in a contingent or non-contingent reinforcement design. : Rats were trained for 10 days to bar press for chocolate pellets (contingent) or received chocolate pellets in a non-contingent design (classical conditioning). Groups were then subjected to abstinence from the reward for 24 h, 7, 14 or 28 days at which point they were tested for responding for reward associated cues. Following the test, brains from all rats were processed and assessed for c-Fos and FosB labeling as well as dendritic spine density in the nucleus accumbens (NAc). : Behavioral measures during the test (lever presses, food hopper entries and locomotor activity) revealed similar behavioral outcomes across all delays indicating the lack of an incubation of craving response on both the contingent and non-contingent designs. Overall, labeling of c-Fos in the NAc was lower for the non-contingent group compared to the operant-trained and food restricted control. Compared to the operant-trained and non-trained control groups, a significantly reduced FosB labeling was noted in the NAc of the classically conditioned groups across all abstinence periods. Spine density in the NAc was elevated in both the classically and operant conditioned compared to the food-restricted, non-trained controls. : Chocolate pellet reward did not result in incubation of craving but did produce behavioral learning that was associated with increased spine density. This suggests that chocolate pellet administration results in long-term structural and functional changes that are present for at least 28 days following abstinence. Contingent and non-contingent administration resulted in differential immediate early gene labeling in the NAc, but the functional significance of this has yet to be elucidated.

Stress is one of the most dangerous latent conditions in our lives and the leading cause of several types of disease. Today, stress is underdiagnosed. This could be attributed to the fact that part of the current diagnostic methods is based mainly on self-reporting and clinical checklists, which are subjective and inaccurate. The other part of the methods includes physiological measurement, such as heart rate variability, which are more accurate but are still affected by other factors and may not be suitable for daily monitoring. Here, we report a novel way to measure stress in a fast, non-invasive, and accurate manner. The approach relies on detecting volatile organic compounds (VOCs) that are emitted as a response to a changes in a bodily condition or a disease and in exchange with the skin, which has been previously shown as a reliable method to detect several diseases. VOCs linked with traumatic stress in rats (Sprague-Dawley male rats, *n*=32) were measured before, during, and after induction of a traumatic event. The results show a significant difference between the VOCs pattern of stressed rats and control in a predictive model with ROC AUC of 0.81 (90% sensitivity and 70% specificity) as well as a long-term effect after one week with *p*-value=0.0091 by Monte Carlo correlation analysis (and *p*-value=0.0044 during stress). These results signify the potential of using this method for a non-invasive, automatic, and real-time prediction of stress for diagnostics and monitoring mental health.

Aims: Chronic stress models represent valid animal models for major depressive disorder (MDD) and can mimic core symptoms of the disease, e.g. anhedonia. It is well documented that chronic stress alters the functional and morphological integrity of neurons in limbic areas such as the hippocampus and prefrontal cortex (PFC). Typical stress-induced structural changes are the dendritic debranching, loss of dendritic spines and synapses. Recent theories suggest that stress may also alter mitochondrial structure and function. The purpose of the present study was to investigate putative changes of mitochondrial morphology and number in neurons of chronically stressed rats and depressed patients. Methods: We carried out a transmission electron microscopic analysis to quantify the number and morphological features of mitochondria in the medial PFC of control (n=4) and stressed (n=4) rats. A random systematic sampling was performed to take ultrastructural images at 40 000x magnification. Images were analysed with an unbiased stereology protocol. Results: Circa 8 000 EM images and nearly 100 000 mitochondria were counted and examined. We found a significant reduction in the number of mitochondria in the infralimbic cortex of rats, yet there were no changes in mitochondrial morphology. Mitochondrial parameters were also analysed in samples collected from the hippocampi of control (n=4) and MDD patients (n=4). Conclusion: In a rodent chronic stress model, we found significant reduction of mitochondrial numbers, but mitochondrial morphology was not altered. Further data from human samples will be presented on the poster.

Reduced Synapse and Axon Numbers in the Prefrontal Cortex of Rats Subjected to a Chronic Stress Model for Depression. Stressful experiences can induce structural changes in neurons of the limbic system. These cellular changes contribute to the development of stress-induced psychopathologies like depressive disorders. In the prefrontal cortex of chronically stressed animals, reduced dendritic length and spine loss have been reported. This loss of dendritic material should consequently result in synapse loss as well, because of the reduced dendritic surface. But so far, no one studied synapse numbers in the prefrontal cortex of chronically stressed animals. Here, we examined synaptic contacts in rats subjected to an animal model for depression, where animals are exposed to a chronic stress protocol. Our hypothesis was that long term stress should reduce the number of axo-spinous synapses in the medial prefrontal cortex. Adult male rats were exposed to daily stress for 9 weeks and afterward we did a post mortem quantitative electron microscopic analysis to quantify the number and morphology of synapses in the infralimbic cortex. We analyzed asymmetric (Type I) and symmetric (Type II) synapses in all cortical layers in control and stressed rats. We also quantified axon numbers and measured the volume of the infralimbic cortex. In our systematic unbiased analysis, we examined 21,000 axon terminals in total. We found the following numbers in the infralimbic cortex of control rats: 1.15 × 10 asymmetric synapses, 1.06 × 10 symmetric synapses and 1.00 × 10 myelinated axons. The density of asymmetric synapses was 5.5/µm and the density of symmetric synapses was 0.5/µm. Average synapse membrane length was 207 nm and the average axon terminal membrane length was 489 nm. Stress reduced the number of synapses and myelinated axons in the deeper cortical layers, while synapse membrane lengths were increased. These stress-induced ultrastructural changes indicate that neurons of the infralimbic cortex have reduced cortical network connectivity. Such reduced network connectivity is likely to form the anatomical basis for the impaired functioning of this brain area. Indeed, impaired functioning of the prefrontal cortex, such as cognitive deficits are common in stressed individuals as

well as in depressed patients.

Dysfunctions of median raphe region (MRR) were associated with stress-related psychiatric disorders, assumably due to its serotoninergic content. Recently we have found that corticotropin-releasing hormone (CRH), the main hypothalamic regulator of stress axis, is also abundant in this area. Therefore, we aimed to reveal the contribution of these peptidergic cells in stress adaptation. Pharmacogenetic technique was used in male CRH-Cre mice. Control, or stimulatory DREADD sequence was injected into the MRR using adeno-associated viral vector. Clozapine-N-oxide was used as a ligand. Parallel with changes in stress-hormone concentration, anxiety- and depression-like behavior was also measured. Stress-induced activation of MRR-CRH-ergic cells were studied in CRH-Cre tdTomato crossbred animals. Accuracy of injections and c-Fos activation were investigated by immunohistochemistry. Stimulation of CRH neurons in MRR increased corticosterone levels and relative spleen weight parallel with anxiety-like behavior in elevated plus maze, light-dark box, and fox odor test compared to controls. Difference was not found in tests measuring depression-like behavior. Acute stress activated the MRR-CRH neurons measured by c-Fos. To summarize, stimulation of MRR-CRH neurons may induce stress-hormone elevation as well as anxiety-like, but not depression-like behavior. Thus, our results support the existence of a new, acute stress regulatory brainstem CRH population, which may play a key role in regulating stress adaptation both at hormonal and behavioral level.

MIR-34 FAMILY IS INVOLVED IN CHRONIC SOCIAL DEFEAT-INDUCED VULNERABILITY TO MOOD DISORDERS AND CARDIAC MITOCHONDRIAL DYSFUNCTIONS

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Chronic stress exposure increases vulnerability to mood disorders. Interestingly, a bidirectional relationship between depressive disorders and cardiovascular disease has been observed in clinical and pre-clinical studies, and chronic stress can favour the onset of both pathologies. This could be due to shared genetic predispositions as well as dysregulated stress-coping response. MicroRNAs (miRs) are involved in brain responses to stressful stimuli. Our previous studies have linked the miR-34 family with neurobiological mechanisms that underlie the regulation of stress response, and the subsequent adopted coping mechanism. Interestingly, we recently observed that rats exposed to Chronic Social Defeat (CSD) showed increased miR-34a levels in heart, coupled with increased risk of cardiovascular dysfunctions, and RNA sequencing suggested compromised mitochondria's function. Here, we hypothesize that miR-34 family is involved in the onset of stress-induced mood disorders as well as cardiovascular disease, affecting coping response and heart's mitochondrial respiration. Wild Type (WT) and knockout (TKO) mice for miR-34 family were tested to assess anxious- and depressive-like behavior. Then they underwent to CSD and retested to evaluate the effect of CSD exposure. A separate cohort of subject underwent to CSD or left unstressed, then heart's Oxygen Consumption Rate (OCR) was measured. We found that TKO coping behavior is less affected by CSD exposure compared to WT. Moreover, we found that TKO mice exhibit lower heart's OCR after CSD compared to other groups. Our results suggest that miR-34 family is involved in CSD-induced vulnerability to cardiovascular and mood disorders, affecting coping behavior and cellular respiratory functions.

Elevated miR-34a expression and altered transcriptional profile are associated with adverse electromechanical remodeling in the heart of male rats exposed to social stress.
This study investigated epigenetic risk factors that may contribute to stress-related cardiac disease in a rodent model. Experiment 1 was designed to evaluate the expression of microRNA-34a (miR-34a), a known modulator of both stress responses and cardiac pathophysiology, in the heart of male adult rats exposed to a single or repeated episodes of social defeat stress. Moreover, RNA sequencing was conducted to identify transcriptomic profile changes in the heart of repeatedly stressed rats. Experiment 2 was designed to assess cardiac electromechanical changes induced by repeated social defeat stress that may predispose rats to cardiac dysfunction. Results indicated a larger cardiac miR-34a expression after repeated social defeat stress compared to a control condition. This molecular modification was associated with increased vulnerability to pharmacologically induced arrhythmias and signs of systolic left ventricular dysfunction. Gene expression analysis identified clusters of differentially expressed genes in the heart of repeatedly stressed rats that are mainly associated with morphological and functional properties of the mitochondria and may be directly regulated by miR-34a. These results suggest the presence of an association between miR-34a overexpression and signs of adverse electromechanical remodeling in the heart of rats exposed to repeated social defeat stress, and point to compromised mitochondria efficiency as a potential mediator of this link. This rat model may provide a useful tool for investigating the causal relationship between miR-34a expression, mitochondrial (dys)function, and cardiac alterations under stressful conditions, which could have important implications in the context of stress-related cardiac disease.

Resilience to anhedonia-passive coping induced by early life experience is linked to a long-lasting reduction of I current in VTA dopaminergic neurons.
Exposure to aversive events during sensitive developmental periods can affect the preferential coping strategy adopted by individuals later in life, leading to either stress-related psychiatric disorders, including depression, or to well-adaptation to future adversity and sources of stress, a behavior phenotype termed "resilience". We have previously shown that interfering with the development of mother-pups bond with the Repeated Cross Fostering (RCF) stress protocol can induce resilience to depression-like phenotype in adult C57BL/6J female mice. Here, we used patch-clamp recording in midbrain slice combined with both and pharmacology to test our hypothesis of a link between electrophysiological modifications of dopaminergic neurons in the intermediate Ventral Tegmental Area (VTA) of RCF animals and behavioral resilience. We found reduced hyperpolarization-activated (I) cation current amplitude and evoked firing in VTA dopaminergic neurons from both young and adult RCF female mice. , VTA-specific pharmacological manipulation of the I current reverted the pro-resilient phenotype in adult early-stressed mice or mimicked behavioral resilience in adult control animals. This is the first evidence showing how pro-resilience behavior induced by early events is linked to a long-lasting reduction of I current and excitability in VTA dopaminergic neurons.

Long term effects of early life stress on HPA circuit in rodent models.
Adaptation to environmental challenges represents a critical process for survival, requiring the complex integration of information derived from both external cues and internal signals regarding current conditions and previous experiences. The Hypothalamic-pituitary-adrenal axis plays a central role in this process inducing the activation of a neuroendocrine signaling cascade that affects the delicate balance of activity and cross-talk between areas that are involved in sensorial, emotional, and cognitive processing such as the hippocampus, amygdala, Prefrontal Cortex, Ventral Tegmental Area, and dorsal raphe. Early life stress, especially early critical experiences with caregivers, influences the functional and structural organization of these areas, affects these processes in a long-lasting manner and may result in long-term maladaptive and psychopathological outcomes, depending on the complex interaction between genetic and environmental factors. This review summarizes the results of studies that have modeled this early postnatal stress in rodents during the first 2 postnatal weeks, focusing on the long-term effects on molecular and structural alteration in brain areas involved in Hypothalamic-pituitary-adrenal axis function. Moreover, a brief investigation of epigenetic mechanisms and specific genetic targets mediating the long-term effects of these early environmental manipulations and at the basis of differential neurobiological and behavioral effects during adulthood is provided.

MicroRNA-34a regulates 5-HT2C expression in dorsal raphe and contributes to the anti-depressant-like effect of fluoxetine.
Selective serotonin reuptake inhibitors (SSRIs) are designed to improve mood by raising extracellular serotonin levels through the blockade of the serotonin transporter. However, they exhibit a slow onset of action, suggesting the involvement of adaptive regulatory mechanisms. We hypothesized that the microRNA-34 family facilitates the therapeutic activity of SSRIs. We show that genetic deletion of these microRNAs in mice impairs the response to chronic, but not acute, fluoxetine treatment, with a specific effect on behavioral constructs that are related to depression, rather than anxiety. Moreover, using a pharmacological strategy, we found that an increased expression of the serotonin 2C (5-HT2C) receptor in the dorsal raphe region of the brain contributes to this phenotype. The onset of the therapeutic efficacy of SSRIs is paralleled by the desensitization of the 5-HT2C receptor in the dorsal raphe, and 5-HT2C is a putative target of microRNA-34. In this study, acute and chronic fluoxetine treatment differentially alters the expression of 5-HT2C and microRNA-34a in the dorsal raphe. Moreover, by in vitro luciferase assay, we demonstrated the repressive regulatory activity of microRNA-34a against 5-HT2C mRNA. Specific blockade of this interaction through local infusion of a target site blocker was sufficient to prevent the behavioral effects of chronic fluoxetine. Our results demonstrate a new miR-34a-mediated regulatory mechanism of 5-HT2C expression in the dorsal raphe and implicate it in eliciting the behavioral responses to chronic fluoxetine treatment.

Xlr4 as a new candidate gene underlying vulnerability to cocaine effects.
Although several studies have been performed in rodents, non-human primates and humans, the biological basis of vulnerability to develop cocaine addiction remains largely unknown. Exposure to critical early events (as Repeated Cross Fostering (RCF)) has been reported to increase sensitivity to cocaine effects in adult C57BL/6J female mice. Using a

microarray approach, here we report data showing a strong engagement of X-linked lymphocyte-regulated 4a and 4b (Xlr4) genes in cocaine effects. The expression of Xlr4, a gene involved in chromatin remodeling and dendritic spine morphology, was reduced into the Nucleus Accumbens (NAc) of adult RCF C57BL/6J female. We used virally mediated accumbal Xlr4 down-modulation (AAVXlr4-KD) to investigate the role of this gene in vulnerability to cocaine effects. AAVXlr4-KD animals show a potentiated behavioral and neurochemical response to cocaine, reinstatement following cocaine withdrawal and cocaine-induced spine density alterations in the Medium-Sized Spiny Neurons of NAc. We propose Xlr4 as a new candidate gene mediating the cocaine effects.

RISC RNA sequencing in the Dorsal Raphè reveals microRNAs regulatory activities associated with behavioral and functional adaptations to chronic stress.
The Dorsal Raphe (DR) is the primary source of serotonergic input in the brain and a center for the homeostatic maintenance of the serotonergic tone. Under repeated stimulation, it can undergo adaptive modifications that alter serotonergic neurotransmission, which can lead to behavioral dysfunction. Post-transcriptional regulation by microRNAs is implicated in these adaptations. However, a global microRNA/target network effect on the DR neuroplasticity has yet to be elucidated. Here we investigate the microRNAs/mRNAs regulatory activity in the mouse DR after a chronic stress experience. First, we assessed the behavioral consequences of repeated restraint stress exposure and the functional adaptations of the DR by measuring the change in acute stress-induced serotonin release. Then, through next generation RNA-Seq of Argonaute2-bound RNA (RISC-Seq) we identified microRNAs and their targets that are associated to the RISC complex of the DR in unstressed and stressed mice. We mapped the potential microRNA/mRNA network within the stress-altered transcripts, uncovering new interactions that contribute to the chronic stress-induced DR modifications.
Brain Res, 2020; 1736

Sex-dependent effects of early unstable post-natal environment on response to positive and negative stimuli in adult mice.
Alterations in early environmental conditions that interfere with the creation of a stable mother-pup bond have been suggested to be a risk factor for the development of stress-related psychopathologies later in life. The long-lasting effects of early experiences are mediated by changes in various cerebral circuits, such as the corticolimbic system, which processes aversive and rewarding stimuli. However, it is evident that the early environment is not sufficient per se to induce psychiatric disorders; interindividual (eg, sex-based) differences in the response to environmental challenges exist. To examine the sex-related effects that are induced by an early experience on later events in adulthood, we determine the enduring effects of repeated cross-fostering (RCF) in female and male C57BL/6J mice. To this end, we assessed the behavioral phenotype of RCF and control (male and female) mice in the saccharine preference test and cocaine-induced conditioned place preference to evaluate the response to natural and pharmacological stimuli and in the elevated plus maze test and forced swimming test to measure their anxiety- and depression-like behavior. We also evaluated FST-induced c-Fos immunoreactivity in various brain regions that are engaged in the response to acute stress exposure (FST). Notably, RCF has opposing effects on the adult response to these tests between sexes, directing male mice toward an "anhedonia-like" phenotype and increasing the sensitivity for rewarding stimuli in female mice.

MicroRNA-34a Regulates the Depression-like Behavior in Mice by Modulating the Expression of Target Genes in the Dorsal Raphè.
Chronic stress exposure is known to increase vulnerability to the expression of psychiatric disorders, such as depression. Clinical and preclinical evidences support the involvement of the microRNA-34 family in stress-related psychiatric conditions and in the regulation of stress responses. However, the mechanism and the multiple targets by which the microRNA-34 family can affect the stress response and stress-related behavioral alteration are not fully known. Here, with the aid of constitutive and conditional genetic strategy, we examined the role of microRNA-34 family in the expression of depression-like phenotype in mice induced by chronic stress exposure, and we identified their "in vivo" targets during the stressful challenge. We found that microRNA-34a, under chronic stress, is significantly up-regulated in the mouse raphe nuclei, where its recruitment is necessary to induce depression-like behavioral alterations and impact the function of the serotonergic system. Moreover, by next-generation RNA-seq of Ago-2-bound mRNAs, we identified genes that are targeted by microRNA-34a in response to chronic stress and that are likely to mediate its effects.

MicroRNA-34 Contributes to the Stress-related Behavior and Affects 5-HT Prefrontal/GABA Amygdalar System through Regulation of Corticotropin-releasing Factor Receptor 1.

Recent studies show that microRNA-34 (miR-34) family is critical in the regulation of stress response also suggesting that it may contribute to the individual responsiveness to stress. We have recently demonstrated that mice carrying a genetic deletion of all miR-34 isoforms (triple knockout, TKO) lack the stress-induced serotonin (5-HT) and GABA release in the medial prefrontal cortex (mpFC) and basolateral amygdala (BLA), respectively. Here, we evaluated if the absence of miR-34 was also able to modify the stress-coping strategy in the forced swimming test. We found that the blunted neurochemical response to stress was associated with lower levels of immobility (index of active coping behavior) in TKO compared to WT mice. Interestingly, among the brain regions mostly involved in the stress-related behaviors, the miR-34 displayed the strongest expression in the dorsal raphe nuclei (DRN) of wild-type (WT) mice. In the DRN, the corticotropin-releasing factor receptors (CRFR) 1 and 2, contribute to determine the stress-coping style and the CRFR1 is a target of miR-34. Thus, we hypothesized that the miR-34-dependent modulation of CRFR1 expression may be involved in the DRN regulation of stress-coping strategies. In line with this hypothesis, we found increased CRFR1 levels in the DNR of TKO compared to WT mice. Moreover, infusion of CRFR1 antagonist in the DRN of TKO mice reverted their behavioral and neurochemical phenotype. We propose that miR-34 modulate the mpFC 5-HT/BLA GABA response to stress acting on CRFR1 in the DRN and that this mechanism could contribute to determine individual stress-coping strategy.

DOPAMINE SYSTEM, NMDA RECEPTOR AND EGF FAMILY EXPRESSIONS IN BRAIN STRUCTURES OF BL6 AND 129SV STRAINS DISPLAYING DIFFERENT BEHAVIORAL ADAPTATION

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Jane Varul, Kattri-Liis Eskla, Maria Piirsalu, Jürgen Innos, Mari-Anne Philips, Tanel Visnapuu, Mario Plaas, Eero Vasar
University of Tartu, Department Of Physiology, Tartu, Estonia

C57BL/6NTac (Bl6) and 129S6/SvEvTac (129Sv) mice display different coping strategies in stressful conditions. Our aim was to evaluate biomarkers related to different adaptation strategies in the brain of male 129Sv and Bl6 mice. We focused on signaling pathways related to the dopamine (DA) system, N-methyl-D-aspartate (NMDA) receptor and epidermal growth factor (EGF) family, shown as the key players in behavioral adaptation. Mice from Bl6 and 129Sv lines were divided into either home cage controls (HCC group) or exposed to repeated motility testing and treated with saline for 11 days (RMT group). Distinct stress responses were reflected in severe body weight loss in 129Sv and the increased exploratory behavior in Bl6 mice. Besides that, amphetamine caused significantly stronger motor stimulation in Bl6. Together with the results from gene expression (particularly *Maob*), this study supports higher baseline activity of DA system in Bl6. Interestingly, the adaptation is reflected with opposite changes of DA markers in dorsal and ventral striatum. In forebrain, stress increased the gene expressions of *Egf-Erbb1* and *Nrg1/Nrg2-Erbb4* pathways more clearly in 129Sv, whereas the corresponding proteins were significantly elevated in Bl6. We suggest that not only inhibited activity of the DA system, but also reduced activity of EGF family and NMDA receptor signaling underlies higher susceptibility to stress in 129Sv. Altogether, this study underlines the better suitability of 129Sv for modelling neuropsychiatric disorders than Bl6.

THE EFFECT OF SOCIAL ISOLATION ON CANCER METASTASES AND THE NUCLEUS ACCUMBENS IN RATS.

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Estherina Trachtenberg, Keren Ruzal, Einat Bigelman, Shamgar Ben-Eliyahu, Inbal Ben-Ami Bartal
Tel Aviv Univerity, Sagol School Of Neuroscience, Tel Aviv, Israel

Background: Social isolation (SI) was found to negatively impact wellbeing, is a risk factor for malignancy, morbidity, and mortality, and is associated with immune suppression, accelerated cancer progression, and neuroendocrine changes. Here we study the impact of SI in rats on metastatic progression and gene expression in the Nucleus Accumbens (NAc). **Methods:** Female and male Fischer-344 rats, 4-6 months old, were randomly assigned to control or SI conditions 1 or 2 weeks prior to IV injection of 1x105 MADB106 mammary adenocarcinoma cells. On day 21 post-injection, lungs, brain and blood were obtained for analysis: Lung metastases were enumerated; Corticosterone (CORT) plasma levels were quantified using ELISA; mRNA was isolated from the NAc, and the expression of OXTR, CRF1, CRF2, 5-HTR, and D1r genes were assessed with RT-PCR. **Results:** One and two weeks of isolation was associated with increased metastases numbers compared to controls ($p=0.055$; $p<0.04$ respectively). In females only, 6 weeks of SI significantly elevated baseline CORT levels ($p=0.004$). SI-female rats showed increased levels of OXTr and 5HTr mRNAs in the NAc (2-fold, $p=0.02$; 3-fold, $p=0.01$; respectively), while SI-males showed decreased levels of 5HTr (0.5-Fold, $p=0.03$) and increased levels of D1r mRNAs (2-Fold, $p=0.04$). CRF1r and CRF2r mRNA levels were not affected. **Conclusion:** SI was associated with metastasis growth and sex-dependent alterations in neuroendocrine signaling. These changes may be part of a mediating mechanism altering immunity; our ongoing studies look deeper to understand the influence of the social environment on immune function through neuro-immune pathways.

H3K4ME3 EPIGENETIC SIGNATURES IN SOCIAL DEFEAT STRESS OF VARYING DURATION

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Polina Kisaretova[1,2], Vasiliy Reshetnikov[2], Nikita Ershov[2], Natalia Zhukova[2], Natalia Bondar[1,2]
[1]Novosibirsk State University, Natural Sciences, Novosibirsk, Russian Federation, [2]Institute of Cytology and Genetics, Siberian Branch of Russian Academy of Sciences, Sector Of Molecular Neurobiology Of Stress, Novosibirsk, Russian Federation

Stress-induced psychiatric disorders are a worldwide problem of contemporary society due to the complexity of therapy and the variety of forms. In this study, we analyzed the effects of social defeat stress (SDS) of varying duration (10, 15 and 30 days) on the genome-wide H3K4me3 landscape in the prefrontal cortex (PFC) of C57BL/6 mice using MNase-ChIP-seq method. For downstream analyses we selected peaks located in promoter regions (±2Kb from TSS) and integrated these results with previously obtained RNA-seq data after 10, 15 and 30 days of SDS. We analyzed data using relaxed thresholds of p-value <0.05 resulting in 1637 deferentially enriched peaks (DEP) for SDS10 and 2033 DEP for SDS30 compared to control. With increase in duration of SDS we observed more genes with DEP that are involved in synaptic plasticity regulation. We identified a cluster of 71 genes with at least one DEP present in all three groups (SDS10, SDS15, SDS30). Only DEP in 4 genes (*Numbl, Gal3st3, Cntn2* and *Gria2)* had unidirectional changes, while others formed unique patterns. Changes in the epigenetic landscape after SDS did not correlate with the level of gene expression. We found few DE genes (7-12%) with DEP in its promoter region. Among them only *Pde10a* gene had DEP in its promoter and altered expression in all groups. Our results demonstrate that the effects of SDS probably depend on combination of changes in multiple H3K4me3 promoter peaks instead of individual peak density. High-resolution MRI data of the brain of C57BL/6J and BTBR mice in three anatomical views.
The research on strain-, sex-, and stress-specific differences in structural and functional connectivity of the brain is important for elucidating various behavioral features and etiologies of psychiatric disorders. Socially impaired BTBR mice are considered a model of autism spectrum disorders. Here we present high-resolution magnetic resonance imaging data from the brain of 89 adolescent mice (C57BL/6J and BTBR) in axial, sagittal, and coronal views. The study [1] includes both females and males differed in early-life experience (normally reared or subjected to prolonged maternal separation: 3 h daily from postnatal day 2 to 15). The MRI data were obtained on a horizontal tomograph Biospec 117/16 instrument with a magnetic field strength of 11.7 T. Thus, multislice Turbo RARE T-weighted images of the brain were captured in eight groups of mice. Altogether, these data allow to evaluate strain-, sex-, and stress-specific alterations in the volumes of various brain structures and to better understand the relation between brain structural differences and behavioral abnormalities.

[Characteristic of the active substance of the Saccharomyces cerevisiae preparation having radioprotective properties].
The paper describes some biological features of the radioprotective effect of double-stranded RNA preparation. It was found that yeast RNA preparation has a prolonged radioprotective effect after irradiation by a lethal dose of 9.4 Gy. 100 % of

animals survive on the 70th day of observation when irradiated 1 hour or 4 days after 7 mg RNA preparation injection, 60 % animals survive when irradiated on day 8 or 12. Time parameters of repair of double-stranded breaks induced by gamma rays were estimated. It was found that the injection of the RNA preparation at the time of maximum number of double-stranded breaks, 1 hour after irradiation, reduces the efficacy of radioprotective action compared with the injection 1 hour before irradiation and 4 hours after irradiation. A comparison of the radioprotective effect of the standard radioprotector B-190 and the RNA preparation was made in one experiment. It has been established that the total RNA preparation is more efficacious than B-190. Survival on the 40th day after irradiation was 78 % for the group of mice treated with the RNA preparation and 67 % for those treated with B-190. In the course of analytical studies of the total yeast RNA preparation, it was found that the preparation is a mixture of single-stranded and double-stranded RNA. It was shown that only double-stranded RNA has radioprotective properties. Injection of 160 μg double-stranded RNA protects 100 % of the experimental animals from an absolutely lethal dose of gamma radiation, 9.4 Gy. It was established that the radioprotective effect of double-stranded RNA does not depend on sequence, but depends on its double-stranded form and the presence of "open" ends of the molecule. It is supposed that the radioprotective effect of double-stranded RNA is associated with the participation of RNA molecules in the correct repair of radiation-damaged chromatin in blood stem cells. The hematopoietic pluripotent cells that have survived migrate to the periphery, reach the spleen and actively proliferate. The newly formed cell population restores the hematopoietic and immune systems, which determines the survival of lethally irradiated animals.

Genes associated with cognitive performance in the Morris water maze: an RNA-seq study.
Learning and memory are among higher-order cognitive functions that are based on numerous molecular processes including changes in the expression of genes. To identify genes associated with learning and memory formation, here, we used the RNA-seq (high-throughput mRNA sequencing) technology to compare hippocampal transcriptomes between mice with high and low Morris water maze (MWM) cognitive performance. We identified 88 differentially expressed genes (DEGs) and 24 differentially alternatively spliced transcripts between the high- and low-MWM-performance mice. Although the sets of DEGs and differentially alternatively spliced transcripts did not overlap, both were found to be enriched with genes related to the same type of biological processes: trans-synaptic signaling, cognition, and glutamatergic transmission. These findings were supported by the results of weighted-gene co-expression network analysis (WGCNA) revealing the enrichment of MWM-cognitive-performance-correlating gene modules with very similar Gene Ontology terms. High-MWM-performance mice manifested mostly higher expression of the genes associated with glutamatergic transmission and long-term potentiation implementation, which are processes necessary for memory acquisition and consolidation. In this set, there were genes participating in the regulation of trans-synaptic signaling, primarily AMPA receptor signaling (Nrn1, Nptx1, Homer3, Prkce, Napa, Camk2b, Syt7, and Nrgn) and calcium turnover (Hpca, Caln1, Orai2, Cpne4, and Cpne9). In high-MWM-performance mice, we also demonstrated significant upregulation of the "flip" splice variant of Gria1 and Gria2 transcripts encoding subunits of AMPA receptor. Altogether, our data helped to identify specific genes in the hippocampus that are associated with learning and long-term memory. We hypothesized that the differences in MWM cognitive performance between the mouse groups are linked with increased long-term potentiation, which is mainly mediated by increased glutamatergic transmission, primarily AMPA receptor signaling.

Data of correlation analysis between the density of H3K4me3 in promoters of genes and gene expression: Data from RNA-seq and ChIP-seq analyses of the murine prefrontal cortex.
H3K4me3 is typically found in the promoter region of genes and is a mark associated with an open chromatin state and active gene transcription. Nonetheless, the role of H3K4me3 in the regulation of transcription is still debated. To improve the understanding of the connection between H3K4me3 density in promoters and gene expression, we assessed the correlation between these two parameters. We utilized genome-wide high-throughput RNA sequencing (RNA-seq) data and H3K4me3-based chromatin immunoprecipitation with high-throughput sequencing (ChIP-seq), carried out on the same samples of the prefrontal cortex from 10 male C57Bl6 mice with different stress experience [Social defeat stress in adult mice causes alterations in gene expression, alternative splicing, and the epigenetic landscape of H3K4me3 in the prefrontal cortex: an impact of early-life stress, 1]. In addition, we assessed the correlation between H3K4me3 density and gene expression in datasets of cell-specific genes. Altogether, the results are useful for the elucidation of H3K4me3 involvement in the regulation of transcription in the murine prefrontal cortex.

Social defeat stress in adult mice causes alterations in gene expression, alternative splicing, and the epigenetic landscape of

H3K4me3 in the prefrontal cortex: An impact of early-life stress.
Chronic stress is the leading risk factor of a broad range of severe psychopathologies. Nonetheless, the molecular mechanisms triggering these pathological processes are not well understood. In our study, we investigated the effects of 15-day social defeat stress (SDS) on the genome-wide landscape of trimethylation at the 4th lysine residue of histone H3 (H3K4me3) and on the transcriptome in the prefrontal cortex of mice that were reared normally (group SDS) or subjected to maternal separation early in life (group MS+SDS). The mice with the history of stress early in life showed increased susceptibility to SDS in adulthood and demonstrated long-lasting genome-wide alterations in gene expression and splicing as well as in the H3K4me3 epigenetic landscape in the prefrontal cortex. Thus, the high-throughput techniques applied here allowed us to simultaneously detect, for the first time, genome-wide epigenetic and transcriptional changes in the murine prefrontal cortex that are associated with both chronic SDS and increased susceptibility to this stressor.

THE INTERACTION OF GR AND TET3 REPRESENTS A POTENTIAL MECHANISTIC LINK TO THE EPIGENETIC EMBEDDING OF GR ACTIVATION

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Anna Sophie Fröhlich[1,2,3], Catarina Raimundo[1], Kira Daniela Höffler[1], Marta Labeur[1], Barbara Wölfel[1], Elisabeth Binder[1]
[1]Max Planck Institute of Psychiatry, Translational Research In Psychiatry, Munich, Germany, [2]Max Planck Institute of Psychiatry, International Max Planck Research School For Translational Psychiatry, Munich, Germany, [3]Ludwig-Maximilians-University of Munich, Faculty Of Biology, Planegg-Martinsried, Germany

Upon **stress exposure** the hypothalamic-pituitary-adrenal axis gets activated which ultimately leads to the release of glucocorticoid hormones. Glucocorticoids bind the **glucocorticoid receptor (GR)** leading to its nuclear translocation, where it binds to DNA regions, known as GR response elements (GREs) and promotes both transcriptional and epigenetic alterations, including changes in **DNA methylation**. However, the exact molecular mechanism remains unclear. The known interaction of **TET3, a DNA demethylase**, with nuclear receptors, such as the thyroid hormone receptor, led us to hypothesize that a similar interaction could exist between GR and TET3. In HeLa cells overexpressing TET3 we have shown using co-immunoprecipitation that **TET3 and GR interact** after activation of GR with dexamethasone (dex), a synthetic glucocorticoid agonist. Additionally, using chromatin immunoprecipitation (ChIP)-qPCR at known intronic GREs of three dex-induced genes (TSC22D3, ZBTB16 and FKBP51), we show significant enrichment of TET3 after dex treatment (Student's t test, veh vs dex for the respective regions p = 0.056, p=0.002, p=0.043, N=2) compared to a control region (DSCAM, p = 0.163). These findings suggest that glucocorticoid stimulation leads to the recruitment of TET3 to GREs, where it potentially contributes through **epigenetic modulation** to the regulation of gene expression. Targeted bisulfite- and assay for transposase-accessible chromatin sequencing will help unravel the changes in the level of DNA methylation and chromatin accessibility at these specific loci. Ultimately, these results highlight the importance to understand the molecular mechanisms driving the **pathological embedding of environmental stimuli**, especially relevant in the aetiology of **stress-related psychiatric disorders**.

ALTERED UNFOLDED PROTEIN RESPONSE IN A DOUBLE-HIT MODEL OF NEURODEVELOPMENT IN CORTEX AND HIPPOCAMPUS

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Karina Macdowell[1,2,3,4], Álvaro G. Bris[2,3,4,5], Cristina Ulecia-Moron[2,3,4,5], Mónica Movilla-Pérez[5], Beatriz Moreno[5], Javier Caso[2,3,4,5], Juan Carlos Leza[2,3,4,5]
[1]Universidad Complutense de Madrid, Farmacología Y Toxicología, Madrid, Spain, [2](CIBERSAM), Centro De Investigación Biomédica En Red De Salud Mental, Madrid, Spain, [3](IUIN), Instituto Universitario De Investigación En Neuroquímica, Madrid, Spain, [4]i+12, Instituto De Investigación Hospital 12 De Octubre, Madrid, Spain, [5]Complutense University of Madrid, Pharmacology And Toxicology, School Of Medicine, Madrid, Spain

Neuropsychiatric diseases have a multifactorial origin where the exposure to stressors in vulnerable phases of neurodevelopment (pre/post-natal and adolescence) is critical. Stressful stimuli produce a disruption of homeostasis that generates a series of complex physiological changes, including immune/inflammatory activation that requires a large protein synthesis machinery that depends on the endoplasmic reticulum. A noxious stimulus, like oxidative stress, can lead to the accumulation of misfolded proteins in the ER lumen; when these accumulate above a critical threshold, cells activate the unfolded protein response (UPR). UPR alterations could be implicated in the pathophysiology of some neurodevelopmental disorders. This study aimed to characterise some key elements of the UPR pathway in the frontal cortex (FC) and hippocampus (Hp) in a Two-Hit model of neurodevelopment. Methods: Wistar rats (eight weeks old) were used (n=9 per group). First prenatal hit was Poly(I:C) exposure on GD15, an immune-activating viral mimetic, and the second hit was isolation (Iso) during adolescence. After sacrifice, FC and Hp were obtained. RT-PCR analysed BDNF and UPR components gene expression. Statistical analysis employed One Way-ANOVA with a Tukey´s post-hoc test. Results: Two-hit animals exhibited an activation of the UPR pathway. In FC, BiP, XBP1s, ATF6, CHOP and BDNF showed elevated gene expression levels in two-hit animals vs control group. In Hp, it only showed upregulated XBP1s and BDNF. Conclusions: This model showed alterations in key elements of the UPR pathway. Furthermore, some of the changes appear to depend on the brain area. These results could appoint new therapeutic strategies and need further investigation.

EFFECTS OF EARLY LIFE STRESS ON HIPPOCAMPAL NPY-Y2 GENE EXPRESSION CHANGES IN MALE MICE VIA DNA METHYLATION

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Derya Kocamaz, Caroline Franzke, Nicole Gröger, Katharina Braun, Jörg Bock
Otto von Guericke University, Institute of Biology, Department Of Zoology And Developmental Neurobiology, Magdeburg, Germany

Early life stress (ELS) can induce epigenetically mediated long-lasting changes of gene expression, which may underlie altered responses towards stress at adulthood. The Neuropeptide Y system is involved the regulation of stress response throughout development via its receptors, specifically the activation of NPY-Y2 receptors has been shown to reduce NPY levels and enhance stress vulnerability. Here, we hypothesized that ELS (maternal separation) as well as adult stress (AS, as swim stress) changes the expression of hippocampal NPY-Y2 receptor gene. We investigated (i) if ELS and AS affect NPY-Y2 gene expression in the hippocampus of male mice via DNA methylation (ii) if ELS-induced epigenetic changes exert a programming effect on NPY-Y2 gene expression in response to AS. Animals were assigned to the following experimental groups: 1) controls, 2) ELS exposure, 3) AS exposure, 4) ELS+AS exposure. We found that ELS and AS have a main effect on NPY-Y2 gene expression and mean DNA-methylation. Especially, increased NPY-Y2 gene expression was found in the AS animals compared to other groups. Also, decreased mean DNA-methylation was found in the AS animals compared to control and ELS animals and increased mean DNA-methylation in ELS+AS animals compared to AS animals. In addition, we determined a strong negative correlation between NPY-Y2 gene expression and mean DNA-methylation. In conclusion, ELS seems to have a protective programming effect on NPY-Y2 gene expression in response to AS via DNA methylation. Therefore, it might be considered that ELS induces protective effects in males against consecutive stressors at later life periods.

ENDOPLASMIC RETICULUM STRESS DYSREGULATION CAN CAUSE NEURODEVELOPMENTAL ALTERATIONS IN THE FRONTAL CORTEX OF A "DOUBLE-HIT" NEURODEVELOPMENTAL DISORDER LIKE-MODEL

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Álvaro G. Bris[1,2,3,4], Cristina Ulecia-Moron[1,2,3,4], Karina Macdowell[1,2,3,4], Beatriz Moreno[1], Mónica Movilla-Pérez[1], Javier Caso[1,2,3,4], Juan Carlos Leza[1,2,3,4]

Aims: Some mental disease constitutes a class of neurodevelopmental disorders, characterize for malfunctions affecting the central nervous system development. Endoplasmic reticulum (ER) disruptions through accumulation of misfolded proteins induces ER stress activating unfolded protein response (UPR). UPR impairments have high impact in cognitive malfunctions and neurodevelopment. We aim to characterize Nrf2 antioxidant pathway and BDNF/UPR key components in frontal cortex in a "Double-Hit" model of neurodevelopment. **Methods:** Young Wistar rats were used (N=11 rats/group). First prenatal hit was maternal deprivation (MD) as first activator of the immune system. Second hit was isolation (Iso). Both MD and Iso groups had their pertinent control groups. Frontal cortex (FC) was obtained after sacrifice. BDNF and Nrf2 pathway parameters protein expression was analyzed by Western Blot (WB). UPR components gene expression was analysed by RT-PCR. Data were analysed employing a One Way-ANOVA with a Tukey´s *post-hoc* test. **Results:** CHOP, XBP1s and Total XBP1 (UPR factors activated in ER stress condition) showed lower levels of gene expression in double-hit group versus control (CT). BDNF gene expression and protein levels as well as Nrf2 and PPARg protein levels were also lower compared to CT. Protein expression of Nrf2 pathway component HO1 was higher, while SOD1 had lower levels of expression compared to CT. **Conclusions:** This MD+Iso model indicates the importance of UPR regulation through Nrf2 and BDNF to compensate elevated levels of ER stress and neurodevelopmental impairments in FC. Thus, this model is a promising candidate to reproduce ER stress dysregulation and potential neurodevelopmental disfunctions.

Despite the growing importance of the cerebellum as a region highly vulnerable to accumulating molecular errors in schizophrenia, limited information is available regarding altered molecular networks with potential therapeutic targets. To identify altered networks, we conducted one-shot liquid chromatography-tandem mass spectrometry in postmortem cerebellar cortex in schizophrenia and healthy individuals followed by bioinformatic analysis (PXD024937 identifier in ProteomeXchange repository). A total of 108 up-regulated proteins were enriched in stress-related proteins, half of which were also enriched in axonal cytoskeletal organization and vesicle-mediated transport. A total of 142 down-regulated proteins showed an enrichment in proteins involved in mitochondrial disease, most of which were also enriched in energy-related biological functions. Network analysis identified a mixed module of mainly axonal-related pathways for up-regulated proteins with a high number of interactions for stress-related proteins. Energy metabolism and neutrophil degranulation modules were found for down-regulated proteins. Further, two double-hit postnatal stress murine models based on maternal deprivation combined with social isolation or chronic restraint stress were used to investigate the most robust candidates of generated networks. CLASP1 from the axonal module in the model of maternal deprivation was combined with social isolation, while YWHAZ was not altered in either model. METTL7A from the degranulation pathway was reduced in both models and was identified as altered also in previous gene expression studies, while NDUFB9 from the energy network was reduced only in the model of maternal deprivation combined with social isolation. This work provides altered stress- and mitochondrial disease-related proteins involved in energy, immune and axonal networks in the cerebellum in schizophrenia as possible novel targets for therapeutic interventions and suggests that METTL7A is a possible relevant altered stress-related protein in this context.

Paliperidone attenuates chronic stress-induced changes in the expression of inflammasomes-related protein in the frontal cortex of male rats.
Several stress-related neuropsychiatric diseases are related to inflammatory phenomena. Thus, a better understanding of stress-induced immune responses could lead to enhanced treatment alternatives. Little is known about the possible involvement of inflammasomes in the stress-induced proinflammatory response. Antipsychotics have anti-inflammatory effects, but the possible antipsychotic treatment actions on inflammasomes remain unexplored. Our aim was to study whether inflammasomes are involved in the neuroinflammation induced by a paradigmatic model of chronic stress and whether the monoamine receptor antagonist paliperidone can modulate the possible stress-induced inflammasomes activation in the frontal cortex (FC). Thus, the effects of paliperidone (1 mg/Kg, oral gavage) administered during a chronic restraint stress protocol (6 h/day for 21 days) on the possible stress-related inflammasomes protein induction were evaluated through Western blot in the FC of male Wistar rats. Stress increased protein expression levels of the inflammasome complexes NALP1, NLRP3 and AIM2 and augmented caspase-1 and mature interleukin (IL)-1β protein levels. Paliperidone pre-treatment normalized the protein expression of the inflammasome pathway. In conclusion, our data indicate an induction of inflammasome complexes by chronic restraint stress in the FC of rats. The antipsychotic paliperidone has an inhibitory action on some of the stress-induced inflammasomes stimulation trying to normalize the neuroinflammatory scenario caused by stress. Considering the emerging role of inflammation in neuropsychiatric diseases, the development of new drugs targeting inflammasome pathways is a promising approach for future therapeutic interventions.

Bacterial translocation affects intracellular neuroinflammatory pathways in a depression-like model in rats.
Recent studies have suggested that depression is accompanied by an increased intestinal permeability which would be related to the inflammatory pathophysiology of the disease. This study aimed to evaluate whether experimental depression presents with bacterial translocation that in turn can lead to the TLR-4 in the brain affecting the mitogen-activated protein kinases (MAPK) and antioxidant pathways. Male Wistar rats were exposed to chronic mild stress (CMS) and the intestinal integrity, presence of bacteria in tissues and plasma lipopolysaccharide levels were analyzed. We also studied the expression in the prefrontal cortex of activated forms of MAPK and some of their activation controllers and the effects of CMS on the antioxidant Nrf2 pathway. Our results indicate that after exposure to a CMS protocol there is increased intestinal permeability and bacterial translocation. CMS also increases the expression of the activated form of the MAPK p38 while decreasing the expression of the antioxidant transcription factor Nrf2. The actions of antibiotic administration to prevent bacterial translocation on elements of the MAPK and Nrf2 pathways indicate that the translocated bacteria are playing a role in these effects. In effect, our results propose a role of the translocated bacteria in the pathophysiology of depression through the p38 MAPK pathway which could aggravate the neuroinflammation and the oxidative/nitrosative damage present in this pathology. Moreover, our results reveal that the antioxidant factor Nrf2 and its activators may be involved in the consequences of the CMS on the brain.

Modulation of the antioxidant nuclear factor (erythroid 2-derived)-like 2 pathway by antidepressants in rats.
Patients with major depression who are otherwise medically healthy have activated inflammatory pathways in their organism. It has been described that depression is not only escorted by inflammation but also by induction of multiple oxidative/nitrosative stress pathways. Nevertheless, there are finely regulated mechanisms involved in preserving cells from damage, such as the antioxidant nuclear transcription factor Nrf2. We aim to explore in a depression-like model the Nrf2 pathway in the prefrontal cortex (PFC) and the hippocampus of rats and to analyze whether antidepressants affect the antioxidant activity of the Nrf2 pathway. Male Wistar rats were exposed to chronic mild stress (CMS) and some of them were treated with desipramine, escitalopram or duloxetine. We studied the expression of upstream and downstream elements of the Nrf2 pathway and the oxidative damage induced by the CMS. After CMS, there is an inhibition of upstream and downstream elements of the Nrf2 pathway in the PFC (e.g. PI3K/Akt, GPx…). Moreover, antidepressant treatments, particularly desipramine and duloxetine, are able to recover some of these elements and to reduce the oxidative damage induced by the CMS. However, in the hippocampus, Nrf2 pathways are not that affected and antidepressants do not have many actions. In conclusion, Nrf2 pathway is differentially regulated by antidepressants in the PFC and hippocampus. The Nrf2 pathway is involved in the oxidative/nitrosative damage detected in the PFC and antidepressants have a therapeutic action through this pathway. However, it seems that Nrf2 is not involved in the effects caused by CMS in the hippocampus.

Regulation of visceral and epicardial adipose tissue for preventing cardiovascular injuries associated to obesity and diabetes.
Nowadays, obesity is seriously increasing in most of the populations all over the world, and is associated with the development and progression of high-mortality diseases such as type-2 diabetes mellitus (T2DM) and its subsequent cardiovascular pathologies. Recent data suggest that both body fat distribution and adipocyte phenotype, can be more determinant for fatal outcomes in obese patients than increased general adiposity. In particular, visceral adiposity is significantly linked to long term alterations on different cardiac structures, and in developed forms of myocardial diseases such as hypertensive and ischaemic heart diseases, and diabetic cardiomyopathy. Interestingly, this depot may be also related to epicardial fat accumulation through secretion of lipids, adipokines, and pro-inflammatory and oxidative factors from adipocytes. Thus, visceral adiposity and its white single-lipid-like adipocytes, are risk factors for different forms of heart disease and heart failure, mainly in higher degree obese subjects. However, under specific stimuli, some of these adipocytes can transdifferentiate to brown multi-mitochondrial-like adipocytes with anti-inflammatory and anti-apoptotic proprieties. Accordingly, in order to improve potential cardiovascular abnormalities in obese and T2DM patients, several therapeutic strategies have been addressed to modulate the visceral and epicardial fat volume and phenotypes. In addition to lifestyle modifications, specific genetic manipulations in adipose tissue and administration of PPARγ agonists or statins, have improved fat volume and phenotype, and cardiovascular failures. Furthermore, incretin stimulation reduced visceral and epicardial fat thickness whereas increased formation of brown adipocytes, alleviating insulin resistance and associated cardiovascular pathologies.

A decrease in presumptive safety elicits behaviors to probe the environment for additional information and engages precautionary physiological responses to prepare the organism in case of threat. The physiological response includes an anticipatory increase in circulating glucocorticoids in the body. Glucocorticoids levels are controlled by corticotropin-releasing hormone neurons in the paraventricular nucleus of the hypothalamus (CRH^{PVN}). Here we show that CRH^{PVN} cells in freely behaving mice show a scalable precautionary response to a decrease in safety. This precautionary response consists of a stable increase in the activity of CRH^{PVN} neurons in low safety environments. This response shows no habituation during repeated trials with individual cells exhibiting faithful activity profiles over multiple days. The stable increase in activity on repeated days is matched by increases in circulating stress hormone, but there is a marked shift in behavior. The precautionary response is scaled by prior experience. Specifically, CRH^{PVN} neurons show an enhanced precautionary state after exposure to a threat (footshock) in a low safety environment. This increase in the precautionary response requires the recruitment of cells that respond faithfully to the footshocks but have low basal precautionary activity, consistent with a perceptron-like learning rule. These findings delineate a scalable precautionary representation in the brain. An increase in the precautionary assembly of CRH^{PVN} neurons following an acute threat may contribute to sensitization to environmental cues in neuropsychiatric stress disorders.

POST-STRESS ACTIVITY OF CALRETININ POSITIVE CELLS IN THE PARAVENTRICULAR THALAMIC NUCLEUS UNDERLIES LONG TERM, STRESS INDUCED DISTURBANCE OF BEHAVIOR

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Anna Jász[1], László Biró[1], Zsolt Buday[1], Bálint Király[2], Balazs Hangya[3], László Acsády[4]
[1]Institute of Experimental Medicine, Laboratory Of Thalamus Research, Budapest, Hungary, [2]Institute of Experimental Medicine, Lendület Laboratory Of Systems Neuroscience, Budapest, Hungary, [3]Institute of Experimental Medicine, Lendület Laboratory, Budapest, Hungary, [4]Institute of Experimental Medicine, Budapest, Hungary, Laboratory Of Thalamus Research, Budapest, Hungary

Behavioral disorders caused by stress affect millions of people around the world, but its neurobiological bases are still unclear. The calretinin-positive neurons of the paraventricular thalamus (PVT/CR+) are in a unique position to participate in stress induced sleep disturbances since their activity is significantly affected by stress and by sleep-wake transitions. In the accompanying study, using optogenetic inhibition, we found that the post-stress activity of PVT/CR+ cells is critical to establish the acute stress induced behavioral changes. Thus, in this study we aimed to determine the activity of PVT/CR+ cells before and after the exposure to a natural stressor (2MT, 10 min). We also tested whether stress induced long term changes in firing activity can be reversed by post-stress photoinhibition. Recordings involved 3 hours sessions for five days before and after stress using movable optrodes. During pre-stress days PVT/CR+ cells displayed strongly state dependent activity. Unit activity within the nest during wakefulness was lower than outside the nest and further decreased during sleep. Following the exposure to 2MT firing rate was elevated for four days with strongest increase in the nest. Both high frequency spike clusters and synchrony among PVT/CR+ cells significantly increased in a state dependent manner. Photoinhibition of PVT/CR+ neurons after the 2MT presentation prevented altered firing rate, increase in high frequency clusters and cross correlations on the poststress days. These data together strongly suggest that altered post-stress activity of PVT/CR+ cells is crucial to establish the neuronal network responsible for the emergence of stress induced behavioral phenotype.

CHRONIC OVERCROWDING STRESS AFFECTS DIFFERENTLY THE NEUROPLASTICITY-RELATED SIGNALING PATHWAYS IN THE RATS' HIPPOCAMPUS AND AMYGDALA

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Michał Wilczkowski, Agnieszka Zelek-Molik, Irena Nalepa
Maj Institute of Pharmacology, Polish Academy of Sciences, Department Of Brain Biochemistry, Krakow, Poland

Undisturbed functioning of synaptic plasticity seems to be critical for computational processes occurring in the brain. Among factors influencing synaptic plasticity is chronic stress. Brain regions especially vulnerable to chronic stress-induced neuroplasticity**,** include the hippocampus, and the amygdala. Interestingly, opposite effects of stressful conditions have been shown in these structures. Despite increasing knowledge, there is still not enough information on which molecules may be involved in stress-related neuroplasticity in these regions. Thus, our goal was to characterize an influence of chronic stress on the mRNA expression of genes encoding for proteins related to the synaptic organization, and on the level of neuroplasticity-related proteins in the amygdala and the hippocampus. Rats underwent overcrowding stress for 3, 7, and 14 days. The TaqMan arrays were used for evaluation of 24 genes in a single sample, together with the RT-qPCR to assess mRNA expression of genes. The level of selected proteins was assessed using western blot. Our results demonstrate region-dependent alterations in the mRNA expression of genes encoding for several intracellular proteins, and similarly, region-dependent changes in the protein abundance. Interestingly, chronic (14 days) overcrowding decreased mRNA expression of focal adhesion kinase (FAK) and protein tyrosine phosphatase non-receptor type 5 in the hippocampus but not in the amygdala. Furthermore, alterations in the level of the FAK after exposure to the chronic stress were consistent with changes in the mRNA expression, suggesting its involvement in stress-related processes. These results imply selected proteins and theirs downstream signaling pathways as potential targets for new pharmacotherapy strategies.

STRESS-INDUCED SOCIAL AVOIDANCE BEHAVIOR AND INCREASE IN INFLAMMATORY CYTOKINES ARE NORMALIZED BY PERIPHERAL INHIBITION OF FAAH IN RATS

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Margherita Barbetti[1], Luca Carnevali[1], Federica Vacondio[2], Francesca Ferlenghi[2], Marco Mor[2], Silvia Rivara[2], Andrea Sgoifo[1]
[1]University of Parma, Stress Physiology Lab, Department Of Chemistry, Life Sciences And Environmental Sustainability, Parma, Italy, [2]University of Parma, Department Of Food And Drug, Parma, Italy

Peripheral inflammation occurring after a traumatic/stressful event has been implicated in the development of post-traumatic stress disorder (PTSD). Therefore, targeting inflammatory mediators in the aftermath of stress exposure may be a valid approach for the prevention of PTSD-related symptoms. **AIMS:** (i) to demonstrate the association between increased pro-inflammatory cytokines and disrupted social behavior in rats exposed to acute social defeat stress; (ii) to verify whether peripheral pharmacological inhibition of the enzyme fatty acid amide hydrolase (FAAH), which terminates the signaling of the anti-inflammatory palmitoylethanolamide (PEA), exerts favorable effects on social behavior. **METHODS**: Male wistar rats were exposed to an episode of social defeat stress/control condition and 30 min later they were injected with either the peripheral FAAH inhibitor URB937 (3mg/kg) or vehicle. 24 hours later, social behavior (social approach/avoidance test) and plasma levels of corticosterone were analyzed. Pro-inflammatory cytokines (IL-1beta, TNFalpha and IL-6) and PEA levels were measured in plasma and brain 6 and 24 hours after stress exposure. **RESULTS:** Stressed rats showed clear social avoidance behavior and increased corticosterone levels 24 hours after social defeat, as well as a significant increase in plasmatic pro-inflammatory cytokines after 6 hours. URB937 increased plasma PEA levels, normalized social behavior, and reduced corticosterone and peripheral cytokines levels. **CONCLUSIONS:** Peripheral inflammation occurring after social defeat may be implicated in the development of social avoidance behavior. Peripheral inhibition of FAAH activity may exert positive effects on social behavior via anti-inflammatory mechanisms and may represent a promising strategy for the prevention of PTSD-like symptomatology.

THE ROLE OF CALRETININ-POSITIVE MIDLINE THALAMIC NEURONS IN STRESS INDUCED BEHAVIOURAL ALTERATIONS

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Zsolt Buday[1], László Biró[1], Anna Jász[1], Gergely Komlósi[1], Róbert Bódizs[2], Orsolya Szalárdy[2], Krisztina Kovács[3], Dániel Kuti[3], László Acsády[1]

Severe acute stress could induce the emergence of psychiatric disorders, although the underlying neuronal mechanisms are presently unresolved. Calretinin expressing neurons in the paraventricular nucleus of the thalamus (PVT/CR+) form a critical hub between brainstem and forebrain and play essential roles in arousal, anxiety and stress regulating circuit operations. Thus, in this study we tested whether the activity of PVT/CR+ neurons, following an exposure to a natural stressor (fox odour, 2MT), contributes to acute stress-induced behavioural changes. We inhibited PVT/CR+ neurons after the stress event using optogenetic inhibition (SwiChR) and measured nesting behavior, locomotion, sleep, and stress hormone levels. We also quantified c-Fos expression in the PVT/CR+ cells and their projection areas. EYFP injected animals served as control. During the stress exposure, both groups showed similar levels of defensive behaviours. Following the stress exposure, the control EYFP group displayed increased EMG activity, disturbed nesting behavior, and elevated corticosterone level. c-Fos expression was increased both in the PVT/CR+ cells and their projection areas. The behavioral changes persisted for five days following the stress exposure. Photoinhibition of PVT/CR+ cells after the stress exposure prevented all these changes, with the exception of acute hormonal stress response, which remained unaffected. This suggests that the post-stress activity of PVT/CR+ cells shapes stress induced behaviour, independently from the hormonal stress response. Collectively, our findings indicate that post-stress activity of PVT/CR+ neurons plays a fundamental role in the emergence of stress-induced behavioral changes, and post-stress inhibition of PVT/CR+ cells is sufficient to prevent these changes.

THE CONSEQUENCES OF CONCURRENT STRESS AND HYPERGLYCEMIA ON REDOX HOMEOSTASIS IN THE ADULT ZEBRAFISH BRAIN.

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Rhea Subba[1], Amal Mondal[2]
[1]Jawaharlal Nehru University, School Of Life Sciences, Delhi, India, [2]Jawaharlal Nehru University, School Of Life Sciences,, New Delhi, India

Aim Diabetes mellitus, a metabolic disorder involving abnormally elevated blood glucose levels (hyperglycemia), may negatively affect the central nervous system. Compromised brain health increases susceptibility towards psychiatric illnesses including depression and anxiety. Patients afflicted with diabetes are vulnerable to developing “diabetic distress”, a term used to describe psychological stress that ensues from a diabetes diagnosis. While similar in nature to the clinical manifestations of depression, diabetic distress is not synonymous to depression, although it may lead to its development. The zebrafish is rapidly gaining impetus as a vertebrate model to study metabolic as well as neurological disorders. Hyperglycemic zebrafish display abnormalities in blood-brain barrier integrity, neuronal signaling pathways, and neural cell proliferation. Redox imbalance appears to be a significant player in this association. However, thorough research examining the neurobiological implications of coexisting hyperglycemia and chronic stress is lacking. For this, we established a model of simultaneous stress and hyperglycemia in adult zebrafish to investigate consequences on brain redox homeostasis. Methods Fishes were exposed to dextrose solution (111mM) alongside chronic unpredictable mild stress (CUMS) for 14 days. Fasting blood glucose levels were measured with a glucometer, after which whole brain samples were utilized for gene expression and biochemical studies. Results Blood glucose levels were dramatically elevated in stressed-hyperglycemic fishes compared to control. Furthermore, there were alterations in the levels and activities of several antioxidant molecules, accompanied by increased brain lipid peroxidation. Conclusions Further investigation could uncover underlying disease mechanisms of comorbid hyperglycemia and chronic stress, opening doors for therapeutic drug development.

Pathophysiology linking depression and type 2 diabetes: Psychotherapy, physical exercise, and fecal microbiome transplantation as damage control.
Diabetes increases the likelihood of developing depression and vice versa. Research on this bidirectional association has somewhat managed to delineate the interplay among implicated physiological processes. Still, further exploration is required in this context. This review addresses the comorbidity by investigating suspected common pathophysiological mechanisms. One such factor is psychological stress which disturbs the hypothalamic-pituitary-adrenal axis causing hormonal imbalance. This includes elevated cortisol levels, a common biomarker of both depression and diabetes. Disrupted insulin signaling drives the hampered neurotransmission of serotonin, dopamine, and norepinephrine. Also, adipokine hormones such as adiponectin, leptin, and resistin and the orexigenic hormone, ghrelin, are involved in both depression and T2DM. This disarray further interferes with physiological processes encompassing sleep, the gut-brain axis, metabolism, and mood stability. Behavioral coping mechanisms, such as unhealthy eating, mediate disturbed glucose homeostasis, and neuroinflammation. This is intricately linked to oxidative stress, redox imbalance, and mitochondrial dysfunction. However, interventions such as psychotherapy, physical exercise, fecal microbiota transplantation, and insulin-sensitizing agents can help to manage the distressing condition. The possibility of glucagon-like peptide 1 possessing a therapeutic role has also been discussed. Nonetheless, there stands an urgent need for unraveling new correlating targets and biological markers for efficient treatment.

Genome-wide gene expression analyses are invaluable tools for increasing our knowledge of biological and disease processes, allowing a hypothesis-free comparison of gene expression profiles across experimental groups, tissues and cell types. Traditionally, transcriptomic data analysis has focused on gene-level effects found by differential expression (DE). In recent years, co-expression network analysis has emerged as an important additional level of investigation, providing information on the molecular connectivity level. We demonstrate how combined DE and network analysis can be used to explore complex datasets. As an example, we analyzed the transcriptional responses following administration of the glucocorticoid/stress hormone receptor agonist dexamethasone in C57Bl/6 mice, in 8 brain regions important for stress processing: the prefrontal cortex, the amygdala, the paraventricular nucleus of the hypothalamus, 4 subregions of the hippocampus as well as the cerebellar cortex. By applying a combination of differential network and DE analyses, we find that these explain distinct but complementary aspects of the responses to stimulus and that network analysis may unravel different biological mechanisms that are not obvious at the level of DE. In addition, network analysis identifies new differentially connected partners of important genes and can be used to generate hypotheses of specific molecular pathways affected. We provide an analysis framework and a publicly available resource for the study of the transcriptional landscape of 8 mouse brain regions named DiffBrainNet (http://134.76.24.68/app/diffbrainnet), that can be used to pinpoint molecular pathways important for basic functioning and response to glucocorticoids in a brain-region specific manner.

Background: inflammation in inflammatory bowel diseases (IBD) is mainly driven by T-cell response to microbial and environmental antigens. Psychological stress is a potential trigger of clinical flares of IBD and drugs based on the sphingosine-1-phosphate (S1P) pathways, which control T-cell recruitment, are currently under clinical trials for IBD. **Aims:** to analyze the sub-chronic stress impact and absence of sphingosine kinase 2 (Sphk2), an enzyme of S1P metabolism, in the colon of mice. **Methods:** wild-type (WT) and Sphk2-/- mice were exposed to a sub-chronic stress mixed model: Control WT (n=5), Control Sphk2-/- (n=5), Stress WT (n=8), and Stress Sphk2-/- (n=8). Tissue and biochemical assays were performed to evaluate stress and immune responses, S1P pathways, and barrier integrity. **Results:** sub-chronic stress increased S1P in the colon, possibly decreasing its degradation enzymes and Sphk2. S1P accumulation could lead to inflammation and immune dysregulation reflected by upregulation of toll-like receptor 4 (TLR4) pathway, inhibition of anti-inflammatory mechanisms, cytokine-expression profile towards a T-helper lymphocyte 17 (Th17) polarization, plasmacytosis, decrease in some IgA+ immune cells, and increase in IgM+ B cells. Stress also enhanced intestinal permeability. Sphk2 knockout mice presented a cytokine-expression profile towards a boosted Th17 response, lower expression of claudin 3,4,5,7, and 8, and structural abnormalities in the colon. **Conclusions:** sub-chronic stress causes colon S1P increase, immune dysregulation, and intestinal permeability. Sphk2 deletion is involved in structural abnormalities and Th17 response but did not aggravate the inflammation originated by stress. Intestinal pathophysiology should consider stress and S1P as modulators of the immune response.

Cannabidiol antidepressant-like effect in the lipopolysaccharide model in mice: Modulation of inflammatory pathways.
Major Depression is a severe psychiatric condition with a still poorly understood etiology. In the last years, evidence supporting the neuroinflammatory hypothesis of depression has increased. In the current clinical scenario, in which the available treatments for depression is far from optimal, there is an urgent need to develop fast-acting drugs with fewer side effects. In this regard, recent pieces of evidence suggest that cannabidiol (CBD), the major non-psychotropic component of Cannabis sativa with anti-inflammatory properties, appears as a drug with antidepressant properties. In this work, CBD 30 mg/kg was administered systemically to mice 30 min before lipopolysaccharide (LPS; 0.83 mg/kg) administration as a neuroinflammatory model, and behavioral tests for depressive-, anhedonic- and anxious-like behavior were performed. NF-κB, IκBα and PPARγ levels were analyzed by western blot in nuclear and cytosolic fractions of cortical samples. IL-6 and TNFα levels were determined in plasma and prefrontal cortex using ELISA and qPCR techniques, respectively. The precursor tryptophan (TRP), and its metabolites kynurenine (KYN) and serotonin (5-HT) were measured in hippocampus and cortex by HPLC. The ratios KYN/TRP and KYN/5-HT were used to estimate indoleamine 2,3-dioxygenase (IDO) activity and the balance of both metabolic pathways, respectively. CBD reduced the immobility time in the tail suspension test and increased sucrose preference in the LPS model, without affecting locomotion and central activity in the open-field test. CBD diminished cortical NF-κB activation, IL-6 levels in plasma and brain, and the increased KYN/TRP and KYN/5-HT ratios in hippocampus

and cortex in the LPS model. Our results demonstrate that CBD produced antidepressant-like effects in the LPS neuroinflammatory model, associated to a reduction in the kynurenine pathway activation, IL-6 levels and NF-κB activation. As CBD stands out as a promising antidepressant drug, more research is needed to completely understand its mechanisms of action in depression linked to inflammation.

Risperidone Ameliorates Prefrontal Cortex Neural Atrophy and Oxidative/Nitrosative Stress in Brain and Peripheral Blood of Rats with Neonatal Ventral Hippocampus Lesion.
Reduction of the dendritic arbor length and the lack of dendritic spines in the pyramidal cells of the prefrontal cortex (PFC) are prevalent pathological features in schizophrenia (SZ). Neonatal ventral hippocampus lesion (NVHL) in male rats reproduces these neuronal characteristics and here we describe how this is a consequence of BDNF/TrkB pathway disruption. Moreover, COX-2 proinflammatory state, as well as Nrf-2 antioxidant impairment, triggers oxidative/nitrosative stress, which also contributes to dendritic spine impairments in the PFC. Interestingly, oxidative/nitrosative stress was also detected in the periphery of NVHL animals. Furthermore, risperidone treatment had a neurotrophic effect on the PFC and antioxidant effects on the brain and periphery of NVHL animals; these cellular effects were related to behavioral improvement. Our data highlight the link between brain development and immune response, as well as several other factors to understand mechanisms related to the pathophysiology of SZ. Prefrontal cortex dysfunction in schizophrenia can be a consequence of morphological abnormalities and oxidative/nitrosative stress, among others. Here, we detailed how impaired plasticity-related pathways and oxidative/nitrosative stress are part of the dendritic spine pathology and their modulation by atypical antipsychotic risperidone treatment in rats with neonatal ventral hippocampus lesion. Moreover, we found that animals with neonatal ventral hippocampus lesion had oxidative/nitrosative stress in the brain as well as in the peripheral blood, an important issue for the translational approaches of this model. Then, risperidone restored plasticity and reduced oxidative/nitrosative stress of prefrontal cortex pyramidal cells, and ultimately improved the behavior of lesioned animals. Moreover, risperidone had differential effects than the brain on peripheral blood oxidative/nitrosative stress.

Changes in brain kynurenine levels gut microbiota and gut-barrier disruption induced by chronic ethanol exposure in mice.
Inflammatory processes have been shown to modify tryptophan (Trp) metabolism. Gut microbiota appears to play a significant role in the induction of peripheral and central inflammation. Ethanol (EtOH) exposure alters gut permeability, but its effects on Trp metabolism and the involvement of gut microbiota have not been studied. We analyzed several parameters of gut-barrier and of peripheral and central Trp metabolism following 2 different EtOH consumption patterns in mice, the binge model, drinking in the dark (DID), and the chronic intermittent (CI) consumption paradigm. Antibiotic treatment was used to evaluate gut microbiota involvement in the CI model. Mice exposed to CI EtOH intake, but not DID, show bacterial translocation and increased plasma LPS immediately after EtOH removal. Gut-barrier permeability to FITC-dextran is increased by CI, and, furthermore, intestinal epithelial tight-junction (TJ) disruption is observed (decreased expression of zonula occludens 1 and occludin) associated with increased matrix metalloproteinase (MMP)-9 activity and iNOS expression. CI EtOH, but not DID, increases kynurenine (Kyn) levels in plasma and limbic forebrain. Intestinal bacterial decontamination prevents the LPS increase but not the permeability to FITC-dextran, TJ disruption, or the increase in MMP-9 activity and iNOS expression. Although plasma Kyn levels are not affected by antibiotic treatment, the elevation of Kyn in brain is prevented, pointing to an involvement of microbiota in CI EtOH-induced changes in brain Trp metabolism. Additionally, CI EtOH produces depressive-like symptoms of anhedonia, which are prevented by the antibiotic treatment thus pointing to an association between anhedonia and the increase in brain Kyn and to the involvement of gut microbiota.-Giménez-Gómez, P., Pérez-Hernández, M., O'Shea, E., Caso, J. R., Martín-Hernández, D., Cervera, L. A., Centelles. M. L. G.-L., Gutiérrez-Lopez, M. D., Colado, M. I. Changes in brain kynurenine levels gut microbiota and gut-barrier disruption induced by chronic ethanol exposure in mice.

Modulation of Monoaminergic Systems by Antidepressants in the Frontal Cortex of Rats After Chronic Mild Stress Exposure.
The standard pharmacological treatment of the major depressive disorder (MDD) is still grounded in a monoaminergic approach. Consequently, antidepressant treatments pursue to heighten serotonergic and noradrenergic neurotransmissions. Thus, the aim of this study was to assess the impact of exposure to a well-characterized animal model, the chronic mild stress (CMS) on serotonin (5-HT) and noradrenaline (NE) levels, and reuptake transporters and receptors in the frontal cortex (FC) of CMS-exposed rats. Moreover, considering the diverse pharmacological profiles of existing antidepressants and the large number of patients not responding to treatments, we have investigated whether generally utilized antidepressants can modulate their expression. Male Wistar rats were exposed to CMS and some of them treated with desipramine, escitalopram, or duloxetine. Possible changes in the described monoaminergic neurotransmission elements were evaluated. CMS induced differences in the expression of reuptake transporters and receptors involved in the monoaminergic neurotransmission pointing towards the weakening of their signaling. CMS antidepressant-treated rats showed an improvement of the monoaminergic tone, being desipramine and duloxetine more influential than escitalopram over noradrenergic elements and having the three antidepressant-tested effects on serotonergic transmission. In summary, there are molecular alterations on the monoaminergic neurotransmission in FC induced by CMS exposure. Besides, antidepressant treatments modulate the elements of these neurotransmission systems differentially.

Chronic Mild Stress Alters Kynurenine Pathways Changing the Glutamate Neurotransmission in Frontal Cortex of Rats.
Immune stimulation might be involved in the pathophysiology of major depressive disorder (MDD). This stimulation induces indoleamine 2,3-dioxygenase (IDO), an enzyme that reduces the tryptophan bioavailability to synthesize serotonin. IDO products, kynurenine metabolites, exert neurotoxic/neuroprotective actions through glutamate receptors. Thus, we study elements of these pathways linked to kynurenine metabolite activity examining whether antidepressants (ADs) can modulate them. Male Wistar rats were exposed to chronic mild stress (CMS), and some of them were treated with ADs. The expression of elements of the IDO pathway, including kynurenine metabolites, and their possible modulation by ADs was studied in the frontal cortex (FC). CMS increased IDO expression in FC compared to control group, and ADs restored the IDO expression levels to control values. CMS-induced IDO expression led to increased levels of the excitotoxic quinolinic acid (QUINA) compared to control, and ADs prevented the rise in such levels. Neither CMS nor ADs changed significantly the antiexcitotoxic kynurenic acid (KYNA) levels. The QUINA/KYNA ratio, calculated as excitotoxicity risk indicator, increased after CMS and ADs prevented this increase. CMS lowered excitatory amino acid transporter (EAAT)-1 and EAAT-4 expression, and some ADs restored their expression levels. Furthermore, CMS decreased N-methyl-D-aspartate receptor (NMDAR)-2A and 2B protein expression, and ADs mitigated this decrease. Our research examines the link between CMS-induced pro-inflammatory cytokines and the kynurenine pathway; it shows that CMS alters the kynurenine pathway in rat FC. Importantly, it also reveals the ability of classic ADs to prevent potentially harmful situations related to the brain scenario caused by CMS.

Bacterial translocation affects intracellular neuroinflammatory pathways in a depression-like model in rats.
Recent studies have suggested that depression is accompanied by an increased intestinal permeability which would be related to the inflammatory pathophysiology of the disease. This study aimed to evaluate whether experimental depression

presents with bacterial translocation that in turn can lead to the TLR-4 in the brain affecting the mitogen-activated protein kinases (MAPK) and antioxidant pathways. Male Wistar rats were exposed to chronic mild stress (CMS) and the intestinal integrity, presence of bacteria in tissues and plasma lipopolysaccharide levels were analyzed. We also studied the expression in the prefrontal cortex of activated forms of MAPK and some of their activation controllers and the effects of CMS on the antioxidant Nrf2 pathway. Our results indicate that after exposure to a CMS protocol there is increased intestinal permeability and bacterial translocation. CMS also increases the expression of the activated form of the MAPK p38 while decreasing the expression of the antioxidant transcription factor Nrf2. The actions of antibiotic administration to prevent bacterial translocation on elements of the MAPK and Nrf2 pathways indicate that the translocated bacteria are playing a role in these effects. In effect, our results propose a role of the translocated bacteria in the pathophysiology of depression through the p38 MAPK pathway which could aggravate the neuroinflammation and the oxidative/nitrosative damage present in this pathology. Moreover, our results reveal that the antioxidant factor Nrf2 and its activators may be involved in the consequences of the CMS on the brain.

Modulation of the antioxidant nuclear factor (erythroid 2-derived)-like 2 pathway by antidepressants in rats.
Patients with major depression who are otherwise medically healthy have activated inflammatory pathways in their organism. It has been described that depression is not only escorted by inflammation but also by induction of multiple oxidative/nitrosative stress pathways. Nevertheless, there are finely regulated mechanisms involved in preserving cells from damage, such as the antioxidant nuclear transcription factor Nrf2. We aim to explore in a depression-like model the Nrf2 pathway in the prefrontal cortex (PFC) and the hippocampus of rats and to analyze whether antidepressants affect the antioxidant activity of the Nrf2 pathway. Male Wistar rats were exposed to chronic mild stress (CMS) and some of them were treated with desipramine, escitalopram or duloxetine. We studied the expression of upstream and downstream elements of the Nrf2 pathway and the oxidative damage induced by the CMS. After CMS, there is an inhibition of upstream and downstream elements of the Nrf2 pathway in the PFC (e.g. PI3K/Akt, GPx…). Moreover, antidepressant treatments, particularly desipramine and duloxetine, are able to recover some of these elements and to reduce the oxidative damage induced by the CMS. However, in the hippocampus, Nrf2 pathways are not that affected and antidepressants do not have many actions. In conclusion, Nrf2 pathway is differentially regulated by antidepressants in the PFC and hippocampus. The Nrf2 pathway is involved in the oxidative/nitrosative damage detected in the PFC and antidepressants have a therapeutic action through this pathway. However, it seems that Nrf2 is not involved in the effects caused by CMS in the hippocampus.

Stressful experiences *in utero* can affect fetal development, increasing the risk for psychiatric disorders. We hypothesized that stressors as diverse as maternal obesity and maternal psychophysical stress might disrupt fetal programming resulting in long-lasting effects on offspring brain development by acting through shared oxidative stress (OS)-mediated mechanisms. We compared a mouse model (C57Bl/6N) of maternal high-fat diet (HFD) consumption (13 weeks, until delivery) to prenatal restraint stress (PNS) repeatedly administered during the last week of pregnancy. To counteract the negative effects of both stressors, the antioxidant N-acetyl-cysteine (NAC, 1 g/kg) was administered to female breeders for 5 weeks until delivery. Emotionality was assessed in adolescent male and female offspring through the elevated-plus-maze (EPM). Moreover, hippocampal gene expression levels of Brain-Derived-Neurotrophic-Factor (*Bdnf*), Nuclear factor erythroid 2–related factor 2 (*Nrf-2*) and Kelch-like ECH-associated protein 1 (*Keap-1*) were measured, by qPCR, as markers of brain plasticity and antioxidant capacity. Prenatal exposure to both HFD and PNS enhanced behavioral disinhibition, increasing time spent in the open arms of the EPM and decreasing the frequency of stretch-attend-posture, especially in female offspring. Moreover, both prenatal stressors led to decreased *Bdnf* (in females) and *Nrf-2* levels, and disrupted *Keap-1* levels. Prenatal NAC was able to counteract these effects on the brain. Overall, different prenatal stressors result in long-term negative effects on the adolescent offspring, increasing risk assessment behaviors and affecting brain antioxidant defenses: rescue by NAC suggests that OS may be a common mechanism, playing a pivotal role in fetal programming of mental disorders. *ERANET-NEURON-JTC-2018-Mental Disorders-"EMBED".*

Maternal Obesity as a Risk Factor for Brain Development and Mental Health in the Offspring.
Maternal obesity plays a key role in the health trajectory of the offspring. Although research on this topic has largely focused on the potential of this condition to increase the risk for child obesity, it is becoming more and more evident that it can also significantly impact cognitive function and mental health. The mechanisms underlying these effects are starting to be elucidated and point to the placenta as a critical organ that may mediate changes in the response to stress, immune function and oxidative stress. Long-term effects of maternal obesity may rely upon epigenetic changes in selected genes that are involved in metabolic and trophic regulations of the brain. More recent evidence also indicates the gut microbiota as a potential mediator of these effects. Overall, understanding cause-effect relationships can allow the development of preventive measures that could rely upon dietary changes in the mother and the offspring. Addressing diets appears more feasible than developing new pharmacological targets and has the potential to affect the multiple interconnected physiological pathways engaged by these complex regulations, allowing prevention of both metabolic and mental disorders.

High-fat diet during adulthood interacts with prenatal stress, affecting both brain inflammatory and neuroendocrine markers in male rats.
Prenatal stress (PNS) affects foetal programming and, through an interaction with subsequent challenges, can increase vulnerability to mood and metabolic disorders. We have previously shown that, following PNS, adult male rats are characterized by increased vulnerability to a metabolic stressor experienced at adulthood (8-week-high-fat diet-HFD). In this study, we specifically assessed whether PNS might interact with an adult metabolic challenge to induce an inflammatory phenotype. Changes in the expression levels of inflammatory (Il-1β, Tnf-α, Il-6) and of stress response mediators (Nr3c1, Fkbp5) as well as of mood and metabolic regulators (Bdnf, Ghs-R) were investigated in the hippocampus, prefrontal cortex

and hypothalamus, brain regions involved in the pathogenesis of depression and prone to inflammation in response to stress. Overall, PNS reduced the expression of Bdnf and Tnf-α, while HFD administered at adulthood counteracted this effect suggesting that PNS impinges upon the same pathways regulating responses to a metabolic challenge at adulthood. Furthermore, HFD and PNS affected the expression of both Nr3c1 and Fkbp5, two neuroendocrine mediators involved in the response to stress, metabolic challenges and in the modulation of the emotional profile (as shown by the correlation between Fkbp5 and the time spent in the open arms of the elevated plus-maze). Overall, these results indicate that the same metabolic and neuroendocrine effectors engaged by PNS are affected by metabolic challenges at adulthood, providing some mechanistic insight into the well-known comorbidity between mood and metabolic disorders.

Natural products improve healthspan in aged mice and rats: A systematic review and meta-analysis.
Over the last decades a decrease in mortality has paved the way for late onset pathologies such as cardiovascular, metabolic or neurodegenerative diseases. This evidence has led many researchers to shift their focus from researching ways to extend lifespan to finding ways to increase the number of years spent in good health; "healthspan" is indeed the emerging concept of such quest for ageing without chronic or disabling diseases and dysfunctions. Regular consumption of natural products might improve healthspan, although the mechanisms of action are still poorly understood. Since preclinical studies aimed to assess the efficacy and safety of these compounds are growing, we performed a systematic review and meta-analysis on the effects of natural products on healthspan in mouse and rat models of physiological ageing. Results indicate that natural compounds show robust effects improving stress resistance and cognitive abilities. These promising data call for further studies investigating the underlying mechanisms in more depth.

Trehalose administration in C57BL/6N old mice affects healthspan improving motor learning and brain anti-oxidant defences in a sex-dependent fashion: a pilot study.
Aim of this study was to characterize the effects of oral trehalose administration (2%w/v) on healthspan in old mice. Trehalose was administered in drinking water for 1 month to male and female C57BL/6N mice aged 25-months. After behavioral phenotyping (grip strength, beam walking and rotarod tests), autophagy (LC3-II/actin) and oxidative stress were tested in the cerebral cortex and gastrocnemius muscle. The latter parameter was indirectly assessed by evaluating carbonyl groups added to proteins as a result of oxidative reactions, in addition to central levels of NRF2 protein, a transcription factor that regulates the expression of antioxidant enzymes. In comparison with sex-matched controls, trehalose-treated males performed better in motor planning and coordination tasks. This behavioral phenotype was associated with an activation of the ubiquitin-proteasome system, autophagy and antioxidant defences in cerebral cortex. Independently from trehalose administration, females were characterized by better motor performance and showed higher levels of ubiquitinated proteins and NRF2 in cerebral cortex, suggesting an up-regulation of basal antioxidant defences. In conclusion, trehalose was effective in counteracting some aspects of age-related decay, with specific effects in male and female subjects.

SEX-DEPENDENT NEURODEVELOPMENTAL VULNERABILITY IN PRENATALLY STRESSED MOUSE OFFSPRING IS MEDIATED BY OXIDATIVE STRESS AND PLACENTAL IMMUNE ACTIVATION

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Alessandra Berry[1], Chiara Musillo[1,2], Roberta Tassinari[3], Sabrina Tait[3], Francesca Maranghi[3], Francesca Cirulli[1]
[1]Istituto Superiore di Sanità, Center For Behavioral Sciences And Mental Health, Rome, Italy, [2]"Sapienza" University of Rome, Phd Program In Behavioral Neuroscience, Department Of Psychology, Rome, Italy, [3]Istituto Superiore di Sanità, Center For Gender-specific Medicine, Rome, Italy

Prenatal stress (PNS) plays a key role in foetal development; inflammation and oxidative stress (OS) may mediate its effects with long-term consequences on the offspring mental health. We set up a PNS mouse model and characterized the effects of such condition on the placenta, maternal behaviour and pups' neurodevelopment, focussing on OS and inflammation pathways. Pregnant C57BL6/N mice underwent restraint-stress during the last week of pregnancy; controls were left undisturbed. Five weeks before mating half subjects from each group were administered with the antioxidant N-Acetyl-cysteine (NAC-1g/kg) until delivery. Both PNS and NAC treatment contained body weight gain during pregnancy; NAC reduced the number of pups/litter. The placenta's labyrinth layer in the PNS-NAC group showed increased macrophages number suggesting that NAC might prime the immune system to respond more efficiently to sub-optimal intrauterine conditions. PNS overall disrupted the maternal circadian alternation between nursing and foraging that was partially restored upon NAC administration. When challenged in the homing test, both PNS and NAC-treated 10-day-old female pups showed greater reactivity being characterised by a reduced latency to reach the nest; male pups performance was not affected by PNS. Our results suggest that PNS affects OS and immune activation in both pre- and post-natal maternal environment leading to a sex-dependent vulnerability in the offspring. Data on NAC administration deserve a thorough investigation to better characterize its efficacy and specific mechanisms of action. Proteomic analyses are ongoing aimed at characterizing placental immunomodulation; targeted gene expression will be carried-out on pups' brain inflammatory mediators. "EMBED"-ERANET-NEURON-JTC-2018.

META-ANALYSIS OF PREFRONTAL CORTEX RNA-SEQ DATA AFTER SOCIAL DEFEAT STRESS OF VARYING DURATION

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Ksenia Ayriyants[1], Natalia Bondar[1], Vasiliy Reshetnikov[1], Polina Kisaretova[1,2]
[1]Institute of Cytology and Genetics of SB RAS, Sector Of Molecular Neurobiology Of Stress, Novosibirsk, Russian Federation, [2]Novosibirsk State University, Natural Sciences, Novosibirsk, Russian Federation

Depression covering over 5% of the world's adult population is enhanced by chronic stress. Chronic social defeat stress (SDS) is an ethologically valid animal model of depression. We conducted a meta-analysis of the prefrontal cortex transcriptomes in the in 5 datasets after 10-day SDS and 2 datasets after 30-day SDS. Moreover, we identified genes bonded with susceptibility and resistance to stress after 10-day SDS. Analysis showed 20 most reproducible genes changed under 10-day SDS. These genes are connected with neuroinflammation (*Vwf, Il1r1, Il6ra*) and expression change of glucocorticoid signaling-related genes (*Fkbp5, Hsd11b*). Stress sensitive mice after 10 days SDS showed a steady decrease in expression of 45 oligodendrocyte-specific genes. Most of these genes are linked with myelination (*Mbp, Mal, Mobp, Plp1, Mag, Ugt8a, Olig2*). Finally, a 30-day SDS leads to a strong increase in the expression of genes associated with transcription, translation, and ATP synthesis. Besides, animals after 30 days of SDS showed increased gene expression linked with microglia activation (*Ifngr1, Tyrobp, Aif1*) and opposite trend in expression of genes contributing to neuroplasticity (*Grin1, Grin2c, Htt*). Surprisingly, DE genes after 10 and 30 days SDS don't overlap. Taking everything into consideration, RNA-seq meta-analysis shed light onto time-dependence of molecular changes in social defeat stress paradigm. This work was supported by the Russian Science Foundation (21-15-00142).

High-resolution MRI data of the brain of C57BL/6J and BTBR mice in three anatomical views.
The research on strain-, sex-, and stress-specific differences in structural and functional connectivity of the brain is important for elucidating various behavioral features and etiologies of psychiatric disorders. Socially impaired BTBR mice are considered a model of autism spectrum disorders. Here we present high-resolution magnetic resonance imaging data from the brain of 89 adolescent mice (C57BL/6J and BTBR) in axial, sagittal, and coronal views. The study [1] includes both females and males differed in early-life experience (normally reared or subjected to prolonged maternal separation: 3 h daily from postnatal day 2 to 15). The MRI data were obtained on a horizontal tomograph Biospec 117/16 instrument with a magnetic field strength of 11.7 T. Thus, multislice Turbo RARE T-weighted images of the brain were captured in eight groups of mice. Altogether, these data allow to evaluate strain-, sex-, and stress-specific alterations in the volumes of various brain structures and to better understand the relation between brain structural differences and behavioral abnormalities.

Sex-specific behavioral and structural alterations caused by early-life stress in C57BL/6 and BTBR mice.
Lately, the development of various mental illnesses, such as depression, personality disorders, and autism spectrum disorders, is often associated with traumatic events in childhood. Nonetheless, the mechanism giving rise to this predisposition is still unknown. Because the development of a disease often depends on a combination of a genetic background and environment, we decided to evaluate the effect of early-life stress on BTBR mice, which have behavioral, neuroanatomical, and physiological features of autism spectrum disorders. As early-life stress, we used prolonged separation of pups from their mothers in the first 2 weeks of life (3 h once a day). We assessed effects of the early-life stress on juvenile (postnatal day 23) and adolescent (postnatal days 37-38) male and female mice of strains C57BL/6 (B6) and BTBR. We found that in both strains, the early-life stress did not lead to changes in the level of social behavior, which is an important characteristic of autism-related behavior. Nonetheless, the early-life stress resulted in increased locomotor activity in juvenile BTBR mice. In adolescent mice, the stress early in life caused a low level of anxiety in B6 males and BTBR females and increased exploratory activity in adolescent BTBR males and females. In addition, adolescent B6 male and female mice with a history of the early-life stress tended to have a thinner motor cortex as assessed by magnetic resonance imaging. As

compared to B6 mice, BTBR mice showed reduced levels of social behavior and exploratory activity but their level of locomotor activity was higher. BTBR mice had smaller whole-brain, cortical, and dorsal hippocampal volumes; decreased motor cortex thickness; and increased ventral-hippocampus volume as compared to B6 mice, and these parameters correlated with the level of exploratory behavior of BTBR mice. Overall, the effects of early postnatal stress are sex- and strain-dependent.

Effects of Short-Term Exposure to Lithium on Antiapoptotic Bcl-xL Protein Expression in Cortex and Hippocampus of Rats after Acute Stress.
The antiapoptotic protein Bcl-xL is involved in development of neurobiological resilience to stress; hence, the possibility of use of psychotropic drugs to increase its expression in brain in response to stress is of considerable interest. Lithium is a neurotropic drug widely used in psychiatry. In work, we studied effects of lithium administration (for 2 or 7 days) on the expression of Bcl-xL mRNA and protein in the hippocampi and cortices of rats subjected to stress that induced depression-like behavior in the animals. In contrast to the brain-derived neurotrophic factor (BDNF), whose expression decreased in the hippocampus in response to acute stress, stress increased the level of Bcl-xL mRNA in the hippocampus, but decreased it in the frontal cortex. Treatment of stressed animals with lithium for 2 or 7 days increased Bcl-xL protein levels 1.5-fold in the hippocampus, but it decreased them in the cortex. Therefore, Bcl-xL expression in the brain can be modulated by both stress and psychotropic drugs, and the effects of these factors are brain region-specific: both stress exposure and lithium administration activated Bcl-xL expression in the hippocampus and suppressed it in the frontal cortex. The activation of Bcl-xL expression in the hippocampus by lithium, demonstrated for the first time in this study, suggests an important role of this protein in the therapeutic effects of lithium in the treatment of stress-induced psychoemotional disorders.

PREDICTING CHRONIC STRESS AMONG HEALTHY FEMALES USING DAILY-LIFE PHYSIOLOGICAL AND LIFESTYLE FEATURES FROM WEARABLE SENSORS

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Noa Magal[1], Sharona Rab[1], Pavel Goldstein[2], Lisa Simon[1], Talita Jiryis[1], Roee Admon[1,3]
[1]University of Haifa, School Of Psychological Sciences, Haifa, Israel, [2]University of Haifa, School Of Public Health, Haifa, Israel, [3]University of Haifa, The Integrated Brain And Behavior Research Center (ibbrc), Haifa, Israel

Chronic stress is a highly prevalent condition that may stem from different sources and can substantially impact physiology and behavior, leading to impaired mental and physical health. Multiple physiological and behavioral lifestyle features can now be recorded unobtrusively in daily-life using wearable sensors. The aim of the current study was to identify a distinct set of physiological and behavioral lifestyle features that are associated with elevated levels of chronic stress across different stress sources. In here, 140 healthy female participants completed the TICS chronic stress inventory before wearing the Fitbit Charge3 sensor for seven consecutive days while maintaining their daily routine. Physiological and lifestyle features that were extracted from sensor data, alongside demographic features, were used to predict high vs. low chronic stress with support vector machine classifiers, applying out-of-sample model testing. The results showed that the model achieved 79% classification accuracy for chronic stress from a social tension source. A mixture of physiological (resting heart-rate, heart-rate circadian characteristics), lifestyle (steps count, sleep onset and sleep regularity) and non-sensor demographic features (smoking status) contributed to this classification. For conclusion, As wearable technologies continue to rapidly evolve, integration of daily-life indicators could improve our understanding of chronic stress and its impact of physiology and behavior.

Is neuroticism really bad for you? Dynamics in personality and limbic reactivity prior to, during and following real-life combat stress.
The personality trait of neuroticism is considered a risk factor for stress vulnerability, putatively via its association with elevated limbic reactivity. Nevertheless, majority of evidence to date that relates neuroticism, neural reactivity and stress vulnerability stems from cross-sectional studies conducted in a "stress-free" environment. Here, using a unique prospective longitudinal design, we assessed personality, stress-related symptoms and neural reactivity at three time points over the course of four and a half years; accounting for prior to, during, and long-time following a stressful military service that included active combat. Results revealed that despite exposure to multiple potentiality traumatic events, majority of soldiers exhibited none-to-mild levels of posttraumatic and depressive symptoms during and following their military service. In contrast, a quadratic pattern of change in personality emerged overtime, with neuroticism being the only personality trait to increase during stressful military service and subsequently decrease following discharge. Elevated neuroticism during military service was associated with reduced amygdala and hippocampus activation in response to stress-related content, and this association was also reversed following discharge. A similar pattern was found between neuroticism and hippocampus-anterior cingulate cortex (ACC) functional connectivity in response to stress-related content. Taken together these findings suggest that stressful military service at young adulthood may yield a temporary increase in neuroticism mediated by a temporary decrease in limbic reactivity, with both effects being reversed long-time following discharge. Considering that participants exhibited low levels of stress-related symptoms throughout the study period, these dynamic patterns may depict behavioral and neural mechanisms that facilitate stress resilience.

THE ROLE OF LOCUS COERULEUS-NORADRENERGIC SYSTEM IN RESILIENCE FOLLOWING CHILD ABUSE

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Déa Slavova[1], Stéphanie De Gois[1], Bruno Giros[1,2], Elsa Isingrini[1]
[1]Integrative Neurosciences and Cognition Center (INCC), Cnrs Umr8002, Université Paris Descartes, Paris, France, [2]Department of Psychiatry, Douglas Hospital, Mc Gill University, Montreal, Canada

The capacity to adapt positively following stressful events, called resilience, involves several neurobiological systems including the noradrenergic (NE) system. Being one of the main effectors of the stress response, the NE system also plays an important role for brain development, especially during critical periods. In the last years, growing evidences in mice and humans showed that its activity is implicated in resilience following stressful events during adulthood. However, there is less evidence for its importance in resilience following early life stress. Here, we used a translational approach to investigate the role of the locus coeruleus-noradrenergic (LC-NE) system in resilience following early life stress. In human LC, we demonstrated by immunohistochemistry that the number of LC-NE neurons was different between post mortem tissues from depressed patients with a history of child abuse (DS-CA) or without (DS), and matched samples from psychiatrically healthy individuals with a history of child abuse (RES-CA) or without (CTL). In parallel, we developed a mice model of maternal separation in which, using a battery of anxio-depressive tests, we identified two groups of mice: one with depressive-like behavior and another with resilient-like phenotype with behavior similar to the control group. Immunofluorescence analysis of the early activated gene c-fos showed a differential activity state of NE neurons in depressive-like mice compared with resilient mice. By demonstrating both a structural and functional role of the LC-NE system, these data highlight the implication of the LC-NE system in resilience following child abuse.

Aim: To investigate possible causes of poor replicability in behavioral neuroscience research, we determined the extent to which common differences in housing and husbandry conditions between rearing facilities (RFs) contribute to the replicability problem by modulating the phenotype of genetically homogenous (inbreed) mice. **Methods:** We reared inbred C57BL/6JRj mice from a single breeding stock in five different RFs throughout early life and adolescence, before transporting them to a single test laboratory. We examined the extent and persistence of variation in the composition of the gut microbiota associated with the different RFs and measured differences in behavioral and physiological phenotypic traits. We also assessed chromatin accessibility in the ventral hippocampus to explore the biological basis of behavioral differences. **Results:** We found persistent effects of RFs on the composition and heterogeneity of the gut microbiota. These effects were paralleled by persistent differences in body weight and behavior. We show that the facility-specific environment influenced developmental programs by affecting neuronal chromatin accessibility profiles, likely modulating the mice' behavioral phenotypes. We detected changes in chromatin organization of genes involved in the regulation of behavior, neurogenesis and presynaptic plasticity events, targeting mainly GABAergic and glutamatergic transmission. **Conclusion:** Our findings demonstrate that common environmental differences between RFs may produce facility-specific phenotypes, from the molecular to the behavioral level, which might explain inconsistency of results between different studies. The results highlight that the animals' environmental background should be accounted for by study design to produce robust and replicable research findings.

SOCIAL DEFEAT DURING ADOLESCENCE INCREASES THE SUSCEPTIBILITY TO AN IMMUNE CHALLENGE LATER IN LIFE

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Cyprien Guerrin, Daniel Vazquez, Kavya Prasad, Janine Doorduin, Erik De Vries
University Medical Center Groningen, Department Of Nuclear Medicine And Molecular Imaging, Groningen, Netherlands

Aims Early-life adverse experiences (first hit) may increase vulnerability to immune challenges experienced later in life (second hit) and subsequently induce the development of stress-related psychopathologies. Microglia have been proposed to play a role in this phenomenon. In the present study, we investigated whether exposure to social adversity during adolescence induces brain and behavioural alterations and whether such adversity increases the susceptibility to an immune challenge experienced in adulthood. **Methods** Males Wistar rats were exposed to repeated social defeat (RSD, first hit) during adolescence (postnatal day [PND] 35-39) and then to an immune challenge consisting of a single injection of lipopolysaccharide (LPS, second hit) at adulthood (PND90). Positron emission tomography scans using [^{11}C]-PBR28 at the tracer and ELISA were performed on PND46, 89, and 93 to measure neuroinflammation and plasma corticosterone respectively. Sucrose preference and social interaction tests were performed on PND40-67-91 to measure anhedonia and social behaviour. **Results** RSD alone induced an increase in neuroinflammation and plasma corticosterone that remained until adulthood. Rats exposed to the combination of RSD and LPS exhibited susceptibility towards the development of anhedonia and social preference dysfunction characterized by a reduction in sucrose preference and a lack of social preference towards a rat over an object, respectively. Rats subjected to both hits also displayed a synergistic increase in brain inflammation characterized by a higher [^{11}C]-PBR28 tracer brain uptake. **Conclusions** Our findings indicate that exposure to social stress during adolescence primes microglia and increases the susceptibility to an immune challenge later in life.

The dual hit hypothesis of schizophrenia: Evidence from animal models.
Schizophrenia is a heterogeneous psychiatric disorder, which can severely impact social and professional functioning. Epidemiological and clinical studies show that schizophrenia has a multifactorial aetiology comprising genetic and environmental risk factors. Although several risk factors have been identified, it is still not clear how they result in schizophrenia. This knowledge gap, however, can be investigated in animal studies. In this review, we summarise animal studies regarding molecular and cellular mechanisms through which genetic and environmental factors may affect brain development, ultimately causing schizophrenia. Preclinical studies suggest that early environmental risk factors can affect the immune, GABAergic, glutamatergic, or dopaminergic system and thus increase the susceptibility to another risk factor later in life. A second insult, like social isolation, stress, or drug abuse, can further disrupt these systems and the interactions between them, leading to behavioural abnormalities. Surprisingly, first insults like maternal infection and early maternal separation can also have protective effects. Single gene mutations associated with schizophrenia did not have a major impact on the susceptibility to subsequent environmental hits.

MULTI-TRAJECTORY ANALYSIS UNCOVERS ADAPTIVE AND MALADAPTIVE PSYCHO-PHYSIOLOGICAL ACUTE STRESS RESPONSE PATTERNS

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Lisa Simon[1], Sharona Rab[1], Pavel Goldstein[2,3], Noa Magal[1], Roee Admon[1,2]
[1]University of Haifa, School Of Psychological Sciences, Haifa, Israel, [2]University of Haifa, The Integrated Brain And Behavior Research Center (ibbrc), Haifa, Israel, [3]University of Haifa, School Of Public Health, Haifa, Israel

Everyday life involves exposure to challenging acute stressful situations. Encounter with such acute stressor(s) elicits multiple physiological and psychological response trajectories that travel at different times-scales and directions. Hence, associating a specific psycho-physiological response pattern as adaptive or maladaptive represents a substantial challenge. The current study aimed, for the first time, to assess multiple physiological stress response trajectories that are simultaneously recorded and investigate their putative relation to psychological responses. Using a within-subject design, 96 healthy female participants underwent an acute laboratory stress induction procedure. Psychological, physiological, and endocrinal responses were assessed before, during and after stress via positive affect and negative affect (PANAS), heart rate (HR) and heart rate variability (HRV) and saliva cortisol, respectively. Fitting an unsupervised multi-trajectory cluster analysis on these data uncovered that acute stress responsivity across multiple trajectories was best described by three latent classes. These three classes were identified based on their stress-induced psychological response patterns as an adaptive stress response (n=55), heightened affective response during stress (n=24) and lack of recovery after stress relief (n=17). All groups exhibited a stress-induced increase in HR and cortisol. Interestingly, only the adaptive group showed the expected stress-induced HRV response, while the two smaller and presumably maladaptive response groups exhibited blunted HRV. Our findings support the important notion that adaptive response to stress depends on psycho-physiological coherence, while its violation may be considered as a core mechanism that promotes stress vulnerability and related psychopathologies.

Now or Later? Stress-Induced Increase and Decrease in Choice Impulsivity Are Both Associated with Elevated Affective and Endocrine Responses.
Exposure to acute stress elicit physiological and psychological responses that can impact decision-making, often expressed as an increased tendency to act in an impulsive manner following stress. Delay discounting (DD) task has emerged as a reliable measure of impulsive behavior in the form of choice impulsivity (CI). Interestingly, studies that examined the effect of acute stress on DD performance reported mixed results. To address this, we conducted a within-subject examination of the impact of acute stress on CI, focusing on individual differences in response patterns. One hundred and fifty healthy female participants completed the DD task twice, before and after undergoing an acute laboratory stress induction procedure. Saliva samples and self-report mood and affect measures were collected at four time points throughout the session. Fifty-nine matched healthy control participants completed only the DD task twice, with no stress in between. Results indicate that the acute stress procedure elicited the expected effects of increased cortisol release and increased negative mood and affect, at the group level. With respect to DD, stress indeed increased CI at the group level, yet participants differed in the magnitude and direction of this effect. Interestingly, regression analysis revealed quadratic relations between stress-induced changes in CI and cortisol release. Indeed, dividing the sample into three sub-groups based on the impact of stress on CI revealed that, compared to participants that exhibited no substantial change in their CI following stress, participants that exhibited either stress-induced increase or decrease in their CI also exhibited more stress-induced cortisol release, as well as more negative affect. Taken together, these findings suggest that elevated physiological and psychological responses to stress are associated with either increased or decreased choice impulsivity, thus depicting quadratic relations between stress and impulsivity.

MULTIMODAL ASSOCIATIONS OF FKBP5 METHYLATION WITH EMOTION-REGULATORY PREFRONTAL-LIMBIC BRAIN CIRCUITS AND REAL-LIFE STRESS RESPONSIVITY

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Thomas Leon Kremer, Junfang Chen, Anais Harneit, Emanuel Schwarz, Andreas Meyer-Lindenberg, Urs Braun, Heike Tost
Heidelberg University, Medical Faculty Mannheim, Mannheim, Germany

Aims *FKBP5*, a molecular stress regulator, contributes to individual differences in major categories of mental health, such as emotion regulation and stress responsivity. Here we examine the neural and real-world correlates of *FKBP5* methylation in a large sample of 395 non-affected individuals. **Methods** *FKBP5* methylation (cg20813374 and cg00130530) was assessed using Infinium EPIC arrays and residualized for age, sex, cell composition and population structure. In SPM12 we prerpocessed structural and functional MRI data following standard procedures. We built general linear models defining *FKBP5* methylation as regressor of interest to predict (i) vmPFC grey matter volume using voxel based morphometry, (ii) vmPFC habituation during emotional face matching and (iii) emotion-regulatory vmPFC-amygdala coupling estimated using psychophysiological interaction. We calculated a Spearman correlation between the *T*-map resulting from the voxel based morphometric analysis and *FKBP5* expression from the allen human brain atlas. Using ambulatory assessment we estimated modulatory effects of *FKBP5* methylation and *FKBP5*-related neural connectivity on daily-life stress responsivity. **Results** *FKBP5* DNAm is associated with (i) anxiety-related morphometric variance in the vmPFC (*FKBP5*: T=3.99, P_{FWE}=.039), (ii) vmPFC habituation to repeated emotional stimuli (T=3.13, P_{FWE}=.024) and (iii) emotion-regulatory vmPFC-amygdala coupling (T=3.45, P_{FWE}=0.020). The brain-wide pattern of morphometric correlation with *FKBP5* methylation is co-located with the brain-wide distribution of *FKBP5* expression (R=-.195, P_{PERM}=.034). *FKBP5* methylation (T=5.43, P<.001) and *FKBP5*-related emotion-regulatory vmPFC-amygdala coupling (T=-2.91, P=.004) modulate daily-life stress responsivity. **Conclusions** Our findings suggest that *FKBP5* DNAm and *FKBP5*-related neural mechanisms are critically important in affective stress responsivity and in maintaining mental health.

Exposure to early-life adversity, such as that caused by neglect and abuse is known to induce maladaptive behaviors and to increase the vulnerability to substance abuse, neuropsychiatric disorders, and other negative outcomes later in life. These behavioral alterations are also accompanied with long lasting changes in the volume, activity and connectivity of several brain regions related to emotional processing, impulse control and decision making, such as the pre-frontal cortex (PFC), nucleus accumbens and the amygdala. However, the mechanisms and cellular correlates that lead to these alterations are yet poorly understood. In our laboratory, we employed a model of maternal separation and maternal stress (MSUS) to study the impact of early-life stress on juvenile behavior, as well as on the inhibitory system of the PFC, which is known to experience intense remodeling during the first weeks of life. Using behavioral, stereological, and electrophysiological analysis, we show that MSUS male mice, but not females, present increased hyperactive, impulsive, and risk-taking behaviors, together with a layer-specific increase in the number of parvalbumin positive interneurons. In addition, we observed an increase in inhibitory activity within the medial orbito-frontal cortex (mOFC), a region reported to play a role in the modulation of reward sensitivity and impulsivity. Chemogenetic tools were also employed to further probe the relationship between the observed mOFC dysfunction and the behavioral phenotypes. Taken together our results show that ELS alters the inhibitory balance of the mOFC, potentially contributing to a risk-taking and impulsive phenotype that is more striking in males.

The old guard: Age-related changes in microglia and their consequences.
Among all major organs, the brain is one of the most susceptible to the inexorable effects of aging. Throughout the last decades, several studies in human cohorts and animal models have revealed a plethora of age-related changes in the brain, including reduced neurogenesis, oxidative damage, mitochondrial dysfunction and cell senescence. As the main immune effectors and first responders of the nervous tissue, microglia are at the center of these events. These cells experience irrevocable changes as a result from cumulative exposure to environmental triggers, such as stress, infection and metabolic dysregulation. The age-related immunosenescent phenotype acquired by microglia is characterized by profound modifications in their transcriptomic profile, secretome, morphology and phagocytic activity, which compromise both their housekeeping and defensive functions. As a result, aged microglia are no longer capable of establishing effective immune responses and sustaining normal synaptic activity, directly contributing to age-associated cognitive decline and neurodegeneration. This review discusses how lifestyle and environmental factors drive microglia dysfunction at the molecular and functional level, also highlighting possible interventions to reverse aging-associated damage to the nervous and immune systems.

Social subordination induced by early life adversity rewires inhibitory control of the prefrontal cortex via enhanced Npy1r signaling.
Social hierarchies are present in most mammalian species. In nature, hierarchies offer a tradeoff between reduction of in-group fighting between males, at the expense of an asymmetric sharing of resources. Early life experiences and stress are known to influence the rank an individual attains in adulthood, but the associated cellular and synaptic alterations are poorly understood. Using a maternal separation protocol, we show that care-deprived mice display a long-lasting submissive phenotype, increased social recognition, and enhanced explorative behavior. These alterations are consistent with an adaptation that favors exploration rather than confrontation within a group setting. At the neuronal level, these animals display dendritic atrophy and enhanced inhibitory synaptic inputs in medial prefrontal cortex (mPFC) neurons. To determine what

could underlie this synaptic modification, we first assessed global gene expression changes via RNAseq, and next focused on a smaller subset of putatively altered synaptic receptors that could explain the changes in synaptic inhibition. Using different cohorts of maternally deprived mice, we validated a significant increase in the expression of Npy1r, a receptor known to play a role in maternal care, anxiety, foraging, and regulation of group behavior. Using electrophysiological recordings in adult mice while blocking NPY1R signaling, we determined that this receptor plays a key role in enhancing GABAergic currents in mice that experience maternal deprivation. Taken together, our work highlights the potential of regulating NPY1R in social anxiety disorders and the alterations induced in brain circuitry as a consequence of early life stress and adversity.

THE ROLE OF FGF14 IN SUSCEPTIBILITY TO DEPRESSION

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Ilaria Balbo, Francesca Montarolo, Filippo Tempia, Eriola Hoxha
University of Turin, Department Of Neuroscience "rita Levi Montalcini", Turin, Italy

Depression is a major health problem in modern society and currently available therapies require prolonged treatments and have limited efficacy. The lack of knowledge about underlying mechanisms limits the development of specific treatments. The main theory is based on the loss of balance between excitation and inhibition in neuronal circuits implicated in depression. FGF14 is an accessory protein of voltage-dependent sodium channels, able to regulate the intrinsic excitability of the cells. The complex Ffg14-voltage dependent sodium channels is a key determinant of the excitation/inhibition balance in brain circuits. Our hypothesis is that Fgf14 can be a target gene for the pharmacological treatment of depression. **Aim:** This study aimed to better understand the role of Fgf14 in brain circuits involved in depression. **Methods:** We analyzed female *Fgf14*$^{-/-}$ mice and wild-type littermates in estrous phase. To induce acute stress in mice test suspension test was used. To mark activation of neuronal circuits cFos labeling was evaluated in different brain regions. **Results:** *Fgf14*$^{-/-}$ showed a resilience to depression induced by tail suspension test. Moreover, we found a statistically significant increase in cFos positive cell density *Fgf14*$^{-/-}$ mice in ventral tegmental area and nucleus accumbens. **Conclusions:** The *Fgf14*$^{-/-}$ mouse could be a valid model to understand the mechanisms altered in depression. These results could be helpful for new therapeutic treatment that could properly act to counterbalance the alterations present in this psychiatric disorder.

Elovl5 is required for proper action potential conduction along peripheral myelinated fibers.
Elovl5 elongates fatty acids with 18 carbon atoms and in cooperation with other enzymes guarantees the normal levels of very long-chain fatty acids, which are necessary for a proper membrane structure. Action potential conduction along myelinated axons depends on structural integrity of myelin, which is maintained by a correct amount of fatty acids and a proper interaction between fatty acids and myelin proteins. We hypothesized that in Elovl5 mice, the lack of elongation of Elovl5 substrates might cause alterations of myelin structure. The analysis of myelin ultrastructure showed an enlarged periodicity with reduced G-ratio across all axonal diameters. We hypothesized that the structural alteration of myelin might affect the conduction of action potentials. The sciatic nerve conduction velocity was significantly reduced without change in the amplitude of the nerve compound potential, suggesting a myelin defect without a concomitant axonal degeneration. Since Elovl5 is important in attaining normal amounts of polyunsaturated fatty acids, which are the principal component of myelin, we performed a lipidomic analysis of peripheral nerves of Elovl5-deficient mice. The results revealed an unbalance, with reduction of fatty acids longer than 18 carbon atoms relative to shorter ones. In addition, the ratio of saturated to unsaturated fatty acids was strongly increased. These findings point out the essential role of Elovl5 in the peripheral nervous system in supporting the normal structure of myelin, which is the key element for a proper conduction of electrical signals along myelinated nerves.

Elovl5 Expression in the Central Nervous System of the Adult Mouse.
(Elongase of Very-Long Fatty Acid 5) gene encodes for an enzyme that elongates long chain fatty acids, with a marked preference for polyunsaturated molecules. In particular, it plays an essential role in the elongation of omega-3 and omega-6 fatty acids, precursors for long-chain polyunsaturated fatty acids (PUFAs). Mutations of cause the spino-cerebellar ataxia type 38 (SCA38), a rare autosomal neurological disease characterized by gait abnormality, dysarthria, dysphagia, hyposmia and peripheral neuropathy, conditions well represented by a mouse model with a targeted deletion of this gene (mice). However, the expression pattern of this enzyme in neuronal and glial cells of the central nervous system (CNS) is still uninvestigated. This work is aimed at filling this gap of knowledge by taking advantage of an Elovl5-reporter mouse line and immunofluorescence analyses on adult mouse CNS sections and glial cell primary cultures. Notably, Elovl5 appears

expressed in a region- and cell type-specific manner. Abundant Elovl5-positive cells were found in the cerebellum, brainstem, and primary and accessory olfactory regions, where mitral cells show the most prominent expression. Hippocampal pyramidal cells of CA2/CA3 where also moderately labeled, while in the rest of the telencephalon Elovl5 expression was high in regions related to motor control. Analysis of primary glial cell cultures revealed Elovl5 expression in oligodendroglial cells at various maturation steps and in microglia, while astrocytes showed a heterogeneous expression of Elovl5. The elucidation of Elovl5 CNS distribution provides relevant information to understand the physiological functions of this enzyme and its PUFA products, whose unbalance is known to be involved in many pathological conditions.

The Emerging Role of Altered Cerebellar Synaptic Processing in Alzheimer's Disease.
The role of the cerebellum in Alzheimer's disease (AD) has been neglected for a long time. Recent studies carried out using transgenic mouse models have demonstrated that amyloid-β (Aβ) is deposited in the cerebellum and affects synaptic transmission and plasticity, sometimes before plaque formation. A wide variability of motor phenotype has been observed in the different murine models of AD, without a consistent correlation with the extent of cerebellar histopathological changes or with cognitive deficits. The loss of noradrenergic drive may contribute to the impairment of cerebellar synaptic function and motor learning observed in these mice. Furthermore, cerebellar neurons, particularly granule cells, have been used as model of Aβ-induced neuronal damage. An unexpected conclusion is that the cerebellum, for a long time thought to be somehow protected from AD pathology, is actually considered as a region vulnerable to Aβ toxic damage, even at the early stage of the disease, with consequences on motor performance.

Emerging roles of Fgf14 in behavioral control.
Sexual disturbances, and aggressivity are a major social problem. However, the molecular mechanisms involved in the control of these behaviors are largely unknown. FGF14, which is an intracellular protein controlling neuronal excitability and synaptic transmission, has been implied in neurologic and psychiatric disorders. Mice with Fgf14 deletion show blunted responses to drugs of abuse. By behavioral tests we show that male Fgf14 knockout mice have a marked reduction of several behaviors including aggressivity and sexual behavior. Other behaviors driven by spontaneous initiative like burying novel objects and spontaneous digging and climbing are also reduced in Fgf14 knockout mice. These deficits cannot be attributed to a generalized decrease of activity levels, because in the open field test Fgf14 knockout mice have the same spontaneous locomotion as wild types and increased rearing. Our results show that Fgf14 is important to preserve a set of behaviors and suggest that fine tuning of neuronal function by Fgf14 is an important mechanism of control for such behaviors.

Purkinje Cell Signaling Deficits in Animal Models of Ataxia.
Purkinje cell (PC) dysfunction or degeneration is the most frequent finding in animal models with ataxic symptoms. Mutations affecting intrinsic membrane properties can lead to ataxia by altering the firing rate of PCs or their firing pattern. However, the relationship between specific firing alterations and motor symptoms is not yet clear, and in some cases PC dysfunction precedes the onset of ataxic signs. Moreover, a great variety of ionic and synaptic mechanisms can affect PC signaling, resulting in different features of motor dysfunction. Mutations affecting Na channels (Na1.1, Na1.6, Naβ4, Fgf14 or Rer1) reduce the firing rate of PCs, mainly via an impairment of the Na resurgent current. Mutations that reduce Kv3 currents limit the firing rate frequency range. Mutations of Kv1 channels act mainly on inhibitory interneurons, generating excessive GABAergic signaling onto PCs, resulting in episodic ataxia. Kv4.3 mutations are responsible for a complex syndrome with several neurologic dysfunctions including ataxia. Mutations of either Cav or BK channels have similar consequences, consisting in a disruption of the firing pattern of PCs, with loss of precision, leading to ataxia. Another category of pathogenic mechanisms of ataxia regards alterations of synaptic signals arriving at the PC. At the parallel fiber (PF)-PC synapse, mutations of glutamate delta-2 (GluD2) or its ligand Crbl1 are responsible for the loss of synaptic contacts, abolishment of long-term depression (LTD) and motor deficits. At the same synapse, a correct function of metabotropic glutamate receptor 1 (mGlu1) receptors is necessary to avoid ataxia. Failure of climbing fiber (CF) maturation and establishment of PC mono-innervation occurs in a great number of mutant mice, including mGlu1 and its transduction pathway, GluD2, semaphorins and their receptors. All these models have in common the alteration of PC output signals, due to a variety of mechanisms affecting incoming synaptic signals or the way they are processed by the repertoire of ionic channels responsible for intrinsic membrane properties. Although the PC is a final common pathway of ataxia, the link between specific firing alterations and neurologic symptoms has not yet been systematically studied and the alterations of the cerebellar contribution to motor signals are still unknown.

Motor Deficits and Cerebellar Atrophy in Knock Out Mice.
Spino-Cerebellar-Ataxia type 38 (SCA38) is caused by missense mutations in the very long chain fatty acid elongase 5 gene, . The main clinical findings in this disease are ataxia, hyposmia and cerebellar atrophy. Mice in which has been knocked out represent a model of the loss of function hypothesis of SCA38. In agreement with this hypothesis, knock out mice reproduced the main symptoms of patients, motor deficits at the beam balance test and hyposmia. The cerebellar cortex of knock out mice showed a reduction of thickness of the molecular layer, already detectable at 6 months of age, confirmed at 12 and 18 months. The total perimeter length of the Purkinje cell (PC) layer was also reduced in knock out mice. Since Elovl5 transcripts are expressed by PCs, whose dendrites are a major component of the molecular layer, we hypothesized that an alteration of their dendrites might be responsible for the reduced thickness of this layer. Reconstruction of the dendritic tree of biocytin-filled PCs, followed by Sholl analysis, showed that the distribution of distal dendrites was significantly reduced in Elovl5 knock out mice. Dendritic spine density was conserved. These results suggest that knock out mice recapitulate SCA38 symptoms and that their cerebellar atrophy is due, at least in part, to a reduced extension of PC dendritic arborization.

INVESTIGATING THE EFFECTS OF A STABLE STIMULUS IN AN UNSTABLE ENVIRONMENT INDUCED BY ATTACHMENT BOND INTERFERENCE

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Camilla Mancini[1], Lucy Babicola[2], Matteo Di Segni[3], Eleonora Castagna[2], Alice Passeri[2], Sebastian Luca D'Addario[3], Diego Andolina[2,3], Carlo Cifani[1], Rossella Ventura[2,3]

Attachment Bond is an emotional, reciprocal bond and experiences affecting its formation may lead to psychopathologies, such as depression, later in life. The neuropeptide Oxytocin (Oxt) is involved in forming attachment bond and is very sensitive to early life experiences. Interestingly, Repeated Cross Fostering (RCF) manipulation increases sensitivity to anhedonic-like behavior and passive coping strategies in DBA female mice by interfering with attachment bond. Moreover, RCF mice show reduced brain Oxt levels. Here, we hypothesized that introducing a Stable Attachment Figure (SAF) during the RCF procedure (inducing instability) may prevent the long-lasting effects of attachment bond alteration, rescuing the brain Oxt levels. To test our hypothesis, control and RCF DBA mice experienced the SAF from PND1 to PND4. Maternal behavior, USV distress calls and Homing test were evaluated in childhood. In adulthood, animals were tested in Social Interaction Test (SIT), Saccharin Preference Test (SPT), Forced Swimming Test (FST) and Tail Suspension Test (TST) to evaluate the rescue effects of SAF on RCF-induced phenotype. SAF did not alter maternal behavior in both Control and RCF groups. No significant effect of SAF was evident in adult Control mice. However, interestingly, SAF prevents the effects of RCF in adulthood probably acting *via* Oxt system.
Overall, our data indicate that the instability induced by RCF is mediated by altered Oxt system. The experience of a stable stimulus (SAF) in the unstable environment (RCF) prevents adulthood negative consequences restoring normal Oxt levels.

Early life adversity affecting the attachment bond alters ventral tegmental area transcriptomic patterning and behavior almost exclusively in female mice.
Early life experiences that affect the attachment bond formation can alter developmental trajectories and result in pathological outcomes in a sex-related manner. However, the molecular basis of sex differences is quite unknown. The dopaminergic system originating from the ventral tegmental area has been proposed to be a key mediator of this process. Here we exploited a murine model of early adversity (Repeated Cross Fostering, RCF) to test how interfering with the attachment bond formation affects the VTA-related functions in a sex-specific manner. Through a comprehensive behavioral screening, within the NiH RDoC framework, and by next-generation RNA-Seq experiments, we analyzed the long-lasting effect of RCF on behavioral and transcriptional profiles related to the VTA, across two different inbred strains of mouse in both sexes. We found that RCF impacted to an extremely greater extent VTA-related behaviors in females than in males and this result mirrored the transcriptional alterations in the VTA that were almost exclusively observed in females. The sexual dimorphism was conserved across two different inbred strains in spite of their divergent long lasting consequences of RCF exposure. Our data suggest that to be female primes a sub-set of genes to respond to early environmental perturbations. This is, to the best of our knowledge, the first evidence of an almost exclusive effect of early life experiences on females, thus mirroring the extremely stronger impact of precocious aversive events reported in clinical studies in women.

Resilience to anhedonia-passive coping induced by early life experience is linked to a long-lasting reduction of I current in VTA dopaminergic neurons.
Exposure to aversive events during sensitive developmental periods can affect the preferential coping strategy adopted by individuals later in life, leading to either stress-related psychiatric disorders, including depression, or to well-adaptation to

future adversity and sources of stress, a behavior phenotype termed "resilience". We have previously shown that interfering with the development of mother-pups bond with the Repeated Cross Fostering (RCF) stress protocol can induce resilience to depression-like phenotype in adult C57BL/6J female mice. Here, we used patch-clamp recording in midbrain slice combined with both and pharmacology to test our hypothesis of a link between electrophysiological modifications of dopaminergic neurons in the intermediate Ventral Tegmental Area (VTA) of RCF animals and behavioral resilience. We found reduced hyperpolarization-activated (I) cation current amplitude and evoked firing in VTA dopaminergic neurons from both young and adult RCF female mice. , VTA-specific pharmacological manipulation of the I current reverted the pro-resilient phenotype in adult early-stressed mice or mimicked behavioral resilience in adult control animals. This is the first evidence showing how pro-resilience behavior induced by early events is linked to a long-lasting reduction of I current and excitability in VTA dopaminergic neurons.

Xlr4 as a new candidate gene underlying vulnerability to cocaine effects.
Although several studies have been performed in rodents, non-human primates and humans, the biological basis of vulnerability to develop cocaine addiction remains largely unknown. Exposure to critical early events (as Repeated Cross Fostering (RCF)) has been reported to increase sensitivity to cocaine effects in adult C57BL/6J female mice. Using a microarray approach, here we report data showing a strong engagement of X-linked lymphocyte-regulated 4a and 4b (Xlr4) genes in cocaine effects. The expression of Xlr4, a gene involved in chromatin remodeling and dendritic spine morphology, was reduced into the Nucleus Accumbens (NAc) of adult RCF C57BL/6J female. We used virally mediated accumbal Xlr4 down-modulation (AAVXlr4-KD) to investigate the role of this gene in vulnerability to cocaine effects. AAVXlr4-KD animals show a potentiated behavioral and neurochemical response to cocaine, reinstatement following cocaine withdrawal and cocaine-induced spine density alterations in the Medium-Sized Spiny Neurons of NAc. We propose Xlr4 as a new candidate gene mediating the cocaine effects.

FEAR EXTINCTION IMPAIRMENTS AND SLEEP ABNORMALITIES IN RATS SELECTED FOR BLUNTED GLUCOCORTICOID RESPONSIVENESS

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Silvia Monari[1], Marie-Isabelle Guillot De Suduiraut[1], Sophie Walker[1], Jocelyn Grosse[1], Olivia Zanoletti[1], Diana Cash[2], Simone Astori[1], Carmen Sandi[1]

Humans show inter-individual differences in vulnerability to develop post-traumatic stress disorder (PTSD) following exposure to trauma. Although low cortisol levels have been linked to PTSD pathophysiology, a causative role for blunted glucocorticoid responsiveness in PTSD is still a matter of debate. We have addressed this question by examining fear extinction in lines of Wistar rats genetically selected for their differential glucocorticoid responsiveness to stress. We observed that rats with blunted corticosterone responsiveness exhibited strong deficits in extinction consolidation compared to rats with 'normative' glucocorticoid responses, and showed higher fear response both few days and several weeks after trauma exposure. Notably, similar to PTSD patients, low-responder rats presented smaller hippocampi, regardless of trauma exposure. Given the hypothesized role of norepinephrine (NE) in PTSD and in sleep-dependent memory consolidation, we monitored hippocampal NE levels with fiber photometry combined with polysomnographic recordings. Our data indicate that low-responder rats had an excess of NE during REM sleep. In addition, during post-extinction sleep, they failed to increase the %time spent in REM sleep, which has been shown to support extinction consolidation. Importantly, the memory deficits in low-responder rats could be normalized by corticosterone injections provided after the extinction session. Conversely, blocking the corticosterone synthesis in rats with normative glucocorticoid levels induced an extinction impairment. Our findings strongly support a causative role for blunted glucocorticoid responsiveness in the biobehavioral traits that provide higher vulnerability to PTSD.

STRESS-ACTIVATED VENTRAL HIPPOCAMPAL NUCLEI SHOW DIFFERENTIAL METHYLATION LANDSCAPE OF TRANSCRIPTION AND SYNAPTIC GTPASE SIGNALLING REGULATION IN THE RESILIENT MICE

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Monika Chanu Chongtham[1], Dewi Hartwich[2], Hristo Todorov[2], Nicolas Ruffini[3], Tamer Butto[2], Eva Weiss[2], Matthias Linke[2], Susanne Gerber[2], Jennifer Winter[2,3]

Introduction: Chronic stress has resulted in a general decline of mental health, worldwide. However, despite being exposed to similar types of stress, differences in resilience to these stressors can be observed between individuals. Such differences result from multiple factors, including genetic/existing epigenetic build-up, prior successful adaptation to similar stress, or presence of social buffering. Increasing number of studies investigate the biological embedding of such experiences in the cell-specific epigenome. Our study examines specific ventral hippocampal nuclei (activated during stress recall) to dissect the DNA methylation landscape in the alternative behavioral states of resilience and susceptibility. **Methods:** We adapted the chronic social defeat stress paradigm on *Arc*$^{creERT2/+}$.R26$^{CAG\text{-}LSL\text{-}Sun1\text{-}sfGFP\text{-}Myc/+}$. This mouse line allows for the trapping of specific nuclei activated (expressing immediate early gene, *Arc*) during social interaction test (stress-recall). Activated nuclei showed *sfGFP* expression on the nuclear membrane and were sorted using “Fluorescent activated nuclei sorting”. DNA methylation states were accessed using Reduced Represented Bisulfite Sequencing (RRBS). **Results:** We identified differential modifications at the basal cytosine level and regional methylation of multiple genes involved in transcription and GTPase signalling between resilience and susceptibility states. Most of these genes are involved in synaptic remodelling. Apart from the genic regions, we also identified differential methylation of important regulatory regions lying in the intergenic regions. **Conclusion:** Differential methylation of genes regulating synaptic function in resilient mice indicates a different synaptic threshold towards environmental insults. Additional longitudinal studies along with exploration of the intergenic regions in a 3D context, could reveal further insights in stress-resilience mechanisms.

LATE-LIFE INFLUENCE OF CHILDHOOD MALTREATMENT ON BRAIN STRUCTURE IS MEDIATED BY PARALLEL AND SEQUENTIAL PATHWAYS OF STRESS, IMMUNE, METABOLIC PHYSIOLOGY

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Sofia Orellana Aguirre[1], Richard Bethlehem[1], Ivan Simpson-Kent[2], Petra Vértes[1], Edward Bullmore[1], Anne-Laura Van Harmelen[3]
[1]University of Cambridge, Department Of Psychiatry, Cambridge, United Kingdom, [2]University of Pennsylvania, Department Of Psychology, Philadelphia, United States of America, [3]Leiden University, Institute Of Education And Child Studies, Leiden, Netherlands

Childhood maltreatment (CM) is associated with abnormal physiology and lifelong psychopathology risks. However, the role of altered physiological systems in enabling temporally distal effects of CM on neurobiology is unclear. We test immune function, metabolic function, and adult stress, three factors reported to influence brain structure, as pathways of distal CM influence on grey matter subcortical volume and cortical thickness (CT). We use an MR imaging subsample of the UK BIOBANK (N=21,738, ages 39-73), where CM was retrospectively assessed, immune and metabolic function measured via circulating C-reactive protein (CRP) levels and body-mass index (BMI) respectively, and stress indexed through self-reported adult trauma (AT). Implementing path modelling at each of 187 bilateral regions, we find and examine the best fitting of two models of distal CM influence on brain structure: (i) a “parallel” model where BMI, AT and CPR act as direct and simultaneous mediators of CM’s distal relationship to brain structure and (ii) an “sequential” model, where CM only influences brain structure through its BMI and AT mediated effects on CRP. We find that CM is “sequentially” related to lower temporo-parietal thickness through BMI’s effects on CRP. In contrast, at the ROIs of best “parallel” fit, CM was related to greater subcortical volume and frontotemporal thickness *directly t*hrough BMI, and lower subcortical volumes and temporo-occipital thickness *directly* through AT. Findings highlight for the first time how the biological embedding of CM on physiology influences neurobiology in late life.

REACT study protocol: resilience after the COVID-19 threat (REACT) in adolescents.
COVID-19-related social isolation and stress may have significant mental health effects, including post-traumatic stress, anxiety and depression. These factors are thought to disproportionately affect populations at risk of psychopathology, such as adolescents with a history of childhood adversity (CA). Therefore, examining which factors may buffer the impact of COVID-19-related stress and isolation in vulnerable adolescents is critical. The Resilience After the COVID-19 Threat (REACT) study assesses whether emotion regulation capacity, inflammation and neuroimmune responses to stress induced in the laboratory prior to the pandemic predict responses to COVID-19-related social isolation and stress in adolescents with CA. We aim to elucidate the mechanisms that enable vulnerable adolescents to maintain or regain good mental health when confronted with COVID-19.

A NOVEL GENE CONTROLS A NEW STRUCTURE: PIGGYBAC TRANSPOSABLE ELEMENT-DERIVED 1, UNIQUE TO MAMMALS, CONTROLS MAMMAL-SPECIFIC NEURONAL PARASPECKLES

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Tamas Rasko[1], Amit Pande[1], Kathrin Radscheit[1], Annika Zink[2], Manvendra Singh[3], Christian Sommer[1], Matthias Selbach[4], Mario Bunse[5], Alessandro Prigione[6], Laurence Hurst[7], Zsuzsanna Izsvak[1]
[1]MDC Berlin, Mobile Dna, Berlin, Germany, [2]Heinrich Heine University, General Pediatrics, Neonatologz And Pediatric Cardiology, Duesseldorf, Germany, [3]Cornell University, Molecular Biology And Genetics, Ithaca, Germany, [4]MDC Berlin, Cardiovascular Research, Berlin, Germany, [5]MDC Berlin, Mario.bunse@mdc-berlin.de, Berlin, Germany, [6]University Children's Hospital, Heinrich Heine University Duesseldorf, Department Of General Pediatrics, Neonatology And Pediatric Cardiology, Duesseldorf, Germany, [7]Millner Center for Evolution, Biology And Biochemistry, Bath, United Kingdom

While new genes can arrive from modes other than duplication, few examples are well characterised. Given a putative link to psychological disorders (e.g. schizophrenia), suggestive of brain functionality, here we characterize *piggyBac* transposable element derived 1 (*PGBD1*). *PGBD1* is non-monotreme mammal-specific and under purifying selection, consistent with functionality. The gene body of human *PGBD1* retains much of the original DNA transposon but has additionally captured SCAN and KRAB domains. Despite gene body retention, PGBD1 has lost transposition abilities, thus transposase functionality is absent. PGBD1 no longer recognises *piggyBac* transposon-like inverted repeats, nonetheless PGBD1 has DNA binding activity. Genome scale analysis identifies enrichment of binding sites in and around genes involved in neuronal development, with association with both histone activating and repressing marks. We focus on one of the repressed genes, the long non-coding RNA *NEAT1*, also dysregulated in schizophrenia, the core structural RNA of paraspeckles. DNA binding assays confirm specific binding of PGBD1 both in the NEAT1 promoter and in the gene body. Depletion of PGBD1 in neuronal progenitor cells (NPCs) results in increased NEAT1/paraspeckles and differentiation, suggesting that PGBD1 has evolved core regulatory functionality for the maintenance of NPCs. In neurons, by contrast, PGBD1 and NEAT1 DNA binding are partially intertwined, and share multiple target genes. We conclude that as paraspeckles are a mammal-specific structure, PGBD1 is a rare example of the evolution of a novel gene coupled to the evolution of a contemporaneous new structure.

Does genetic BDNF deficiency in rats interact with neurotransmitter control of prepulse inhibition? Implications for schizophrenia.
Several studies have suggested a role of BDNF in the development of schizophrenia. For example, post-mortem studies have shown significantly reduced levels of BDNF protein expression in the brain of schizophrenia patients. We investigated the relationship between reduced levels of BDNF in the brain and the regulation of prepulse inhibition (PPI), a behavioral endophenotype of schizophrenia. We used BDNF heterozygous mutant rats which display a 50% decrease of mature BDNF protein levels. Previously, we observed normal baseline PPI and responses to the dopamine D1/D2 receptor agonist, apomorphine, in these rats. Here, we focused on the effects of the NMDA receptor antagonist, MK-801, its interaction with mGluR2/3 and mGluR5 receptors, and the PPI response to serotonergic drugs. MK-801 administration caused a dose-dependent reduction of PPI and increase of startle amplitudes. Baseline PPI and the effect of 0.02-0.1mg/kg of MK-801 were not significantly altered in male or female BDNF heterozygous rats, although the MK-801-induced increase in startle levels was reduced. Co-treatment with the mGluR2/3 agonist, LY379,268, or the mGluR5 antagonist, MPEP, did not alter the effect of MK-801 on PPI in controls or BDNF mutant rats. Treatment with the serotonin-1A receptor agonist, 8-OH-DPAT, the serotonin-2A receptor agonist, DOI, or the serotonin releaser, fenfluramine, induced differential effects on PPI and startle but these effects were not different between the genotypes. These results show that a significant decrease of BDNF protein expression does not lead to reduced PPI at baseline or changes in the regulation of PPI via NMDA receptors or serotonergic mechanisms. These findings in a genetic rat model of BDNF deficiency do not support a role for similar reductions of BDNF levels in schizophrenia in the disruption of PPI, widely reported as an endophenotype of the illness. The potential implications

of these results for our understanding of changes in PPI and BDNF expression in schizophrenia are discussed.

Fluorescence correlation spectroscopy in thin films at reflecting substrates as a means to study nanoscale structure and dynamics at soft-matter interfaces.
Structure and dynamics at soft-matter interfaces play an important role in nature and technical applications. Optical single-molecule investigations are noninvasive and capable to reveal heterogeneities at the nanoscale. In this work we develop an autocorrelation function (ACF) approach to retrieve tracer diffusion parameters obtained from fluorescence correlation spectroscopy (FCS) experiments in thin liquid films at reflecting substrates. This approach then is used to investigate structure and dynamics in 100-nm-thick 8CB liquid crystal films on silicon wafers with five different oxide thicknesses. We find a different extension of the structural reorientation of 8CB at the solid-liquid interface for thin and for thick oxide. For the thin oxides, the perylenediimide tracer diffusion dynamics in general agrees with the hydrodynamic modeling using no-slip boundary conditions with only a small deviation close to the substrate, while a considerably stronger decrease of the interfacial tracer diffusion is found for the thick oxides.

MEDIAL PREFRONTAL CORTEX ENCODES BEHAVIORAL STRATEGY DURING STRESS

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Ole Christian Sylte[1,2], Mateo N'Diaye[1,2], Jonas-Frederic Sauer[1]
[1]Albert-Ludwigs-University Freiburg, Institute Of Physiology I, Medical Faculty, Freiburg, Germany, [2]Albert-Ludwigs-University Freiburg, Faculty Of Biology, Freiburg, Germany

In stressful situations, individuals use different strategies to cope with stressors, dysfunction of which may underlie individuals' vulnerability to stress-related disorders. The medial prefrontal cortex (mPFC) is involved in behavioral responses to stress, but the dynamics of encoding stress-related behavioral strategies by mPFC neurons remains poorly understood. Here, we used 1-photon calcium imaging to record large populations of layer 5 mPFC pyramidal neurons in mice during repeated exposure to stress in a tail suspension test (TST). In this paradigm, mice rapidly switch between active and passive coping styles, thus allowing us to directly assess stress coping-related neuronal responses using various correlational and decoding-approaches. In line with previous research, we observed that some cells were selectively activated by either active or passive stress coping. From neuronal activity alone, we were able to predict the stress coping strategy of the animal with 99% accuracy. Recording from the same set of neurons during baseline movement in the home-cage revealed that neuronal responses during stress coping were unrelated to general movement. Furthermore, we found that neurons retained consistent responses during active and passive coping styles over multiple days of TST exposure, with only minor drift in the response profile. These results implicate a strong and temporally consistent involvement of mPFC populations in stress responses, which might be of importance to understand mechanisms underlying stress-related disorders.

Effects of perinatal fluoxetine exposure on novelty-induced social and non-social investigation behaviors in a seminatural environment.
Selective serotonin reuptake inhibitors (SSRIs) are increasingly prescribed as medication for various affective disorders during pregnancy. SSRIs cross the placenta and affect serotonergic neurotransmission in the fetus, but the neurobehavioral consequences for the offspring remain largely unclear. Recent rodent research has linked perinatal SSRI exposure to alterations in both social and non-social aspects of behavior. However, this research has mainly focused on behavior within simplified environments. The current study investigates the effects of perinatal SSRI exposure on social and non-social investigation behaviors of adult rat offspring upon introduction to a novel seminatural environment with unknown conspecifics. During the perinatal period (gestational day 1 until postnatal day 21), rat dams received daily treatment with either an SSRI (fluoxetine, 10 mg/kg) or vehicle. Adult male and female offspring were observed within the first hour after introduction to a seminatural environment. The results showed that perinatal fluoxetine exposure altered aspects of non-social investigation behaviors, while not altering social investigation behaviors. More specifically, both fluoxetine-exposed males and females spent more total time on locomotor activity than controls. Furthermore, fluoxetine-exposed females spent less time exploring objects and specific elements in the environment. The data suggest that perinatal exposure to SSRIs leads to a quicker, less detailed investigation strategy in novel environments and that the alteration is mostly pronounced in females.

CELL-TYPE-SPECIFIC DOPAMINE SIGNALING IN VENTRAL HIPPOCAMPUS TRACKS ANXIETY

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Arthur Godino, Marine Salery, Angelica Minier-Toribio, John Fullard, Eric Parise, Freddyson Martinez-Rivera, Carole Morel, Sarah Montgomery, Ming-Hu Han, Panagiotis Roussos, Eric Nestler
Icahn School of Medicine at Mount Sinai, Nash Family Department Of Neuroscience And Friedman Brain Institute, New York, United States of America

Despite accumulating evidence for a role of both the ventral hippocampus (vHipp) and the mesocorticolimbic dopamine system in encoding anxiety-relevant information, surprisingly little is known about how dopamine signaling selectively affects vHipp representations of emotionally-salient stimuli to guide innate approach/avoidance behaviors. To address these shortcomings, we here study dopaminoceptive neurons in mouse vHipp – which can be segregated based on their expression of either the dopamine D1 or D2 receptor – to delineate a model of dopamine action in vHipp. At the histological level, D1- and D2-expressing cells exhibit a precise topographical organization across vHipp subfields, which we further dissected using RNA-sequencing of single, sorted nuclei from D1- and D2-cells. Functionally, we showed that anxiogenic environments trigger distinct patterns of calcium activity in D1 and D2 cells, together with higher dopamine release in vHipp. Bidirectional chemogenetic and optogenetic manipulation of D1- or of D2-neurons' activity causally demonstrated their distinct roles in mediating anxiety and approach/avoidance behaviors. Intriguingly, cocaine exposure modified vHipp dopamine dynamics, with D1- and D2-expressing neurons differently modulating drug-related behaviors, suggesting drug-induced plastic changes in this circuit. Together, we propose that dopamine dynamics in vHipp operate as a feedback loop that bidirectionally tracks anxiety levels to gate exploratory behaviors through differential recruitment of vHipp D1- and D2-neurons, which in turn mediate opposite approach/avoidance and anxiety-like responses. This work paves the way for further studies of dopamine signal processing in limbic regions, and underscores the complexity of the circuit mechanisms that govern affective states.

Long-term behavioral and cell-type-specific molecular effects of early life stress are mediated by H3K79me2 dynamics in medium spiny neurons.
Animals susceptible to chronic social defeat stress (CSDS) exhibit depression-related behaviors, with aberrant transcription across several limbic brain regions, most notably in the nucleus accumbens (NAc). Early life stress (ELS) promotes susceptibility to CSDS in adulthood, but associated enduring changes in transcriptional control mechanisms in the NAc have not yet been investigated. In this study, we examined long-lasting changes to histone modifications in the NAc of male and female mice exposed to ELS. Dimethylation of lysine 79 of histone H3 (H3K79me2) and the enzymes (DOT1L and KDM2B) that control this modification are enriched in D2-type medium spiny neurons and are shown to be crucial for the expression of ELS-induced stress susceptibility. We mapped the site-specific regulation of this histone mark genome wide to reveal the transcriptional networks it modulates. Finally, systemic delivery of a small molecule inhibitor of DOT1L reversed ELS-induced behavioral deficits, indicating the clinical relevance of this epigenetic mechanism.

Drug-activated cells: From immediate early genes to neuronal ensembles in addiction.
Beyond their rapid rewarding effects, drugs of abuse can durably alter an individual's response to their environment as illustrated by the compulsive drug seeking and risk of relapse triggered by drug-associated stimuli. The persistence of these associations even long after cessation of drug use demonstrates the enduring mark left by drugs on brain reward circuits. However, within these circuits, neuronal populations are differently affected by drug exposure and growing evidence indicates that relatively small subsets of neurons might be involved in the encoding and expression of drug-mediated associations. The identification of sparse neuronal populations recruited in response to drug exposure has benefited greatly from the study of immediate early genes (IEGs) whose induction is critical in initiating plasticity programs in recently activated neurons. In

particular, the development of technologies to manipulate IEG-expressing cells has been fundamental to implicate broadly distributed neuronal ensembles coincidently activated by either drugs or drug-associated stimuli and to then causally establish their involvement in drug responses. In this review, we summarize the literature regarding IEG regulation in different learning paradigms and addiction models to highlight their role as a marker of activity and plasticity. As the exploration of neuronal ensembles in addiction improves our understanding of drug-associated memory encoding, it also raises several questions regarding the cellular and molecular characteristics of these discrete neuronal populations as they become incorporated in drug-associated neuronal ensembles. We review recent efforts towards this goal and discuss how they will offer a more comprehensive understanding of addiction pathophysiology.

Cocaine-regulated microRNA miR-124 controls poly (ADP-ribose) polymerase-1 expression in neuronal cells.
MiR-124 is a highly expressed miRNA in the brain and regulates genes involved in neuronal function. We report that miR-124 post-transcriptionally regulates PARP-1. We have identified a highly conserved binding site of miR-124 in the 3'-untranslated region (3'UTR) of Parp-1 mRNA. We demonstrate that miR-124 directly binds to the Parp-1 3'UTR and mutations in the seed sequences abrogate binding between the two RNA molecules. Luciferase reporter assay revealed that miR-124 post-transcriptionally regulates Parp-1 3'UTR activity in a dopaminergic neuronal cell model. Interestingly, the binding region of miR-124 in Parp-1 3'UTR overlapped with the target sequence of miR-125b, another post-transcriptional regulator of Parp-1. Our results from titration and pull-down studies revealed that miR-124 binds to Parp-1 3'UTR with greater affinity and confers a dominant post-transcriptional inhibition compared to miR-125b. Interestingly, acute or chronic cocaine exposure downregulated miR-124 levels concomitant with upregulation of PARP-1 protein in dopaminergic-like neuronal cells in culture. Levels of miR-124 were also downregulated upon acute or chronic cocaine exposure in the mouse nucleus accumbens (NAc)-a key reward region of brain. Time-course studies revealed that cocaine treatment persistently downregulated miR-124 in NAc. Consistent with this finding, miR-124 expression was also significantly reduced in the NAc of animals conditioned for cocaine place preference. Collectively, these studies identify Parp-1 as a direct target of miR-124 in neuronal cells, establish miR-124 as a cocaine-regulated miRNA in the mouse NAc, and highlight a novel pathway underlying the molecular effects of cocaine.

Epigenetic Mechanisms of Opioid Addiction.
Opioid use kills tens of thousands of Americans each year, devastates families and entire communities, and cripples the health care system. Exposure to opioids causes long-term changes to brain regions involved in reward processing and motivation, leading vulnerable individuals to engage in pathological drug seeking and drug taking that can remain a lifelong struggle. The persistence of these neuroadaptations is mediated in part by epigenetic remodeling of gene expression programs in discrete brain regions. Although the majority of work examining how epigenetic modifications contribute to addiction has focused on psychostimulants such as cocaine, research into opioid-induced changes to the epigenetic landscape is emerging. This review summarizes our knowledge of opioid-induced epigenetic modifications and their consequential changes to gene expression. Current evidence points toward opioids promoting higher levels of permissive histone acetylation and lower levels of repressive histone methylation as well as alterations to DNA methylation patterns and noncoding RNA expression throughout the brain's reward circuitry. Additionally, studies manipulating epigenetic enzymes in specific brain regions are beginning to build causal links between these epigenetic modifications and changes in addiction-related behavior. Moving forward, studies must leverage advanced chromatin analysis and next-generation sequencing approaches combined with bioinformatics pipelines to identify novel gene networks regulated by particular epigenetic modifications. Improved translational relevance also requires increased focus on volitional drug-intake models and standardization of opioid exposure paradigms. Such work will significantly advance our understanding of how opioids cause persistent changes to brain function and will provide a platform on which to develop interventions for treating opioid addiction.

Synaptic Microtubule-Associated Protein EB3 and SRC Phosphorylation Mediate Structural and Behavioral Adaptations During Withdrawal From Cocaine Self-Administration.
Addictive behaviors, including relapse, are thought to depend in part on long-lasting drug-induced adaptations in dendritic spine signaling and morphology in the nucleus accumbens (NAc). While the influence of activity-dependent actin remodeling in these phenomena has been studied extensively, the role of microtubules and associated proteins remains poorly understood. We report that pharmacological inhibition of microtubule polymerization in the NAc inhibited locomotor

sensitization to cocaine and contextual reward learning. We then investigated the roles of microtubule end-binding protein 3 (EB3) and SRC kinase in the neuronal and behavioral responses to volitionally administered cocaine. In synaptoneurosomal fractions from the NAc of self-administering male rats, the phosphorylation of SRC at an activating site was induced after 1 d of withdrawal, while EB3 levels were increased only after 30 d of withdrawal. Blocking SRC phosphorylation during early withdrawal by virally overexpressing SRCIN1, a negative regulator of SRC activity known to interact with EB3, abolished the incubation of cocaine craving in both male and female rats. Conversely, mimicking the EB3 increase observed after prolonged withdrawal increased the motivation to consume cocaine in male rats. In mice, the overexpression of either EB3 or SRCIN1 increased dendritic spine density and altered the spine morphology of NAc medium spiny neurons. Finally, a cocaine challenge after prolonged withdrawal recapitulated most of the synaptic protein expression profiles observed at early withdrawal. These findings suggest that microtubule-associated signaling proteins such as EB3 cooperate with actin remodeling pathways, notably SRC kinase activity, to establish and maintain long-lasting cellular and behavioral alterations following cocaine self-administration. Drug-induced morphological restructuring of dendritic spines of nucleus accumbens neurons is thought to be one of the cellular substrates of long-lasting drug-associated memories. The molecular basis of these persistent changes has remained incompletely understood. Here we implicate for the first time microtubule function in this process, together with key players such as microtubule-bound protein EB3 and synaptic SRC phosphorylation. We propose that microtubule and actin remodeling cooperate during withdrawal to maintain the plastic structural changes initially established by cocaine self-administration. This work opens new translational avenues for further characterization of microtubule-associated regulatory molecules as putative drug targets to tackle relapse to drug taking.

Cocaine Self-administration Alters Transcriptome-wide Responses in the Brain's Reward Circuitry.

Global changes in gene expression underlying circuit and behavioral dysregulation associated with cocaine addiction remain incompletely understood. Here, we show how a history of cocaine self-administration (SA) reprograms transcriptome-wide responses throughout the brain's reward circuitry at baseline and in response to context and/or cocaine re-exposure after prolonged withdrawal (WD).

Granulocyte-colony stimulating factor controls neural and behavioral plasticity in response to cocaine.

Cocaine addiction is characterized by dysfunction in reward-related brain circuits, leading to maladaptive motivation to seek and take the drug. There are currently no clinically available pharmacotherapies to treat cocaine addiction. Through a broad screen of innate immune mediators, we identify granulocyte-colony stimulating factor (G-CSF) as a potent mediator of cocaine-induced adaptations. Here we report that G-CSF potentiates cocaine-induced increases in neural activity in the nucleus accumbens (NAc) and prefrontal cortex. In addition, G-CSF injections potentiate cocaine place preference and enhance motivation to self-administer cocaine, while not affecting responses to natural rewards. Infusion of G-CSF neutralizing antibody into NAc blocks the ability of G-CSF to modulate cocaine's behavioral effects, providing a direct link between central G-CSF action in NAc and cocaine reward. These results demonstrate that manipulating G-CSF is sufficient to alter the motivation for cocaine, but not natural rewards, providing a pharmacotherapeutic avenue to manipulate addictive behaviors without abuse potential.

Genome-wide DNA hydroxymethylation identifies potassium channels in the nucleus accumbens as discriminators of methamphetamine addiction and abstinence.

Epigenetic consequences of exposure to psychostimulants are substantial but the relationship of these changes to compulsive drug taking and abstinence is not clear. Here, we used a paradigm that helped to segregate rats that reduce or stop their methamphetamine (METH) intake (nonaddicted) from those that continue to take the drug compulsively (addicted) in the presence of footshocks. We used that model to investigate potential alterations in global DNA hydroxymethylation in the nucleus accumbens (NAc) because neuroplastic changes in the NAc may participate in the development and maintenance of drug-taking behaviors. We found that METH-addicted rats did indeed show differential DNA hydroxymethylation in comparison with both control and nonaddicted rats. Nonaddicted rats also showed differences from control rats. Differential DNA hydroxymethylation observed in addicted rats occurred mostly at intergenic sites located on long and short interspersed elements. Interestingly, differentially hydroxymethylated regions in genes encoding voltage (Kv1.1, Kv1.2, Kvb1 and Kv2.2)- and calcium (Kcnma1, Kcnn1 and Kcnn2)-gated potassium channels observed in the NAc of

nonaddicted rats were accompanied by increased mRNA levels of these potassium channels when compared with mRNA expression in METH-addicted rats. These observations indicate that changes in differentially hydroxymethylated regions and increased expression of specific potassium channels in the NAc may promote abstinence from drug-taking behaviors. Thus, activation of specific subclasses of voltage- and/or calcium-gated potassium channels may provide an important approach to the beneficial treatment for METH addiction.

Epigenetic landscape of amphetamine and methamphetamine addiction in rodents.
Amphetamine and methamphetamine addiction is described by specific behavioral alterations, suggesting long-lasting changes in gene and protein expression within specific brain subregions involved in the reward circuitry. Given the persistence of the addiction phenotype at both behavioral and transcriptional levels, several studies have been conducted to elucidate the epigenetic landscape associated with persistent effects of drug use on the mammalian brain. This review discusses recent advances in our comprehension of epigenetic mechanisms underlying amphetamine- or methamphetamine-induced behavioral, transcriptional, and synaptic plasticity. Accumulating evidence demonstrated that drug exposure induces major epigenetic modifications-histone acetylation and methylation, DNA methylation-in a very complex manner. In rare instances, however, the regulation of a specific target gene can be correlated to both epigenetic alterations and behavioral abnormalities. Work is now needed to clarify and validate an epigenetic model of addiction to amphetamines. Investigations that include genome-wide approaches will accelerate the speed of discovery in the field of addiction.

Cell-type- and region-specific modulation of cocaine seeking by micro-RNA-1 in striatal projection neurons.
The persistent and experience-dependent nature of drug addiction may result in part from epigenetic alterations, including non-coding micro-RNAs (miRNAs), which are both critical for neuronal function and modulated by cocaine in the striatum. Two major striatal cell populations, the striato-nigral and striato-pallidal projection neurons, express, respectively, the D1 (D1-SPNs) and D2 (D2-SPNs) dopamine receptor, and display distinct but complementary functions in drug-evoked responses. However, a cell-type-specific role for miRNAs action has yet to be clarified. Here, we evaluated the expression of a subset of miRNAs proposed to modulate cocaine effects in the nucleus accumbens (NAc) and dorsal striatum (DS) upon sustained cocaine exposure in mice and showed that these selected miRNAs were preferentially upregulated in the NAc. We focused on miR-1 considering the important role of some of its predicted mRNA targets, Fosb and Npas4, in the effects of cocaine. We validated these targets in vitro and in vivo. We explored the potential of miR-1 to regulate cocaine-induced behavior by overexpressing it in specific striatal cell populations. In DS D1-SPNs miR-1 overexpression downregulated Fosb and Npas4 and reduced cocaine-induced CPP reinstatement, but increased cue-induced cocaine seeking. In DS D2-SPNs miR-1 overexpression reduced the motivation to self-administer cocaine. Our results indicate a role of miR1 and its target genes, Fosb and Npas4, in these behaviors and highlight a precise cell-type- and region-specific modulatory role of miR-1, illustrating the importance of cell-specific investigations.

Major depressive disorder is one of the most frequently diagnosed disabling mental illnesses. Resilience to stress is critical for the development of depression. While there is emerging evidence in depression for disruption of circadian rhythms, the role of circadian clock in stress resilience is not well understood. Here, we have investigated the effects of repeated swim stress on the development of depression-like behavior in a mouse model with genetically modified circadian clockwork – mice expressing dominant negative clock gene Rev-ERBα (dnRev-ERBα). The development of depression-like behavior was analyzed by utilizing the chronic despair mouse model (CDM) for depression. In this paradigm the mice undergo 10 minutes of forced swimming per day for 5 consecutive days (induction phase). The effects on mood-related behavior are examined 1 week later (test phase) via forced swim (FST) and the tail suspension test (TST). dnRev-ERBα mice showed strong and significant resistance towards development of chronic despair behavior. WT mice had gradual increase of the immobility time during the induction phase of CDM, while the dnRev-ERBα mice showed constant low immobility time. FST and TST performed during the test phase confirmed the stress resilient phenotype of the dnRev-ERBα. The analyses of locomotor and exploratory behavior in open field test (OFT) indicate no significant changes. Moreover, dnRev-ERBα mice had an increased anxyolitic behavior in OFT – shorter time spent in the center of the arena. Our data suggest the potential role of Rev-ERBα in response to stress and development of depression.

THE ANXIOLYTIC AND ANTIDEPRESSANT EFFECTS OF UROCORTIN 2 AND UROCORTIN 3 FRAGMENTS IN MICE

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Zsolt Bagosi[1], Zsolt Bozsó[2], Katalin Ibos[1], Éva Bodnár[1], Krisztina Csabafi[1]
[1]University of Szeged, Department Of Pathophysiology, Szeged, Hungary, [2]University of Szeged, Department Of Medical Chemistry, Szeged, Hungary

Urocortin 2 (Ucn2) and urocortin 3 (Ucn3) are selective agonists of the corticotropin-releasing factor receptor type 2 (CRFR2). Previous studies indicated that Ucn2 and Ucn3 have anxiolytic and antidepressant properties in mice. In the present study we aimed to identify the biologically active center of these peptides, through which they might exert their beneficial effects. Therefore, male C57BL/6 mice were treated intracerebroventricularly (icv) with smaller fragments of Ucn2 and Ucn3, and then they were investigated in an elevated plus-maze test and a forced swim test for anxiety-like and depression-like behavior, respectively. The following fragments were tested: Ucn2(1-21), Ucn2(22-38), Ucn3(18-38), Ucn3(19-27), Ucn3(28-38), Ucn3(34-38), Ucn3(36-38), Ucn3(34-36), and Ucn3(34-38). The only effective fragment of Ucn2 inducing both anxiolytic and antidepressant behavior was Ucn2(1-21). Many of the fragments of Ucn3 were effective, but the most significant anxiolytic and antidepressant actions were produced by Ucn3(36-38). The present study demonstrates that the whole sequences of the selective CRFR2 agonists are not necessary to exert their anxiolytic and antidepressant properties, and that the biologically active center is the N-terminal for Ucn2 and the C-terminal for Ucn3. Future studies are yet to demonstrate the efficacy of these peptide fragments in treating anxiety and depression in humans.

Anxiolytic- and antidepressant-like actions of Urocortin 2 and its fragments in mice.
The aim of the present study was to investigate the potential anxiolytic- and antidepressant-like actions of Urocortin 2 (Ucn2) and its two fragments, Ucn2 (1-21) and Ucn2 (22-38), in mice, in an attempt to identify the biologically active sequence of this 38 amino acid neuropeptide. In this purpose, male C57BL/6 mice were treated intracerebroventricularly (icv) with 0.125, 0.25, 0.5 and 1 μg/2 μl of Ucn2, Ucn2 (1-21) or Ucn2 (22-38). After 30 min, the mice were evaluated in an elevated plus-maze test and a forced swim test for anxiety- and depression-like behavior, respectively. Each test lasted 5 min. Ucn2 at dose of 0.25 μg/2 μl and Ucn2 (1-21) at dose of 0.125 μg/2 μl, but not Ucn2 (22-38), increased significantly the number of entries into and the time spent in the open-arms, without influencing the total number of entries. In parallel, the same doses of Ucn2 and Ucn2 (1-21), but not Ucn2 (22-38), increased significantly the climbing and the swimming activity, while decreasing significantly the time of immobility. In addition, Ucn2 at doses of 0.125 μg/2 μl and 0.5 μg/2 μl decreased significantly the time of immobility, but they did not change the other parameters. The present study demonstrates that Ucn2 exerts anxiolytic- and antidepressant-like effects in C57BL/6 mice, which are mediated by the N-terminal, but not the C-terminal fragment of the peptide. The establishment of the smallest active sequence by further fragmentation of Ucn2 (1-21) may allow the synthesis of new anxiolytic and antidepressant drugs.

Introduction: Maternal obesity is inseparably linked to adverse health outcomes for the mother and her children. It is associated with an increased risk of neurobehavioral problems in the offspring such are neurodevelopmental disorder, anxiety and depression-spectrum disorders. **Our objective** was to determine the influence of maternal HFD on post-weaning depression-like behavior and hormonal state. **Methods:** Adult naive female Wistar rats were assigned to either standard diet (CD) or HFD. A mixture of vegetable oils was used as a source of fat (HFD 40% and CD 4% energy derived from fat). The animals were fed for four weeks before breeding, during mating, pregnancy, and lactation, and until behavioural tests were completed. Sucrose preference testing (SPT) and forced swimming (FST) have been used to assess anhedonia and depression-like behavior. **Results:** HFD-fed dams showed significant increases in body weight (g) and BMI ($p<0.05$). HFD group showed significantly increased climbing time but did not affect immobility time and sucrose preference. However, the correlation analysis revealed a strong negative correlation between total fluid consumption and climbing time in HFD ($r=-0.81$) and total fluid consumption and E2 levels ($r=-0.52$). In fact, HFD lowered estradiol serum levels ($p<0.05$) and slightly elevated corticosterone levels ($p>0.05$). Further analysis revealed a moderate negative correlation between E2 and corticosterone levels ($r=-0.51$) in HFD dams. **Conclusion:** According to the data presented, HFD dams have a higher risk of developing depressive-like behavior, likely due to lower estradiol levels.

The effect of subchronic supplementation with folic acid and l-arginine on homocysteine-induced seizures.
The aim of the present study was to examine the effect of subchronic co-administration of folic acid (F) and l-arginine (A) on behavioural and electroencephalographic (EEG) characteristics of dl homocysteine thiolactone (H) induced seizures in adult rats. The activity of membrane ATPases in different brain regions were also investigated. Rats were treated with F, A, or vehicle for 15 days (regimen: F 5 mg/kg + A 500 mg/kg (F5A500); F 10 mg/kg + A 300 mg/kg (F10A300)). Seizures were elicited by convulsive dose of H (H, F5A500H, F10A300H) Subchronic supplementation with F and A did not affect seizure incidence, number of seizure episodes, and severity in F5A500H and F10A300H groups vs. H group. However, a tendency to increase latency and decrease the number of seizure episodes was noticed in the F10A300H group. EEG mean spectral power densities during ictal periods were significantly lower in F10A300H vs. H group. The activity of Na/K-ATPase and Mg-ATPase was significantly increased in almost all examined structures in rats treated with F and A. We can conclude that subchronic supplementation with folic acid and l-arginine has an antiepileptic effect in dl homocysteine thiolactone induced epilepsy.

GLUTAMATERGIC AND CYTOSKELETAL PROTEIN PHOSPHORYLATION ASSOCIATED WITH THE ANTIDEPRESSANT-LIKE PROPERTIES OF THE IRON CHELATOR DEFERIPRONE IN A MOUSE MODEL OF DEPRESSION

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Volkan Uzungil[1], Isaline Mees[1], Shanshan Li[2], Anthony Hannan[2], Thibault Renoir[2]
[1]University of Melbourne, Florey Institute, Parkville, Australia, [2]University of Melbourne, The Florey Institute, Parkville, Australia

Aims: Depression severity has recently been linked to increased levels of iron in various regions of the brain. The serotonin transporter knock-out (5-HTT KO) mouse is utilised as a model of depression, as individuals who are carriers of the short ('s') allele of the promoter region of the gene having increased vulnerability to stress and reduced response to first-line antidepressant therapies. Deferiprone is an iron chelator drug which we have found to have acute antidepressant-like properties in a battery of depression-related behaviours. Methods: A phosphoproteomics analysis of the prefrontal cortex was conducted following acute deferiprone treatment in wild-type (WT) controls and 5-HTT KO mice to determine the rapid post-translational modifications following treatment. Due to batch effects, multiple comparisons were not conducted for the differential expression analysis. Under- or over-phosphorylated phosphopeptides were matched to their respective molecular mechanisms using gene ontology and pathway analysis. Results: The analysis revealed that in both WT and 5-HTT KO mice there were differential expression in the phosphorylation of proteins involved in cytoskeletal organisation following deferiprone treatment. In comparison, there were selective differentially expressed phosphorylation in 5-HTT KO mice of proteins involved in glutamatergic signalling. Additionally, tyrosine hydroxylase was also shown to be down-phosphorylated by deferiprone treatment in 5-HTT KO mice, which has been linked to both iron regulation and depression. Conclusions: These data indicate that the antidepressant-like properties of deferiprone may be mediated by molecular mechanisms underpinned by glutamatergic signalling and cytoskeletal organisation.

Microbiome Profiling Reveals Gut Dysbiosis in the Metabotropic Glutamate Receptor 5 Knockout Mouse Model of Schizophrenia.
Schizophrenia (SZ) is a psychiatric disorder that constitutes one of the top 10 global causes of disability. More recently, a potential pathogenic role for the gut microbial community (microbiota) has been highlighted, with numerous studies describing dysregulated microbial profiles in SZ patients when compared to healthy controls. However, no animal model of SZ has previously recapitulated the gut dysbiosis observed clinically. Since the metabotropic glutamate receptor 5 (mGlu5) knockout mice provide a preclinical model of SZ with strong face and predictive validity, in the present study we performed gut microbiome profiling of mGlu5 knockout (KO) and wild-type (WT) mice by 16S rRNA sequencing of bacterial genomic DNA from fecal samples, analyzing bacterial diversity and taxonomic composition, as well as gastrointestinal parameters as indicators of gut function. We found a significant genotype difference in microbial beta diversity. Analysis of composition of microbiomes (ANCOM) models were performed to evaluate microbiota compositions, which identified a decreased relative abundance of the family and genus in this mouse model of SZ. We also identified a signature of bacteria discriminating between the genotypes (KO and WT), consisting of the Erysipelotrichales, Bacteroidales, and Clostridiales orders and macroscopic gut differences. We thus uncovered global differential community composition in the gut microbiota profile between mGlu5 KO and WT mice, outlining the first evidence for gut dysbiosis in a genetic animal model of SZ. Our findings suggest that this widely used preclinical model of SZ also has substantial utility for investigations of gut dysbiosis and associated signaling via the microbiota-gut-brain axis, as potential modulators of SZ pathogenesis. Our discovery opens up new avenues to explore gut dysbiosis and its proposed links to brain dysfunction in SZ, as well as novel therapeutic approaches to this devastating disorder.

Cognitive theories of depression have proposed that depression is caused by negative attributional styles. Yet, we still lack an understanding how attributional styles arise and are maintained in the healthy and depressed population. Here, we investigated the underlying cognitive mechanisms of credit assignment, i.e. learning about the causes of events. For this, we developed a novel behavioural paradigm. In this new task, participants play several 'mini games' together with another player. The participants' task was to infer across trials how well they and the other player perform, and how much influence each of them exert over the environment. Using this paradigm, we investigated how people learn about the causes of positive and negative events in a social context. We employed this paradigm in a large online study which allowed us to develop computational models quantifying how people attribute outcomes. We found that people vary in how they attribute positive and negative feedback to themselves, others and their influence over the environment. Furthermore, they actively explored their environment in order to reduce uncertainty. In the future, these results will be important for improving existing as well as proposing novel treatments for depression.

ASSOCIATION OF CANONICAL NF-κB SIGNALING PATHWAY WITH APOPTOTIC CELL DEATH AND CELL PROLIFERATION IN GLUCOCORTICOID-INDUCED NEUROTOXICITY AND AFTER VITAMIN D3 SUPPLEMENTATION

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Ihor Shymanskyi, Olha Lisakovska, Anna Khomenko, Dmytro Labudzynskyi, Mykola Veliky
Palladin Institute of Biochemistry, Department Of Biochemistry Of Vitamins And Coenzymes, Kyiv, Ukraine

Aim: To investigate the canonical pathway of nuclear factor κB (NF-κB) activation in association with the intensity of apoptotic and proliferative processes in different structural areas of the brain in glucocorticoid(GC)-induced neurotoxicity and under vitamin D_3 (VD_3) action. **Methods:** Female Wistar rats received prednisolone (5 mg/kg b.w.) with/without VD_3 (1000 IU/kg b.w., 30 days). NF-κB/p65 and its phosphorylated forms, as well as molecular markers of apoptosis (AIF, Bax, Bcl-2, caspase-8, and p17 subunit of caspase-3) were determined by qRT-PCR and/or Western blotting. The number of apoptotic cells was studied by the TUNEL. Proliferative activity of cells in histological sections of the cerebral cortex and hippocampus was evaluated using double immunofluorescent labeling with 5-bromo-2'-deoxyuridine or Ki67 and marker proteins of neurons, micro- and macroglia (NG2, Iba-1, GFAP respectively). **Results:** We showed an increase in the expression of the NF-κB p65 subunit and an intensification of its specific phosphorylation at Ser311, Ser536, and Thr435. There was a significant decrease in the number of NG2-positive cells in the hippocampus and increasing number of astroglial cells in different brain sections. GC activated apoptotic cell death predominantly by intrinsic (mitochondral) mechanism. Elevated apoptosis was accompanied by inhibition of cell proliferation in different areas of the brain, mainly due to microglia. VD_3 supplementation partially restored most of the GC-induced abnormalities in the brain, but exacerbated the inhibition of cell proliferation. **Conclusions:** VD_3 attenuated GC-induced changes in rat brain suggesting modulation of NF-κB-associated processes in the mechanism of antiapoptic, antiproliferative and neuroprotective actions of VD_3.

OXIDATIVE BALANCE ALTERATIONS IN THE RAT VENTRAL HIPPOCAMPUS ARE ASSOCIATED TO THE VULNERABILITY AND RESILIENCE TO STRESS-INDUCED ANHEDONIA

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Vittoria Spero[1], Sabrina D'Amelio[1], Eleonora Buscemi[1], Mariusz Papp[2], Raffaella Molteni[1]
[1]University of Milan, Medical Biotechnology And Translational Medicine, Milan, Italy, [2]Maj Institute of Pharmacology Polish Academy of Sciences, Department Of Pharmacology, Krakow, Poland

Aims Major Depressive Disorder (MDD) is a severe psychiatric disorder with an aetiology and pathophysiology partially unknown. Although its insurgence is the result of the interaction between vulnerability genes and stressful events, only the so-called "vulnerable" subjects develop the psychopathology while the resilient population overcomes the stressful experience. Accordingly, the identification of the molecular alteration underlying MDD vulnerability and resilience is essential to develop novel and more efficient therapeutic intervention strategies. **Methods** Adult male rats were exposed to 2 weeks of chronic mild stress (CMS) paradigm and the sucrose consumption test was used to divide the animals in stress-vulnerable (anhedonic) and resilient (non anhedonic). 24 hours after the last stress, gene and protein expression of specific mediators of the oxidative balance and related cell survival pathways have been assessed within the ventral hippocampus. **Results** We observed that CMS has a significant impact on oxidative balance in vulnerable animals, which showed a lower activation of both Nrf2 antioxidant pathway and mTOR/p62 pathway in comparison with resilient animals. **Conclusions**
Our data suggest that Nrf2-related antioxidant pathway might represents a novel pharmacological target for stress-related disorders. Hence, favouring its activation could redirect the molecular stress response toward a resilient coping behaviour.

Introduction: We proved that neurogenic inflammatory spots exhibit the characteristics as acupuncture points. In addition, stimulation of neurogenic spots alleviates pathological conditions in rat hypertension model via endogenous opioid systems. It is not clear which depth of neurogenic spots in skin generates therapeutic effects when stimulated. **Methods:** The effects of acupuncture at various needle depths on blood pressure was examined in a rat immobilization-induced hypertension (IMH) model. In vivo extracellular recordings and immunohistochemistry of c-Fos were performed in ventrolateral periaqueductal gray (vlPAG) or rostral ventrolateral medulla (rVLM). **Results**: IMH rats revealed neurogenic spots bilaterally or unilaterally on the wrist, and 67% of those spots matched with acupoints, such as PC6, PC7,HT7. When electrical acupuncture at PC6 in the depths of 1,2,3mm was applied, acupuncture of 3mm-depth most effectively reduced the blood pressure, compared to those of 1 or 2mm depths or control groups. Following electrical stimulation of PC6 areas, c-Fos expression was dominant in 3mm-group. In vivo extracellular recording of RVLM showed that the electrical discharge rates of rVLM following acupuncture stimulation increased up to 150% of baseline 5min after acupuncture at 3mm depth, while that of 1mm group reached about 120% of baseline after stimulation. **Conclusion**: Our data suggest that neurogenic spots generated therapeutic effects at deep skin rather than shallow skin, when stimulation. **Key words**: IMH, rVLM, vlPAG, neurogenic inflammatory spot, acupuncture **Acknowledgement:** This research was supported by the National Research Foundation of Korea (NRF) grant funded by the Korean government (MSIT) (Nos. 2018R1A5A2025272, 2019R1A2C1002555 and KMDF_PR_20200901_01179991006790).

ALTERATIONS OF KYNURENINE PATHWAY IN PERIPHERAL AND CENTRAL NERVOUS SYSTEM UNDER HYPOBARIC HYPOXIC STRESS

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Kalyani Verma, Ekta Kohli
Defence Institute of Physiology and Allied Sciences, DRDO, Department Of Neurobiology, NEW DELHI, India

Aim: The present study is an attempt to understand the alterations of kynurenine pathway (KP) under hypobaric hypoxia (HH) and its interrelation with depression-like behaviour. **Methods:** Male Sprague-Dawley rats weighing 230–250 g were exposed to HH (at 25,000 ft.) for 1, 3, and 7 days. Forced Swim Test was used to record the immobility as a parameter of passive behaviour, reflecting depression in rats. The level of KP metabolites in serum, cerebrospinal fluid (CSF), and hippocampus was estimated using high-performance liquid chromatography. **Results:** Tryptophan levels in serum, CSF, and the hippocampus increased after a single day of HH exposure, but decreased over a longer period of HH exposure. Up to 3-day HH, kynurenines were found to be reduced in serum (peripheral system) but increased in CSF and the hippocampus (central system), indicating an influx of kynurenines. However, serotonin levels were significantly reduced both peripherally and centrally. On behavioural assessment, a significant increase in immobility, indicating the depression state was found to be highest on 3day HH exposure. A time-dependent positive correlation between immobility time, kynurenine, and quinolinic acid was observed. On 7-day HH, 3-hydroxyanthranillic acid and quinolinic acid levels were lower in comparison to the control, signifying impairment in the formation of NAD+ which consequently dysfunctions oxidative phosphorylation. **Conclusion:** Under HH stress, alteration in KP's metabolic status was found which has a positive correlation with depression-like behaviour. This study signifies that KP can be used as a therapeutic target to treat HH related psychological and physiological abnormalities.

5-HT RAPHE - VENTRAL HIPPOCAMPUS PATHWAY: WHAT ROLE IN AVERSIVE BEHAVIORS?

POSTER SESSION 02 - SECTION: STRESS, ANXIETY AND DEPRESSION

Fiona Henderson[1,2], Félix Perreault[1], Anne-Sophie Simard[1,2], Chloé Fafard[1,2], Guillaume Ducharme[2], Bénédicte Amilhon[1,2]
[1]Université de Montréal, Département de Neurosciences, Montréal, QC, Canada, [2]CHU Sainte-Justine, Centre de recherche, Montréal, QC, Canada

Serotonin (5-HT) is clearly involved in modulating emotions but the precise mechanisms through which serotonergic neurons are recruited and how they react to aversive stimuli remains to be characterized. In particular, the ventral hippocampus (vHP) is densely innervated by serotonergic fibers and has also been involved in emotional behaviour. Thus, the serotonergic raphe - vHP pathway is ideally positioned to modulate emotional behaviours. This study aims at investigating how the activity of 5-HT neurons changes to adapt to aversive situations. Our objectives are 1- to analyze the correlation between serotonin neural dynamics and anxiety-like behaviors and 2- to investigate the impact of optogenetic activation of vHP-projecting serotonergic neurons on these behaviors. We used viral strategies in SERT-cre mice to enable conditional expression of the calcium sensor GCaMP6s in vHP-projecting 5-HT neurons to perform fiber photometry recordings during exploration of aversive environments. Furthermore, the opsin ChETA was conditionally expressed in SERT-cre mice to photoactivate the 5-HT raphe – vHP pathway during anxiety tests. We found that the activity of serotonergic neurons is modulated during exploration of an aversive environment and that activation of vHP-projecting 5-HT neurons increases anxiety-like behaviors in female but not male mice. The results generated by this project will provide a deeper insight into the neuronal circuits underlying emotional behaviors to adapt to aversive situations.

GHRELIN INDUCES HEDONIC FEEDING THROUGH THE ACTIVATION OF CENTRAL AMYGDALA HTR2A NEURONS

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Christian Peters, Federica Fermani, Hansol Lim, Songwei He, Rüdiger Klein
Max Planck Institute of Neurobiology, Department Of Molecules - Signaling - Development, Martinsried, Germany

Ghrelin, known as the hunger hormone, promotes homeostatic feeding influencing the activity of the hypothalamus, and hedonic feeding through extra-hypothalamic areas. The latter behavior may involve the amygdala, a highly conserved brain region important for the expression of defensive and appetitive behaviors. Previous work from our lab showed that the activation of Htr2a+ neurons in central amygdala (CeA) increases food intake through a positive valence signal (Douglass et al, 2017). We hypothesized that part of the rewarding mechanism induced by ghrelin to increase appetite occurs through CeA^{Htr2a} neurons. Our results show that ghrelin increases c-Fos staining and excitatory neurotransmission in CeA^{Htr2a}, but not $CeA^{PKC\delta}$ neurons, a major anorexigenic subpopulation. Chemogenetic inhibition of CeA^{Htr2a} neurons completely blocked the orexigenic effects of systemic application of ghrelin. Direct infusion of ghrelin into the CeA increased food consumption of satiated mice, an effect that was dependent on ghrelin (GHSR) and opioid receptors. In vivo calcium imaging in freely moving animals showed that systemic ghrelin injections increased the activities of CeA^{Htr2a} neurons in a pattern similar to the presence of food. Our findings also indicate that the neurons activated by ghrelin in CeA project to the parabrachial nucleus (PBN), inhibiting PBN neurons and promoting feeding. This conclusion is consistent with our previous observations that at least part of the orexigenic activities of CeA^{Htr2a} neurons are mediated by projections to the PBN. These findings suggest that ghrelin enters the brain and directly activates a cell type-specific appetitive CeA-to-PBN circuit to induce hedonic feeding.

The melanocortin system has been extensively studied for its role in regulating feeding behavior and the metabolism. However, the role of this system in early development and the establishment of these neuronal circuits are less well known. We sought to study the establishment of key connections from the arcuate nucleus of the hypothalamus (ARC) neurons, namely agouti-related peptide (AgRP) and Pro-opiomelanocortin (POMC), in early development and their persistence into adulthood. In addition to this, we analyzed how the loss of the melanocortin 3 receptor (MC3R), expressed by AgRP neurons, affect these AgRP and POMC neuronal projections specifically within the hypothalamus. qPCR data collected throughout the development suggest a dynamic regulation for the MC3R expression in the hypothalamus. Therefore, using the MC3R-GFP mouse model, we were able to assess the dynamic development of MC3R neurons in the hypothalamus. These results suggest that MC3R is absolutely critical for the development of POMC and AgRP neuronal connections within the hypothalamus. Elaborating on previous literature assessing the structural development of ARC neuronal projections, we identified, throughout development, the positive labelling of the individual of AgRP and POMC neuropeptides themselves to intra but also interesting extra-hypothalamic structures. The dynamic regulation of MC3R expression and establishment of neuronal connectivity in early development underscores the probable role of the melanocortin system not only in adult feeding behavior, but also in early formation of AgRP and POMC neurocircuits. **Keywords**: Hypothalamus, Melanocortin, brain development.

H3K27 DEMETHYLASE KDM6A/UTX CONTROLS NGN3, POMC AND NPY EXPRESSION IN A SEX-SPECIFIC WAY IN THE DEVELOPING NEUROENDOCRINE HYPOTHALAMUS

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Lucas E. Cabrera Zapata[1], María Julia Cambiasso[2,3], María Ángeles Arévalo[1,4]
[1]Instituto Cajal, Consejo Superior De Investigaciones Científicas (csic), Madrid, Spain, [2]Instituto de Investigación Médica Mercedes y Martín Ferreyra, Inimec-conicet, Universidad Nacional De Córdoba, Córdoba, Argentina, [3]Facultad de Odontología, Universidad Nacional De Córdoba, Córdoba, Argentina, [4]CIBERFES, Instituto De Salud Carlos Iii, Madrid, Spain

Kdm6a is an X-linked H3K27me3/2 demethylase and component of COMPASS/COMPASS-like H3K4 methyltransferase complexes promoting transcription genome-wide critical for tissue/cell-specific differentiation. Previous results showed higher Kdm6a levels in XX than in XY hypothalamic neurons and a female-specific requirement for Kdm6a in mediating increased axogenesis before brain masculinization. Here we explored Kdm6a role in the specification of hypothalamic neuronal subtypes using sex-segregated E14 mouse hypothalamic neuronal cultures transfected with siRNAs to knockdown Kdm6a expression (Kdm6a-KD). First, we evaluated by immunocytochemistry Kdm6a-KD effect on Ngn3, a transcription factor regulating neuronal sub-specification in hypothalamus. Kdm6a-KD downregulated Ngn3 in females but not in males, abolishing basal sex differences previously reported. Then, we analyzed Kdm6a-KD effect on *Ascl1*, *Pomc*, *Npy*, *Sf1*, *Gad1* and *Th* expression by RT-qPCR. While Kdm6a-KD downregulated *Ascl1* in both sexes equally, sex-specific results were obtained for *Pomc*, *Npy* and *Th*. *Pomc* and *Th* expressed higher in female than in male neurons and Kdm6a-KD reduced their levels only in females, while *Npy* expressed higher in male than in female neurons and Kdm6a-KD upregulated its expression only in females. Identical results were found by immunocytochemistry for Pomc and Npy. No effects of sex/treatment on *Sf1* or *Gad1* expression were found. Finally, using ChIP-qPCR we found higher H3K27me3 levels at *Ngn3*, *Pomc* and *Npy* promoters in male than in female neurons, in line with Kdm6a higher expression and demethylase activity in females. These results indicate that Kdm6a plays a key sex-specific role in controlling the differentiation of neuronal populations regulating food intake and energy homeostasis.

NEURAL NETWORKS INVOLVED IN OLFACTION - FOOD INTAKE INTERACTIONS : ROLE OF THE HYPOTHALAMUS IN ODOR PROCESSING

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Maya Faour, Julien Castel, Serge Luquet, Claire Martin
Unité de Biologie Fonctionnelle et Adaptative (BFA), Université de Paris, CNRS 8251, Paris, Paris, France

Body weight of most animals is remarkably stable over time, suggesting that a complex physiological system balances food intake and energy expenditure over the long term. This homeostatic control system is the arcuate nucleus (ARC) of the hypothalamus. By integrating internal (hormones) as well as external (sensory cues) feeding signals, the ARC controls eating behaviour. It contains 2 populations of neurons, Agouti-related peptide (AgRP) and pro-opiomelanocortin (POMC) neurons, whose activity is respectively modulated by hunger and satiety hormones such as ghrelin and leptin. Recent studies showed that the activity of AgRP neurons was also modulated by food odors, since the presentation of palatable but hidden food leads to a clear decrease in the activity of these neurons (Betley et al., 2015, Chen et al., 2015). However, the functional connection between AgRP neurons and the Olfactory Bulb (OB) - first cortical relay of the olfactory system- remains unexplored. The aim of this study is to determine whether hypothalamic AgRP neurons modulate odor processing in the OB. In order to investigate this question, AgRP DTR mice were used. In this transgenic mouse model, perinatal ablation of AgRP neurons is achieved by toxin-mediated ablation of AgRP neurons in the first week after birth (Luquet et al., 2005). Control mice and mice lacking AgRP neurons were then compared and subjected to multiple behavioural Tests. Our data show that mice with AgRP neuron’s ablation tend to have different Olfactory behaviour, suggesting that beside regulating food intake, hypothalamic AgRP neurons impact OB-mediated food-odor processing.

Heart rate increases during inspiration and decreases during expiration, a phenomenon called respiratory sinus arrhythmia (RSA). We recently showed that brainstem preBötzinger complex (preBötC) neurons, which generate the inspiratory rhythm, also generate RSA by providing an inhibitory modulation of adjacent cardiac parasympathetic neurons of the nucleus ambiguus (nA). A high RSA amplitude is physiologically and psychologically beneficial. The neuromodulator oxytocin (OT) is known to beneficially influence individuals' health and OTergic axons project to brainstem cardiorespiratory nuclei. We hypothesized that OT amplifies RSA by modulating the synaptic connectivity between preBötC and nA neurons. Optogenetic stimulation of OTergic fibers in the preBötC/nA area amplified RSA, in OTcre::Ai27 anesthetized mice. This effect was abolished after OT receptor antagonist injection. To investigate the intrinsic brainstem mechanism involved, we used the *in situ* working heart-brainstem preparation and we recorded inspiratory, cardiac parasympathetic and sympathetic nerve activities, as well as heart rate and blood pressure. After OT agonist microinjection into the preBötC/nA area, the respiratory modulation of cardiac parasympathetic activity and RSA amplitude were amplified, without modifications of respiratory and other cardiovascular parameters. Anatomically, OTergic fibers make synaptic contacts with a subset of preBötC inhibitory neurons that express the oxytocin receptor. These experiments identify a new pathway for RSA amplification: OT modulates the inhibitory connection between preBötC/nA neurons, leading to an amplification of the respiratory modulation of cardiac parasympathetic activity, which amplifies RSA. We will next perform behavioral experiments to identify the physiological conditions in which this mechanism is activated.

CENTRAL REGULATION OF AUTONOMIC AND CARDIAC FUNCTION

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Kristian Herrera[1,2], Erin Song[2], Virginia Rutten[3], Luis Hernandez[2], Misha Ahrens[3], Florian Engert[2], Mark Fishman[1]

Much of neuroscience is focused on the role of the brain in generating adaptive behaviors based on external sensory stimuli. However, another crucial role of the brain is to govern the operation of the organs of the body and to optimize their function for current or predicted environmental and internal conditions. While the direct neural regulators of organ function in the autonomic nervous system (vagal and sympathetic) are known, little is known about how the central nervous systems orchestrate their activity. Here we try to understand how the brain of the larval zebrafish integrates sensory information about threatening environmental changes to generate appropriate changes in heart rate. Using pharmacological perturbations, we find that the brain must be modulating cholinergic vagal activity. We then perform brain-wide imaging during threat presentation, where we observe that heart rate correlates with switches in ventral habenular functional states, as well as the activity of a glutamatergic nucleus within the thalamus. Optogenetic stimulation of this nucleus leads to abrupt reductions of cardiac activity, suggesting it is involved in upregulating vagal activity. Together our results push toward the brainwide description of a circuit responsible for transforming sensory input into changes of visceral dynamics.

Coordination of two enhancers drives expression of olfactory trace amine-associated receptors.
Olfactory sensory neurons (OSNs) are functionally defined by their expression of a unique odorant receptor (OR). Mechanisms underlying singular OR expression are well studied, and involve a massive cross-chromosomal enhancer interaction network. Trace amine-associated receptors (TAARs) form a distinct family of olfactory receptors, and here we find that mechanisms regulating Taar gene choice display many unique features. The epigenetic signature of Taar genes in TAAR OSNs is different from that in OR OSNs. We further identify that two TAAR enhancers conserved across placental mammals are absolutely required for expression of the entire Taar gene repertoire. Deletion of either enhancer dramatically decreases the expression probabilities of different Taar genes, while deletion of both enhancers completely eliminates the TAAR OSN populations. In addition, both of the enhancers are sufficient to drive transgene expression in the partially overlapped TAAR OSNs. We also show that the TAAR enhancers operate in cis to regulate Taar gene expression. Our findings reveal a coordinated control of Taar gene choice in OSNs by two remote enhancers, and provide an excellent model to study molecular mechanisms underlying formation of an olfactory subsystem.

Navigational strategies underlying temporal phototaxis in Drosophila larvae.
Navigating across light gradients is essential for survival for many animals. However, we still have a poor understanding of the algorithms that underlie such behaviors. Here, we developed a novel closed-loop phototaxis assay for Drosophila larvae in which light intensity is always spatially uniform but updates depending on the location of the animal in the arena. Even though larvae can only rely on temporal cues during runs, we find that they are capable of finding preferred areas of low light intensity. Further detailed analysis of their behavior reveals that larvae turn more frequently and that heading angle changes increase when they experience brightness increments over extended periods of time. We suggest that temporal integration of brightness change during runs is an important - and so far largely unexplored - element of phototaxis.

Larval Zebrafish Use Olfactory Detection of Sodium and Chloride to Avoid Salt Water.
Salinity levels constrain the habitable environment of all aquatic organisms. Zebrafish are freshwater fish that cannot tolerate high-salt environments and would therefore benefit from neural mechanisms that enable the navigation of salt gradients to

avoid high salinity. Yet zebrafish lack epithelial sodium channels, the primary conduit land animals use to taste sodium. This suggests fish may possess novel, undescribed mechanisms for salt detection. In the present study, we show that zebrafish indeed respond to small temporal increases in salt by reorienting more frequently. Further, we use calcium imaging techniques to identify the olfactory system as the primary sense used for salt detection, and we find that a specific subset of olfactory receptor neurons encodes absolute salinity concentrations by detecting monovalent anions and cations. In summary, our study establishes that zebrafish larvae have the ability to navigate and thus detect salinity gradients and that this is achieved through previously undescribed sensory mechanisms for salt detection.

Probabilistic Models of Larval Zebrafish Behavior Reveal Structure on Many Scales.
Nervous systems have evolved to combine environmental information with internal state to select and generate adaptive behavioral sequences. To better understand these computations and their implementation in neural circuits, natural behavior must be carefully measured and quantified. Here, we collect high spatial resolution video of single zebrafish larvae swimming in a naturalistic environment and develop models of their action selection across exploration and hunting. Zebrafish larvae swim in punctuated bouts separated by longer periods of rest called interbout intervals. We take advantage of this structure by categorizing bouts into discrete types and representing their behavior as labeled sequences of bout types emitted over time. We then construct probabilistic models-specifically, marked renewal processes-to evaluate how bout types and interbout intervals are selected by the fish as a function of its internal hunger state, behavioral history, and the locations and properties of nearby prey. Finally, we evaluate the models by their predictive likelihood and their ability to generate realistic trajectories of virtual fish swimming through simulated environments. Our simulations capture multiple timescales of structure in larval zebrafish behavior and expose many ways in which hunger state influences their action selection to promote food seeking during hunger and safety during satiety.

Phenotypic Landscape of Schizophrenia-Associated Genes Defines Candidates and Their Shared Functions.
Genomic studies have identified hundreds of candidate genes near loci associated with risk for schizophrenia. To define candidates and their functions, we mutated zebrafish orthologs of 132 human schizophrenia-associated genes. We created a phenotype atlas consisting of whole-brain activity maps, brain structural differences, and profiles of behavioral abnormalities. Phenotypes were diverse but specific, including altered forebrain development and decreased prepulse inhibition. Exploration of these datasets identified promising candidates in more than 10 gene-rich regions, including the magnesium transporter cnnm2 and the translational repressor gigyf2, and revealed shared anatomical sites of activity differences, including the pallium, hypothalamus, and tectum. Single-cell RNA sequencing uncovered an essential role for the understudied transcription factor znf536 in the development of forebrain neurons implicated in social behavior and stress. This phenotypic landscape of schizophrenia-associated genes prioritizes more than 30 candidates for further study and provides hypotheses to bridge the divide between genetic association and biological mechanism.

High-throughput screening for selective appetite modulators: A multibehavioral and translational drug discovery strategy.
How appetite is modulated by physiological, contextual, or pharmacological influence is still unclear. Specifically, the discovery of appetite modulators is compromised by the abundance of side effects that usually limit in vivo drug action. We set out to identify neuroactive drugs that trigger only their intended single behavioral change, which would provide great therapeutic advantages. To identify these ideal bioactive small molecules, we quantified the impact of more than 10,000 compounds on an extended series of different larval zebrafish behaviors using an in vivo imaging strategy. Known appetite-modulating drugs altered feeding and a pleiotropy of behaviors. Using this multibehavioral strategy as an active filter for behavioral side effects, we identified previously unidentified compounds that selectively increased or reduced food intake by more than 50%. The general applicability of this strategy is shown by validation in mice. Mechanistically, most candidate compounds were independent of the main neurotransmitter systems. In addition, we identified compounds with multibehavioral impact, and correlational comparison of these profiles with those of known drugs allowed for the prediction of their mechanism of action. Our results illustrate an unbiased and translational drug discovery strategy for ideal psychoactive compounds and identified selective appetite modulators in two vertebrate species.

ARGININE VASOPRESSIN INCREASES THE EXCITATORY SYNAPTIC DRIVE AND FIRING ACTIVITY OF DEVELOPING SEROTONERGIC NEURONS IN NEONATAL DORSAL RAPHE NUCLEUS

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Ester Orav, Bojana Kokinovic, Sari Lauri, Henrike Hartung
University of Helsinki, Neuroscience Center, Helsinki, Finland

Birth stress, a risk factor for psychiatric disorders, triggers a surge of the stress hormone arginine vasopressin (AVP). The effect of AVP on developing neuronal networks such as the dorsal raphe nucleus (DRN) serotonin system are largely unknown. **Aims:** To investigate the effect of AVP on the synaptic drive and firing activity of neonatal serotonergic neurons *in vitro* and *in vivo* and to reveal the origin of the vasopressinergic innervation of neonatal DRN. **Methods:** Electrophysiological recordings were performed *in vitro* in acute brain slices containing DRN from P10-12 rat pups with the whole-cell patch clamp method and *in vivo* in urethane anaesthetised rat pups by juxtacellular recording and labelling. The origin of the vasopressinergic innervation in neonatal DRN was determined by retrograde tracer injections (Fluorogold) combined with immunohistochemistry against AVP. **Results:** We found that 10 nM AVP significantly increased the frequency and amplitude of sEPSCs in serotonergic neurons while the effect on sIPSCs was less pronounced. AVP also strongly augmented their action potential firing. Neonatal serotonergic neurons display a wide range of firing patterns *in vivo* but are characterised by a broad action potential waveform. They also seem to respond to AVP *in vivo*. The vasopressinergic innervation of neonatal DRN emerges nearly exclusively from sparse cell groups in medial amygdala and BNST. **Conclusions:** AVP is a powerful modulator of neonatal serotonergic activity in DRN. Abnormal AVP release by birth stress may alter the functional development of the DRN serotonin system and contribute to increased susceptibility to psychiatric disorders later on.

BASOLATERAL AMYGDALA CIRCUITRY DURING STRESS EXPOSURE

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Robert Aukema[1], Gavin Petrie[1], Benjamin Lau[1], Samantha Baglot[2], Lauren Seabrook[1], Maria Morena[3], Sandra Kadhim[1], Andrei Nastase[1], Stephanie Borgland[1], Matthew Hill[1]

AIMS. Anxiety disorders are increasingly prevalent, highly disabling, and often resistant to treatment. To develop more targeted, effective treatments, we must better understand how the brain identifies environmental stimuli as stressful. Importantly, which specific brain circuits and cell types respond to threat? Here, we investigate temporal, spatial, and circuit-specific activation patterns within the basolateral amygdala, a key brain region involved in emotional processing. **METHODS.** In adult rats, fiber photometry recorded temporal patterns of activation within the BLA to novel stimuli: swim, restraint, footshock, bobcat odor, citral odor, and crackers. In a different subset of rats, brains were collected to plot the spatial pattern of activation via labelling of FOS+ neurons following exposure to each stimulus. Using restraint as a model for stress, we then used retrograde tracing (CTb) and immunohistochemistry (cFos) to map topographical distribution and circuit-specific activation of BLA projection populations targeting six downstream brain regions. Finally, we employed chemogenetics or optogenetics, respectively, to inhibit or stimulate BLA projection neurons, and blood was subsequently collected to measure plasma levels of corticosterone. **RESULTS.** BLA projection neurons exhibited unique spatial and temporal patterns of activation to different novel stimuli. Exposure to restraint stress increased FOS expression in discrete BLA projection populations within the anterior basal amygdala. Modulation of this cluster of BLA projection neurons bidirectionally influenced plasma corticosterone levels. **CONCLUSIONS.** Aversive stimuli elicit unique spatiotemporal patterns of activation in the BLA, and activation of the BLA is both necessary and sufficient to generate an endocrine response to aversive stimuli.

Maternal-fetal transmission of delta-9-tetrahydrocannabinol (THC) and its metabolites following inhalation and injection exposure during pregnancy in rats.
Cannabis use during pregnancy has increased over the past few decades, with recent data indicating that, in youth and young adults especially, up to 22% of people report using cannabis during pregnancy. Animal models provide the ability to study prenatal cannabis exposure (PCE) with control over timing and dosage; however, these studies utilize both injection and inhalation approaches. While it is known that Δ9-tetrahydrocannabinol (THC; primary psychoactive component of cannabis) can cross the placenta, examination of the transmission and concentration of THC and its metabolites from maternal blood into the placenta and fetal brain remains relatively unknown, and the influence of route of administration has never been examined. Pregnant female rats were exposed to either vaporized THC-dominant cannabis extract for pulmonary consumption or subcutaneous injection of THC repeatedly during the gestational period. Maternal blood, placenta, and fetal brains were collected following the final administration of THC for analysis of THC and its metabolites, as well as endocannabinoid concentrations, through mass spectrometry. Both routes of administration resulted in the transmission of THC and its metabolites in placenta and fetal brain. Repeated exposure to inhaled THC vapor resulted in fetal brain THC concentrations that were about 30% of those seen in maternal blood, whereas repeated injections resulted in roughly equivalent concentrations of THC in maternal blood and fetal brain. Neither inhalation nor injection of THC during pregnancy altered fetal brain endocannabinoid concentrations. Our data provide the first characterization of maternal-fetal transmission of THC and its metabolites following both vaporized delivery and injection routes of administration. These data are important to establish the maternal-fetal transmission in preclinical injection and inhalation models of PCE and may provide insight into predicting fetal exposure in human studies.

Genetic Variants of Fatty Acid Amide Hydrolase Modulate Acute Inflammatory Responses to Colitis in Adult Male Mice.
Cannabinoids, including derived phytocannabinoids and endogenous cannabinoids (endocannabinoids), are typically considered anti-inflammatory. One such endocannabinoid is -arachidonoylethanolamine (anandamide, AEA), which is metabolized by fatty acid amide hydrolase (FAAH). In humans, there is a loss of function single nucleotide polymorphism (SNP) in the FAAH gene (C385A, rs324420), that leads to increases in the levels of AEA. Using a mouse model with this SNP, we investigated how this SNP affects inflammation in a model of inflammatory bowel disease. We administered 2,4,6-trinitrobenzene sulfonic acid (TNBS) intracolonically, to adult male FAAH SNP mice and examined colonic macroscopic tissue damage and myeloperoxidase activity, as well as levels of plasma and amygdalar cytokines and chemokines 3 days after administration, at the peak of colitis. We found that mice possessing the loss of function alleles (AC and AA), displayed no differences in colonic damage or myeloperoxidase activity compared to mice with wild type alleles (CC). In contrast, in plasma, colitis-induced increases in interleukin (IL)-2, leukemia inhibitory factor (LIF), monocyte chemoattractant protein (MCP)-1, and tumor necrosis factor (TNF) were reduced in animals with an A allele. A similar pattern was observed in the amygdala for granulocyte colony stimulating factor (G-CSF) and MCP-1. In the amygdala, the mutant A allele led to lower levels of IL-1α, IL-9, macrophage inflammatory protein (MIP)-1β, and MIP-2 independent of colitis-providing additional understanding of how FAAH may serve as a regulator of inflammatory responses in the brain. Together, these data provide insights into how FAAH regulates inflammatory processes in disease.

Pharmacokinetics and central accumulation of delta-9-tetrahydrocannabinol (THC) and its bioactive metabolites are influenced by route of administration and sex in rats.
Up to a third of North Americans report using cannabis in the prior month, most commonly through inhalation. Animal models that reflect human consumption are critical to study the impact of cannabis on brain and behaviour. Most animal studies to date utilize injection of delta-9-tetrahydrocannabinol (THC; primary psychoactive component of cannabis). THC injections produce markedly different physiological and behavioural effects than inhalation, likely due to distinctive pharmacokinetics. The current study directly examined if administration route (injection versus inhalation) alters metabolism and central accumulation of THC and metabolites over time. Adult male and female Sprague-Dawley rats received either an intraperitoneal injection or a 15-min session of inhaled exposure to THC. Blood and brains were collected at 15, 30, 60, 90 and 240-min post-exposure for analysis of THC and metabolites. Despite achieving comparable peak blood THC concentrations in both groups, our results indicate higher initial brain THC concentration following inhalation, whereas injection resulted in dramatically higher 11-OH-THC concentration, a potent THC metabolite, in blood and brain that increased over time. Our results provide evidence of different pharmacokinetic profiles following inhalation versus injection. Accordingly, administration route should be considered during data interpretation, and translational animal work should strongly consider using inhalation models.

Endocannabinoids, cannabinoids and the regulation of anxiety.
Cannabis has been used for hundreds of years, with its ability to dampen feelings of anxiety often reported as a primary reason for use. Only recently has the specific role cannabinoids play in anxiety been thoroughly investigated. Here we discuss the body of evidence describing how endocannabinoids and exogenous cannabinoids are capable of regulating the generation and termination of anxiety states. Disruption of the endogenous cannabinoid (eCB) system following genetic manipulation, pharmacological intervention or stress exposure reliably leads to the generation of an anxiety state. On the other hand, upregulation of eCB signaling is capable of alleviating anxiety-like behaviors in multiple paradigms. When considering exogenous cannabinoid administration, cannabinoid receptor 1 (CB1) agonists have a biphasic, dose-dependent effect on anxiety such that low doses are anxiolytic while high doses are anxiogenic, a phenomenon that is evident in both rodent models and humans. Translational studies investigating a loss of function mutation in the gene for fatty acid amide hydrolase, the enzyme responsible for metabolizing AEA, have also shown that AEA signaling regulates anxiety in humans. Taken together, evidence reviewed here has outlined a convincing argument for cannabinoids being powerful regulators of both the manifestation and amelioration of anxiety symptoms, and highlights the therapeutic potential of targeting the eCB system for the development of novel classes of anxiolytics. This article is part of the special issue on 'Cannabinoids'.

Upregulation of Anandamide Hydrolysis in the Basolateral Complex of Amygdala Reduces Fear Memory Expression and Indices of Stress and Anxiety.

Increased anandamide (AEA) signaling through inhibition of its catabolic enzyme fatty acid amide hydrolase (FAAH) in the basolateral complex of amygdala (BLA) is thought to buffer against the effects of stress and reduces behavioral signs of anxiety and fear. However, examining the role of AEA signaling in stress, anxiety, and fear through pharmacological depletion has been challenging due to the redundant complexity of its biosynthesis and the lack of a pharmacological synthesis inhibitor. We developed a herpes simplex viral vector to rapidly yet transiently overexpress FAAH specifically within the BLA to assess the impact of suppressing AEA signaling on stress, fear, and anxiety in male rats. Surprisingly, FAAH overexpression in BLA dampened stress-induced corticosterone release, reduced anxiety-like behaviors, and decreased conditioned fear expression. Interestingly, depleting AEA signaling in the BLA did not prevent fear conditioning itself or fear reinstatement. These effects were specific to the overexpression of FAAH because they were reversed by intra-BLA administration of an FAAH inhibitor. Moreover, the fear-suppressive effects of FAAH overexpression were also mitigated by intra-BLA administration of a low dose of a GABA receptor antagonist, but not an NMDA/AMPA/kainate receptor antagonist, suggesting that they were mediated by an increase in GABAergic neurotransmission. Our data suggest that a permissive AEA tone within the BLA might gate GABA release and that loss of this tone through elevated AEA hydrolysis increases inhibition in the BLA, which in turn reduces stress, anxiety, and fear. These data provide new insights on the mechanisms by which amygdalar endocannabinoid signaling regulates emotional behavior. Amygdala endocannabinoid signaling is involved in the regulation of stress, anxiety, and fear. Our data indicate that viral-mediated augmentation of anandamide hydrolysis within the basolateral amygdala reduces behavioral indices of stress, anxiety, and conditioned fear expression. These same effects have been previously documented with inhibition of anandamide hydrolysis in the same brain region. Our results indicate that the ability of anandamide signaling to regulate emotional behavior is nonlinear and may involve actions at distinct neuronal populations, which could be influenced by the basal level of anandamide. Modulation of anandamide signaling is a current clinical therapeutic target for stress-related psychiatric illnesses, so these data underscore the importance of fully understanding the mechanisms by which anandamide signaling regulates amygdala-dependent changes in emotionality.

Protective effects of elevated anandamide on stress and fear-related behaviors: translational evidence from humans and mice.
Post-traumatic stress disorder (PTSD) is a common, debilitating condition with limited treatment options. Extinction of fear memories through prolonged exposure therapy, the primary evidence-based behavioral treatment for PTSD, has only partial efficacy. In mice, pharmacological inhibition of fatty acid amide hydrolase (FAAH) produces elevated levels of anandamide (AEA) and promotes fear extinction, suggesting that FAAH inhibitors may aid fear extinction-based treatments. A human FAAH 385C->A substitution encodes an FAAH enzyme with reduced catabolic efficacy. Individuals homozygous for the FAAH 385A allele may therefore offer a genetic model to evaluate the impact of elevations in AEA signaling in humans, helping to inform whether FAAH inhibitors have the potential to facilitate fear extinction therapy for PTSD. To overcome the challenge posed by low frequency of the AA genotype (appr. 5%), we prospectively genotyped 423 individuals to examine the balanced groups of CC, AC, and AA individuals (n = 25/group). Consistent with its loss-of-function nature, the A allele was dose dependently associated with elevated basal AEA levels, facilitated fear extinction, and enhanced the extinction recall. Moreover, the A-allele homozygotes were protected against stress-induced decreases in AEA and negative emotional consequences of stress. In a humanized mouse model, AA homozygous mice were similarly protected against stress-induced decreases in AEA, both in the periphery, and also in the amygdala and prefrontal cortex, brain structures critically involved in fear extinction and regulation of stress responses. Collectively, these data suggest that AEA signaling can temper aspects of the stress response and that FAAH inhibition may aid the treatment for stress-related psychiatric disorders, such as PTSD.

Prenatal immune activation potentiates endocannabinoid-related plasticity of inhibitory synapses in the hippocampus of adolescent rat offspring.
There is strong evidence that immune activation from prenatal infection increases the risk for offspring to develop schizophrenia. The endocannabinoid (eCB) system has been implicated in the pathophysiology of schizophrenia while models of cortical dysfunction postulate an imbalance between neuronal excitation and inhibition in the disorder. The current study examined the impact of prenatal immune activation on eCB-mediated inhibitory mechanisms. We compared two forms of eCB-related plasticity of evoked inhibitory postsynaptic currents, namely depolarization-induced suppression of inhibition (DSI) and metabotropic glutamate receptor-induced long term depression (mGluR-iLTD), in both the dorsal and ventral hippocampus between adolescent offspring from rat dams that received either saline or bacterial lipopolysaccharide (LPS) during pregnancy. Compared to prenatal saline offspring, prenatal LPS offspring displayed prolonged DSI and stronger

mGluR-iLTD in the dorsal and ventral hippocampus, respectively. The sensitivity of mGluR-iLTD to the CB1 receptor antagonist AM251 was also lower in the dorsal hippocampus of prenatal LPS compared to prenatal saline offspring. Testing whether changes in eCB receptor signaling or levels could contribute to these changes in inhibitory transmission, we found region specific increases in 2-arachidonoylglycerol-stimulated signaling and in basal and mGluR-induced levels of anandamide in prenatal LPS offspring when compared to prenatal saline offspring. Our findings indicate that prenatal immune activation can lead to long-term changes in eCB-related plasticity of hippocampal inhibitory synaptic transmission in adolescent rat offspring. Perturbation of the eCB system resulting from prenatal immune activation could represent a mechanism linking early life immune events to the development of psychopathology in adolescence.

PHASIC AND TONIC LOCUS COERULEUS STIMULATIONS LEAD TO OPPOSITE VALENCE LEARNING VIA DISTINCT ADRENOCEPTORS IN THE BASOLATERAL AMYGDALA

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Kyron Power, Tamunotonye Omoluabi, Tayebeh Sepahvand, Qi Yuan
Memorial University, Faculty Of Medicine, St. John's, Canada

AIMS: The locus coeruleus (LC) signals opposing valences via two different firing modes: tonic and phasic. LC activation engages the basolateral amygdala (BLA) for the formation of opposite valences. Light-induced LC phasic and tonic firing patterns preferentially recruited BLA neurons projecting to the nucleus accumbens (NAc) reward circuitry and to the central nucleus of the amygdala (CeA) aversive circuitry, respectively. Here, we ask if different adrenoceptors in the BLA are involved in opposite valences generated by either LC light patterns, or natural conditioning. **METHODS**: α1-adrenoceptor antagonist prozasin or β1/2-adrenoceptor antagonist propranolol was infused bilaterally in the BLA 30 min before behavioral training. A conditioned odor preference test was carried out in TH-CRE rats expressing ChR2 in the LC. LC light stimulation (10 Hz phasic or 25 Hz tonic) was paired with a conditioned odor. Odor reward learning using food pellet pairing and odor aversive learning using foot shock pairing were carried out in separate cohorts. Retrograde CTB tracers were infused in the CeA and NAc to map fear- and reward circuitry. Adrenoceptor expressions in the BLA were measured by immunohistochemistry. **RESULTS**: Reward conditioning, by either LC phasic stimulation or food reward training, activated more NAc-projecting cells in the BLA and was impaired by either α1- or β1/2-adrenoceptor blockade. Aversive learning, by either LC high tonic stimulation, or shock training, was dependent on β1/2-, but not α1-adrenoceptor activation. **CONCLUSIONS**: Positive and negative valence learning may induce different patterns of NE release and engage diverge populations of the neurons in the BLA.

THE ROLE OF MICRORNA-34A ON DORSAL RAPHE NUCLEI NEUROTRANSMISSION IN RESPONSE TO SPECIFIC VALENCE STIMULI

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Serafina Manila Guzzo[1], Donald Ielpo[2], Giovanni Porcheddu[3], Luisa Lo Iacono[2], Cristina Marchetti[3], Rossella Ventura[2,4], Carlo Cifani[1], Diego Andolina[2,4]

To survive, an individual must be able to discriminate aversive and appetitive stimuli within the environment and elicit adaptation behavioral responses.
Serotoninergic (5-HT) neurons in the Dorsal Raphe Nucleus (DRN) play critical roles in behaviors motivated by environmental stimuli valence. Within the DRN, 5-HT neurons are modulated by GABAergic activity. However, it is still unclear how GABAergic neurons are modulated to process environmental information.
MicroRNAs are important molecules for the regulation of transcriptional changes induced by environmental challenges. Our previous studies have shown that MicroRNA-34 (MiR-34) is highly expressed in the DRN and that its blockade alters 5-HT release while improving the stress-induced phenotype.
Here, we tested the hypothesis that MiR-34 regulates the 5-HT response via GABAergic modulation after negative stimuli. First, by using RNA scope in situ hybridization, we demonstrate that MiR-34 is predominantly expressed on DRN GABAergic neurons. We then use microdialysis and electrophysiology on a mouse model that has MiR-34 deletion on GABAergic neurons (GAD2 MiR-34loxP/loxP) and we showed that, only after negative stimuli such as restraint (and not positive such as white chocolate), MiR-34 regulates GABAergic release on 5-HT neurons. In particular, GAD2 MiR-34loxP/loxP mice have altered behavioral responses to negative stimuli (forced swimming test) compared to control groups (miR-34loxP/loxP and Gad2-CRE mice). Additionally, these mice models did not show any behavioral changes after positive stimuli (sucrose preference test) compared to control groups.
Overall, our results demonstrated a new regulatory mechanism in which MiR-34 modulates GABAergic neurotransmission on DRN 5-HT neurons in response to negative stimuli valence.

MALE MICE ENGAGING DIFFERENTLY IN EMOTIONAL EATING PRESENT DISTINCT PLASMATIC AND NEUROLOGICAL PROFILES

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Christine Heberden, Elise Maximin, Laurent Naudon, Sylvie Rabot
INRAE, Micalis, Jouy en Josas, France

Objective: When exposed to stressful events, individuals tend to turn to “comfort food” which provides a temporary relief from stress. The emotional eating drive is highly variable among subjects. We explored the plasmatic and neurobiological differences between “high and low emotional eaters” (HEE and LEE) in male mice. Methods: Male mice were daily exposed for 5 weeks to an unpredictable chronic mild stress paradigm. More, every 3 or 4 days, they were submitted to a 1-hr restraint stress, immediately followed by a 3-hr period during which a choice between chow and chocolate sweet cereals was proposed. Plasmatic and neurobiological characteristics were analyzed and compared in mice displaying high vs low intakes. Results: LEE displayed higher plasma corticosterone and lower levels of the neuropeptide Y (NPY) than HEE, but acylated and total ghrelin were similar in both groups. In the brain, the abundance of NPY neurons in the arcuate nucleus of the hypothalamus was similar in both groups, but was higher in the ventral hippocampus and the basal lateral amygdala of LEE. Surprisingly in the lateral hypothalamus LEE had also more orexin positive neurons but no more melanin concentrating hormone neurons. Both NPY and orexin are orexigenic peptides, and mood regulators. Discussion: The difference in the responses to post-stress food was reflected in plasma and brain structures implicated in emotion and eating regulation. These results concur with the psychological side of food consumption. A subsequent question is whether the abundance of orexin and NPY neurons was stress-acquired or a trait.

COMPLEMENTARY LATERAL HYPOTHALAMIC POPULATIONS RESIST HUNGER PRESSURE TO BALANCE NUTRITIONAL AND SOCIAL NEEDS

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Anne Petzold[1,2], Hanna Van Den Munkhof[1,2], Rebecca Figge[1,2], Tatiana Korotkova[1,2]
[1]Max Planck Institute, Metabolism Research, Cologne, Germany, [2]University of Cologne, Institute For Vegetative Physiology, Cologne, Germany

Diets often fail due to the inability to resist even moderate hunger pressure. However, neuronal mechanisms of sensing and resisting metabolic pressure such as hunger remain poorly understood. The lateral hypothalamus (LH) regulates feeding and drinking, in part through leptin receptor-expressing ($LepR^{LH}$) and neurotensin-expressing (Nts^{LH}) neurons. In this study, we show how these neural populations enable resistance to metabolic deprivation to enable behavioural flexibility. Using single cell Ca^{2+} imaging in freely moving animals, we found that $LepR^{LH}$ neurons encode food stimuli, whereby the magnitude of food-elicited responses reflected food intake under moderate, but not under strong hunger pressure. Failure to resist moderate hunger pressure was encoded by escalating inhibition of a leptin-sensitive $LepR^{LH}$ subpopulation at a fast time scale. Similarly, $LepR^{LH}$ neurons of thirsty animals encode water stimuli. Optogenetic activation of $LepR^{LH}$ neurons suppressed food or water intake in moderately hungry or thirsty animals, and promoted the exploration of social stimuli. Conversely, hunger pressure intensified water encoding of Nts^{LH} neurons, whereby the magnitude of water-elicited responses reflected food intake. Detailed behavioural analysis reveals that Nts^{LH} neurons track food intake to scale water intake accordingly, ensuring the balance between feeding and drinking, even discounting social interaction in favour of water. In summary, hunger pressure gates $LepR^{LH}$ and Nts^{LH} populations in a complementary manner to enable the flexible fulfilment of competing essential needs. Decoding brain state transitions in the pedunculopontine nucleus: cooperative phasic and tonic mechanisms.
Cholinergic neurons of the pedunculopontine nucleus (PPN) are most active during the waking state. Their activation is deemed to cause a switch in the global brain activity from sleep to wakefulness, while their sustained discharge may contribute to upholding the waking state and enhancing arousal. Similarly, non-cholinergic PPN neurons are responsive to brain state transitions and their activation may influence some of the same targets of cholinergic neurons, suggesting that they operate in coordination. Yet, it is not clear how the discharge of distinct classes of PPN neurons organize during brain states. Here, we monitored the in vivo network activity of PPN neurons in the anesthetized rat across two distinct levels of cortical dynamics and their transitions. We identified a highly structured configuration in PPN network activity during slow-wave activity that was replaced by decorrelated activity during the activated state (AS). During the transition, neurons were predominantly excited (phasically or tonically), but some were inhibited. Identified cholinergic neurons displayed phasic and short latency responses to sensory stimulation, whereas the majority of non-cholinergic showed tonic responses and remained at high discharge rates beyond the state transition. In vitro recordings demonstrate that cholinergic neurons exhibit fast adaptation that prevents them from discharging at high rates over prolonged time periods. Our data shows that PPN neurons have distinct but complementary roles during brain state transitions, where cholinergic neurons provide a fast and transient response to sensory events that drive state transitions, whereas non-cholinergic neurons maintain an elevated firing rate during global activation.

Chronic BDNF deficiency leads to an age-dependent impairment in spatial learning.
Brain-derived neurotrophic factor (BDNF) is a crucial mediator of neural plasticity and, consequently, of memory formation. In hippocampus-dependent learning tasks BDNF also seems to play an essential role. However, there are conflicting results concerning the spatial learning ability of aging BDNF(+/-) mice in the Morris water maze paradigm. To evaluate the effect of chronic BDNF deficiency in the hippocampus on spatial learning throughout life, we conducted a comprehensive study to test

differently aged BDNF(+/-) mice and their wild type littermates in the Morris water maze and to subsequently quantify their hippocampal BDNF protein levels as well as expression levels of TrkB receptors. We observed an age-dependent learning deficit in BDNF(+/-) animals, starting at seven months of age, despite stable hippocampal BDNF protein expression and continual decline of TrkB receptor expression throughout aging. Furthermore, we detected a positive correlation between hippocampal BDNF protein levels and learning performance during the probe trial in animals that showed a good learning performance during the long-term memory test.

TUBERAL NUCLEUS SOMATOSTATIN NEURONS IN THE REGULATION OF HIGH-FAT EATING RELATED BEHAVIORS

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Esra Senol[1], Yu Fu[1,2,3]
[1]Agency for Science, Technology and Research, Institute Of Molecular Cell And Biology, Singapore, Singapore, [2]National University of Singapore, Physiology, Yong Loo Lin School Of Medicine, Singapore, Singapore, [3]Nanyang Technological University, Lee Kong Chian School Of Medicine, Singapore, Singapore

Even though high-fat food is preferentially chosen over regular food, the neuronal regulation of high-fat intake is not well identified. Diverse hypothalamic neuronal populations, including arcuate agouti-related protein expressing neurons (^{ARC}AgRP), tuberal nucleus somatostatin neurons (^{TN}SST), GABAergic neurons in the lateral hypothalamus (^{LH}VGAT) have been identified over the decade in the feeding regulation of mice; however, how they differentially participate in high-fat intake regulation is still unclear. By staining neuronal activity marker, cFos, we observed a specific higher cFos positive neurons after consuming high-fat in ^{TN}SST neurons but not in ^{ARC}AgRP or ^{LH}VGAT. Subsequently, to investigate the effect of post-ingestive mechanisms on ^{TN}SST activity, we infused different caloric solutions to the mice by gavaging. We found no significant difference among different caloric solutions; thus, the ^{TN}SST response to different caloric solutions mainly not through the post-ingestive mechanisms. Furthermore, in vivo imaging of ^{TN}SST neurons revealed that majority of them demonstrated preferential response to high-fat even before consuming it. However, the preferential response of ^{TN}SST neurons did not dictate choice of high-fat in hungry mice, since chemogenetic activation of the either there three population led to preferential consumption in sated mice and inhibition of ^{TN}SST or ^{ARC}AgRP or ^{LH}VGAT neurons resulted in less consumption of high-fat. Interestingly, only inhibiting ^{TN}SST neurons, but not other two neuronal populations, abolished the conditioned place preference induced by high-fat, suggesting that reinforcing effect of high-fat specifically requires ^{TN}SST neurons. Therefore, we revealed an unique high-fat-specific response and role of ^{TN}SST neurons.

Neural circuit control of innate behaviors.
All animals possess a plethora of innate behaviors that do not require extensive learning and are fundamental for their survival and propagation. With the advent of newly-developed techniques such as viral tracing and optogenetic and chemogenetic tools, recent studies are gradually unraveling neural circuits underlying different innate behaviors. Here, we summarize current development in our understanding of the neural circuits controlling predation, feeding, male-typical mating, and urination, highlighting the role of genetically defined neurons and their connections in sensory triggering, sensory to motor/motivation transformation, motor/motivation encoding during these different behaviors. Along the way, we discuss possible mechanisms underlying binge-eating disorder and the pro-social effects of the neuropeptide oxytocin, elucidating the clinical relevance of studying neural circuits underlying essential innate functions. Finally, we discuss some exciting brain structures recurrently appearing in the regulation of different behaviors, which suggests both divergence and convergence in the neural encoding of specific innate behaviors. Going forward, we emphasize the importance of multi-angle and cross-species dissections in delineating neural circuits that control innate behaviors.

A neural circuit for excessive feeding driven by environmental context in mice.
Despite notable genetic influences, obesity mainly results from the overconsumption of food, which arises from the interplay of physiological, cognitive and environmental factors. In patients with obesity, eating is determined more by external cues than by internal physiological needs. However, how environmental context drives non-homeostatic feeding is elusive. Here, we identify a population of somatostatin (SST) neurons in the mouse hypothalamic tuberal nucleus that are preferentially activated by palatable food. Activation of SST neurons enabled a context to drive non-homeostatic feeding in sated mice and required inputs from the subiculum. Pairing a context with palatable food greatly potentiated synaptic transmission between

the subiculum and SST neurons and drove non-homeostatic feeding that could be selectively suppressed by inhibiting SST neurons or the subiculum but not other major orexigenic neurons. These results reveal how palatable food, through a specific hypothalamic circuit, empowers environmental context to drive non-homeostatic feeding.

A distinct parabrachial-to-lateral hypothalamus circuit for motivational suppression of feeding by nociception.
The motivation to eat is not only shaped by nutrition but also competed by external stimuli including pain. How the mouse hypothalamus, the feeding regulation center, integrates nociceptive inputs to modulate feeding is unclear. Within the key nociception relay center parabrachial nucleus (PBN), we demonstrated that neurons projecting to the lateral hypothalamus (PBN) are nociceptive yet distinct from danger-encoding central amygdala-projecting (PBN) neurons. Activation of PBN strongly suppressed feeding by limiting eating frequency and also reduced motivation to work for food reward. Refined approach-avoidance paradigm revealed that suppression of PBN, but not PBN, sustained motivation to obtain food. The effect of PBN neurons on feeding was reversed by suppressing downstream LH neurons. Thus, distinct from a circuit for fear and escape responses, PBN neurons channel nociceptive signals to LH neurons to suppress motivational drive for feeding. Our study provides a new perspective in understanding feeding regulation by external competing stimuli.

ANTAGONISTIC CONTROL OF SOCIAL INTERACTION BY LEPTIN RECEPTOR-EXPRESSING AND NEUROTENSIN-EXPRESSING NEURONS IN THE LATERAL HYPOTHALAMUS

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Rebecca Figge[1,2], Anne Petzold[1,2], Hanna Van Den Munkhof[1,2], Tatiana Korotkova[1,2]

The lateral hypothalamus (LH) plays a major role in regulating consummatory behaviors to maintain homeostasis. However, hunger and thirst are continuously weighed against competing needs, according to state and opportunity. The neuronal mechanisms of representation and prioritization of multiple innate rewards remain poorly understood. We investigated how distinct neuronal populations of leptin receptor- (LepR) and neurotensin-expressing cells (Nts) in the LH guide increasingly hungry animals through behavioral choices. For that purpose, we used opto- and chemogenetic stimulation as well as single cell, deep-brain calcium imaging in freely moving mice in various nutritional states. Stimulation of LepR neurons promoted interaction with females but not males despite moderate hunger pressure. Furthermore, LepR neurons exhibited stronger responses to females than to males during spontaneous social interaction. Hunger pressure led to increase of food-selective and decrease of social-selective LepR neurons, suggesting need-dependent competitive coding of these orthogonal stimuli by LepR neurons. In contrast, activation of Nts neurons reduced social interaction, and activity of Nts neurons did not differentiate the sex of conspecifics. Here, we demonstrate that LepR and Nts populations exert opposite effects on social interaction with LepR neurons promoting social exploration and Nts neurons restraining social drive. This complementary control of innate drives enables flexible fulfillment of orthogonal needs according to current opportunities and gated by physiological demands. **We gratefully acknowledge support by the ERC Consolidator Grant (772994, FeedHypNet, to T.K.) and the DFG (233886668-GRK1960, to R.F., Project-ID 431549029 – SFB 1451, to T.K., EXC2030 CECAD, to T.K.).**

Background: Infusions of sucrose directly into the stomach modulates food seeking behavior and activates ventral tegmental area (VTA) dopaminergic neurons. However, how information regarding different macronutrients is transmitted and detected in brain reward areas remains unknown. Here we tested if VTA dopaminergic activity is differently modulated by distinct reinforcing macronutrients. Methods: Dopamine transporter (DAT)-Cre mice were injected with GcaMP6f, a genetically encoded fluorescent calcium indicator, and implanted with a gradient index lens, in the VTA. Fluorescent imaging of VTA neurons was recorded using a microendoscope during a 25-minute session. During each session a different reinforcer - sucrose, sucralose, or corn oil - was delivered into the stomach through a previously implanted intragastric catheter. Reinforcer order was randomized. Corn oil and sucrose solutions were isocaloric and sucralose, a non-caloric sweetener, was used as control. Results: The number of neurons detected on average for the sessions of each reinforcer did not differ significantly. However, the mean activity of VTA dopaminergic neurons increased significantly after intragastric infusions of sucrose when compared with isocaloric corn oil or sucralose sessions. Accordingly, the percentage of positively modulated neurons after reinforcer delivery was significantly higher in sessions when sucrose was infused when compared with the other two reinforcers, with no lateralization of the response. Furthermore, the neurons that are positively modulated by sucrose are not positively modulated by corn oil. Conclusion: This preliminary data indicates that VTA dopaminergic neurons are modulated by sucrose but not by corn oil or sucralose, indicating a nutrient-specific response.

CENTRAL AMYGDALA AND FEEDING BEHAVIOR: SINGLE CELL TRANSCRIPTOME ANALYSIS AND REGULATION BY FASTING

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Songwei He, Christian Peters, Rüdiger Klein
Max-Planck Institute of Neurobiology, Department Of Molecules – Signaling - Development, Martinsried, Germany

The relationship between different cell types and brain functions is of central interest in understanding mouse behavior. The development of single cell sequencing technologies has greatly accelerated our ability to classify and study cell types based on their transcriptomes. It has been used to characterize transcriptional changes in specific cell types in response to external cues or changes in internal states. Here, we explored cell types and their transcriptional variations in the central amygdala (CeA), a brain region that mediates defensive and appetitive responses. We performed single nuclei RNA sequencing in adult mice and compared the results with known genetic and functionally defined populations, which have been studied in different behavioral contexts. We identified at least seven transcriptionally and spatially discrete cell types (three in the lateral division, CeL; three in the medial division, CeM; and one in the capsular division, CeC). Five of these cell types have been previously characterized for their role in feeding behavior, while the other two seem novel and uncharacterized. To begin investigating whether these cell types show individual responses during appetitive behavior, we compared their transcriptomes in food-deprived and satiated mice. We found alternations of the transcriptomes at different dimensions across cell types. Particularly, we see changes in synaptic-related genes in the Htr2a/Sst neurons, a population that is known to promote hedonic feeding (Douglass et al., Nat. Neuro., 2017).

IDENTIFYING NEURONAL CIRCUITS THAT COORDINATE SUGAR AND WATER INGESTION

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Amanda Gonzalez-Segarra[1], Alexander Del Toro[2], Amanda Abusaif[1], Kristin Scott[1]
[1]University of California, Berkeley, Molecular And Cell Biology, Berkeley, United States of America, [2]Brown University, Neuroscience, Providence, United States of America

While the mechanisms animals use to eat is beautifully diverse, all organisms need to acquire nutrients from their environment to survive. Food ingestion is tightly regulated by internal signals of nutrient abundance in order to maintain homeostasis. Recent studies have identified four neurons called Interoceptive Subesophageal zone Neurons (ISNs) in *Drosophila melanogaster* that respond to endogenous hunger and thirst signals to oppositely regulate sugar and water ingestion. Upon activation, ISNs increase sugar ingestion but decrease water ingestion. While the key molecular pathways that lead to ISN activation have been identified, it is still unknown how ISN activity translates to a behavioral response. The goal of this study is to examine how competing needs are coordinated by the nervous system by identifying and characterizing the neural circuit downstream of the ISNs. We used the full adult fly brain electron microscopy volume to trace the ISNs and their downstream targets. Interestingly, we have identified two distinct pathways downstream of the ISNs: a neuroendocrine circuit that connects the ISNs to *Drosophila* insulin-like peptide producing cells (IPCs), and a local circuit that connects the ISNs to motor neurons controlling feeding. Future experiments involve gaining genetic access to these neurons to conduct behavioral and functional connectivity experiments to characterize their involvement in sucrose and water ingestion. This study will provide insight into how the nervous system organizes competing internal needs to drive opposing behavioral responses.

A NEURAL MECHANISM INVOLVED IN THE MOTIVATIONAL SUPPRESSION OF FEEDING BY NOCICEPTION.

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Alison Kok
Agency for Science, Technology and Research (A*STAR), Institute Of Molecular And Cell Biology, Singapore, Singapore

Our understanding of neural circuits of feeding regulation have focused on a top down approach of the influence of the hypothalamus in regulating feeding. However, the mechanism in how suppression of activity of these neurons can lead to an 'off switch' in feeding behaviour is unclear. The presence of competing states, such as pain and hunger, will result in mice displaying protective behaviour towards pain which results in suppressed motivation in fulfilling the needs of hunger. Utilizing an acute shock-food reward behavioural paradigm, we showed that attenuation of lateral hypothalamus projecting parabrachial nucleus (^{LH}PBN) neurons resulted in hungry mice obtaining food even in the presence of shock; thus demonstrating that ^{LH}PBN is involved in modulating the prioritization of pain in a pain-reward conflict. In addition, the activation of ^{LH}PBN neurons in fasted mice trained in a progressive operant task reduced its motivation to work for rewards. This behavioural change was not due to an effect from changes in valuation towards reward as mice were able to obtain maximum number of rewards when they were put through a simpler fixed ratio task. We also confirmed that both activation and attenuation of ^{LH}PBN neurons had no effect on the physical sensation of pain in mice, as mice showed no altered paw sensitivity in a von frey test. Thus, the findings of this study have revealed a neural mechanism involved in the motivational suppression of feeding by nociception.

Introduction: RXFP3 (relaxin-family peptide 3 receptor) is the cognate G-protein-coupled receptor for the neuropeptide, relaxin-3. RXFP3 is expressed widely throughout the brain, including the hypothalamus, where it has been shown to modulate feeding behaviour and neuroendocrine activity in rodents. **Aim:** In studies to better characterise potential mechanisms that underlie these effects, this study determined whether RXFP3 is expressed by dopaminergic neurons within the arcuate nucleus (ARC) and dorsomedial hypothalamus (DMH), in addition to the ventral tegmental area (VTA). **Methods:** Neurons that express RXFP3 were visualised in coronal brain sections from RXFP3-Cre/tdTomato mice, which express the tdTomato fluorophore within RXFP3-positive cells, and dopaminergic neurons in these areas were visualised by simultaneous immunohistochemical detection of tyrosine hydroxylase-immunoreactivity (TH-IR). **Results:** Approximately 20% of ARC neurons containing TH-IR co-expressed tdTomato fluorescence, suggesting RXFP3 can influence the dopamine pathway from the ARC to the pituitary gland that controls prolactin release. The ability of prolactin to reduce leptin sensitivity and increase food consumption therefore represents a potential mechanism by which RXFP3 activation mediates its demonstrated effects on feeding. Notably, intra-hypothalamic injection of relaxin-3 increased plasma prolactin levels (McGowan et al. 2014). A similar proportion of DMH neurons containing TH-IR expressed RXFP3-related tdTomato fluorescence, consistent with a possible RXFP3-mediated regulation of stress and neuroendocrine circuits. In contrast, RXFP3 was barely detected within the VTA. **Conclusion:** These findings identify potential hypothalamic mechanisms by which RXFP3 influences neuroendocrine control of metabolism, and further highlight the therapeutic potential of targeting this receptor in feeding-related disorders

THE NEURONAL LOGIC OF HOW INTERNAL STATES CONTROL FOOD CHOICE

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Daniel Münch, Dennis Goldschmidt, Carlos Ribeiro
Fundação Champalimaud, Champalimaud Research, Lisboa, Portugal

When deciding what to eat, animals evaluate sensory information about food quality alongside multiple ongoing internal states. How internal states interact to alter sensorimotor processing and shape decisions such as food choice remains poorly understood. Here, we use pan-neuronal volumetric activity imaging in the *Drosophila* brain to investigate the neuronal basis of internal state dependent nutrient appetites. We created a functional atlas of the ventral fly brain and find that metabolic state shapes sensorimotor processing across large sections of the neuropil. Reproductive state, in contrast, acts locally to define how sensory information is translated into feeding motor output. Thereby, these two states synergistically modulate protein-specific food intake and thus food choice. Finally, using a novel computational strategy, we identify driver lines innervating state-modulated regions and show that the newly identified “borboleta” region is sufficient to direct food choice towards protein-rich food. We therefore identify a generalizable principle by which distinct internal states are integrated to shape decision-making and propose a strategy to uncover and functionally validate how internal states shape behavior.

Nutrient homeostasis - translating internal states to behavior.
Behavioral neuroscience aims to describe a causal relationship between neuronal processes and behavior. Animals' ever-changing physiological needs alter their internal states. Internal states then alter neuronal processes to adapt the behavior of the animal enabling it to meet its needs. Here, we describe nutrient-specific appetites as an attractive framework to study how internal states shape complex neuronal processes and resulting behavioral outcomes. Understanding how neurons detect nutrient states and how these are integrated at the level of neuronal circuits will provide a multilevel description of the mechanisms underlying complex feeding and foraging decisions.

An expression atlas of variant ionotropic glutamate receptors identifies a molecular basis of carbonation sensing.
Through analysis of the Drosophila ionotropic receptors (IRs), a family of variant ionotropic glutamate receptors, we reveal that most IRs are expressed in peripheral neuron populations in diverse gustatory organs in larvae and adults. We characterise IR56d, which defines two anatomically-distinct neuron classes in the proboscis: one responds to carbonated solutions and fatty acids while the other represents a subset of sugar- and fatty acid-sensing cells. Mutational analysis indicates that IR56d, together with the broadly-expressed co-receptors IR25a and IR76b, is essential for physiological responses to carbonation and fatty acids, but not sugars. We further demonstrate that carbonation and fatty acids both promote IR56d-dependent attraction of flies, but through different behavioural outputs. Our work provides a toolkit for investigating taste functions of IRs, defines a subset of these receptors required for carbonation sensing, and illustrates how the gustatory system uses combinatorial expression of sensory molecules in distinct neurons to coordinate behaviour.

Take time: odor coding capacity across sensory neurons increases over time in Drosophila.
Due to the highly efficient olfactory code, olfactory sensory systems are able to reliably encode enormous numbers of olfactory stimuli. The olfactory code consists of combinatorial activation patterns across sensory neurons, thus its capacity exceeds the number of involved classes of sensory neurons by a manifold. Activation patterns are not static but vary over time, caused by the temporally complex response dynamics of the individual sensory neuron responses. We systematically analyzed the temporal dynamics of olfactory sensory neuron responses to a diverse set of odorants. We find that response dynamics depend on the combination of sensory neuron and odorant and that information about odorant identity can be extracted from the time course of the response. We also show that new response dynamics can arise when mixing two odorants. Our data show that temporal dynamics of odorant responses are able to significantly enhance the coding capacity of olfactory sensory systems.

The Circuitry of Olfactory Projection Neurons in the Brain of the Honeybee, .
In the honeybee brain, two prominent tracts - the medial and the lateral antennal lobe tract - project from the primary olfactory center, the antennal lobes (ALs), to the central brain, the mushroom bodies (MBs), and the protocerebral lobe (PL). Intracellularly stained uniglomerular projection neurons were reconstructed, registered to the 3D honeybee standard brain atlas, and then used to derive the spatial properties and quantitative morphology of the neurons of both tracts. We evaluated putative synaptic contacts of projection neurons (PNs) using confocal microscopy. Analysis of the patterns of axon terminals revealed a domain-like innervation within the MB lip neuropil. PNs of the lateral tract arborized more sparsely within the lips and exhibited fewer synaptic boutons, while medial tract neurons occupied broader regions in the MB calyces and the PL. Our data show that uPNs from the medial and lateral tract innervate both the core and the cortex of the ipsilateral MB lip but differ in their innervation patterns in these regions. In the mushroombody neuropil collar we found evidence for ALT boutons suggesting the collar as a multi modal input site including olfactory input similar to lip and basal ring. In addition, our data support the conclusion drawn in previous studies that reciprocal synapses exist between PNs, octopaminergic-, and GABAergic cells in the MB calyces. For the first time, we found evidence for connections between both tracts within the AL.

DoOR 2.0--Comprehensive Mapping of Drosophila melanogaster Odorant Responses.
Odors elicit complex patterns of activated olfactory sensory neurons. Knowing the complete olfactome, i.e. the responses in all sensory neurons for all relevant odorants, is desirable to understand olfactory coding. The DoOR project combines all available Drosophila odorant response data into a single consensus response matrix. Since its first release many studies were published: receptors were deorphanized and several response profiles were expanded. In this study, we add unpublished data to the odor-response profiles for four odorant receptors (Or10a, Or42b, Or47b, Or56a). We deorphanize Or69a, showing a broad response spectrum with the best ligands including 3-hydroxyhexanoate, alpha-terpineol, 3-octanol and linalool. We include all of these datasets into DoOR, provide a comprehensive update of both code and data, and new tools for data analyses and visualizations. The DoOR project has a web interface for quick queries (http://neuro.uni.kn/DoOR), and a downloadable, open source toolbox written in R, including all processed and original datasets. DoOR now gives reliable odorant-responses for nearly all Drosophila olfactory responding units, listing 693 odorants, for a total of 7381 data points.

More than apples and oranges--detecting cancer with a fruit fly's antenna.
Cancer cells and non-cancer cells differ in their metabolism and they emit distinct volatile compound profiles, allowing to recognise cancer cells by their scent. Insect odorant receptors are excellent chemosensors with high sensitivity and a broad receptive range unmatched by current gas sensors. We thus investigated the potential of utilising the fruit fly's olfactory system to detect cancer cells. Using in vivo calcium imaging, we recorded an array of olfactory receptor neurons on the fruit fly's antenna. We performed multidimensional analysis of antenna responses, finding that cell volatiles from different cell types lead to characteristic response vectors. The distances between these response vectors are conserved across flies and can be used to discriminate healthy mammary epithelial cells from different types of breast cancer cells. This may expand the repertoire of clinical diagnostics, and it is the first step towards electronic noses equipped with biological sensors, integrating artificial and biological olfaction.

Weaker ligands can dominate an odor blend due to syntopic interactions.
Most odors in natural environments are mixtures of several compounds. Perceptually, these can blend into a new "perfume," or some components may dominate as elements of the mixture. In order to understand such mixture interactions, it is necessary to study the events at the olfactory periphery, down to the level of single-odorant receptor cells. Does a strong ligand present at a low concentration outweigh the effect of weak ligands present at high concentrations? We used the fruit fly receptor dOr22a and a banana-like odor mixture as a model system. We show that an intermediate ligand at an intermediate concentration alone elicits the neuron's blend response, despite the presence of both weaker ligands at higher concentration, and of better ligands at lower concentration in the mixture. Because all of these components, when given alone, elicited significant responses, this reveals specific mixture processing already at the periphery. By measuring complete dose-response curves we show that these mixture effects can be fully explained by a model of syntopic interaction at a single-receptor binding site. Our data have important implications for how odor mixtures are processed in general, and what preprocessing occurs before the information reaches the brain.

ASSESSMENT OF THE INSULAR CORTEX SUBREGIONS ACTIVITY INDUCED BY TASTE EXPOSURE.

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Marta Valero[1], Beatriz Gomez-Chacon[2], Milagros Gallo[1]
[1]Institute of Neuroscience "F. Olóriz" - Biomedical research Centre - University of Granada, Department Of Psychobiology, Armilla, Spain, [2]University of Granada, Department Of Psychobiology, Institute Of Neurosciences, Center Of Biomedical Research, Armilla, Spain

Previous research on the role of particular insular cortex regions in processing taste and taste novelty recognition has pointed to the insular disgranular gustatory cortex. However, studies dissociating disgranular (gustatory), granular (visceral) and agranular insular cortex regions are lacking. The present study aimed to assess activity changes associated with taste novelty and familiarization in the insular cortex subregions of adult Wistar rats. As an index of neural activation, the number of positive c-Fos cells was counted in different groups during the water baseline (BL), first (Novel), second (Familiar 2) and sixth (Familiar 6) exposures to a sodium saccharin solution (0,5%). All groups showed reduced saccharin consumption on Day 1 indicating taste neophobia which was attenuated on the following exposures. The results showed lower number of Fos positive nuclei in the agranular than granular and disgranular insular cortex regions with no differences between the groups so that this region was used as the control area. Higher number of Fos positive cells was found in the disgranular insular cortex when compared with the control region in the Novel group, this supporting the role in processing taste novelty found in previous studies. The granular insular cortex exhibited higher number of Fos positive cells than the control agranular area in all the groups, this indicating a nonspecific involvement of the insular granular cortex receiving visceral afferents in fluids intake which can be related with basal hydromineral regulation. Supported by PSI2017-86381-P (MINECO) and PID2020-114269GB-I00 (MICIU, Spain). Key Words: Neophobia, c-fos, taste learning, insular cortex, rats.

Neuropeptides play a key role in regulating animal's physiology and behavior. One of their important functions is to mediate information about the internal state of the animal, which is essential for controlling several behaviors, such as feeding. While we know that animals modify their food choices to respond to the lack of specific nutrients, the mechanisms mediating nutrient-specific appetites remain unclear. We have identified *marmite*, an uncharacterized gene encoding a secreted peptide with unknown function in *Drosophila*. Bioinformatic analyses suggest that it is a member of a broad family of poorly characterized conserved neuropeptides including vertebrate orthologues, which have previously been proposed to control feeding. We found that *marmite* expression is upregulated in amino acid-rich diets compared to amino-acid-poor diets. To characterize whether *marmite* is involved in feeding decisions, we used the flyPAD technology, a capacitance-based setup that enables a quantitative feeding analysis, together with CRISPR-Cas9-based genome engineering techniques. Neuronal knockdown of *marmite* or neuronal silencing of *marmite*-expressing neurons increases yeast feeding in fully-fed flies. Moreover, activation of these neurons is sufficient to reduce yeast feeding in a *marmite*-dependent manner, suggesting that *marmite* acts as an amino acid specific satiety signal. We also investigated the functional conservation of *marmite* and its vertebrate orthologues and we found that neuronal expression of either *marmite* or the human orthologue is sufficient to decrease feeding in flies. Thus, we have identified a novel class of conserved neuropeptides that play a key role in nutritional homeostasis and feeding decisions across phyla.

Metabolic cross-feeding in imbalanced diets allows gut microbes to improve reproduction and alter host behaviour.
The impact of commensal bacteria on the host arises from complex microbial-diet-host interactions. Mapping metabolic interactions in gut microbial communities is therefore key to understand how the microbiome influences the host. Here we use an interdisciplinary approach including isotope-resolved metabolomics to show that in Drosophila melanogaster, Acetobacter pomorum (Ap) and Lactobacillus plantarum (Lp) a syntrophic relationship is established to overcome detrimental host diets and identify Ap as the bacterium altering the host's feeding decisions. Specifically, we show that Ap uses the lactate produced by Lp to supply amino acids that are essential to Lp, allowing it to grow in imbalanced diets. Lactate is also necessary and sufficient for Ap to alter the fly's protein appetite. Our data show that gut bacterial communities use metabolic interactions to become resilient to detrimental host diets. These interactions also ensure the constant flow of metabolites used by the microbiome to alter reproduction and host behaviour.

Commensal bacteria and essential amino acids control food choice behavior and reproduction.
Choosing the right nutrients to consume is essential to health and wellbeing across species. However, the factors that influence these decisions are poorly understood. This is particularly true for dietary proteins, which are important determinants of lifespan and reproduction. We show that in Drosophila melanogaster, essential amino acids (eAAs) and the concerted action of the commensal bacteria Acetobacter pomorum and Lactobacilli are critical modulators of food choice. Using a chemically defined diet, we show that the absence of any single eAA from the diet is sufficient to elicit specific appetites for amino acid (AA)-rich food. Furthermore, commensal bacteria buffer the animal from the lack of dietary eAAs: both increased yeast appetite and decreased reproduction induced by eAA deprivation are rescued by the presence of commensals. Surprisingly, these effects do not seem to be due to changes in AA titers, suggesting that gut bacteria act through a different mechanism to change behavior and reproduction. Thus, eAAs and commensal bacteria are potent modulators of feeding decisions and reproductive output. This demonstrates how the interaction of specific nutrients with the microbiome can shape behavioral decisions and life history traits.

Assessing the molecular basis of transferable quinolone resistance in Escherichia coli and Salmonella spp. from food-producing animals and food products.
Enterobacteriaceae resistant to quinolones frequently arise in animals, being easily disseminated through the food-chain. The aim of this study was to investigate the presence of plasmid-mediated quinolone resistance (PMQR) determinants in Salmonella spp. (n=183) and Escherichia coli (n=180) isolates, collected from food-producing animals and food products among swine, poultry, rabbits and cattle. All isolates were subjected to antimicrobial susceptibility testing and molecular screening of PMQR determinants. β-Lactamase-encoding genes, and the quinolone resistance determining region (QRDR) of gyrA, gyrB, parC and parE genes were also investigated in PMQR-positive isolates. Plasmid characterization was performed by conjugation, followed by replicon-typing. Genetic relatedness of PMQR-positive E. coli was examined by Multilocus Sequence Typing, while Salmonella was previously serotyped. The association of mobile genetic elements and PMQR was investigated through PCR mapping assays. Overall, 4.1% (15/363) isolates harbored qnrB2 (n=3), qnrB19 (n=3), and qnrS1 (n=9) genes. All but one isolate presented one to four mutations in QRDR of gyrA or parC genes, which is consistent with the range of MIC values detected (0.19-64 mg/L) for ciprofloxacin; 60% (9/15) of qnr-harboring isolates were non-susceptible to β-lactam antibiotics which was justified by the presence of β-lactamases from TEM (TEM-1, n=8; TEM-135, n=1) and SHV (SHV-108, n=1) families. Analysis of mobile genetic elements revealed that qnr genes were detected nearby relevant genetic elements like intI1, ISEcl2, IS26 and ISCR1 and enclosed in diverse Inc. type plasmids. This study illustrated the existence of Qnr-producing E. coli and Salmonella from food-producing animals, associated to specific mobile elements that might mediate their transference between species and among distinct settings.

VENTRAL TEGMENTAL AREA GLUTAMATERGIC NEURONS PLAY A ROLE IN FEAR-INDUCED HYPOPHAGIA THROUGH LATERAL HYPOTHALAMIC GLUTAMATERGIC INPUTS

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Flavia Barbano[1], Emma Chen[1], Shiliang Zhang[2], Bing Liu[1], Marisela Morales[1]
[1]NIDA/NIH, Neuronal Networks Section, Baltimore, United States of America, [2]National Institute on Drug Abuse, Confocal And Electron Microscopy Core, Baltimore, United States of America

We have shown that Ventral Tegmental Area (VTA) dopamine neurons are intermixed with glutamate neurons that receive glutamatergic inputs from lateral hypothalamus (LH), and this LH-VTA pathway plays a role in innate escape behavior. Here, we tested the role of this pathway in another innate behavior, feeding. By viral vectors, we selectively expressed channelrhodopsin (ChR2-mice), halorhodopsin (Halo-mice) or eYFP (control-mice) in LH-glutamatergic neurons. After food restriction, we found that VTA photostimulation of LH-glutamate fibers in ChR2-mice, but not in Halo- or control-mice, suppressed eating, indicating that VTA release of glutamate from LH inputs plays a role in feeding behavior. By in vivo recordings, we found that mice approach to an anesthetized rat induced activation of LH-glutamate neurons innervating VTA, indicating that VTA release of glutamate from LH inputs plays a role in innate fear behavior. Next, we tested food restricted Halo- and control-mice in absence of phostimulation and found that all mice decreased their food intake in the presence of the anesthetized rat. In contrast, VTA photoinhibition increased food intake in the presence of the anesthetized rat just in the Halo-mice, suggesting that inhibition of VTA glutamate release from LH neurons blocks fear-induced hypophagia. By genetic ablation of VTA-glutamatergic neurons, we found that in the presences or absence of the anesthetized rat, ablated mice ate the same amount of food, suggesting that fear-induced hypophagia is mediated by VTA glutamate neurons. We conclude that LH-glutamate neurons convey information to VTA-glutamate neurons for feeding modulation in response to innate threats.

CB1 RECEPTORS IN POMC NEURONS COORDINATE RESPONSES TO FEAR AND FOOD

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Cristina Miralpeix[1], Abel Eraso-Pichot[1], Urszula Skupio[1], Luigi Bellocchio[2], Carmelo Quarta[1], Giovanni Marsicano[1], Daniela Cota[1]

Pro-opiomelanocortin (POMC) expressing neurons in the arcuate nucleus of the hypothalamus are typically activated by energy availability and promote satiety. Recent findings from our lab have demonstrated that POMC neurons activity is affected in the first stages of dietary conditions leading to obesity, probably through a signaling pathway involving the cannabinoid CB1 receptors. Brain CB1 receptors are key physiological determinants of synaptic and behavioral functions. However, the role of CB1 receptors specifically in POMC neurons remains poorly understood. Here we have generated a novel mouse line that lacks CB1 only in POMC-expressing cells (POMC-CB1-KO). As compared to their control littermates, POMC-CB1-KO mice do not show any relevant change in the control of energy homeostasis. However, our behavioral analyses have shown that POMC-CB1-KO mice have a clear exacerbation of the fear-conditioned response. Although CB1 has been already described to control fear memories in other brain areas, the role of CB1 receptor in POMC neurons in the regulation of fear memory have never been assessed before. Considering that the canonical function of POMC neurons is the control of food intake, we hypothesized that CB1 receptors-dependent signaling in these neurons is at the intersection of fear and feeding responses. Accordingly, POMC-CB1-KO mice displayed blunted fear-induced suppression of feeding. While further studies are currently ongoing to decipher the potential underlying circuits involved in these responses, these results demonstrate that CB1 receptor in POMC neurons might play a key role in the balance between fear and feeding behavior, two motivational states essential for survival.

MELANOCORTIN SIGNALING IN THE PVH CAUSES SATIETY BY INPUT-SPECIFIC REGULATION OF SYNAPTIC PLASTICITY

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Marielle Minere[1], Henning Fenselau[1], Bradford Lowell[2], Nasim Biglari[1], Jon Resch[2], Thomas Wunderlich[1], Jens Brüning[1]
[1]Max Planck Institute, Metabolism, Cologne, Germany, [2]Beth Israel Deaconess Medical Center, Endocrinology, Boston, United States of America

Melanocortin-4 receptor (MC4R) signaling in the paraventricular hypothalamus (PVH) is fundamental for appetite regulation. Arcuate nucleus POMC (ARC^{POMC}) neurons release the anorexigenic MC4R agonist α-MSH in the PVH, but it remains unclear which downstream events in PVH^{MC4R} satiety neurons are critical for α-MSH's effects to reduce food intake. Here, by combining cell-type-specific chemogenetics and optogenetics, we electrophysiologically identify that α-MSH released by ARC^{POMC} neurons strengthens glutamatergic synaptic activity onto PVH^{MC4R} neurons. This occurs postsynaptically, and remarkably is selective for input coming from parallel-projecting ARC^{Glut} satiety neurons; glutamatergic input to these same PVH^{MC4R} neurons from median preoptic nucleus neurons is unaffected by α-MSH/MC4R signaling. Importantly, genetic deficiency of α-MSH, or fasting which naturally reduces activity of ARC^{POMC} neurons, greatly diminishes the ability of ARC^{Glut} satiety neurons to evoke action-potential firing in downstream PVH^{MC4R} neurons, and α-MSH deficiency completely blocks the ability of ARC^{Glut} satiety neurons to decrease feeding. Thus, ARC^{POMC} neurons and α-MSH/MC4R signaling in PVH^{MC4R} neurons induce satiety by adjusting the gain on transmission across the ARC^{Glut}àPVH^{MC4R} synapse.

PNOC Neurons Promote Hyperphagia and Obesity upon High-Fat-Diet Feeding.
Calorie-rich diets induce hyperphagia and promote obesity, although the underlying mechanisms remain poorly defined. We find that short-term high-fat-diet (HFD) feeding of mice activates prepronociceptin (PNOC)-expressing neurons in the arcuate nucleus of the hypothalamus (ARC). PNOC neurons represent a previously unrecognized GABAergic population of ARC neurons distinct from well-defined feeding regulatory AgRP or POMC neurons. PNOC neurons arborize densely in the ARC and provide inhibitory synaptic input to nearby anorexigenic POMC neurons. Optogenetic activation of PNOC neurons in the ARC and their projections to the bed nucleus of the stria terminalis promotes feeding. Selective ablation of these cells promotes the activation of POMC neurons upon HFD exposure, reduces feeding, and protects from obesity, but it does not affect food intake or body weight under normal chow consumption. We characterize PNOC neurons as a novel ARC neuron population activated upon palatable food consumption to promote hyperphagia.

Hypothalamic Pomc Neurons Innervate the Spinal Cord and Modulate the Excitability of Premotor Circuits.
Locomotion requires energy, yet animals need to increase locomotion in order to find and consume food in energy-deprived states. While such energy homeostatic coordination suggests brain origin, whether the central melanocortin 4 receptor (Mc4r) system directly modulates locomotion through motor circuits is unknown. Here, we report that hypothalamic Pomc neurons in zebrafish and mice have long-range projections into spinal cord regions harboring Mc4r-expressing V2a interneurons, crucial components of the premotor networks. Furthermore, in zebrafish, Mc4r activation decreases the excitability of spinal V2a neurons as well as swimming and foraging, while systemic or V2a neuron-specific blockage of Mc4r promotes locomotion. In contrast, in mice, electrophysiological recordings revealed that two-thirds of V2a neurons in lamina X are excited by the Mc4r agonist α-MSH, and acute inhibition of Mc4r signaling reduces locomotor activity. In addition, we found other Mc4r neurons in spinal lamina X that are inhibited by α-MSH, which is in line with previous studies in rodents where Mc4r agonists reduced locomotor activity. Collectively, our studies identify spinal V2a interneurons as evolutionary conserved second-order neurons of the central Mc4r system, providing a direct anatomical and functional link between energy homeostasis and locomotor

control systems. The net effects of this modulatory system on locomotor activity can vary between different vertebrate species and, possibly, even within one species. We discuss the biological sense of this phenomenon in light of the ambiguity of locomotion on energy balance and the different living conditions of the different species.

Differential Coassembly of α1-GABARs Associated with Epileptic Encephalopathy.
GABA receptors (GABARs) are profoundly important for controlling neuronal excitability. Spontaneous and familial mutations to these receptors feature prominently in excitability disorders and neurodevelopmental deficits following disruption to GABA-mediated inhibition. Recent genotyping of an individual with severe epilepsy and Williams-Beuren syndrome identified a frameshifting variant in a major GABAR gene, This truncated the α1 subunit between the third and fourth transmembrane domains and introduced 24 new residues forming the mature protein, α1* Cell surface expression of mutant murine GABARs is severely impaired compared with WT, due to retention in the endoplasmic reticulum. Mutant receptors were differentially coexpressed with β3, but not with β2, subunits in mammalian cells. Reduced surface expression was reflected by smaller IPSCs, which may underlie the induction of seizures. The mutant does not have a dominant-negative effect on native neuronal GABAR expression since GABA current density was unaffected in hippocampal neurons, although mutant receptors exhibited limited GABA sensitivity. To date, the underlying mechanism is unique for epileptogenic variants and involves differential β subunit expression of GABAR populations, which profoundly affected receptor function and synaptic inhibition. GABARs are critical for controlling neural network excitability. They are ubiquitously distributed throughout the brain, and their dysfunction underlies many neurologic disorders, especially epilepsy. Here we report the characterization of an α1-GABAR variant that results in severe epilepsy. The underlying mechanism is structurally unusual, with the loss of part of the α1 subunit transmembrane domain and part-replacement with nonsense residues. This led to compromised and differential α1 subunit cell surface expression with β subunits resulting in severely reduced synaptic inhibition. Our study reveals that disease-inducing variants can affect GABAR structure, and consequently subunit assembly and cell surface expression, critically impacting on the efficacy of synaptic inhibition, a property that will orchestrate the extent and duration of neuronal excitability.

GABAR isoform and subunit structural motifs determine synaptic and extrasynaptic receptor localisation.
GABA receptors (GABARs) are the principal inhibitory neurotransmitter receptors in the central nervous system. They control neuronal excitability by synaptic and tonic forms of inhibition mostly mediated by different receptor subtypes located in specific cell membrane subdomains. A consensus suggests that α1-3βγ comprise synaptic GABARs, whilst extrasynaptic α4βδ, α5βγ and αβ isoforms largely underlie tonic inhibition. Although some structural features that enable the spatial segregation of receptors are known, the mobility of key synaptic and extrasynaptic GABARs are less understood, and yet this is a key determinant of the efficacy of GABA inhibition. To address this aspect, we have incorporated functionally silent α-bungarotoxin binding sites (BBS) into prominent hippocampal GABAR subunits which mediate synaptic and tonic inhibition. Using single particle tracking with quantum dots we demonstrate that GABARs that are traditionally considered to mediate synaptic or tonic inhibition are all able to access inhibitory synapses. These isoforms have variable diffusion rates and are differentially retained upon entering the synaptic membrane subdomain. Interestingly, α2 and α4 subunits reside longer at synapses compared to α5 and δ subunits. Furthermore, a high proportion of extrasynaptic δ-containing receptors exhibited slower diffusion compared to δ subunits at synapses. A chimera formed from δ-subunits, with the intracellular domain of γ2L, reversed this behaviour. In addition, we observed that receptor activation affected the diffusion of extrasynaptic, but not of synaptic GABARs. Overall, we conclude that the differential mobility profiles of key synaptic and extrasynaptic GABARs are determined by receptor subunit composition and intracellular structural motifs. This article is part of the special issue entitled 'Mobility and trafficking of neuronal membrane proteins'.

MULTIMODAL MAPPING OF LATERAL HYPOTHALAMIC CIRCUITS THAT MEDIATE THE REGULATORY METABOLIC FUNCTIONS OF AGRP NEURONS

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Paul Mirabella, Saskia Stenzel, Henning Fenselau
Max Planck Institute for Metabolism Research, Synaptic Transmission In Energy Homeostasis Group, Köln, Germany

The ability to identify and characterise the cellular components of neural circuits is crucial for furthering our understanding of how the brain orchestrates complex homeostatic processes such as energy balance and peripheral glucose metabolism. Starvation-sensitive, agouti-related peptide (AgRP)-expressing neurons of the arcuate nucleus are known to control feeding behaviour and insulin resistance through inhibition of downstream neurons. However, the genetic identity of such synaptically-connected neurons remains elusive in most second-order sites, including the lateral hypothalamic area (LHA). Here, using a dual Cre- and Dre-recombinase-dependent strategy, we performed targeted ChR2-assisted circuit mapping (CRACM) studies to elucidate AgRP neuron connections to genetically-defined LHA neurons. We demonstrate that discrete neuronal populations receive monosynaptic, GABAergic input from AgRP neurons, and reveal their relative topographical distribution throughout the rostro-caudal extent of the LHA. Furthermore, immunohistochemical and fluorescent *in situ* hybridisation analyses show the extent of overlap between these identified downstream neuronal populations as well as their innervation by AgRP neurons. Subsequent systematic investigation of these circuits with complementary opto- and chemo-genetic approaches demonstrated the relevant contributions of these pathways to the feeding behaviour and insulin resistance that are evoked by AgRP terminal activation in the LHA. These findings identify not only previously unknown effector populations in the LHA that are involved in homeostatic control of metabolism, but also demonstrate the ability of dual recombinatorial strategies to precisely map neural circuits in the brain.

Suppression of Corticostriatal Circuit Activity Improves Cognitive Flexibility and Prevents Body Weight Loss in Activity-Based Anorexia in Rats.
The ability to adapt behavior to changing environmental circumstances, or cognitive flexibility, is impaired in multiple psychiatric conditions, including anorexia nervosa (AN). Exaggerated prefrontal cortical activity likely underpins the inflexible thinking and rigid behaviors exhibited by patients with AN. A better understanding of the neural basis of cognitive flexibility is necessary to enable treatment approaches that may target impaired executive control.

SINGLE-CELL MOLECULAR AND FUNCTIONAL MAPPING OF POMC NEURONS IN OBESITY: A MULTI-MODAL APPROACH

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Aims: The brain plays a crucial role in maintaining the body's energy needs, a process involving the activity of a group of hypothalamic neurons that express the neuropeptidergic marker pro-opiomelanocortin (POMC). POMC neuronal dysfunction can cause obesity and its associated metabolic sequelae. However, this population of neurons is highly diverse at a molecular and functional level, and whether or not such heterogeneity is implicated in disease establishment or progression has yet to be elucidated. Methods: Here, using a fate-tracing approach in combination with histological and electrophysiological tools, we have characterized POMC neuronal cells at a single-cell resolution in control lean and diet-induced obese (DIO) mice. We 'traced' with a reporter protein POMC neurons in adult mice, thus studying these neuronal cells independently from the expression of their main marker POMC. We used immunohistochemistry, fluorescent in-situ hybridization, and RNAscope to cluster genetically 'traced' POMC neuronal cells based on their expression of POMC. Results: These different approaches allowed the identification of a previously uncharacterized sub-population that expresses negligible POMC mRNA which we named ''Ghost''-POMC neurons. Intriguingly, DIO mice present an increased number of Ghost-POMC neurons relative to control animals. Furthermore, using whole-cell patch-clamp of traced POMC neurons with subsequent single-cell molecular profiling by qPCR, we observed that DIO leads to selective electrical alterations in these clusters with an atypical molecular profile. Conclusions: Thus, Ghost-POMC neurons might constitute a novel subpopulation of POMC neurons that undergo dysfunction in response to prolonged dietary cues, perhaps contributing to obesity establishment or progression.

OXYTOCIN INFLUENCES THE DEVELOPMENT OF THE MELANOCORTIN SYSTEM AND ADIPOSITY DURING DISTINCT PERIODS OF POSTNATAL LIFE

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Pierre-Yves Barelle[1], Fabienne Schaller[2], Françoise Muscatelli[3], Sebastien Bouret[4]
[1]UMR-s1172, Haut-de-france, Lille, France, [2]Inserm, Inmed, Marseille, France, [3]Institut de neurobiologie de la méditerranée, INSERM, Aix-marseille University, Marseille, France, [4]University of Lille, Lille Neuroscience & Cognition-inserm Umr-s 1172, Lille, France

Aims. The melanocortin system plays a critical role in the central regulation of metabolism. It consists of hypothalamic neurons producing pro-opiomelanocortin (POMC) and neurons producing agouti-related peptide (AgRP). It is now accepted that abnormal development of the melanocortin system contributes to obesity in later life. Recent data indicated that oxytocin (OT) treatment has beneficial effects on appetite, particularly when the neurohormone is administered neonatally. Here, we investigated whether OT influences the development of the melanocortin system with enduring consequences on adiposity, whether there is a critical period during which OT exerts maximal neurodevelopmental effects. Methods. A chemogenetic approach was used to silence OT neurons in *Ot*-Cre::hM4Di-DREADD mice during distinct periods of life (P0-P7, *early postnatal*; P25-P32, *juvenile period*; and P63-P70, *adulthood*). Neuroanatomical analysis was used to examine the effect of OT neurons' inhibition on the development of melanocortin circuits. We also evaluated the long-term impact of OT neurons silencing on body weight, fat mass, and adipocyte size. Results. Neonatal inhibition of OT neurons disrupted the development of POMC and AgRP axonal projections. It also increases body weight without affecting adiposity. In contrast, OT neurons inhibition during juvenile or adult life does not alter melanocortin circuits but it increases body weight. Juvenile OT neurons' inhibition also increased fat mass associated with bigger adipocytes. Conclusions. OT influences the development of melanocortin circuits during a critical period restricted to neonatal life. However, OT can still exert metabolic effects in later life through mechanisms that remain to be investigated.

Communication between the gut and the brain is critical for homeostatic regulation of metabolism. Sensory neurons relay nutrient-related signals to the brain, but investigating the functional neurocircuits of distinct populations has been limited by the difficulty of targeting the ganglia they reside in. Here, we describe an intersectional genetic approach for mapping and manipulating molecularly distinct sensory neurons. We reconstruct the gut innervation patterns of numerous discrete vagal and spinal populations and define their downstream targets in the brainstem and spinal cord. Chemogenetic manipulations, coupled with behavioral analysis and optogenetic mapping, demonstrate that stomach-innervating vagal afferents relay anorexigenic signals via the nucleus of the solitary tract to parabrachial nucleus neurons that control meal termination. Further, we show that stomach-innervating vagal afferent activation improves glucose tolerance, and that their inhibition elevates blood glucose levels independent of food intake. Small intestine-innervating vagal afferents, in contrast, increase hepatic glucose production upon stimulation, and activate parabrachial neurons that control normoglycemia, but are dispensable for feeding regulation. These findings highlight functionally distinct sensory neuron circuits in the control of feeding and glucose metabolism.

Narcolepsy type 1 is a sleep disorder characterized by excessive daytime sleepiness and cataplexy. Postmortem brain analysis showed a large reduction of orexin-producing neurons in the lateral hypothalamus of narcolepsy patients. Transcriptional control of orexin is not well-known. In this study the role of MicroRNAs (miRNAs) as epigenetic regulators of orexin gene expression were tested. MiRNAs are small, non-coding, highly conserved RNAs which can block mRNA translation into protein. Dicer is an essential protein in the production of mature and functional miRNAs that can regulate or silence expression of target genes. Thus, we inactivated miRNAs in orexin neurons by deleting the floxed-Dicer alleles in orexin-Cre-ki mice (Orexin-Dicer-ko). We found that orexin expression is completely lost in Orexin-Dicer-ko mice, both at mRNA and protein levels, resulting in the typical narcolepsy symptoms such as cataplexy, sleepiness, difficulties to maintain long wakefulness and shorter Rapid-Eyes-Movements (REM) sleep latency. Interestingly, conditional deletion of miRNAs maturation in adult mice by using a tet-off system (Orexin-Dicer-cko) did not lead to the loss of orexin neurons 4 weeks after shutting down of miRNA maturation but a decrease of orexin neurons is observed 8 weeks after Dicer deletion. These results suggest that orexin neurons could survive without mature miRNAs during 4 weeks but not 8 weeks. Our findings suggest a major role for miRNAs in the development and maintenance of orexin neurons and add Orexin-Dicer-ko and Orexin-Dicer-cko as news mouse models of narcolepsy.

Hypocretinergic interactions with the serotonergic system regulate REM sleep and cataplexy.
Loss of muscle tone triggered by emotions is called cataplexy and is the pathognomonic symptom of narcolepsy, which is caused by hypocretin deficiency. Cataplexy is classically considered to be an abnormal manifestation of REM sleep and is treated by selective serotonin (5HT) reuptake inhibitors. Here we show that deleting the 5HT transporter in hypocretin knockout mice suppressed cataplexy while dramatically increasing REM sleep. Additionally, double knockout mice showed a significant deficit in the buildup of sleep need. Deleting one allele of the 5HT transporter in hypocretin knockout mice strongly increased EEG theta power during REM sleep and theta and gamma powers during wakefulness. Deleting hypocretin receptors in the dorsal raphe neurons of adult mice did not induce cataplexy but consolidated REM sleep. Our results indicate that cataplexy and REM sleep are regulated by different mechanisms and both states and sleep need are regulated by the hypocretinergic input into 5HT neurons.

Impact of Fetal Growth Restriction on the Neonatal Microglial Proteome in the Rat.
Microglial activation is a key modulator of brain vulnerability in response to intra-uterine growth restriction (IUGR). However, the consequences of IUGR on microglial development and the microglial proteome are still unknown. We used a model of IUGR induced by a gestational low-protein diet (LPD) in rats. Microglia, isolated from control and growth-restricted animals at P1 and P4, showed significant changes in the proteome between the two groups. The expression of protein sets associated with fetal growth, inflammation, and the immune response were significantly enriched in LPD microglia at P1 and P4. Interestingly, upregulation of protein sets associated with the oxidative stress response and reactive oxygen species production was observed at P4 but not P1. During development, inflammation-associated proteins were upregulated between P1 and P4 in both control and LPD microglia. By contrast, proteins associated with DNA repair and senescence pathways were upregulated in only LPD microglia. Similarly, protein sets involved in protein retrograde transport were significantly downregulated in only LPD microglia. Overall, these data demonstrate significant and multiple effects of LPD-induced IUGR

on the developmental program of microglial cells, leading to an abnormal proteome within the first postnatal days. Nutrients, 2021; 13

VISUALIZING INPUT-OUTPUT ARCHITECTURE OF OREXIN NEURONS WITH RETROGRADE TRACING VECTORS

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Yuki Saito, Yoan Cherasse, Yasutaka Niwa, Takeshi Sakurai
University of Tsukuba, Wpi-iiis, Sakurai/hirano Laboratory, Tsukuba, Japan

Orexin-producing neurons (orexin neurons), located in the lateral hypothalamic area (LHA), play a highly important role in maintaining wakefulness. Orexin neurons send widespread projections to nuclei containing monoaminergic neurons such as ventral tegmental area (VTA), locus coeruleus (LC), tuberomammillary nucleus (TMN), and raphe nuclei (Nambu, et al., 1999), all of which contain monoaminergic neurons. We previously identified input neurons that make direct synaptic contacts to orexin neurons with modified rabies vector-based retrograde tracing (Saito, et al., 2018). This study showed orexin neurons receive input from various regions of the brain. It has been still unknown whether orexin neuron populations that send projections to particular regions receive biased input circuits. In this study, to identify the neuronal inputs to the orexin neurons with projections to particular regions, we used projection sites-specific rabies monosynaptic retrograde tracing (Piñol, et al., 2018). We used newly generated *orexin-iCre KI* mice to analyze the input-output relationship of orexin neuronal circuits using the modified multi-color simple-cTRIO method. This new method allowed us to detect more than two different input-output pathways in the same brain. This study revealed that orexin neurons projecting to each output region also send projections to all brain regions we examined previously. Orexin neurons integrate information from the broad areas of the brain and broadcast it to all monoaminergic nuclei and the other regions. However, we found some biased input and output architectures.

GATING OF HUNGER AND ANXIETY SIGNALING THROUGH NPY-DEPENDENT SYNAPTIC PLASTICITY IN THE BNST

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Stephan Dodt[1,2,3,4], Jens Brüning[1], Henning Fenselau[1]
[1]Max-Planck-Institute für Stoffwechselforschung, Synaptic Transmission In Energy Homeostasis, Köln, Germany, [2]Max-Planck-Institute für Stoffwechselforschung, Neuronale Control Of Metabolism, Köln, Germany, [3]Universitätsklinikum Bonn, Institute For Pharmacology And Toxocology, Bonn, Germany, [4]Deutsche Forschungsgemeinschaft, Rtg 1873, Bonn, Germany

Effective coordination of hunger drive requires suppression of competing motivational systems, such as anxiety-related behavior and fear action. Hypothalamic agouti-related peptide (**AgRP**)-expressing neurons are a central element in the control of hunger. They are activated by energy deficit, such as fasting, and their acute stimulation triggers voracious food consumption. One projection site through which AgRP neurons influence feeding behavior is the bed nucleus of the stria terminalis (**BNST**). While the BNST is also a key node for the control of anxiety, it is unknown whether and how AgRP neurons' projections to the BNST affect hunger state-dependent modulation of anxiety signaling. Here, using optogenetics combined with electrophysiological recordings, we show that synaptic connectivity between AgRP hunger neurons and neurons in the BNST is strengthened in response to fasting as well as upon an exclusive stimulation of AgRP neurons. Moreover, analysis of GABAergic synaptic transmission onto the same BNST neurons from the central amygdala (CeA), which is essential for driving anxiety, is profoundly reduced in the fasted state. Importantly, these effects are mediated by NPY released from AgRP neurons, since there are no comparable effects in NPY-KO mice, whereas selective re-expression of NPY exclusively in AgRP neurons of NPY-KO mice is sufficient to reproduce the fasting-induced adaptations of both AgRP and CeA synapses. Our data provide evidence that AgRP neuron-mediated release of NPY triggers plastic changes in the synaptic formation of AgRP neurons in the BNST while it also causes heterosynaptic adaptation of another neuronal circuit which controls anxiety.

LRP2 FUNCTION IN THE CONTROL OF LEPTIN TRANSPORT BY HYPOTHALAMIC TANYCYTES

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Fatima Timzoura
Inserm, University of Lille, CHU Lille UMR-S 1172 Lille Neuroscience & Cognition Research Center, Development And Plasticity Of The Neuroendocrine Brain, Lille, France

Introduction. Obesity is the primary risk factor for the development of type 2 diabetes and cardiovascular diseases. Obese patients show high circulating leptin levels that fail to reduce appetite or increase energy expenditure. Although the leptin receptor (LepR) is thought to be a key candidate for leptin transport, emerging data suggest that low-density lipoprotein receptor-related protein-2 (LRP2) function as potential leptin transporter that can deliver circulating leptin into the brain, through tanycytes, likely via its association with the LepR. Methods. To investigate the physiological role of LRP2 in leptin transport by tanycytes, we will investigate the effect of selectively knocking out LRP2 in tanycytes on energy expenditure (O_2 consumption and locomotor activity will be measured using the metabolic cages) and body composition (fat and lean body mass will be assessed with MRI) using the Rax-CreER^{T2}; LRP2$^{lox/lox}$ mouse model. We will also determine whether deleting LRP2 from tanycytes blocks leptin uptake in the ME and its transport into the mediobasal hypothalamus (MBH) in vivo by assessing leptin-induced Stat3 phosphorylation in the hypothalamus. Results/expected results. If tanycytic LRP2 plays a role in leptin transport mice lacking LRP2 in tanycytes will display hyperphagia and obesity. Conclusions. Our results will establish the role of tanycytic LRP2 in the transport of blood-borne leptin into the hypothalamus in association or not with the LepR.

Polycystic ovary syndrome is transmitted via a transgenerational epigenetic process.
Polycystic ovary syndrome (PCOS) is the most common reproductive and metabolic disorder affecting women of reproductive age. PCOS has a strong heritable component, but its pathogenesis has been unclear. Here, we performed RNA sequencing and genome-wide DNA methylation profiling of ovarian tissue from control and third-generation PCOS-like mice. We found that DNA hypomethylation regulates key genes associated with PCOS and that several of the differentially methylated genes are also altered in blood samples from women with PCOS compared with healthy controls. Based on this insight, we treated the PCOS mouse model with the methyl group donor S-adenosylmethionine and found that it corrected their transcriptomic, neuroendocrine, and metabolic defects. These findings show that the transmission of PCOS traits to future generations occurs via an altered landscape of DNA methylation and propose methylome markers as a possible diagnostic landmark for the condition, while also identifying potential candidates for epigenetic-based therapy.

The Relaxin-Family Peptide 3 receptor (RXFP3) is a G-protein-coupled receptor that modulates several physiological processes, such as appetite. RXFP3 has promise as a target for treating obesity and other neurological disorders, but realising its clinical potential requires developing an RXFP3-specific drug that penetrates the blood-brain barrier. **AIM:** These studies involved the *in vivo* testing of a recently developed RXFP3 antagonist (inhibitor) drug, that has been designed to cross the blood-brain barrier. **METHODS:** On the test day, adult male C57Bl-6 mice were intraperitoneally injected with an RXFP3 antagonist drug (dose: 0.25 µmol/kg and 0.50 µmol/kg) and given highly palatable food from 30–60 min post-injection. To determine the pharmacological selectivity of this effect, RXFP3 knock-out mice were tested in parallel. P-values were calculated using two-way ANOVA (repeated measures/multiple comparisons) **RESULTS:** Mice that received a dose of 0.25 µmol/kg displayed no significant differences in food consumption compared to saline-injected controls. By increasing the dose to 0.50 µmol/kg, RXFP3 antagonist treatment significantly reduced food consumption to approximately 30% of saline values (P=0.0055). RXFP3 antagonist treatment did not alter food consumption in RXFP3 knock-out mice, suggesting that the anorexigenic effects of this drug during the 30–60 min period are primarily driven by 'on target' activity at the RXFP3 receptor. However, video analysis of home-cage behaviours revealed 'off-target' sedative effects in the 20 mins after drug injection for both wild-type and RXFP3 knock-out mice. **CONCLUSION:** Characterisation of the pharmacological profile of this and related compounds assist the further refinement and development of RXFP3 antagonists.

Phenotyping neurons activated in the mouse brain during restoration of salt debt.
Salt overconsumption contributes to hypertension, which is a major risk factor for stroke, heart and kidney disease. Characterising neuronal pathways that may control salt consumption is therefore important for developing novel approaches for reducing salt overconsumption. Here, we identify neurons within the mouse central amygdala (CeA), lateral parabrachial nucleus (LPBN), intermediate nucleus of the solitary tract (iNTS), and caudal NTS (cNTS) that are activated and display Fos immunoreactivity in mice that have consumed salt in order to restore a salt debt, relative to salt replete and salt depleted controls. Double-label immunohistochemical studies revealed that salt restoring mice had significantly greater densities of activated enkephalin neurons within the CeA and iNTS, while statistically significant changes within the LPBN and cNTS were not observed. Furthermore, within the CeA, restoration of salt debt conferred a significant increase in the density of activated calretinin neurons, while there was no change relative to control groups in the density of activated neurons that co-expressed protein kinase C delta (PKC-δ). Taken together, these studies highlight the importance of opioid systems within the CeA and iNTS in neuronal processes associated with salt restoration, and may aid the development of future pharmacological and other strategies for reducing salt overconsumption.

Differential Level of RXFP3 Expression in Dopaminergic Neurons Within the Arcuate Nucleus, Dorsomedial Hypothalamus and Ventral Tegmental Area of RXFP3-Cre/tdTomato Mice.
RXFP3 (relaxin-family peptide 3 receptor) is the cognate G-protein-coupled receptor for the neuropeptide, relaxin-3. RXFP3 is expressed widely throughout the brain, including the hypothalamus, where it has been shown to modulate feeding behavior

and neuroendocrine activity in rodents. In order to better characterize its potential mechanisms of action, this study determined whether RXFP3 is expressed by dopaminergic neurons within the arcuate nucleus (ARC) and dorsomedial hypothalamus (DMH), in addition to the ventral tegmental area (VTA). Neurons that express RXFP3 were visualized in coronal brain sections from RXFP3-Cre/tdTomato mice, which express the tdTomato fluorophore within RXFP3-positive cells, and dopaminergic neurons in these areas were visualized by simultaneous immunohistochemical detection of tyrosine hydroxylase-immunoreactivity (TH-IR). Approximately 20% of ARC neurons containing TH-IR coexpressed tdTomato fluorescence, suggesting that RXFP3 can influence the dopamine pathway from the ARC to the pituitary gland that controls prolactin release. The ability of prolactin to reduce leptin sensitivity and increase food consumption therefore represents a potential mechanism by which RXFP3 activation influences feeding. A similar proportion of DMH neurons containing TH-IR expressed RXFP3-related tdTomato fluorescence, consistent with a possible RXFP3-mediated regulation of stress and neuroendocrine circuits. In contrast, RXFP3 was barely detected within the VTA. TdTomato signal was absent from the ARC and DMH in sections from Rosa26-tdTomato mice, suggesting that the cells identified in RXFP3-Cre/tdTomato mice expressed authentic RXFP3-related tdTomato fluorescence. Together, these findings identify potential hypothalamic mechanisms through which RXFP3 influences neuroendocrine control of metabolism, and further highlight the therapeutic potential of targeting RXFP3 in feeding-related disorders.

For effective foraging, animals will often restrict their food intake, passing up a nutritional food source if their surroundings indicate that a preferred or more nutritionally dense option will be available in the near future, thus allowing them to maximize their energy input. This behavioural construct is known as anticipatory negative contrast (ANC) and has been experimentally investigated for determining the psychological processes regarding restrictive eating and those involving over-consumption (i.e. binge-like eating). Using a rat model of ANC where a carbohydrate-rich solution (maltodextrin 2%, saccharine 0.2%) is followed by a preferred condensed milk solution (50/50% condensed milk/carbohydrate-rich solution), the current study aims to relate activity in the medial prefrontal cortex (mPFC) and lateral hypothalamus (LH) – brain regions critical for impulse control and food-seeking behaviour, respectively - to licking behaviour during different phases of ANC. Using a fibre photometry approach where the Ca^{2+} indicator GCamp6s was expressed and imaged for measuring population activity, PFC and LH activity was monitored in separate animals and related to food intake during both phases throughout ANC training. Our preliminary results suggest that both the mPFC and LH neural populations respond to licking for both solutions, each showing differential learning-related alterations in their response profiles as ANC develops. These differential changes in PFC and LH activity may underlie different neural mechanisms for establishing ANC.

Phosphodiesterase type 1 inhibition alters medial prefrontal cortical activity during goal-driven behaviour and partially reverses neurophysiological deficits in the rat phencyclidine model of schizophrenia.
Positive modulation of cAMP signalling by phosphodiesterase (PDE) inhibitors has recently been explored as a potential target for the reversal of cognitive and behavioural deficits implicating the corticoaccumbal circuit. Previous studies show that PDE type 1 isoform B (PDE1B) inhibition may improve memory function in rodent models; however, the contribution of PDE1B inhibition to impulsivity, attentional and motivational functions as well as its neurophysiological effects have not been investigated. To address this, we recorded single unit activity in medial prefrontal cortex (mPFC) and nucleus accumbens (NAc) in Lister Hooded rats treated with the PDE1B inhibitor Lu AF64386 and tested in the 5-choice serial reaction time task (5-CSRTT). We also asked whether PDE1B inhibition modulates neurophysiological deficits produced by subchronic phencyclidine (PCP) treatment, a rat pharmacological model of schizophrenia. Lu AF64386 significantly affected behavioural parameters consistent with a reduction in goal-directed behaviour, however without affecting accuracy. Additionally, it reduced mPFC neuronal activity. Pre-treatment with PCP did not affect behavioural parameters, however it significantly disrupted overall neuronal firing while increasing phasic responses to reward-predicting cues and disrupting mPFC-NAc cross-talk. The latter two effects were reversed by Lu AF64386. These findings suggest PDE1B inhibition may be beneficial in disorders implicating a dysfunction of the mPFC-NAc network.

Predictive and motivational factors influencing anticipatory contrast: A comparison of contextual and gustatory predictors in food restricted and free-fed rats.
In anticipation of palatable food, rats can learn to restrict consumption of a less rewarding food type resulting in an increased consumption of the preferred food when it is made available. This construct is known as anticipatory negative contrast (ANC) and can help elucidate the processes that underlie binge-like behavior as well as self-control in rodent motivation models. In the current investigation we aimed to shed light on the ability of distinct predictors of a preferred food choice to generate contrast effects and the motivational processes that underlie this behavior. Using a novel set of rewarding solutions, we directly compared contextual and gustatory ANC predictors in both food restricted and free-fed Sprague-Dawley rats. Our

results indicate that, despite being food restricted, rats are selective in their eating behavior and show strong contextually-driven ANC similar to free-fed animals. These differences mirrored changes in palatability for the less preferred solution across the different sessions as measured by lick microstructure analysis. In contrast to previous research, predictive cues in both food restricted and free-fed rats were sufficient for ANC to develop although flavor-driven ANC did not relate to a corresponding change in lick patterning. These differences in the lick microstructure between context- and flavor-driven ANC indicate that the motivational processes underlying ANC generated by the two predictor types are distinct. Moreover, an increase in premature port entries to the unavailable sipper - a second measure of ANC - in all groups reveals a direct influence of response competition on ANC development.

CHEMOGENETIC CONTROL OF TMN-HA NEURONS ACTIVITY MODULATES THE EXPRESSION OF MEMORY AND FEEDING BEHAVIOUR.

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Background: The histaminergic system has a cardinal role in regulating animals' performance in various learning paradigms and feeding behaviour. However, our current knowledge of the role of neuronal histamine (HA) in memory and feeding behaviour is based on its depletion, or acute local injections of histaminergic ligands, which present inherent technical limitations. Aim: Here, we investigated the impact of activating or silencing endogenous histaminergic neurotransmission using chemogenetic tools. Methods: To interrogate the function of brain HA we used the DREADDs-driven technology injecting HDC-Cre mice bilaterally into the TMN with excitatory or inhibitory DREADDs to transfect histaminergic cells. The mice were then tested for social, fear memories and feeding behaviour. Results: We observed an opposite effect when TMN^{HA} cells are modulated. When stimulated the HA cells lead to an improvement of social and fear memories, while if inhibited an impairment is apparent. Consistently, TMN^{HA} stimulation induces a reduction of food intake. TMN^{HA} inhibition, instead, is responsible for increased food intake. Conclusions: We revealed that selective chemogenetic activation or inhibition of TMN^{HA} cells results in facilitation or impairment of memory, respectively. Similarly, HA cells activation reduces, whereas its inhibition increases food intake. These results confirm and expand previous reports regarding the role of neuronal HA in the regulation of memory and feeding behaviour and pave the way for future studies to deconstruct specific histaminergic neural pathways involved in different types and memory phases as well as the regulatory mechanisms underlying the control of feeding.

HIGH FAT DIET FEEDING DISRUPTS NUCLEUS ACCUMBENS CORE REGULATED MOTIVATIONAL CONTROL OVER FOOD-SEEKING BEHAVIOUR

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Joanne Gladding, Vincent Laurent
UNSW, School Of Psychology, Kensington, Australia

Food intake is governed by homeostatic and hedonic mechanisms and is disrupted in obesity. The nucleus accumbens core (NAcC) is a hedonic regulator, mediating the metabolic control of food intake. This function can be studied using the general Pavlovian Instrumental Transfer (gPIT) paradigm, during which a stimulus predicting a food outcome is found to energize performance of an instrumental action earning another food outcome. This energizing effect is distorted in obesity-prone rats, in rats tested sated and in rats with abnormal functioning of the NAcC or its cholinergic interneurons (CINs). However, whether obesity-related brain insulin resistance can modulate gPIT and if this modulation involves a loss of insulin function on NAcC CINs is unknown. Here we investigated the effect of high fat diet (HFD) feeding and excision of the insulin receptor on NAcC CINs (Knockout) on gPIT. We used a dietary induced obesity protocol and Cre-Lox transgenics to assess gPIT when mice were hungry or sated. We found that gPIT was not disrupted in HFD and Knockout mice when tested hungry. When tested sated though, gPIT was abolished in Knockout and control mice but was left intact in HFD mice. This persistent food-seeking was associated with changes in NAcC CINs functioning, but not with changes to NAcC CINs insulin signalling. These results indicate that a HFD can disrupt the ability for motivational states to control gPIT, but that overeating despite a lack of hunger may not be driven by insulin resistance or insulin dependent mechanisms.

The Effect of Intrahippocampal Insulin Infusion on Spatial Cognitive Function and Markers of Neuroinflammation in Diet-induced Obesity.
Obesity and high fat diet consumption contribute to the development of metabolic disorders, insulin resistance, neuroinflammation, and cognitive impairments. CNS administration of insulin into the brain can attenuate these cognitive impairments. The present study investigated whether hippocampal-dependent spatial memory impairments in a dietary induced mouse model of obesity could be improved by the direct administration of insulin into the hippocampus and whether this was associated with markers of hippocampal inflammation. C57Bl/6J mice consumed a low fat or high fat diet for 16 weeks and continuous intrahippocampal saline or insulin infusion for the final 4 weeks, during a period of behavioral testing, before gene expression analysis was performed. The high fat diet group demonstrated poorer spatial memory performance in the Morris water maze and Y-maze, supporting the hypothesis that high fat diet leads to hippocampal dependent cognitive impairment. Insulin infusion into the hippocampus reversed the deficit of high fat diet consumption on both of the tasks. Increased expression of inflammatory markers was detected in the hippocampus in the high fat diet group and expression of these markers was ameliorated in insulin infused mice. This demonstrates that CNS insulin can improve hippocampal-dependent memory and that hippocampal inflammation may be a factor in the development of cognitive deficits associated with diet-induced obesity. Furthermore, these data suggest that insulin may act to attenuate high fat diet induced cognitive deficits by reducing neuroinflammation.

The effect of insulin receptor deletion in neuropeptide Y neurons on hippocampal dependent cognitive function in aging mice.
Insulin is known to act in the central nervous system to regulate several physiological and behavioural outcomes, including energy balance, glucose homeostasis and cognitive functioning. However, the neuronal populations through which insulin enhances cognitive performance remain unidentified. Insulin receptors are found in neuropeptide-Y (NPY) expressing neurons, which are abundant in the hypothalamus and hippocampus; regions involved in feeding behaviour and spatial memory, respectively. Here we show that mice with a tissue specific knockout of insulin receptors in NPY expressing neurons (IR□o□x/l□o□x; NPYC□r□e□/+) display an impaired performance in the probe trial of the Morris Water Maze compared with control mice at both the 6 and the 12, but not at the 24 months time point, consistent with a crucial role of insulin and NPY in

cognitive functioning. By 24 months of age all groups demonstrated similar reductions in spatial memory performance. Together, these data suggest that the mechanisms through which insulin influences cognitive functioning are, at least in part, via insulin receptor signaling in NPY expressing neurons. These results also highlight that cognitive impairments observed in aging may be due to impaired insulin signaling.

EFFECT OF SATURATED VS UNSATURATED DIETARY FAT ON LEPTIN RECEPTOR SIGNALLING IN THE PREFRONTAL CORTEX AND HIPPOCAMPUS

POSTER SESSION 02 - SECTION: HYPOTHALAMIC CIRCUITS, HUNGER AND SATIETY

Jesús Fernández Felipe[1], Ana Belén Sanz Martos[2], Victoria Cano[1], Nuria Del Olmo[2], Mariano Ruiz Gayo[1], Beatriz Merino[1]
[1]CEU San Pablo University, Department Of Pharmaceutical And Health Sciences, Madrid, Spain, [2]Universidad Nacional de Educación a Distancia, Department Of Psychobiology, Madrid, Spain

Introduction: High-fat diets (HFDs) have a negative impact on cognition and neurotransmission when consumed during the juvenile period. The mechanism remains unknown, but a role of leptin receptors (LepR) has been proposed. Indeed, HFDs increase leptin production, able to promote leptin resistance in tissues like the hippocampus (HIP). However, the contribution of diet components to this endocrine alteration remains to be characterized. **AIM:** To evaluate in prefrontal cortex (PFC) and HIP the influence of **u**nsaturated **o**i**l**-enriched (UOLF) *vs* **s**aturated **o**i**l**-enriched **f**oods (SOLF) on i) LepR signalling pathways and ii) suppressor of cytokine signalling 3 (SOCS3) expression. **Methods**: Five-week-old male mice fed standard chow or UOLF/SOLF. After eight weeks of dietary treatment, mice received a single dose of leptin (1 mg/kg), and PFC/HIP samples were handled for PCR/western blot analysis. **Results**: In SOLF-fed mice, pSTAT3 was not enhanced by leptin neither in PFC nor in HIP. In contrast, in UOLF-mice, pSTAT3 was increased ($p<0.05$) by leptin in both areas. In regard to pAKT and pAMPK, leptin increased pAKT ($p<0.05$) and pAMPK levels ($p<0.05$) in SOLF mice but failed to promote pAKT and pAMPK in UOLF animals. Secondly, SOCS3 density was specifically augmented in the PFC of UOLF-mice. Finally, none of the two diets modified *Lepr* gene expression in PFC/HIP, compared to chow-fed mice. **Conclusions**: Our study shows that saturated and unsaturated fat intake negatively affects LepR signalling in the PFC/HIP. Differences between diets might account for the specific effects these diets have on cognition and HIP synaptic transmission and plasticity.

INTERROGATING MODULATORY EFFECTS OF CA2 ON THE PERSISTENCE AND ASSOCIATIVITY OF CA1 PLASTICITY IN MICE HIPPOCAMPUS

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Mohammad Zaki Bin Ibrahim, Nicholas Wee Kiat Koh, Sreedharan Sajikumar
National University of Singapore, Yong Loo Lin School Of Medicine Department Of Physiology, Singapore, Singapore

The hippocampus plays an integral role in episodic memory, particularly by neurons in CA1 subfield. Beyond the canonical circuitry is the CA2 region, implicated in social memory. There also exists monosynaptic connections from CA2 innervating CA1, which functional relevance is relatively unknown. We aimed to examine how the CA2-CA1 connections can modulate maintenance of long-term potentiation (LTP) in the Schaffer collateral (SC)-CA1 synapses. Field electrophysiology of hippocampal slices from young male C57BL/6 mice was performed to measure synaptic modification via long-term potentiation (LTP), a cellular correlate of learning and memory. Subthreshold stimulation of SC-CA1 synapses exhibit early form of LTP (early-LTP) but not persistent late form of LTP (late-LTP). However, when “primed” by activation of CA2, SC-CA1 synapses exhibit protein synthesis-dependent late-LTP upon subthreshold stimulation within a temporal window. Following this, we investigated the associativity of the CA2-primed late-LTP via the synaptic tagging and capture hypothesis (STC). When a second set of SC-CA1 synapses is weakly stimulated following CA2 priming, both the first and second population of SC-CA1 synapses can only exhibit early-LTP, thus not participating in STC. The CA2-primed late-LTP can only participate in STC when prior CA2 activation is increased in magnitude. This set of results demonstrate that CA2 connections onto CA1 can influence the synaptic plasticity of CA1, suggesting possible implications of how social behavioural states can modulate persistence of memory. Our next steps will involve analysing the molecular pathways and players involved in plasticity and signalling, and replicating the electrophysiological result using behavioural models.

Metaplastic Reinforcement of Long-Term Potentiation in Hippocampal Area CA2 by Cholinergic Receptor Activation. Hippocampal CA2, an inconspicuously positioned area between the well-studied CA1 and CA3 subfields, has captured research interest in recent years because of its role in social memory formation. However, the role of cholinergic inputs to the CA2 area for the regulation of synaptic plasticity remains to be fully understood. We show that cholinergic receptor activation with the nonselective cholinergic agonist, carbachol (CCh), triggers a protein synthesis-dependent and NMDAR-independent long-term synaptic depression (CCh-LTD) at entorhinal cortical (EC)-CA2 and Schaffer collateral (SC)-CA2 synapses in the hippocampus of adult male Wistar rats. The activation of muscarinic acetylcholine receptors (mAChRs) is critical for the induction of CCh-LTD with the results suggesting an involvement of M3 and M1 mAChRs in the early facilitation of CCh-LTD, while nicotinic AChR activation plays a role in the late maintenance of CCh-LTD at CA2 synapses. Remarkably, we find that CCh priming lowers the threshold for the subsequent induction of persistent long-term potentiation (LTP) of synaptic transmission at EC-CA2 and the plasticity-resistant SC-CA2 pathways. The effects of such a cholinergic-dependent synaptic depression on subsequent LTP at EC-CA2 and SC-CA2 synapses have not been previously explored. Collectively, the results demonstrate that CA2 synaptic learning rules are regulated in a metaplastic manner, whereby modifications triggered by prior cholinergic stimulation can dictate the outcome of future plasticity events. Moreover, the reinforcement of LTP at EC inputs to CA2 following the priming stimulus coexists with concurrent sustained CCh-LTD at the SC-CA2 pathway and is dynamically scaled by modulation of SC-CA2 synaptic transmission. The release of the neuromodulator acetylcholine is critically involved in processes of hippocampus-dependent memory formation. Cholinergic afferents originating in the medial septum and diagonal bands of Broca terminating in the hippocampal area CA2 might play an important role in the modulation of area-specific synaptic plasticity. Our findings demonstrate that cholinergic receptor activation induces an LTD of synaptic transmission at entorhinal cortical- and Schaffer collateral-CA2 synapses. This cholinergic activation-mediated LTD displays a bidirectional metaplastic switch to LTP on a future timescale. This suggests that such bidirectional synaptic modifications triggered by the dynamic modulation of tonic cholinergic receptor activation may support the formation of CA2-dependent memories given the increased hippocampal cholinergic tone during active wakefulness observed in exploratory behavior.

Long-term plasticity in the hippocampus: maintaining within and 'tagging' between synapses.

Synapses between neurons are malleable biochemical structures, strengthening and diminishing over time dependent on the type of information they receive. This phenomenon known as synaptic plasticity underlies learning and memory, and its different forms, long-term potentiation (LTP) and long-term depression (LTD), perform varied cognitive roles in reinforcement, relearning and associating memories. Moreover, both LTP and LTD can exist in an early transient form (early-LTP/LTD) or a late persistent form (late-LTP/LTD), which are triggered by different induction protocols, and also differ in their dependence on protein synthesis and the involvement of key molecular players. Beyond homosynaptic modifications, synapses can also interact with one another. This is encapsulated in the synaptic tagging and capture hypothesis (STC), where synapses expressing early-LTP/LTD present a 'tag' that can capture the protein synthesis products generated during a temporally proximal late-LTP/LTD induction. This 'tagging' phenomenon forms the framework of synaptic interactions in various conditions and accounts for the cellular basis of the time-dependent associativity of short-lasting and long-lasting memories. All these synaptic modifications take place under controlled neuronal conditions, regulated by subcellular elements such as epigenetic regulation, proteasomal degradation and neuromodulatory signals. Here, we review current understanding of the different forms of synaptic plasticity and its regulatory mechanisms in the hippocampus, a brain region critical for memory formation. We also discuss expression of plasticity in hippocampal CA2 area, a long-overlooked narrow hippocampal subfield and the behavioural correlate of STC. Lastly, we put forth perspectives for an integrated view of memory representation in synapses.

Aim: To study the mechanisms and functional significance of learning-induced long-lasting modulation of inhibitory synaptic transmission. Olfactory discrimination (OD) rule learning results with simultaneous enhancement in excitatory and inhibitory connections onto piriform cortex layer-II principal neurons. Ground cause of this increased inhibitory synaptic modifications and its intimate assistance in memory formation is yet to be described. **Methods:** We used transgenic mice (VGAT-ChR2-EYFP), optogenetic stimulation protocol and whole-cell patch clamp recording in piriform cortex brain slices, five days after learning. **Results:** Employment of quantal analysis to explore the dominancy of GABA mediated presynaptic inputs, revealed no significant changes in quantal release probability and number of released vesicles between neurons from trained and control animals, though a significant increase in the quantal size of the inhibitory post synaptic currents (IPSCs) after learning, indicating learning-induced enhancement of inhibition is maintained via a post-synaptic mechanism. Next, we examined how such learning-induced modifications affect subsequent plasticity of synaptic inhibition on principal neurons by inducing long-lasting changes with repetitive firing of postsynaptic neuron. To that end, we elicited brief repetitive depolarizing current pulses at resting (-70mV) and hyperpolarizing (-90mV) membrane potential. As expected, we found that predisposition for long-lasting depression (LLD, at resting state) is increased after learning. Such enhancement is L-type Ca^{+2} channels dependent. Surprisingly, the predisposition for long-lasting potentiation (LLP, at hyperpolarising state) was also enhanced after learning. **Conclusion:** In sharp contrast to excitatory synaptic transmission, learning enhances greatly the ability to modify the strength of synaptic inhibition onto principal neurons in both directions.

A Cellular Mechanism of Learning-Induced Enhancement of Synaptic Inhibition: PKC-Dependent Upregulation of KCC2 Activation.
Long-term memory of complex olfactory learning is expressed by wide spread enhancement in excitatory and inhibitory synaptic transmission onto piriform cortex pyramidal neurons. A particularly interesting modification in synaptic inhibition is the hyperpolarization of the reversal potential of the fast post synaptic inhibitory potential (fIPSP). Here we study the mechanism underlying the maintenance of such a shift in the fIPSP. Blocking of the neuronal specific K-Cl co-transporter (KCC2) in neurons of trained rats significantly depolarized the averaged fIPSP reversal potential of the spontaneous miniature inhibitory post synaptic currents (mIPSCs), to the averaged pre-training level. A similar effect was obtained by blocking PKC, which was previously shown to upregulate KCC2. Accordingly, the level of PKC-dependent phosphorylation of KCC2, at the serine 940 site, was significantly increased after learning. In contrast, blocking two other key second messenger systems CaMKII and PKA, which have no phosphorylation sites on KCC2, had no effect on the fIPSP reversal potential. Importantly, the PKC inhibitor also reduced the averaged amplitude of the spontaneous miniature excitatory synaptic currents (mEPSCs) in neurons of trained rats only, to the pre-training level. We conclude that learning-induced hyper-polarization of the fIPSP reversal potential is mediated by PKC-dependent increase of KCC2 phosphorylation.

A new paradigm for investigating temporal order memory shows higher order associations are present in recent but not in remote retrieval.
Memory of a sequence of distinct events requires encoding the temporal order as well as the intervals that separates these events. In this study, using order-place association task where the animal learns to associate the location of the food pellet to the order of entry into the event arena, we probe the nature of temporal order memory in mice. In our task, individual trials become distinct events, as the animal is trained to form a unique association between entry order and a correct location. The inter-trial intervals (> 30 min) are chosen deliberately to minimize the inputs from working memory. We develop this paradigm initially using four order-place associates and later extend it to five paired associates. Our results show that animals not only

acquire these explicit (entry order to place) associations but also higher order associations that can only be inferred implicitly (temporal relation between the events) from the temporal order of these events. As an indicator of such higher order learning during the probe trial, the mice exhibit predominantly prospective errors that decline proportionally with temporal distance. On the other hand, prior to acquiring the sequence, the retrospective errors are dominant. In addition, we also tested the nature of such acquisitions when temporal order CS is presented along with flavored pellet as a compound stimulus comprising of order and flavor both simultaneously being paired with location. Results from these experiments indicate that the animal learns both order-place and flavor-place associations. Comparing with pure order-place training, we find that the additional flavor stimulus in a compound training paradigm did not interfere with the ability of the animals to acquire the order-place associations. When tested remotely, pure order-place associations could be retrieved only after a reminder training. Further higher order associations representing the temporal relationship between the events is markedly absent in the remote time.

Dopamine D3 receptors (D3-Rs) are involved in several functions such as reward, social behavior, and movement control. Indeed, D3Rs have been proposed as a therapeutical target for addiction, schizophrenia, and Parkinson's disease. More recently, some studies have evidenced the involvement of D3-Rs in cognition, demonstrating that activation of D3-Rs impairs attention and memory, whereas their inhibition induced a pro-cognitive effect. However, the specific contribution of D3-Rs in hippocampal synaptic plasticity and memory has not been thoroughly investigated. Here, we examined the role of D3-Rs in hippocampal long-term potentiation (LTP) and memory in mice. For this purpose, we first performed extracellular electrophysiological recordings at CA3-CA1 synapses of hippocampal slices treated with a D3-Rs antagonist. Then, we investigated the effect of D3-Rs inhibition on recognition memory studied by Object Recognition Test on wild-type mice treated with a D3-Rs antagonist and on D3 knock out (D3-KO) mice. We found that perfusion of hippocampal slices with a D3-Rs antagonist was able to convert early-LTP into late-LTP. These effects were depended upon protein kinase A (PKA). Behavioral experiments confirmed the cognitive enhancing effect of D3-Rs inhibition, as wild type mice treated with a D3-Rs antagonist and D3-KO animals showed a conversion from short-term into long-term memory. We also demonstrated that D3-Rs inhibition rescued the impairment of synaptic plasticity and memory typically found in aged mice. In conclusion, our findings suggest that D3-Rs plays a role in synaptic plasticity and memory and that their inhibition can be useful to rescue cognitive dysfunction occurring during aging.

Antioxidant Activity of Fluoxetine and Vortioxetine in a Non-Transgenic Animal Model of Alzheimer's Disease.
Depression is a risk factor for the development of Alzheimer's disease (AD). A neurobiological and clinical continuum exists between AD and depression, with neuroinflammation and oxidative stress being involved in both diseases. Second-generation antidepressants, in particular selective serotonin reuptake inhibitors (SSRIs), are currently investigated as neuroprotective drugs in AD. By employing a non-transgenic AD model, obtained by intracerebroventricular (i.c.v.) injection of amyloid-β (Aβ) oligomers in 2-month-old C57BL/6 mice, we recently demonstrated that the SSRI fluoxetine (FLX) and the multimodal antidepressant vortioxetine (VTX) reversed the depressive-like phenotype and memory deficits induced by Aβ oligomers rescuing the levels of transforming growth factor-β1 (TGF-β1). Aim of our study was to test FLX and VTX for their ability to prevent oxidative stress in the hippocampus of Aβ-injected mice, a brain area strongly affected in both depression and AD. The long-term intraperitoneal (i.p.) administration of FLX (10 mg/kg) or VTX (5 and 10 mg/kg) for 24 days, starting 7 days before Aβ injection, was able to prevent the over-expression of inducible nitric oxide synthase (iNOS) and NADPH oxidase 2 (Nox2) induced by Aβ oligomers. Antidepressant pre-treatment was also able to rescue the mRNA expression of glutathione peroxidase 1 (Gpx1) antioxidant enzyme. FLX and VTX also prevented Aβ-induced neurodegeneration in mixed neuronal cultures treated with Aβ oligomers. Our data represent the first evidence that the long-term treatment with the antidepressants FLX or VTX can prevent the oxidative stress phenomena related to the cognitive deficits and depressive-like phenotype observed in a non-transgenic animal model of AD.

Innate Preferences Affect Results of Object Recognition Task in Wild Type and Alzheimer's Disease Mouse Models.
Object recognition task (ORT) is a widely used behavioral paradigm to assess memory in rodent models, due to its easy technical execution, the lack of aversive stressful stimuli, and the possibility to repeat the test on the same animals. However, mouse exploration might be strongly influenced by a variety of variables.

Genetic deletion of α7 nicotinic acetylcholine receptors induces an age-dependent Alzheimer's disease-like pathology.
The accumulation of amyloid-beta peptide (Aβ) and the failure of cholinergic transmission are key players in Alzheimer's disease (AD). However, in the healthy brain, Aβ contributes to synaptic plasticity and memory acting through α7 subtype nicotinic acetylcholine receptors (α7nAChRs). Here, we hypothesized that the α7nAChR deletion blocks Aβ physiological function and promotes a compensatory increase in Aβ levels that, in turn, triggers an AD-like pathology. To validate this hypothesis, we studied the age-dependent phenotype of α7 knock out mice. We found that α7nAChR deletion caused an impairment of hippocampal synaptic plasticity and memory at 12 months of age, paralleled by an increase of Amyloid Precursor Protein expression and Aβ levels. This was accompanied by other classical AD features such as a hyperphosphorylation of tau at residues Ser 199, Ser 396, Thr 205, a decrease of GSK-3β at Ser 9, the presence of paired helical filaments and neurofibrillary tangles, neuronal loss and an increase of GFAP-positive astrocytes. Our findings suggest that α7nAChR malfunction might precede Aβ and tau pathology, offering a different perspective to interpret the failure of anti-Aβ therapies against AD and to find novel therapeutical approaches aimed at restoring α7nAChRs-mediated Aβ function at the synapse.

Fluoxetine and Vortioxetine Reverse Depressive-Like Phenotype and Memory Deficits Induced by Aβ Oligomers in Mice: A Key Role of Transforming Growth Factor-β1.
Depression is a risk factor for the development of Alzheimer's disease (AD), and the presence of depressive symptoms significantly increases the conversion of mild cognitive impairment (MCI) into AD. A long-term treatment with antidepressants reduces the risk to develop AD, and different second-generation antidepressants such as selective serotonin reuptake inhibitors (SSRIs) are currently being studied for their neuroprotective properties in AD. In the present work, the SSRI fluoxetine and the new multimodal antidepressant vortioxetine were tested for their ability to prevent memory deficits and depressive-like phenotype induced by intracerebroventricular injection of amyloid-β (1-42) (Aβ) oligomers in 2-month-old C57BL/6 mice. Starting from 7 days before Aβ injection, fluoxetine (10 mg/kg) and vortioxetine (5 and 10 mg/kg) were intraperitoneally injected daily for 24 days. Chronic treatment with fluoxetine and vortioxetine (both at the dose of 10 mg/kg) was able to rescue the loss of memory assessed 14 days after Aβ injection by the passive avoidance task and the object recognition test. Both antidepressants reversed the increase in immobility time detected 19 days after Aβ injection by forced swim test. Vortioxetine exerted significant antidepressant effects also at the dose of 5 mg/kg. A significant deficit of transforming growth factor-β1 (TGF-β1), paralleling memory deficits and depressive-like phenotype, was found in the hippocampus of Aβ-injected mice in combination with a significant reduction of the synaptic proteins synaptophysin and PSD-95. Fluoxetine and vortioxetine completely rescued hippocampal TGF-β1 levels in Aβ-injected mice as well as synaptophysin and PSD-95 levels. This is the first evidence that a chronic treatment with fluoxetine or vortioxetine can prevent both cognitive deficits and depressive-like phenotype in a non-transgenic animal model of AD with a key contribution of TGF-β1.

Neuromodulatory Action of Picomolar Extracellular Aβ42 Oligomers on Presynaptic and Postsynaptic Mechanisms Underlying Synaptic Function and Memory.
Failure of anti-amyloid-β peptide (Aβ) therapies against Alzheimer's disease (AD), a neurodegenerative disorder characterized by high amounts of the peptide in the brain, raised the question of the physiological role of Aβ released at low concentrations in the healthy brain. To address this question, we studied the presynaptic and postsynaptic mechanisms underlying the neuromodulatory action of picomolar amounts of oligomeric Aβ (oAβ) on synaptic glutamatergic function in male and female mice. We found that 200 pm oAβ induces an increase of frequency of miniature EPSCs and a decrease of paired pulse facilitation, associated with an increase in docked vesicle number, indicating that it augments neurotransmitter release at presynaptic level. oAβ also produced postsynaptic changes as shown by an increased length of postsynaptic density, accompanied by an increased expression of plasticity-related proteins such as cAMP-responsive element binding protein phosphorylated at Ser133, calcium-calmodulin-dependent kinase II phosphorylated at Thr286, and brain-derived neurotrophic factor, suggesting a role for Aβ in synaptic tagging. These changes resulted in the conversion of early into late long-term potentiation through the nitric oxide/cGMP/protein kinase G intracellular cascade consistent with a cGMP-dependent switch from short- to long-term memory observed after intrahippocampal administration of picomolar amounts of oAβ These effects were present upon extracellular but not intracellular application of the peptide and involved α7 nicotinic acetylcholine receptors. These observations clarified the physiological role of oAβ in synaptic function and memory formation providing solid fundamentals for investigating the pathological effects of high Aβ levels in the AD brains. High levels of

oligomeric amyloid-β (oAβ) induce synaptic dysfunction leading to memory impairment in Alzheimer's disease (AD). However, at picomolar concentrations, the peptide is needed to ensure long-term potentiation (LTP) and memory. Here, we show that extracellular 200 pm oAβ concentrations increase neurotransmitter release, number of docked vesicles, postsynaptic density length, and expression of plasticity-related proteins leading to the conversion of early LTP into late LTP and of short-term memory into long-term memory. These effects require α7 nicotinic acetylcholine receptors and are mediated through the nitric oxide/cGMP/protein kinase G pathway. The knowledge of Aβ function in the healthy brain might be useful to understand the causes leading to its increase and detrimental effect in AD.

Activation of Serotonin 5-HT Receptors Modulates Hippocampal Synaptic Plasticity by Stimulation of Adenylate Cyclases and Rescues Learning and Behavior in a Mouse Model of Fragile X Syndrome.
We have previously demonstrated that activation of serotonin 5-HT receptors (5-HTR) reverses metabotropic glutamate receptor-mediated long term depression (mGluR-LTD) in the hippocampus of wild-type (WT) and Knockout (KO) mice, a model of Fragile X Syndrome (FXS) in which mGluR-LTD is abnormally enhanced. Here, we have investigated intracellular mechanisms underlying the effect of 5-HTR activation using patch clamp on hippocampal slices. Furthermore, we have tested whether administration of LP-211, a selective 5-HTR agonist, can rescue learning and behavior in KO mice. In the presence of an adenylate cyclase blocker, mGluR-LTD was slightly enhanced in WT and therefore the difference between mGluR-LTD in WT and KO slices was no longer present. Conversely, activation of adenylate cyclase by either forskolin or Pituitary Adenylate Cyclase Activating Polypeptide (PACAP) completely reversed mGluR-LTD in WT and KO. 5-HTR activation reversed mGluR-LTD in WT and corrected exaggerated mGluR-LTD in KO; this effect was abolished by blockade of either adenylate cyclase or protein kinase A (PKA). Exposure of hippocampal slices to LP-211 caused an increased phosphorylation of extracellular signal regulated kinase (ERK), an intracellular effector involved in mGluR-LTD, in WT mice. Conversely, this effect was barely detectable in KO mice, suggesting that 5-HTR-mediated reversal of mGluR-LTD does not require ERK stimulation. Finally, an acute administration of LP-211 improved novel object recognition (NOR) performance in WT and KO mice and reduced stereotyped behavior in KO mice. Our results indicate that mGluR-LTD in WT and KO slices is bidirectionally modulated in conditions of either reduced or enhanced cAMP formation. Activation of 5-HT receptors reverses mGluR-LTD by activation of the cAMP/PKA intracellular pathway. Importantly, a systemic administration of a 5-HTR agonist to KO mice corrected learning deficits and repetitive behavior. We suggest that selective 5-HTR agonists might become novel pharmacological tools for FXS therapy.

The effect of amyloid-β peptide on synaptic plasticity and memory is influenced by different isoforms, concentrations, and aggregation status.
The increase of oligomeric amyloid-beta (oAβ) has been related to synaptic dysfunction, thought to be the earliest event in Alzheimer's disease pathophysiology. Conversely, the suppression of endogenous Aβ impaired synaptic plasticity and memory, suggesting that the peptide is needed in the healthy brain. However, different species, aggregation forms and concentrations of Aβ might differently influence synaptic function/dysfunction. Here, we have tested the contribution of monomeric and oligomeric Aβ42 and Aβ40 at 200 nM and 200 pM concentrations on hippocampal long-term potentiation and spatial memory. We found that, when at 200 nM, oAβ40, oAβ42, and monomeric Aβ42 impaired long-term potentiation and memory, whereas only oAβ42 200 pM enhanced synaptic plasticity and memory and rescued the detrimental effect due to depletion of endogenous Aβ. Interestingly, quantification of monomer-like and oligomer-like species carried out by transmission electron microscopy revealed an increase of the monomer/oligomer ratio in the oAβ42 200 pM preparation, suggesting that the content of monomers and oligomers depends on the final concentration of the solution.

Sub-efficacious doses of phosphodiesterase 4 and 5 inhibitors improve memory in a mouse model of Alzheimer's disease.
Cyclic nucleotides cAMP and cGMP cooperate to ensure memory acquisition and consolidation. Increasing their levels by phosphodiesterase inhibitors (PDE-Is) enhanced cognitive functions and rescued memory loss in different models of aging and Alzheimer's disease (AD). However, side effects due to the high doses used limited their application in humans. Based on previous studies suggesting that combinations of sub-efficacious doses of cAMP- and cGMP-specific PDE-Is improved synaptic plasticity and memory in physiological conditions, here we aimed to study whether this treatment was effective to counteract the AD phenotype in APPswe mice. We found that a 3-week chronic treatment with a combination of sub-efficacious doses of the cAMP-specific PDE4-I roflumilast (0.01 mg/kg) and the cGMP-specific PDE5-I vardenafil (0.1 mg/kg) improved recognition, spatial and contextual fear memory. Importantly, the cognitive enhancement persisted for 2 months

beyond administration. This long-lasting action, and the possibility to minimize side effects due to the low doses used, might open feasible therapeutic strategies against AD.

28696204: Puzzo D, Piacentini R, Fá M, Gulisano W, Li Puma DD, Staniszewski A, Zhang H, Tropea MR, Cocco S, Palmeri A, Fraser P, D'Adamio L, Grassi C, Arancio O
LTP and memory impairment caused by extracellular Aβ and Tau oligomers is APP-dependent.
The concurrent application of subtoxic doses of soluble oligomeric forms of human amyloid-beta (oAβ) and Tau (oTau) proteins impairs memory and its electrophysiological surrogate long-term potentiation (LTP), effects that may be mediated by intra-neuronal oligomers uptake. Intrigued by these findings, we investigated whether oAβ and oTau share a common mechanism when they impair memory and LTP in mice. We found that as already shown for oAβ, also oTau can bind to amyloid precursor protein (APP). Moreover, efficient intra-neuronal uptake of oAβ and oTau requires expression of APP. Finally, the toxic effect of both extracellular oAβ and oTau on memory and LTP is dependent upon APP since APP-KO mice were resistant to oAβ- and oTau-induced defects in spatial/associative memory and LTP. Thus, APP might serve as a common therapeutic target against Alzheimer's Disease (AD) and a host of other neurodegenerative diseases characterized by abnormal levels of Aβ and/or Tau.

Amyloid-β Peptide Is Needed for cGMP-Induced Long-Term Potentiation and Memory.
High levels of amyloid-β peptide (Aβ) have been related to Alzheimer's disease pathogenesis. However, in the healthy brain, low physiologically relevant concentrations of Aβ are necessary for long-term potentiation (LTP) and memory. Because cGMP plays a key role in these processes, here we investigated whether the cyclic nucleotide cGMP influences Aβ levels and function during LTP and memory. We demonstrate that the increase of cGMP levels by the phosphodiesterase-5 inhibitors sildenafil and vardenafil induces a parallel release of Aβ due to a change in the approximation of amyloid precursor protein (APP) and the β-site APP cleaving enzyme 1. Moreover, electrophysiological and behavioral studies performed on animals of both sexes showed that blocking Aβ function, by using anti-murine Aβ antibodies or APP knock-out mice, prevents the cGMP-dependent enhancement of LTP and memory. Our data suggest that cGMP positively regulates Aβ levels in the healthy brain which, in turn, boosts synaptic plasticity and memory. Amyloid-β (Aβ) is a key pathogenetic factor in Alzheimer's disease. However, low concentrations of endogenous Aβ, mimicking levels of the peptide in the healthy brain, enhance hippocampal long-term potentiation (LTP) and memory. Because the second messenger cGMP exerts a central role in LTP mechanisms, here we studied whether cGMP affects Aβ levels and function during LTP. We show that cGMP enhances Aβ production by increasing the APP/BACE-1 convergence in endolysosomal compartments. Moreover, the cGMP-induced enhancement of LTP and memory was disrupted by blockade of Aβ, suggesting that the physiological effect of the cyclic nucleotide on LTP and memory is dependent upon Aβ.

Long-term synaptic plasticity is considered as the cellular substrate of learning and memory. This includes long-term synaptic potentiation (LTP), corresponding to a persistent increase of synaptic transmission. The most common form of LTP depends on glutamatergic NMDA receptors whose activation requires the binding of glutamate and of a co-agonist that was identified to be D-serine at hippocampal CA3-CA1 synapses. Our previous work in the hypothalamus has indicated that the close apposition of the astrocytic processes with synaptic neuronal elements was essential for the D-serine availability in the synaptic cleft. Interestingly, activation of cell adhesion molecules depends on the close apposition of two membrane elements, making them very likely to participate in this glia-neuron interaction process. Data obtained in astrocytic cultures have shown that the D-serine release was induced by the activation of astrocytic EphB3 receptors. However, we do not know whether this requires the interaction of the astrocytic EphB3 receptor with its neuronal synaptic partner and whether it could impact NMDAR functions. Here, we first established that the activation of EphB3 receptors in acute hippocampal slices from the brain of adult mice led to an increase of D-serine availability at CA3-CA1 synapses inducing an increase of NMDAR activity. Then, selective inhibition of astrocytic EphB3 using a viral approach impaired the induction of LTP as well as novel object recognition memory. Importantly, exogenous application of D-serine was able to rescue LTP and memory deficits. Altogether, our data indicate that astrocytic EphB3 receptors play a key role in NMDAR functions.

Activity-dependent synaptic plasticity is a crucial mechanism in the formation of memory in neuronal networks. Experimental results indicate that postsynaptic dendritic spine plasticity occurs at the stimulated (homosynaptic plasticity) and non-stimulated spines (heterosynaptic plasticity) over minutes or even hours. The disruption of this plasticity is linked to neurodegenerative disorders and memory deficits. However, the exact mechanisms that drive the growth and shrinkage of synaptic spines, particularly those not directly stimulated, are not fully understood. We will present a mathematical model that can provide insight into processes that define these dynamics. Inspired by the calcium levels hypothesis, where different amounts of calcium lead to either growth or shrinkage, we introduce a dual-role protein that governs the proposed dynamics in conjunction with calcium. Comparing our model predictions with the experimental results, we observed that (i) both collaboration as well as competition, are key drivers of heterosynaptic plasticity and (ii) the temporal and spatial arrangements of simultaneously stimulated spines have a crucial impact on the resulting spine dynamics. We discuss our results in relation to previous models and show how a number of disparate experimental results that reported heterosynaptic LTP or LTD can be understood using our model.

THE ROLE OF IMPAIRED SYNAPTIC PLASTICITY IN ABERRANT SALIENCE AND PSYCHOSIS

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Thomas Blackmore, Veronika Samborska, Layla Stahr, Katerina Dangas, Mark Walton, David Bannerman, Marios Panayi
University of Oxford, Experimental Psychology, Oxford, United Kingdom

Impaired synaptic plasticity is prevalent in conditions ranging from Alzheimer's Disease to depression and schizophrenia and may explain transdiagnostic symptom overlap. Here we present a preclinical analysis of rodent models relevant to psychosis in behavioural habituation assays, to see how disrupted synaptic plasticity could generate aberrant salience. Increased locomotor responding in these models may reflect increased attending to environmental stimuli and impairments in habituation of translational relevance to psychosis. We investigated two commonly used models of disrupted synaptic plasticity; NMDAR receptor blockade (MK-801), and genetic ablation of the *Gria1* gene encoding the GluA1 AMPA receptor subunit (GluA1$^{-/-}$), and one widely used model of hyperdopaminergia (amphetamine). While all models generated robust hyperactivity to novelty, only amphetamine led to hyperlocomotion in a familiar environment. MK-801 and GluA1$^{-/-}$ impaired short-term habituation over several assays but left long-term habituation intact. Intriguingly, responding over prolonged novelty exposure led to an *increase* in responding, indicating sensitisation, of potential relevance to clinical psychosis. Furthermore, this sensitisation was shown to be stimulus-specific, further suggesting this may be a driver of aberrant salience. Amphetamine, however, failed to disrupt expression of habituation, though locomotion increased independent of stimulus novelty. This work suggests a causal role of synaptic plasticity in responding to novel and familiar stimuli and demonstrates mechanisms through which impaired plasticity can lead to impaired habituation and aberrant salience. Impaired plasticity aberrantly increased subjects responding to stimuli and represents a potential mechanism of how psychosis may develop not just in schizophrenia, but also other disorders of impaired hippocampal plasticity.

MULTIPLE MECHANISTICALLY DISTINCT TIMESCALES OF NEOCORTICAL PLASTICITY OCCUR DURING HABITUATION

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Fran Chaloner[1,2], Samuel Cooke[1,2]
[1]King's College London, Centre For Neurodevelopmental Disorders, London, United Kingdom, [2]King's College London, Basic And Clinical Neuoscience, London, United Kingdom

The recognition of familiar but innocuous stimuli limits their cognitive burden and minimizes energy use, while enabling detection of novel, potentially significant stimuli. A unique, long-lasting form of neocortical plasticity, known as stimulus-selective response potentiation (SRP), occurs as mice develop long-lasting familiarity. This form of response potentiation is manifest in layer 4 of primary visual cortex (V1) over days of repeated presentation of phase-reversing sinusoidal grating stimuli, while behaviourally manifest habituation occurs across a similar timescale. Habituation and accompanying SRP are highly stimulus-selective and reliant on NMDA receptors and parvalbumin-expressing (PV+) interneurons in V1. However, modification of cortical response and visual-evoked behaviour have yet to be investigated over shorter timescales within the same paradigm. Here, we characterise several timescales of plasticity, revealing mechanistically distinct processes and elucidating interactions between them. Notably, while the behavioural response habituates both over the course of minutes and days, layer 4 visual evoked potentials (VEPs) depress over minutes but increase over days. Adaptation of the VEP also occurs over the shorter timescale of seconds. This very short-term form of plasticity is modulated by familiarity, such that adaptation is pronounced for novel but not familiar stimuli. Genetic knock-down of NMDA receptors impairs all timescales of plasticity while only long-term familiarity requires unhindered PV+ neuronal function. Notably, however, the modulation of short-term adaptation by long-term familiarity is reliant on PV+ interneurons. Our findings therefore indicate that distinct forms of plasticity and habituation occur across different timescales and provide insight into their underlying mechanisms and interactions.

Reactivation of neuronal activity is thought to support the consolidation of hippocampus-dependent memory traces. However, to date, direct evidence for an effect of neuronal reactivation on synaptic plasticity is missing. Here we found that Hebbian pairing followed by postsynaptic reactivation in the presence of dopamine activates a two-step coincidence detector mechanism for rapid protein synthesis-dependent LTP. Using computational modeling, we show that this synaptic learning rule adds specificity to traditional reinforcement learning models by controlling memory allocation in the network. We predicted that this mechanism would make reactivated neurons activate more strongly and carry more spatial information than non-reactivated cells. Using calcium imaging in freely moving mice performing a reward-based navigation task, we show that neurons that were reactivated after finding a reward have increased calcium responses and place map peaks compared to non-reactivated cells. Taken together, our findings suggest that reactivation-induced synaptic plasticity enables the selective encoding of salient events in long-term memory.

Thalamus mediates neocortical Down state transition via GABA-receptor-targeting interneurons.
Slow-wave sleep is characterized by near-synchronous alternation of active Up states and quiescent Down states in the neocortex. Although the cortex itself can maintain these oscillations, the full expression of Up-Down states requires intact thalamocortical circuits. Sensory thalamic input can drive the cortex into an Up state. Here we show that midline thalamic neurons terminate Up states synchronously across cortical areas. Combining local field potential, single-unit, and patch-clamp recordings in conjunction with optogenetic stimulation and silencing in mice in vivo, we report that thalamic input mediates Down transition via activation of layer 1 neurogliaform inhibitory neurons acting on GABA receptors. These results strengthen the evidence that thalamocortical interactions are essential for the full expression of slow-wave sleep, show that Down transition is an active process mediated by cortical GABA receptors, and demonstrate that thalamus synchronizes Down transitions across cortical areas during natural slow-wave sleep.

Increased basal antioxidant levels in RCAN1 - deficient mice lowers oxidative injury after acute paraquat insult.
RCAN1 is an inhibitor of the phosphatase calcineurin, which is involved in the regulation of oxidative stress and apoptosis, among other important cell processes. Here we have used RCAN1 deficient mice (RCAN1) to elucidate its role after an acute oxidative insult such as paraquat injection. We have observed that RCAN1 mice show less oxidative damage than wildtype (WT) mice after treatment. Under basal conditions, RCAN1 animals express more calcineurin, heme oxygenase-1, Nrf2, and catalase compared to WT mice (controls). This may explain the less severe effect of paraquat treatment on RCAN1 mice compared to WT. We showed that oxidative stress is involved in the early stages of apoptosis, thus we determined the apoptotic effector BAD and found that decreases in RCAN1 mice after treatment with paraquat compared with WT in similar experimental conditions. Our results suggest that RCAN1 may be involved in the balance between oxidant and antioxidant species production .

Oral Monosodium Glutamate Administration Causes Early Onset of Alzheimer's Disease-Like Pathophysiology in APP/PS1

Mice.
Glutamate excitotoxicity has long been related to Alzheimer's disease (AD) pathophysiology, and it has been shown to affect the major AD-related hallmarks, amyloid-β peptide (Aβ) accumulation and tau phosphorylation (p-tau). We investigated whether oral administration of monosodium glutamate (MSG) has effects in a murine model of AD, the double transgenic mice APP/PS1. We found that AD pathogenic factors appear earlier in APP/PS1 when supplemented with MSG, while wildtype mice were essentially not affected. Aβ and p-tau levels were increased in the hippocampus in young APP/PS1 animals upon MSG administration. This was correlated with increased Cdk5-p25 levels. Furthermore, in these mice, we observed a decrease in the AMPA receptor subunit GluA1 and they had impaired long-term potentiation. The Hebb-Williams Maze revealed that they had memory deficits. We show here for the first time that oral MSG supplementation can accelerate AD-like pathophysiology in a mouse model of AD.

Partial restoration of physiological UP-state activity by GABA pathway modulation in an acute brain slice model of epilepsy.
In addition to reducing seizures, anti-epileptic treatments should preserve physiological network activity. Here, we used a thalamocortical slice preparation displaying physiological slow oscillations to investigate the effects of anticonvulsant drugs on physiological activity and epileptiform activity in two pharmacological epilepsy models. Thus, we compared the effects of GABA pharmacology on spontaneous physiological and pathological events in slices of the mouse barrel cortex. We show that both reducing inhibition using GABAR blockers and enhancing excitation by lowering Mg concentration allow for the transition from physiological slow oscillations to epileptiform activity. Our results indicate that GABAR antagonists have pro-convulsive properties by increasing event duration in the low inhibition model and event frequency in the high excitation model. Moreover, we show that GABAR agonists and GABA uptake blockers, known for their anticonvulsant properties, act primarily on epileptiform burst frequency and allow for a partial restoration of physiological events. As a proof of principle, these results indicate that a slice model with spontaneous network events may be a useful pipeline to investigate the effects of anti-epileptic drugs on both epileptiform and physiological network activity.

New Functions of APC/C Ubiquitin Ligase in the Nervous System and Its Role in Alzheimer's Disease.
The E3 ubiquitin ligase Anaphase Promoting Complex/Cyclosome (APC/C) regulates important processes in cells, such as the cell cycle, by targeting a set of substrates for degradation. In the last decade, APC/C has been related to several major functions in the nervous system, including axon guidance, synaptic plasticity, neurogenesis, and neuronal survival. Interestingly, some of the identified APC/C substrates have been related to neurodegenerative diseases. There is an accumulation of some degradation targets of APC/C in Alzheimer's disease (AD) brains, which suggests a dysregulation of the protein complex in the disorder. Moreover, recently evidence has been provided for an inactivation of APC/C in AD. It has been shown that oligomers of the AD-related peptide, Aβ, induce degradation of the APC/C activator subunit cdh1, in vitro in neurons in culture and in vivo in the mouse hippocampus. Furthermore, in the AD mouse model APP/PS1, lower cdh1 levels were observed in pyramidal neurons in CA1 when compared to age-matched wildtype mice. In this review, we provide a complete list of APC/C substrates that are involved in the nervous system and we discuss their functions. We also summarize recent studies that show neurobiological effects in cdh1 knockout mouse models. Finally, we discuss the role of APC/C in the pathophysiology of AD.

Aβ Induces Excitotoxicity Mediated by APC/C-Cdh1 Depletion That Can Be Prevented by Glutaminase Inhibition Promoting Neuronal Survival.
The E3 ubiquitin ligase anaphase-promoting complex/cyclosome (APC/C) is activated by the fizzy-related protein homolog/CDC20-like protein 1 (cdh1) in post-mitotic neurons. Growing evidence suggests that dysregulation of APC/C-Cdh1 is involved in neurodegenerative diseases. Here we show in neurons that oligomers of amyloid beta (Aβ), a peptide related to Alzheimer's disease, cause proteasome-dependent degradation of cdh1. This leads to a subsequent increase in glutaminase (a degradation target of APC/C-Cdh1), which causes an elevation of glutamate levels and further intraneuronal Ca(2+) dysregulation, resulting in neuronal apoptosis. Glutaminase inhibition prevents glutamate excitotoxicity and apoptosis in Aβ treated neurons. Furthermore, glutamate also decreases cdh1 and leads to accumulation of glutaminase, suggesting that there may be a positive feedback loop of cdh1 inactivation. We confirmed the main findings in vivo using microinjection of either Aβ or glutamate in the CA1 region of the rat hippocampus. We show here for the first time in vivo that both Aβ and glutamate cause nuclear exclusion of cdh1 and an increase in glutaminase. These results show that maintaining normal APC/C-Cdh1 activity may be a useful target in Alzheimer's disease treatment.

Reductive Stress: A New Concept in Alzheimer's Disease.
Reactive oxygen species play a physiological role in cell signaling and also a pathological role in diseases, when antioxidant defenses are overwhelmed causing oxidative stress. However, in this review we will focus on reductive stress that may be defined as a pathophysiological situation in which the cell becomes more reduced than in the normal, resting state. This may occur in hypoxia and also in several diseases in which a small but persistent generation of oxidants results in a hormetic overexpression of antioxidant enzymes that leads to a reduction in cell compartments. This is the case of Alzheimer's disease. Individuals at high risk of Alzheimer's (because they carry the ApoE4 allele) suffer reductive stress long before the onset of the disease and even before the occurrence of mild cognitive impairment. Reductive stress can also be found in animal models of Alzheimer's disease (APP/PS1 transgenic mice), when their redox state is determined at a young age, i.e. before the onset of the disease. Later in their lives they develop oxidative stress. The importance of understanding the occurrence of reductive stress before any signs or symptoms of Alzheimer's has theoretical and also practical importance as it may be a very early marker of the disease.

Molecular mechanisms linking amyloid β toxicity and Tau hyperphosphorylation in Alzheimer′s disease.
Neurofibrillary tangles (aggregates of cytoskeletal Tau protein) and senile plaques (aggregates mainly formed by amyloid β peptide) are two landmark lesions in Alzheimer′s disease. Some researchers have proposed tangles, whereas others have proposed plaques, as primary lesions. For a long time, these were thought of as independent mechanisms. However, experimental evidence suggests that both lesions are intimately related. We review here some molecular pathways linking amyloid β and Tau toxicities involving, among others, glycogen synthase kinase 3β, p38, Pin1, cyclin-dependent kinase 5, and regulator of calcineurin 1. Understanding amyloid β and Tau toxicities as part of a common pathophysiological mechanism may help to find molecular targets to prevent or even treat the disease.

Aβ and tau toxicities in Alzheimer's are linked via oxidative stress-induced p38 activation: protective role of vitamin E.
Oxidative stress is a hallmark of Alzheimer's disease (AD). We propose that rather than causing damage because of the action of free radicals, oxidative stress deranges signaling pathways leading to tau hyperphosphorylation, a hallmark of the disease. Indeed, incubation of neurons in culture with 5 μM beta-amyloid peptide (Aβ) causes an activation of p38 MAPK (p38) that leads to tau hyperphosphorylation. Inhibition of p38 prevents Aβ-induced tau phosphorylation. Aβ-induced effects are prevented when neurons are co-incubated with trolox (the water-soluble analog of vitamin E). We have confirmed these results in vivo, in APP/PS1 double transgenic mice of AD. We have found that APP/PS1 transgenic mice exhibit a high level of P-p38 in the hippocampus but not in cortex and this is prevented by feeding animals with a diet supplemented with vitamin E. Our results underpin the role of oxidative stress in the altered cell signaling in AD pathology and suggest that antioxidant prevention may be useful in AD therapeutics.

MECHANISMS OF PRESYNAPTIC CAMP DEPENDENT POTENTIATION

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Morgane Chiesa[1], Sara Ferrando Colomer[1], Diana Ixmatlahua[1], John Armstrong[1], Anis Contractor[2]

Hippocampal mossy fiber (MF) synapses play a key role in the processing of spatial information in the CA3 region of the hippocampus. These synapses exhibit a presynaptic cyclic adenosine monophosphate (cAMP)-dependent long-term potentiation (LTP) that switches the MF mode of action from a conditional to full detonator synapse, thus facilitating plasticity in the CA3 network. The downstream targets of cAMP, protein kinase A and Epac2, have been proposed to contribute to the mechanisms of elevated glutamate release at MF synapses. However, it is still unclear how each of these signaling pathways contributes to the induction and maintenance of MF LTP. In particular, Epac2 was only recently discovered to play a role. This guanine nucleotide exchanging factor is highly expressed in the dentate gyrus and has been recognized to regulate neurotransmitters release in other neurons and insulin secretion in the pancreas. To directly evaluate the role of presynaptic Epac2 in cAMP potentiation at MF synapses, we employed a novel mouse with loxP sites inserted in the Epac2 locus. We are using both a dentate specific Cre mouse cross for chronic ablation of Epac2 throughout development and a dentate specific viral strategy for acute ablation in adult mice. Electrophysiological recordings from CA3 neurons are utilized to evaluate basal synaptic properties and the integrity of short- and long-term potentiation of MF synapses following Epac2 ablation. Taken together, these experiments will provide a further understanding of the basic mechanisms underlying MF LTP, a process that is disrupted in normal aging and neuropsychiatric disorders.

Brain Volumes in Mice are Smaller at Birth After Term or Preterm Cesarean Section Delivery.
The rate of cesarean section (CS) delivery has steadily increased over the past decades despite epidemiological studies reporting higher risks of neonatal morbidity and neurodevelopmental disorders. Yet, little is known about the immediate impact of CS birth on the brain, hence the need of experimental studies to evaluate brain parameters following this mode of delivery. Using the solvent clearing method iDISCO and 3D imaging technique, we report that on the day of birth, whole-brain, hippocampus, and striatum volumes are reduced in CS-delivered as compared to vaginally-born mice, with a stronger effect observed in preterm CS pups. These results stress the impact of CS delivery, at term or preterm, during parturition and at birth. In contrast, cellular activity and apoptosis are reduced in mice born by CS preterm but not term, suggesting that these early-life processes are only impacted by the combination of preterm birth and CS delivery.

Term or Preterm Cesarean Section Delivery Does Not Lead to Long-term Detrimental Consequences in Mice.
Epidemiological studies have provided contradictory data on the deleterious sequels of cesarean section (C-section) delivery and their links with developmental brain disorders such as Autism Spectrum Disorders. To gain better insight on these issues, we have now compared physiological, morphological, and behavioral parameters in vaginal, term, and preterm C-section delivered mice. We report that C-section delivery does not lead to long-term behavioral alterations though preterm C-section delivery modifies communicative behaviors in pups. Moreover, C-section delivery neither alters the gamma-aminobutyric acid (GABA) developmental excitatory to inhibitory shift nor the frequency or amplitude of glutamatergic and GABAergic postsynaptic currents in hippocampal pyramidal neurons. However, these neurons present an underdeveloped dendritic arbor at birth in pups born by C-section delivery, but this difference disappears 1 day later suggesting an accelerated growth after birth. Therefore, C-section delivery, with prematurity as an aggravating factor, induces transient developmental delays but neither impacts the GABA developmental sequence nor leads to long-term consequences in mice. The deleterious sequels of C-section delivery described in epidemiological studies might be due to a perinatal insult that could be aggravated by C-section delivery.

Enhanced Glutamatergic Currents at Birth in Shank3 KO Mice.
Autism spectrum disorders (ASD) are neurodevelopmental disorders induced by genetic and environmental factors. In our recent studies, we showed that the GABA developmental shifts during delivery and the second postnatal week are abolished in two rodent models of ASD. Maternal treatment around birth with bumetanide restored the GABA developmental sequence and attenuated the autism pathogenesis in offspring. Clinical trials conducted in parallel confirmed the usefulness of bumetanide treatment to attenuate the symptoms in children with ASD. Collectively, these observations suggest that an alteration of the GABA developmental sequence is a hallmark of ASD. Here, we investigated whether similar alterations occur in the Shank3 mouse model of ASD. We report that in CA3 pyramidal neurons, the driving force and inhibitory action of GABA are not different in naïve and Shank3-mutant age-matched animals at birth and during the second postnatal week. In contrast, the frequency of spontaneous excitatory postsynaptic currents is already enhanced at birth and persists through postnatal day 15. Therefore, in CA3 pyramidal neurons of Shank3-mutant mice, glutamatergic but not GABAergic activity is affected at early developmental stages, hence reflecting the heterogeneity of mechanisms underlying the pathogenesis of ASD.

Alteration in the time and/or mode of delivery differentially modulates early development in mice.
Delivery is a complex biological process involving hormonal and mechanical stimuli that together condition the survival and development of the fetus out of the womb. Accordingly, changes in the time or way of being born are associated with an alteration of fundamental biological functions and hypothesized to promote the emergence of neurodevelopmental disorders. Hence, the steadily rise in preterm birth and cesarean section (CS) delivery rates over the past years has become a worldwide health concern. In our previous work, we reported that even though no long-term autistic-like deficits were observed, mice born preterm by CS presented early transient neuronal and communicative defects. However, understanding if these alterations were due to an early birth combined with CS delivery, or if prematurity solely could lead to a similar outcome remained to be evaluated. Using mice born either at term or preterm by vaginal or CS delivery, we assessed early life ultrasonic vocalizations and the onset of eye opening. We report that alterations in communicative behaviors are finely attuned and specifically affected either by preterm birth or by the association between CS delivery and preterm birth in mice, while delayed onset of eye opening is due to prematurity. Moreover, our work further underlies a gender-dependent vulnerability to changes in the time and/or way of being born with distinct outcomes observed in males and females. Thus, our results shed light on the intricacy of birth alterations and might further explain the disparities reported in epidemiological studies.

Early alterations in a mouse model of Rett syndrome: the GABA developmental shift is abolished at birth.
Genetic mutations of the Methyl-CpG-binding protein-2 (MECP2) gene underlie Rett syndrome (RTT). Developmental processes are often considered to be irrelevant in RTT pathogenesis but neuronal activity at birth has not been recorded. We report that the GABA developmental shift at birth is abolished in CA3 pyramidal neurons of Mecp2 mice and the glutamatergic/GABAergic postsynaptic currents (PSCs) ratio is increased. Two weeks later, GABA exerts strong excitatory actions, the glutamatergic/GABAergic PSCs ratio is enhanced, hyper-synchronized activity is present and metabotropic long-term depression (LTD) is impacted. One day before delivery, maternal administration of the NKCC1 chloride importer antagonist bumetanide restored these parameters but not respiratory or weight deficits, nor the onset of mortality. Results suggest that birth is a critical period in RTT with important alterations that can be attenuated by bumetanide raising the possibility of early treatment of the disorder.

DIFFERENT LTP MECHANISMS AMONG DENTATE GRANULE CELLS WITH DIFFERENT TYPES OF SPIKING PATTERN

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Yoonsub Kim, Suk-Ho Lee, Won-Kyung Ho
Seoul National University College of Medicine, Physiology, Seoul, Korea, Republic of

Mature granule cells (GCs) in the dentate gyrus are characterized by low excitability due to low input resistance and hyperpolarized resting membrane potential. Nevertheless, burst firing is often observed in GCs as in other pyramidal neurons where it plays important roles for neuronal signaling and synaptic plasticity. However, physiological significance of bursting in GCs is not well understood. In the present study, we classified mature GCs into regular-spiking (RS-GCs) and burst-spiking (BS-GCs) based on their initial firing frequency, and investigated how they responded differently to synaptic inputs. Excitatory postsynaptic potentials evoked by stimulating lateral perforant pathway were potentiated after a high-frequency stimulation (HFS, 10 stimuli at 100 Hz) with a subthreshold intensity. This potentiation, referred to as LTP-sub, was found to be NMDAR-dependent. There was no significance difference in the magnitude of LTP-sub between groups (128.90 ± 5.00%, BS-GCs; 139.69 ± 5.30%, RS-GCs). Interestingly, we could induce further potentiation in BS-GCs (138.73 ± 6.70%), but not in RS-GCs (98.67 ± 6.42%), by applying the second HFS with a higher intensity that evoked at least 3 action potentials (APs). This AP-dependent LTP (referred to as LTP-AP) was dependent on L-type calcium channel (LTCC). We found that initial AP frequency induced by the second HFS was higher in BS-GCs (133.66 ± 12.17 Hz) than in RS-GCs (81.17 ± 10.68 Hz). Taken together, it is suggested that intrinsic firing properties affect synaptically driven firing, and that bursting behavior is critical for inducing LTP-AP in GCs.

CHANGES OF SPIKE TIMING IN TOPOLOGICALLY CONSTRAINED NETWORKS UNDER REPEATED ELECTRICAL STIMULATION

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Stephan Ihle, Sophie Girardin, Tobias Ruff, Jens Duru, Benedikt Maurer, János Vörös
ETH Zürich, Department Of Information Technology And Electrical Engineering, Zürich, Switzerland

The exact mechanisms of how learning and memory is achieved is arguably one of the fundamental questions tackled by the field of neuroscience. However, after many years of research, the answer remains elusive. To find the exact mechanism, we believe it is important to observe neuronal activity with single cell resolution. It is difficult to achieve this in mammal model organisms. Instead, we propose using small primary neuronal networks cultured in-vitro on top of multi-electrode arrays (MEA) in order to record the electrical activity of neurons. By physically confining the space in which neurites can grow using polydimethylsiloxane (PDMS) microstructures, the topology of such networks can be constrained [1]. It is possible to highly parallelize experiments by compartmentalizing the MEA into multiple independent networks. By stimulating networks of primary rat hippocampal cells repeatedly every 250 ms, we have recently shown that the spiking response of the network stays remarkably constant for multiple hours [2]. However some networks showed highly reproducible changes in spike timing. Changes in spike timing can be interpreted as a form of plasticity. We found that roughly 20% of the spikes expressed depressing effects, while 5% experienced potentiating responses. We further observed that the number of depressing spike responses increased over time, while there was no significant change in potentiating effects. These results show that topologically constrained networks are a useful tool for plasticity research. [1]: Forró, et al. *Biosensors and Bioelectronics* 122 (2018): 75-87. GROUP I METABOTROPIC GLUTAMATE RECEPTOR-MEDIATED MODULATION OF EXCITATORY SYNAPTIC TRANSMISSION SHOWS INTERNEURON SPECIFICITY IN THE HUMAN NEOCORTEX

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Joanna Sandle[1], Gábor Molnár[1], Karri Lamsa[2], Pal Barzo[1], Gábor Tamás[1]
[1]University of Szeged, Department Of Physiology, Anatomy And Neuroscience, Szeged, Hungary, [2]University of Szeged, Physiology, Anatomy And Neuroscience Department, Szeged, Hungary

Activation of group I metabotropic glutamate receptors (mGluR) in the brain mediates changes in neuronal excitability, synaptic transmission, and network activity of cortical circuits. Influence of mGluRs on neural activity in the neocortex has been linked to learning-related plasticity, brain state-modulation as well as various human neurological disorders but studies investigating their effect in human brain are scarce. We performed intracellular recordings from synaptically-connected glutamatergic pyramidal cell-to-GABAergic interneuron pairs in layer 2/3 of human neocortical slices to study the effect of group I mGluR activation on these neurons and their synaptic communication. We found that activation of group I mGluRs by agonist (S)-3,5-dihydroxyphenylglycine (DHPG) modulated interneurons in subtype-dependent manner. We observed depression of excitatory synaptic transmission strength in non fast-spiking adaptive firing interneurons whereas most fast-spiking basket cells and axo-axonic cells exhibited potentiation of their synaptic excitatory input by the agonist. Parallel experiments in Wistar rat showed DHPG-mediated strengthening of glutamatergic input to fast-spiking basket cells. Our results demonstrate cell type-specific modulation of human neocortical neurons and their synaptic excitation by group I metabotropic receptor activation.

STUDY OF SYNAPTIC PLASTICITY MECHANISMS UNDERLYING MEMORY CONSOLIDATION IN THE HIPPOCAMPO-NEOCORTICAL NETWORK

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Cecilia Castelli[1], Frederic Lanore[2], Yann Humeau[3], Aurélie Lampin-Saint-Amaux[3], Marilyn Lepleux[3]
[1]CNRS, Iins, Bordeaux, France, [2]IINS, Umr 5297, Bordeaux, France, [3]IINS, Cnrs - Umr 5297, Bordeaux, France

Learning and consolidation of a behavioural response is a multistep process, taking place over multiple days, which implicates an active communication between the hippocampus and multiple associative cortical areas. The consolidation phase happens during slow wave sleep when hippocampal Sharp Wave-Ripples (SW-Rs) events occur. SW-Rs are replays of wakeful-acquired memory and are known to be involved in memory consolidation. SW-Rs are thought to strengthen synaptic connections within memory-related assemblies via synaptic plasticity mechanisms, however direct proof of this concept has been hard to obtain. The aim of my research is to unravel the synaptic mechanism underlying hippocampal to associative cortical areas communication in the context of memory consolidation and address whether and when synaptic plasticity takes place at hippocampal to cortical synapses. To this aim, I record local field potentials and unitary activity from extracellular electrodes placed in the dorsal hippocampus, medial prefrontal (mPFC) and posterior parietal (PPC) cortices in freely behaving animals performing a spatial memory task (Delayed Spatial Alternation task) and during a 3 hours resting period following the task. My results show that neuronal firing of excitatory pyramidal cells and inhibitory interneurons in the mPFC, during the occurrence of hippocampal SW-Rs, is enhanced after learning suggesting a change in synaptic strength between these two brain areas. My goal is now to manipulate synaptic plasticity at these afferences to unravel the synaptic mechanisms underlying memory consolidation in cortical associative areas.

INTERPLAY OF THALAMO- AND CORTICOSTRIATAL PLASTICITY IN BEHAVIORAL FLEXIBILITY

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Elodie Perrin[1], Sylvie Perez[1], Marie Vandecasteele[1], Hugues Berry[2], Laurent Venance[1]
[1]Collège de France, Center For Interdisciplinary Research In Biology, Paris, France, [2]University of Lyon - INRIA, Liris, Villeurbanne, France

The striatum is a major site of memory formation as the acquisition of a behavioral repertoire has been associated with cortico-striatal (CS) plasticity. Striatum integrates inputs from the cortex and thalamus that display concomitant or sequential activity. If a vast literature has focused on CS plasticity, little remains known about thalamo-striatal (TS) plasticity rules, their interplay with CS plasticity, and involvement in behavioral flexibility. We recorded in vivo plasticity in mice engaged in procedural learning on a horizontal ladder and found CS-LTP of opto-evoked LFP upon learning of a rung pattern#1 (without modification of TS-evoked-LFP), whereas this plasticity was canceled upon novelty (change for a rung pattern#2) to the profit of a TS-LTP. In vivo recording, of TS/CS activity during this task revealed activity patterns reminiscent of time-coding plasticity. Therefore, we characterized the input-timing dependent plasticity at CS and TS synapses in brain slices, in supra- and subthreshold regimes. We found that most temporal combinations induced LTP except when thalamus (supra) activity precedes cortical one, where LTD was observed, highlighting the crucial impact of timing in cortical and thalamic activities for the memory engram at striatal synapses. Ex vivo occlusion experiment showed that CS-LTP and TS-LTP were engaged during procedural learning and novelty, respectively. Interestingly, the modification of the rung patterning induced an increase in TS synaptic weight, while CS transmission decreases. The ability of TS plasticity to override CS plasticity could allow for flexible behavior, helping the exit of an existing automatism in favor of a new behavioral strategy.

ENDOCANNABINOID-MEDIATED PLASTICITY AT CORTICO-STRIATAL SYNAPSES DURING FAST LEARNING

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Charlotte Piette[1], Sylvie Perez[1], Laurent Venance[2], Jonathan Touboul[3]
[1]College de France, Cirb, Paris, France, [2]Collège de France, Center For Interdisciplinary Research In Biology (cirb), Paris, France, [3]Brandeis University, Department Of Mathematics, Waltham, United States of America

Fast learning designates the mechanisms underlying the acquisition of a long-term memory after a unique and brief experience. Considering that a brief exposure to a stimulus involves only a small number of spiking events and based on our earlier *in vitro* work uncovering a new form of synaptic potentiation induced by a very low number of temporally coupled cortical and striatal spikes and dependent on the endocannabinoid system (Cui et al., 2015), we hypothesize that the endocannabinoid system could underlie the acquisition of fast learning in the dorsolateral striatum. We developed a fast learning task in which mice learn to avoid contacting an adhesive tape after a single brief exposure. This experience induces a long-lasting memory, along with a cortico-striatal potentiation observed *in vivo*, by following the striatal response to optogenetically-evoked cortical stimulation. *Ex vivo* occlusion plasticity experiments confirmed the involvement of the endocannabinoid pathway. Furthermore, mice in which endocannabinoid-mediated potentiation (eCB-LTP) is altered, by either genetically knocking-out dopaminergic type-2 receptors (Xu et al., 2018) or inhibiting striatal CB1 receptors via striatal micro-infusions of AM251, exhibited degraded fast learning performance. Recordings of cortical and striatal units performed using Neuropixel probes in acute behaving animals in the Mobile Home Cage (Neurotar) allow us to extract neuronal activity patterns that may be responsible for eCB-LTP induction. The strength of cortico-striatal synapses is modified during the encoding of one-shot memories. Importantly, the endocannabinoid system, which can be activated with low spiking activity levels, appears to be a key molecular substrate for fast learning.

VALENCE-DEPENDENT SYNAPTIC PLASTICITY IN SOCIAL CONTEXT INSTRUCTS APPROACH/AVOIDANCE BEHAVIOR

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Pedro Espinosa[1], Mattia Lucchini[1,2], Federica Campanelli[1], Valentina Tiriticco[1], Benoît Girard[1], Camilla Bellone[1]
[1]University of Geneva, Department Of Basic Neuroscience, Geneva, Switzerland, [2]University of Geneva, Neufo, Genève, Switzerland

To decide whether to approach or avoid a conspecific, individuals need first to recognize the possibly positive (appetitive) or negative (aversive) valence of the stimulus and learn this association. The Nucleus Accumbens (NAc) is a key brain region of the mesocorticolimbic circuits for evaluating valence. However, how valence is codified at the synaptic level in a social context is still an open question. Within the NAc, D1 receptor-containing Medium Spiny Neurons (MSNs) have been related to rewarding and motivational aspects of social behavior. Using a free social interaction paradigm and calcium imaging techniques, we demonstrated that D1-MSNs respond to positive and negative social valence stimuli. Using anatomical tracing and *in vitro*electrophysiological recordings, we found D1-MSN strongly connected with glutamatergic neurons from the Anterior Insular Cortex (AIC) that also express D1Rs revealing a novel D1R-D1R top-down circuit between AIC and NAc. A day after the first social interaction, we evaluated glutamatergic synaptic parameters and found a dichotomous, long-term valence-dependent synaptic plasticity that occurs specifically in these neurons. Interestingly, these forms of plasticity are triggered by different firing frequencies from AIC inputs. Specifically, we showed that low-frequency stimulation drives positive valence-like plasticity, whereas high-frequency stimulation induces negative valence-like plasticity. By recruiting the same D1R positive neurons within the AIC-NAc circuit, we demonstrated long-term synaptic plasticity signature of social valence tuned by firing frequency.

INTACT INDUCTION AND PRESYNAPTIC OCCLUSION OF SHORT AND LONG-TERM POTENTIATION IN SYNAPTOPHYSIN FAMILY KNOCKOUTS

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Sergio Del Olmo Cabrera, John Wesseling
Instituto de Neurociencias, Molecular And Cellular Physiology Of Synaptic Transmission, San Juan de Alicante, Alicante, Spain

Synaptophysin/gyrin family proteins are ubiquitous components of synaptic vesicle membranes. Baseline synaptic strength is elevated in quadruple knockouts owing to elevated probability of release of neurotransmitter from readily releasable vesicles within presynaptic terminals. And, both short- and long-term synaptic potentiation are severely degraded. Deficits in short-term potentiation could result directly from the elevated baseline release via an occlusion mechanism. However, key types of long-term potentiation that require NMDA receptors for induction (NMDAR-LTP) are thought to be expressed by unrelated mechanisms, such as more AMPA receptors. Nevertheless, we now find that NMDAR-LTP in knockouts can be rescued by reducing extracellular Ca^{2+}, which lowers release probability back to wildtype levels. Likewise, increasing Ca^{2+} occludes LTP expression at wildtype synapses without blocking induction. The results indicate that both short- and long-term synaptic plasticity deficits in synaptophysin knockouts are caused by the elevated baseline release, and that the longest-lasting components of NMDAR-LTP are expressed by presynaptic mechanisms subject to the same kinds of endogenous limitations that shape short-term plasticity.

iSuRe-Cre is a genetic tool to reliably induce and report Cre-dependent genetic modifications.
Most biomedical research aimed at understanding gene function uses the Cre-Lox system, which consists of the Cre recombinase-dependent deletion of genes containing LoxP sites. This system enables conditional genetic modifications because the expression and activity of the recombinase Cre/CreERT2 can be regulated in space by tissue-specific promoters and in time by the ligand tamoxifen. Since the precise Cre-Lox recombination event is invisible, methods were developed to report Cre activity and are widely used. However, numerous studies have shown that expression of a given Cre activity reporter cannot be assumed to indicate deletion of other LoxP-flanked genes of interest. Here, we report the generation of an inducible dual reporter-Cre mouse allele, iSuRe-Cre. By significantly increasing Cre activity in reporter-expressing cells, iSuRe-Cre provides certainty that these cells have completely recombined floxed alleles. This genetic tool increases the ease, efficiency, and reliability of conditional mutagenesis and gene function analysis.

Elevated synaptic vesicle release probability in synaptophysin/gyrin family quadruple knockouts.
Synaptophysins 1 and 2 and synaptogyrins 1 and 3 constitute a major family of synaptic vesicle membrane proteins. Unlike other widely expressed synaptic vesicle proteins such as vSNAREs and synaptotagmins, the primary function has not been resolved. Here, we report robust elevation in the probability of release of readily releasable vesicles with both high and low release probabilities at a variety of synapse types from knockout mice missing all four family members. Neither the number of readily releasable vesicles, nor the timing of recruitment to the readily releasable pool was affected. The results suggest that family members serve as negative regulators of neurotransmission, acting directly at the level of exocytosis to dampen connection strength selectively when presynaptic action potentials fire at low frequency. The widespread expression suggests that chemical synapses may play a frequency filtering role in biological computation that is more elemental than presently envisioned.

Dual ifgMosaic: A Versatile Method for Multispectral and Combinatorial Mosaic Gene-Function Analysis.

Improved methods for manipulating and analyzing gene function have provided a better understanding of how genes work during organ development and disease. Inducible functional genetic mosaics can be extraordinarily useful in the study of biological systems; however, this experimental approach is still rarely used in vertebrates. This is mainly due to technical difficulties in the assembly of large DNA constructs carrying multiple genes and regulatory elements and their targeting to the genome. In addition, mosaic phenotypic analysis, unlike classical single gene-function analysis, requires clear labeling and detection of multiple cell clones in the same tissue. Here, we describe several methods for the rapid generation of transgenic or gene-targeted mice and embryonic stem (ES) cell lines containing all the necessary elements for inducible, fluorescent, and functional genetic mosaic (ifgMosaic) analysis. This technology enables the interrogation of multiple and combinatorial gene function with high temporal and cellular resolution.

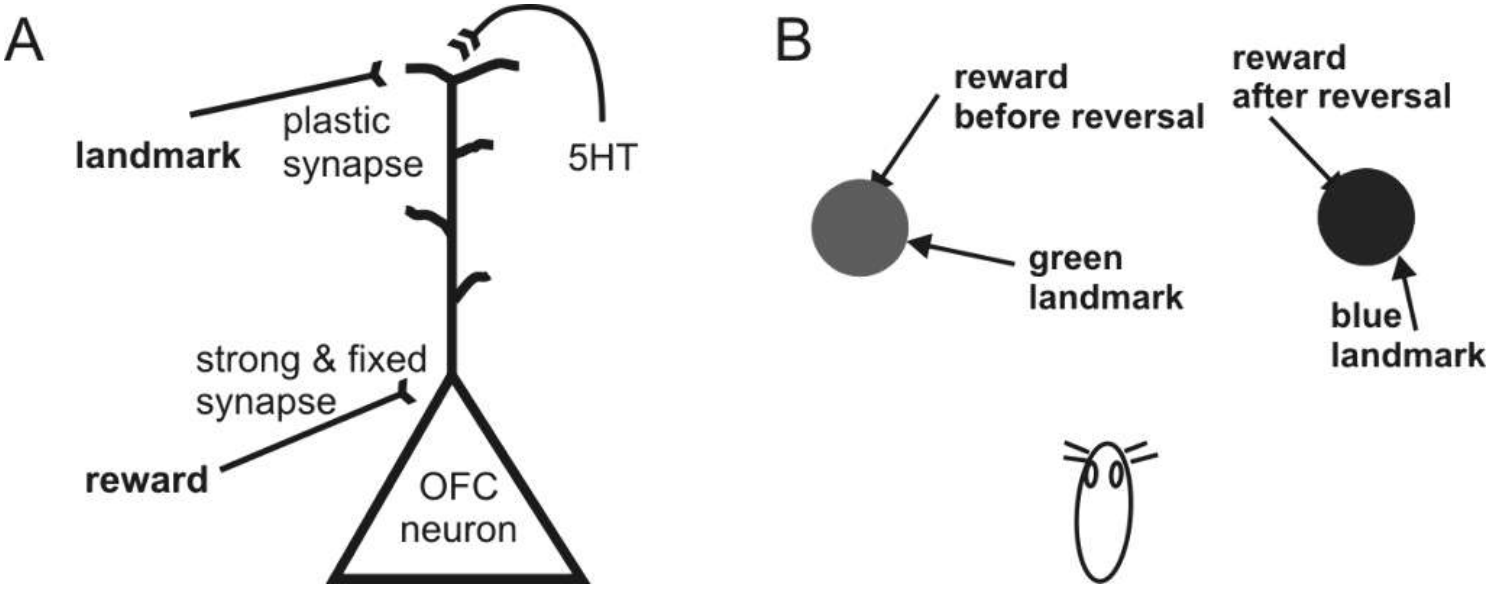
BEYOND THE REWARD PREDICTION ERROR: ACHIEVING REVERSAL LEARNING WITH HEBBIAN CORTICAL PLASTICITY AND SEROTONERGIC MODULATION

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Bernd Porr, Gillian Burnet
University of Glasgow, Biomedical Engineering, Glasgow, United Kingdom

We present a model of reversal learning which uses cortical neurons for its computations and won't require a reward prediction
error.



It utilises the structure and functional differentiation of cortical pyramidal neurons, in particular here of orbitofrontal cortex (OFC) neurons (see Panel A). The primary reward drives non-plastic synapses close to the soma of pyramidal neurons and causes strong postsynaptic responses which in turn cause a large calcium influx. New associations such as place or landmark information (Panel B) are established with Hebbian plasticity via plastic synapses in the dendritic tree (Panel A). LTP is triggered when strong somatic reward inputs drive a cortical neuron into spiking and cause a strong influx of calcium. LTD is triggered when the primary reward is not driving the OFC pyramidal neurons causing less and slower changing postsynaptic activity. Serotonin here acts as an accelerator for both LTP and LTD being a rectified reward prediction error. Experiments of a simulated animal (Panel B) performing a reversal task were run for a control scenario, for one with less serotonin and one with a simulated application of serotonin reuptake inhibitors. We show that Hebbian plasticity is able to model reversal learning and that serotonin controls the rate of plasticity which in turn regulates the animal's flexibility. Reduced serotonin increases the number of non-rewarding actions during reversal. SSRIs can help to overcome this deficiency, but we'd predict that any drug boosting plasticity, such as psychedelics, will have this

effect.

CLOSED-LOOP OPTOGENETIC STIMULATION CHANGES SPIKE TRANSMISSION GAIN IN FREELY MOVING MICE

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Lidor Spivak, Shirly Someck, Eran Stark, Amir Levi
Tel Aviv University, Sagol School Of Neuroscience, tel aviv, Israel

The precise timing and temporal ordering of neural spikes leads to the strengthening or weakening of synapses, and are thought to play a crucial role in circuit refinement, learning and memory. Spike timing-dependent plasticity (STDP) has been studied extensively in vitro and quantified mainly using the amplitude or the slope of the postsynaptic potentials. However, the extent to which spike transmission itself is affected by spike timing in intact animals is unknown. Here, we studied how spike transmission between two neurons is modified by inducing spikes in postsynaptic neurons, contingent on presynaptic spike timing. For that, we performed closed-loop optogenetic stimulation experiments, in which a pyramidal cell (PYR) spike triggered light activation of parvalbumin-immunoreactive interneurons (INT). Experiments were carried out in neocortex and hippocampal region CA1 of six freely-moving mice. The closed-loop manipulation resulted in new multi-neuronal spatiotemporal spike patterns, in which the presynaptic PYR fired several milliseconds before increased firing rate of the postsynaptic INT. We found that following repetitive timed spiking of the pre- and postsynaptic cells, spike transmission gain increased in most PYR-INT pairs in which the INT was light activated. In contrast, PYR-INT pairs in which the INT was not activated by light did not show a consistent increase of spike transmission gain. Thus, our results show that the temporal ordering of multi-neuronal spike trains induces persistent changes in spike transmission gain. **Funding: ERC #679253, ISF #638/16, and CIHR-IDRC-ISF #2558/18**

ALL OPTICAL INTERROGATION OF CA1 SYNAPSES AND NEURONS IN VIVO

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Cynthia Rais, J. Simon Wiegert
Universitätsklinikum Hamburg-Eppendorf, Synaptic Wiring And Information Processing Lab, Center For Molecular Neurobiology (zmnh), Hamburg, Germany

The hippocampus encodes information about an animal's position in space, integrating internal representations about the environment with sensory inputs, including tactile, auditory and visual stimuli. Most prominently, spatial information is encoded in CA1 place cells. However, while spatial memories can be retained over long time periods, place cell ensembles reorganize over days. While the cellular dynamics of hippocampal coding are well-described, less is known about functional and structural dynamics of individual Schaffer collateral synapses. There is no consensus with regard to the stability of synapses over time. While some studies suggest high turnover of spines, others found high stability. Moreover, a link between synaptic function and structural plasticity is missing. While shown *in vitro* that spine survival is influenced by functional plasticity, it is not known to what extent this link between synapse stability and activity *in vivo* is preserved. Thus, to better understand how dynamic remapping of cellular ensembles is related to synapse dynamics, we need to establish a link between functional and structural synaptic plasticity *in vivo*. In this study, we chronically imaged dendritic spines on CA1 cells in the awake mouse, monitoring their synaptic responses by optogenetically stimulating presynaptic CA3 cells. Using this approach, we were able to induce local, synaptic calcium responses at individual spines and to assess the stability of these functionally identified synapses over a time period of two weeks.

Anesthetics fragment hippocampal network activity, alter spine dynamics, and affect memory consolidation.
General anesthesia is characterized by reversible loss of consciousness accompanied by transient amnesia. Yet, long-term memory impairment is an undesirable side effect. How different types of general anesthetics (GAs) affect the hippocampus, a brain region central to memory formation and consolidation, is poorly understood. Using extracellular recordings, chronic 2-photon imaging, and behavioral analysis, we monitor the effects of isoflurane (Iso), medetomidine/midazolam/fentanyl (MMF), and ketamine/xylazine (Keta/Xyl) on network activity and structural spine dynamics in the hippocampal CA1 area of adult mice. GAs robustly reduced spiking activity, decorrelated cellular ensembles, albeit with distinct activity signatures, and altered spine dynamics. CA1 network activity under all 3 anesthetics was different to natural sleep. Iso anesthesia most closely resembled unperturbed activity during wakefulness and sleep, and network alterations recovered more readily than with Keta/Xyl and MMF. Correspondingly, memory consolidation was impaired after exposure to Keta/Xyl and MMF, but not Iso. Thus, different anesthetics distinctly alter hippocampal network dynamics, synaptic connectivity, and memory consolidation, with implications for GA strategy appraisal in animal research and clinical settings.

DENDRITIC SPINE NECK RESTRICTION REGULATES HETEROSYNAPTIC PLASTICITY

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Rahul Gupta[1], Cian O'Donnell[2]
[1]University of Bristol, Department Of Computer Sciences, Bristol, United Kingdom, [2]Magee Campus-Ulster University, School Of Computing, Engineering And Intelligent Systems, Londonderry, United Kingdom

Synaptic plasticity is a widely recognised physiological correlate of learning and memory. An important but poorly understood phenomenon is heterosynaptic plasticity. Long-term potentiation (LTP) and depression (LTD) at an stimulated synapse (homosynaptic plasticity) can cause either LTP or LTD at neighbouring synapses, depending on experimental conditions. The factors determining these forms of heterosynaptic plasticity are currently unknown. Here, we propose a new theory that explains how differential restrictions imposed by dendritic spine neck plasticity on membrane and cytosolic diffusions of plasticity-associated molecular signals may control the rules of heterosynaptic plasticity. To demonstrate this theory in practice, we developed a compartment-based reaction-diffusion model of Ca^{2+}/Calmodulin-dependent Kinase II (CaMKII)-Calcineurin synaptic signalling and AMPA receptor (AMPAR) trafficking in a 100 micronmeter long dendritic branch bearing hundreds of spines. We fit the AMPAR trafficking parameters to previously published fluorescence imaging data from glutamate uncaging experiments on single spine in CA1 pyramidal neurons (Patterson et al, PNAS 2010). We found that the model could replicate all four forms of heterosynaptic plasticity, depending on where a spine neck sits in the two-dimensional parameter space of membrane vs. cytosolic diffusion restrictions. For high neck surface restriction, homosynaptic LTP and LTD consistently lead to heterosynaptic LTD. For lesser neck surface restriction, homosynaptic LTP and LTD cause heterosynaptic LTP or LTD depending on relative intensities of synaptic CaMKII and Calcineurin activation, and neck restriction to Calcineurin diffusion. This model makes new predictions for experiments and offers a theoretical bridge between molecular processes and learning rules in the brain.

CAMP MODULATES NEURONAL EXCITABILITY, NOT LONG-TERM PLASTICITY

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Oana Constantin, Daniel Udwari, Paul Lamothe, Lennart Beck, Christine Gee, Thomas Oertner
Center for Molecular Neurobiology Hamburg (ZMNH), Institute For Synaptic Physiology, Hamburg, Germany

Cyclic adenosine monophosphate (cAMP) is a ubiquitous second messenger that, when raised by forskolin, usually together with picrotoxin and rolipram to block GABAA and phosphodiesterases induces long-term potentiation (LTP) of synaptic transmission and expression of immediate early genes such as cFos by activating the postsynaptic PKA-CREB pathway. Most studies, however, have relied on pharmacological tools whose actions are not confined to specific cells or synaptic compartments. Here, we take advantage of recent developments in photoactivatable adenylyl cyclases to raise cAMP in single postsynaptic hippocampal CA1 neurons, in many presynaptic CA3 neurons, many postsynaptic CA1 neurons or in all excitatory neurons to investigate compartment-specific effects of cAMP at Schaffer collateral synapses. Surprisingly, optogenetically raising cAMP in single postsynaptic CA1 neurons induced neither LTP nor cFos expression. Whereas, similarly to the effects of forskolin, optogenetically increasing cAMP in excitatory neurons throughout the whole hippocampal slice, induced LTP and strong cFos expression. Interestingly, raising cAMP in only presynaptic or only postsynaptic neurons was insufficient to induce LTP and moderately increased the intensity of cFos labeling. In contrast to current models of intracellular signaling cascades, there is no direct pathway leading from cAMP to cFos induction in individual neurons. Rather cAMP increases excitability and transmitter release and these are required for cFos and LTP. The function of neuronal cAMP as a plasticity trigger thus requires an intact, synaptically connected network.

PACmn for improved optogenetic control of intracellular cAMP.
Cyclic adenosine monophosphate (cAMP) is a ubiquitous second messenger that transduces extracellular signals in virtually all eukaryotic cells. The soluble Beggiatoa photoactivatable adenylyl cyclase (bPAC) rapidly raises cAMP in blue light and has been used to study cAMP signaling pathways cell-autonomously. But low activity in the dark might raise resting cAMP in cells expressing bPAC, and most eukaryotic cyclases are membrane-targeted rather than soluble. Our aim was to engineer a plasma membrane-anchored PAC with no dark activity (i.e., no cAMP accumulation in the dark) that rapidly increases cAMP when illuminated.

Synthetic Light-Activated Ion Channels for Optogenetic Activation and Inhibition.
Optogenetic manipulation of cells or living organisms became widely used in neuroscience following the introduction of the light-gated ion channel channelrhodopsin-2 (ChR2). ChR2 is a non-selective cation channel, ideally suited to depolarize and evoke action potentials in neurons. However, its calcium (Ca) permeability and single channel conductance are low and for some applications longer-lasting increases in intracellular Ca might be desirable. Moreover, there is need for an efficient light-gated potassium (K) channel that can rapidly inhibit spiking in targeted neurons. Considering the importance of Ca and K in cell physiology, light-activated Ca-permeant and K-specific channels would be welcome additions to the optogenetic toolbox. Here we describe the engineering of novel light-gated Ca-permeant and K-specific channels by fusing a bacterial photoactivated adenylyl cyclase to cyclic nucleotide-gated channels with high permeability for Ca or for K, respectively. Optimized fusion constructs showed strong light-gated conductance in oocytes and in rat hippocampal neurons. These constructs could also be used to control the motility of larvae, when expressed in motoneurons. Illumination led to body contraction when motoneurons expressed the light-sensitive Ca-permeant channel, and to body extension when expressing the light-sensitive K channel, both effectively and reversibly paralyzing the larvae. Further optimization of these constructs will be required for application in adult flies since both constructs led to eclosion failure when expressed in motoneurons.

Rhodopsin-cyclases for photocontrol of cGMP/cAMP and 2.3 Å structure of the adenylyl cyclase domain.
The cyclic nucleotides cAMP and cGMP are important second messengers that orchestrate fundamental cellular responses. Here, we present the characterization of the rhodopsin-guanylyl cyclase from Catenaria anguillulae (CaRhGC), which produces cGMP in response to green light with a light to dark activity ratio >1000. After light excitation the putative signaling state forms with τ = 31 ms and decays with τ = 570 ms. Mutations (up to 6) within the nucleotide binding site generate rhodopsin-adenylyl cyclases (CaRhACs) of which the double mutated YFP-CaRhAC (E497K/C566D) is the most suitable for rapid cAMP production in neurons. Furthermore, the crystal structure of the ligand-bound AC domain (2.25 Å) reveals detailed information about the nucleotide binding mode within this recently discovered class of enzyme rhodopsin. Both YFP-CaRhGC and YFP-CaRhAC are favorable optogenetic tools for non-invasive, cell-selective, and spatio-temporally precise modulation of cAMP/cGMP with light.

AVERSION LEARNING MEDIATED BY DOPAMINERGIC NEUROTRANSMISSION IN THE ANTERIOR CINGULATE CORTEX

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Lotte Jonker, Walter Senn, Thomas Nevian
University of Bern, Department Of Physiology, Bern, Switzerland

Synaptic plasticity is instrumental for cognitive functions. Moreover, cortical plasticity rules can be influenced by neuromodulatory inputs. The anterior cingulate cortex (ACC) is a brain region involved in error detection, pain processing and aversive learning. The ACC is highly regulated by dopaminergic inputs, mainly from the ventral tegmental area (VTA). However, the relationship between synaptic plasticity and the role of dopamine (DA) in the ACC in the context of aversive learning has not yet been characterized. We found that chemogenetic inhibition of ACC neuronal activity suppressed aversive learning. Likewise, silencing ACC inputs from the VTA impaired aversive learning. Moreover, at a cellular level, our results demonstrate that at L5 pyramidal neurons in the ACC, DA facilitates plasticity at electrically-evoked proximal, but not distal, synapses in an NMDAR-mediated, dopamine-1-receptor dependent manner. These results suggest that DA contributes to strengthen synaptic connections of ACC L5 pyramidal neurons, a mechanism that in vivo is partly mediated by VTA inputs underlying aversive learning.

Long-Lasting, Pathway-Specific Impairment of a Novel Form of Spike-Timing-Dependent Long-Term Depression by Neuropathic Pain in the Anterior Cingulate Cortex.
Malfunctioning synaptic plasticity is one of the major mechanisms contributing to the development of chronic pain. We studied spike-timing dependent depression (tLTD) in the anterior cingulate cortex (ACC) of male mice, a brain region involved in processing emotional aspects of pain. tLTD onto layer 5 pyramidal neurons depended on postsynaptic calcium-influx through GluN2B-containing NMDARs and retrograde signaling via nitric oxide to reduce presynaptic release probability. After chronic constriction injury of the sciatic nerve, a model for neuropathic pain, tLTD was rapidly impaired; and this phenotype persisted even beyond the time of recovery from mechanical sensitization. Exclusion of GluN2B-containing NMDARs from the postsynaptic site specifically at projections from the anterior thalamus to the ACC caused the tLTD phenotype, whereas signaling downstream of nitric oxide synthesis remained intact. Thus, transient neuropathic pain can leave a permanent trace manifested in the disturbance of synaptic plasticity in a specific afferent pathway to the cortex. Synaptic plasticity is one of the main mechanisms that contributes to the development of chronic pain. Most studies have focused on potentiation of excitatory synaptic transmission, but very little is known about the reduction in synaptic strength. We have focused on the ACC, a brain region associated with the processing of emotional and affective components of pain. We studied spike-timing dependent LTD, which is a biologically plausible form of synaptic plasticity, that depends on the relative timing of presynaptic and postsynaptic activity. We found a long-lasting and pathway-specific suppression of the induction mechanism for spike-timing dependent LTD from the anterior thalamus to the ACC, suggesting that this pathology might be involved in altered emotional processing in pain.

Efficient Low-Pass Dendro-Somatic Coupling in the Apical Dendrite of Layer 5 Pyramidal Neurons in the Anterior Cingulate Cortex.
Signal propagation in the dendrites of many neurons, including cortical pyramidal neurons in sensory cortex, is characterized by strong attenuation toward the soma. In contrast, using dual whole-cell recordings from the apical dendrite and soma of layer 5 (L5) pyramidal neurons in the anterior cingulate cortex (ACC) of adult male mice we found good coupling, particularly of slow subthreshold potentials like NMDA spikes or trains of EPSPs from dendrite to soma. Only the fastest EPSPs in the ACC were reduced to a similar degree as in primary somatosensory cortex, revealing differential low-pass filtering capabilities. Furthermore, L5 pyramidal neurons in the ACC did not exhibit dendritic Ca spikes as prominently found in the apical dendrite of S1 (somatosensory cortex) pyramidal neurons. Fitting the experimental data to a NEURON model revealed

that the specific distribution of , , , and was sufficient to explain the electrotonic dendritic structure causing a leaky distal dendritic compartment with correspondingly low input resistance and a compact perisomatic region, resulting in a decoupling of distal tuft branches from each other while at the same time efficiently connecting them to the soma. Our results give a biophysically plausible explanation of how a class of prefrontal cortical pyramidal neurons achieve efficient integration of subthreshold distal synaptic inputs compared with the same cell type in sensory cortices. Understanding cortical computation requires the understanding of its fundamental computational subunits. Layer 5 pyramidal neurons are the main output neurons of the cortex, integrating synaptic inputs across different cortical layers. Their elaborate dendritic tree receives, propagates, and transforms synaptic inputs into action potential output. We found good coupling of slow subthreshold potentials like NMDA spikes or trains of EPSPs from the distal apical dendrite to the soma in pyramidal neurons in the ACC, which was significantly better compared with S1. This suggests that frontal pyramidal neurons use a different integration scheme compared with the same cell type in somatosensory cortex, which has important implications for our understanding of information processing across different parts of the neocortex.

Mitochondrial Dynamics in Visual Cortex Are Limited In Vivo and Not Affected by Axonal Structural Plasticity.
Mitochondria buffer intracellular Ca and provide energy [1]. Because synaptic structures with high Ca buffering [2-4] or energy demand [5] are often localized far away from the soma, mitochondria are actively transported to these sites [6-11]. Also, the removal and degradation of mitochondria are tightly regulated [9, 12, 13], because dysfunctional mitochondria are a source of reactive oxygen species, which can damage the cell [14]. Deficits in mitochondrial trafficking have been proposed to contribute to the pathogenesis of Parkinson's disease, schizophrenia, amyotrophic lateral sclerosis, optic atrophy, and Alzheimer's disease [13, 15-19]. In neuronal cultures, about a third of mitochondria are motile, whereas the majority remains stationary for several days [8, 20]. Activity-dependent mechanisms cause mitochondria to stop at synaptic sites [7, 8, 20, 21], which affects synapse function and maintenance. Reducing mitochondrial content in dendrites decreases spine density [22, 23], whereas increasing mitochondrial content or activity increases it [7]. These bidirectional interactions between synaptic activity and mitochondrial trafficking suggest that mitochondria may regulate synaptic plasticity. Here we investigated the dynamics of mitochondria in relation to axonal boutons of neocortical pyramidal neurons for the first time in vivo. We find that under these circumstances practically all mitochondria are stationary, both during development and in adulthood. In adult visual cortex, mitochondria are preferentially localized at putative boutons, where they remain for several days. Retinal-lesion-induced cortical plasticity increases turnover of putative boutons but leaves mitochondrial turnover unaffected. We conclude that in visual cortex in vivo, mitochondria are less dynamic than in vitro, and that structural plasticity does not affect mitochondrial dynamics.

TWO-PHOTON CALCIUM IMAGING EXPERIMENTS UNCOVER CEREBELLAR CORTEX MICROCIRCUIT PROPERTIES

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Francesco Mainardi[1], Marialuisa Tognolina[1], Egidio D'Angelo[1,2]
[1]University of Pavia, Dept. Of Brain And Behavioural Sciences, Pavia, Italy, [2]IRCCS Mondino Foundation, Brain Connectivity Center, Pavia, Italy

Investigation of microcircuits functioning is growing in interest in neuroscience research, as they have a key role in processing incoming inputs. The study of the dynamic interactions between the different elements generating the microcircuit activity requires the acquisition of data from several single neurons, which must be uniquely identified and whose activity must be monitored over time. We investigated the cerebellar cortex microcircuit by performing two-photon calcium imaging experiments in acute cerebellar slices with a scanless spatial-light modulator two-photon microscope (SLM-2PM) that allows to monitor the activity of hundreds of neurons simultaneously over time, while maintaining single-cell resolution. We acquired stimulus-induced calcium signals (10 pulses@50Hz delivered to the afferent mossy fibers) from neurons located in different regions of the circuit (granular layer, Purkinje cells layer and molecular interneurons layer), showing different trends and temporal activations. We monitored these activities before and after the induction of long-term synaptic plasticity at the mossy fibers-granule cells synapses. The expression of long-term plasticity at the input stage of the circuit reverberated throughout the entire network, resulting in the expression of both short-term and long-term plasticity in Purkinje cells and molecular layer interneurons. These data are crucial in order to understand the role of different neuronal types in shaping the cerebellar cortex activity and to uncover how the latter is modulated by different forms of plasticity, providing experimental validation of both model predictions of circuit properties and hypothesis about cerebellar cortex functioning.

Aims: Synaptic plasticity is a cellular mechanism that crucially supports hippocampus-dependent memory formation. This phenomenon, in turn, is potently influenced by catecholaminergic neuromodulation. The locus coeruleus (LC) is a major source of catecholamines for the brain. Changes in LC tonus that is triggered by novel experience leads to noradrenaline (NA) release in the hippocampus, particularly in the dentate gyrus (DG). Patterned stimulation of the LC in frequency ranges related to phasic activation of the LC triggers long-term depression (LTD) in the hippocampus *in vivo.*In recent years it has emerged that the LC co-releases dopamine (DA) under particular experimental circumstances. In this study, we explored whether both neurotransmitters contribute equally to hippocampal LTD triggered by LC stimulation (LC-LTD). **Methods:** Adult male rats underwent chronic implantation of a stimulating electrode into both the LC and the medial perforant path, and a recording electrode into the DG. A cannula was implanted into the lateral cerebral ventricle to permit pharmacological treatment. We examined the effect of pharmacological antagonism of dopamine D1/D5 receptors (D1/5R) and beta-adrenergic receptors (b-AR) on synaptic plasticity evoked in the DG by LC stimulation using different stimulation patterns ranging from 2 -100Hz. **Results:** Whereas D1/D5R are critically involved in LC-LTD that is triggered by low frequency stimulation of the LC, b-AR are predominantly involved in LC-LTD induced by high-frequency stimulation. **Conclusions:** Our results indicate that D1/D5R and b-AR contribute in a differentiated manner to frequency-dependent hippocampal LC-LTD.

SYNAPTIC AND INTRINSIC POTENTIATION IN O-LM INTERNEURONS IS INDUCED BY THETA PATTERNS OF STIMULATION

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Malika Sammari[1], Yanis Inglebert[1], Norbert Ankri[1], Michaël Russier[1], Salvatore Incontro[1], Dominique Debanne[2]
[1]INSERM UMR1072, AMU, Faculté De Médecine, Marseille, France, [2]Inserm UMR1072, AMU, Faculté De Médecine, Marseille, France

Oriens lacunosum-moleculare (O-LM) interneurons display a non-conventional form of long-term synaptic potentiation (LTP) conferred by calcium-permeable AMPA receptors (CP-AMPAR). So far, this form of LTP has been induced in O-LM cells by physiologically unrealistic protocols. We report here the induction of both synaptic and intrinsic potentiation in O-LM interneurons following stimulation of afferent glutamatergic inputs in the theta (θ) frequency range. LTP is induced by synaptic activation of CP-AMPAR whereas long-term potentiation of intrinsic excitability (LTP-IE) results from the mGluR1-dependent down-regulation of Kv7 voltage-dependent potassium channel and hyperpolarization activated and cyclic nucleotide-gated (HCN) channel through the depletion of phosphatidylinositol-4,5-bi-phosphate (PIP2). LTP and LTP-IE are reversible, demonstrating that both synaptic and intrinsic changes are bidirectional in O-LM cells. We conclude that physiological stimuli such as θ patterns induce synaptic and intrinsic potentiation in O-LM interneurons. Funded by FRM

The formation of new episodic memories requires the hippocampus. The CA1 hippocampal area exhibits high level synaptic structural plasticity, which is thought to support temporary information storage. By tracking excitatory synapses, it has indeed been shown that hippocampal CA1 has more excitatory structural turnover than neocortical areas, and that such turnover negatively correlates with the ability of mice to recall a hippocampal-dependent memory. However, little is known about the dynamics of inhibitory synapses. Inhibitory neurons have a critical role in episodic memory and the position of inhibitory synapses on CA1 pyramidal neurons strongly influences the computations these neurons carry out. Thus, understanding the dynamics of inhibitory synapses is fundamental to decipher the circuit-level mechanisms underlying encoding of new information. Inhibitory synapses, however, lack a morphological feature, which makes it difficult to visualize them *in vivo.* To solve this issue, we tested and optimized different labelling methods with the aim to track inhibitory synapses on excitatory CA1 pyramidal neurons using *in vivo* time-lapse, deep-brain, 2-photon microscopy in mice. The most promising method was a double viral injection in which one virus expressed cytosolic tdTomato in frame with Cre recombinase under the control of an excitatory promotor and thereby driving the expression of a second virus carrying a Cre-dependent GFP, fused to the inhibitory post-synaptic protein: Gephyrin. Utilizing this labelling method, I tracked inhibitory synapses before and after fear conditioning training to investigate the relationship between CA1 inhibitory synaptic dynamics and hippocampal-dependent learning.

MAINTAINING NEUROPLASTICITY IN HEALTHY AGEING: SEX-DEPENDENT ROLE OF NEUROPEPTIDE Y

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Katharina Klinger[1], Gürsel Çalışkan[1,2], Oliver Stork[2]
[1]Otto-von-Guericke Universität, Institute Of Biology, Magdeburg, Germany, [2]Otto-von-Guericke Universität, Center For Behavioral Brain Sciences, Magdeburg, Germany

Aging-related cognitive decline is associated with a reduced number of neuropeptide Y (NPY)-expressing interneurons and a loss of cholinergic function in the hippocampus. Furthermore, NPY-expressing interneurons in the dorsal DG (dDG) are modulated by the cholinergic system and are critically involved in memory formation and storage. In the current study, we therefore investigated with extracellular field potential recordings the effect of NPYergic neurotransmission on synaptic plasticity in a sex- and age-dependent manner, under intact inhibitory neurotransmission, in mice. Our data show that theta burst stimulation induced long-term potentiation (LTP) in aged mice is dependent on cholinergic and NPYergic neurotransmission in a sex-specific manner. This is indicated by a loss of LTP in old male mice, which could be restored by increasing the cholinergic activity through physostigmine. Strikingly, this cholinergic effect was strictly dependent on NPY and could be blocked by an Y1 receptor antagonist BIBP3226. In contrast, in old female mice, LTP was not abolished during ageing but dependent on NPYergic neurotransmission. Interestingly, LTP was independent of Y1-R blockade under moderate cholinergic activation. Together, these observations suggest that NPYergic neurotransmission becomes critical for maintaining dDG LTP in old female mice and for the recovery of synaptic plasticity under moderate cholinergic activation in old male mice. Observed alterations in baseline excitability might contribute to these phenomena. The mechanisms of NPY-mediated facilitation of plasticity in the aged dDG are currently under investigation.

The C57Bl/6 mouse strain is very popular in brain research. Recent findings reported that synaptic plasticity in the form of long-term potentiation (LTP) is markedly reduced in hippocampal slice preparations from the C57Bl/6, compared to the CBA/CaOlaHsd mice. Furthermore, LTP has been shown to depend on D1-like receptors in rodents, and that the D1-like receptor variants, D1 and D5, have shown different functional relevance for hippocampal synaptic plasticity. In this study, we investigated whether strain-dependent differences in persistent hippocampal synaptic plasticity are also evident in freely behaving mice. We also explored how pharmacological agonism or antagonism of D1-like receptors differently modulates LTP in these strains. Finally, we assessed differences in D1-like expression between strains using immunohistochemistry. Male CBA/CaOlaHsd and C57Bl/6 mice (7-8 weeks old) underwent implantation of a stimulating electrode in the Schaffer collaterals and a recording electrode in Stratum radiatum to obtain synaptic responses in the CA1 region of the hippocampus. A cannula was implanted i.c.v. for pharmacological treatment. Freely behaving C57Bl/6 mice expressed significantly poorer LTP and short-term potentiation (STP) compared to CBA/CaOlaHsd mice. Synaptic potentiation also differed markedly between the mouse strains in the presence of a D1-like receptor agonist or antagonist. The plasticity outcome was considered in light of D1-like expression in the hippocampus. Our findings show that C57Bl/6 mice exhibit poorer CA1 synaptic potentiation in comparison with CBA/CaOlaHsd mice. Effects may be mediated partially by the dopaminergic system. This work was supported by a German Research Foundation (DFG) grant to DMV (SFB 874/B1, project no.:122679504).

CHOLECYSTOKININERGIC SIGNALING EXERTS MAJOR CONTROL ON CORTICO-STRIATAL SYNAPTIC PLASTICITY AND MOTOR BEHAVIOR.

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Chloé Guillaume, Patricia Parnet, Vincent Paillé
Université de Nantes, Institut des Maladies de l'Appareil Digestif (IMAD), INRAe, Umr 1280 Physiopathologies Des Adaptations Nutritionnelles, Nantes, France

Cholecystokinin (CCK) is well-known as the intestine satiety hormone, but this molecule is also detected at high concentrations in the brain, and plays a major role, yet not totally unraveled, on synaptic plasticity and memory. In order to better understand processes by which CCK impact plasticity, we chose to focus our attention on the striatum. This CCK2R rich region, presents a high level of plasticity and is involved in procedural learning and motor behavior. To elucidate the role of CCK in the striatal synapse, we use an *in-vivo* and *ex-vivo* approaches. In our *ex-vivo* approach, we evaluated the impact of CCK2R antagonist on cortico-striatal plasticity using patch-clamp of MSNs of horizontal brain slices of juvenile rats (20-35 days). To induce plasticity, we used a Spike Timing Dependent Plasticity (STDP) protocol. To confirm these electrophysiology data, we evaluated the effect of an injection of CCK2R antagonist or CCK on the motor behavior of juvenile rats *in-vivo*. Different motor tests were performed: rotarod, stepping test, open-field. C-fos immunohistochemistry performed on the brains collected at the end of the protocol would allow us to confirm the direct implication of striatum CCK2R in this function. Interestingly, we demonstrated that the CCK2R antagonist was able to completely reverse the cortico-striatal synaptic plasticity (i.e. LTP protocol leads to LTD). Moreover, *in-vivo* experiments showed a sex-dependent impairment of motor behavior following an injection of CCK2R antagonist. Overall, our results demonstrated that CCK and its receptor CCK2R are essential for encoding information processing in the cortico-striatal network.

DIVERGENCE OF FREQUENCY-DEPENDENT INDUCTION OF LTP AND LTD BY THE LATERAL AND MEDIAL PERFORANT PATH INPUTS TO THE DENTATE GYRUS

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Hardy Hagena, Jens Colitti-Klausnitzer, Valentyna Dubovyk, Denise Manahan-Vaughan
Ruhr University Bochum, Department Of Neurophysiology, Bochum, Germany

Aim: The entorhinal cortex segregates information sent to the hippocampus via the lateral (LPP) and medial perforant paths (MPP). Whether frequency-dependent LPP and MPP information-relay results in expression of different forms of homosynaptic plasticity within the respective synapses is unclear. We compared frequency-dependent long-term potentiation (LTP) and long-term depression (LTD) at MPP and LPP synapses in the dentate gyrus (DG) of freely behaving rats. We also compared neurotransmitter receptor expression at the level of synaptic inputs of the MPP and LPP in the molecular layer of the DG. **Methods:** Male Wistar rats underwent implantation of a recording electrode in the dentate gyrus and a stimulation electrode in the MPP or LPP. Frequency-dependent synaptic plasticity was tested using afferent frequencies in the range of 1- 200Hz. Immunohistochemistry was performed to examine the expression of GluN1, GluN2A and GluN2B subunits of the NMDA receptor in the molecular layer. **Results:** MPP–DG synapses exhibit a predisposition toward LTP expression, whereas LPP-DG synapses prefer to express synaptic depression at the afferent frequencies tested. GluN1, GluN2A, or GluN2B subunits were equally expressed in the molecular layer of the DG, suggesting that input properties, and not receptor distribution, determine the response of LPP or MPP synapses in the DG. **Conclusion:** LPP and MPP enable distinct forms of synaptic plasticity in response to the same frequencies and thus, may support the functional differentiation of information input to, and experience-dependent information storage in, the hippocampus. SYNAPTIC MECHANISMS UNDERLYING INNATE AND LEARNED SOCIAL FEAR

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Giulia Casarotto, Anastasia Gemelli, Camilla Bellone
University of Geneva, Basic Neuroscience, Geneva, Switzerland

When animals encounter danger in a social context, they usually respond to the situation by freezing or flying. The fear that accompanies these behaviors can be innate or learned and in both cases is critical for survival. Indeed, animals innately fear predators while learning to fear aggressive conspecifics. Whether innate and learned social fears share common neuronal circuits and mechanisms is still largely unknown. Here, we first developed a behavioral paradigm that allows us to induce and test learned and innate social fear. cFos immunohistochemistry and fiber photometry recordings revealed that the olfactory tubercle (OT), situated in the ventral striatum, it is active during both the expression of learned and innate fear. Using tracing approaches, we anatomically characterized the different glutamatergic inputs to this region. We found that the two main inputs to the OT are the olfactory bulb (OB) and the basolateral amygdala (BLA). We characterized shared and unique forms of synaptic plasticity induced by innate and learned social fear and their role in the expression of the fear response. Our study will provide the foundation for understanding the synaptic mechanisms underlying learned and innate social fear responses.

DOPAMINE D2-LIKE RECEPTORS BIDIRECTIONALLY REGULATE CA1 SYNAPTIC PLASTICITY AND MODULATE CUMULATIVE SPATIAL MEMORY IN RATS

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Violeta Maria Caragea[1,2], Denise Manahan-Vaughan[2]
[1]Ruhr-University Bochum, International Graduate School Of Neuroscience, Bochum, Germany, [2]Ruhr-Universität Bochum, Department Of Neurophysiology, Bochum, Germany

Dopamine plays an important role in modulating hippocampal synaptic plasticity and memory. Dopamine D1/ D5 receptors (D1/5R) and D2-like receptors (D2R) are positively and negatively coupled to adenylyl cyclase, respectively. Substantial evidence supports a role for D1/5R in supporting the persistency of hippocampal long-term potentiation (LTP) and depression (LTD). Less is known about the role of D2R in these phenomena. In this study, we explored the influence of D2R on synaptic plasticity at Schaffer collateral (SC)-CA1 synapses *in vivo*, and on spatial memory in rats. Intracerebral pharmacological antagonism of D2R prevented the expression of both short-term (<1 h) and long-term potentiation (>4 h), as well as the expression of short-term depression (STD, <1 h) at CA1-SC synapses of freely behaving adult rats. The same dose of D2R antagonist also altered the retention of a cumulative (semantic-like) spatial memory task and significantly impaired retention of recent spatiotemporal aspects of an episodic-like memory task. Taken together, our findings indicate that the D2R bidirectionally modulate synaptic plasticity in the hippocampal CA1 region, and play an important role in enabling cumulative and episodic-like forms of spatial learning. This work was funded by the Deutsche Forschunggemeinschaft (SFB 874/B10, project number: 122679504).

CELLULAR MECHANISM OF SILENT SYNAPSES FORMATION IN CENTRAL AMYGDALA IN COCAINE-INDUCED LOCOMOTOR SENSITIZATION

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Justyna Wisniewska, Anna Beroun
Nencki Institute of Experimental Biology, Laboratory Of Neuronal Plasticity, Braincity, Warsaw, Poland

Drugs of abuse, such as cocaine, are known to induce extremely durable forms of memory. One of the features of cocaine-induced plasticity is the induction of silent synapses - immature excitatory connections, that represent the brain's increased capacity to learn. They possess NMDA receptors but lack AMPA receptors on their surface. We showed that exposure to cocaine induces silent synaptic connections in the neurons of the amygdalar complex - a key brain structure in aversive and appetitive learning (memorizing negative and positive events respectively). Such silent synaptic contacts are transient and their disappearance could indicate their integration into the circuitry by accumulation of AMPA receptors in LTP-like manner. Alternatively, silent synapses could be formed via endocytosis of AMPA receptors, hence representing an ongoing LTD process in response to cocaine exposure. To elucidate the cellular mechanism of silent synapses formation in central amygdala in cocaine-induced locomotor sensitization we used MMP-9 (matrix metalloproteinase 9) KO mice, as the lack of MMP-9 function blocks LTP. MMP-9 KO mice and their wild type littermates received daily i.p. injections of cocaine for 1 or 7 days. Locomotor activity was measured and electrophysiological recordings of silent synapses levels were conducted. The results showed lower cocaine sensitization in KO mice, as well as decreased percentage of silent synapses in central amygdala. This suggests the requirement of amygdalar LTP in the formation of silent synapses during cocaine-induced locomotor sensitization.

ACTIVITY-DEPENDENT MODULATION OF ACTIN DYNAMICS BY CDC42 MODULATES SYNAPTIC COOPERATION AND COMPETITION

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Rosalina Fonseca, Natalia Madeira, Mariana Nunes
NOVA Medical School, Cellular And Systems Neurobiology, Lisboa, Portugal

Persistent forms of LTP require the synthesis of plasticity-related proteins (PRPs) to be maintained. Thus, the maintenance of synaptic plasticity relies on the interplay between input-specific synaptic tags and the capture of PRPs at activated synapses. Given this interplay, different groups of activated synapses can interact by cooperation, if PRPs are available, or competition, if PRPs are limited. Synaptic cooperation and competition are two forms of heterosynaptic plasticity that allow neurons to integrate events occurring within large time windows of minutes to hours. Previous results from our laboratory showed a critical role of actin dynamics in synaptic tagging and maintenance of LTP (Fonseca, 2012) and LTD (Szabó, 2016). Our data support the hypothesis that a local activity-dependent remodelling of actin, through CaMKII activation, renders the synapse locally and transiently permissive to plasticity modifications. We found that continuous synaptic activation is necessary for the capture of PRPs by activated synapses, suggesting a critical role of continuous neuronal activity for the consolidation of plasticity. Interestingly, the activation of Cdc42, a GTPase also involved in the modulation of the actin cytoskeleton is necessary for the maintenance of LTP through tagging and capture of PRPs. Cdc42 activity is necessary for LTP maintenance in the first hour, after induction, and for the capture of PRPs by cooperation. Interestingly, synaptic competition is also blocked by Cdc42 inhibition. Given that Cdc42 activation is spatially restricted, our results show that local remodelling of actin, by CaMKII and Cdc42 activation are key modulators of heterosynaptic cooperation and competition.

MIDBRAIN DOPAMINE NEURONS TRIGGER HIPPOCAMPAL LONG TERM POTENTIATION AND CONTEXTUAL LEARNING

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Fares Sayegh, Juliana Pi Macedo, Catherine Macri, Camille Lejards, Lionel Dahan
Centre de Recherches sur la Cognition Animale (CRCA) Centre de Biologie Intégrative (CBI), Université Paul Sabatier, Cnrs, Toulouse, France

The classical unsupervised model of hebbian Long Term Potentiation (LTP) fails to explain why some events are learnt while others are not. An alternative model postulates that a neuromodulator may act as a teaching signal triggering LTP. We used optogenetic tools to specifically manipulate the dopamine pathway originating from the midbrain and innervating the dorsal hippocampus. We show that dopamine midbrain projections can trigger LTP at Schaeffer Collaterals *in vivo,* in anaesthetized mice. In order to test for the role of this pathway in contextual learning, we used a variation of the contextual fear conditioning in which the context and its association to the electric shock take place on two consecutive days. We show that inhibiting the midbrain to hippocampus dopamine pathway impairs contextual learning while its stimulation promotes it. We thus discovered a new form of LTP triggered by dopamine which is compatible with computational models of hippocampo-dependent learning and we show that midbrain dopamine projections to the dorsal hippocampus are involved in contextual learning. We propose that, when something has to be learnt, midbrain dopamine provides a teaching signal to the hippocampus which induces hippocampal LTP responsible for learning and memory.

ASTROCYTE-MEDIATED SWITCH IN SPIKE TIMING-DEPENDENT PLASTICITY DURING HIPPOCAMPAL DEVELOPMENT

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Antonio Rodríguez-Moreno[1], Rafael Falcón-Moya[1], Mikel Pérez-Rodríguez[1], José Prius-Mengual[1], Andrade-Talavera Andrade-Talavera[2]
[1]Universidad Pablo de Olavide, Department Of Physiology, Anatomy And Cell Biology, Sevilla, Spain, [2]Universidad Pablo de Olavide, Physiology, Anatomy And Cell Biology, SEVILLA, Spain

Presynaptic spike timing-dependent long-term depression (t-LTD) at hippocampal CA3-CA1 synapses is evident until the 3rd postnatal week in mice, disappearing during the 4th week. At more mature stages, we found that the protocol that induced t-LTD induced t-LTP. We characterized this form of t-LTP and the mechanisms involved in its induction, as well as that driving this switch from t-LTD to t-LTP. We found that this t-LTP is expressed presynaptically at CA3-CA1 synapses, as witnessed by coefficient of variation, number of failures, pairedpulse ratio and miniature responses analysis. Additionally, this form of presynaptic t-LTP does not require NMDARs but the activation of mGluRs and the entry of Ca2+ into the postsynaptic neuron through L-type voltage-dependent Ca2+ channels and the release of Ca2+ from intracellular stores. Nitric oxide is also required as a messenger from the postsynaptic neuron. Crucially, the release of adenosine and glutamate by astrocytes is required for t-LTP induction and for the switch from t-LTD to t-LTP. Thus, we have discovered a developmental switch of synaptic transmission from t-LTD to t-LTP at hippocampal CA3-CA1 synapses in which astrocytes play a central role and revealed a form of presynaptic LTP and the rules for its induction.

EXTENDED TIMESCALE PLASTICITY IN THE PREFRONTAL CORTEX PROVIDES EVIDENCE OF ELIGIBILITY TRACES PERMISSIVE TO SUPERVISED LEARNING

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Léa Caya-Bissonnette, Richard Naud, Jean-Claude Béïque
University of Ottawa, Cellular And Molecular Medicine, Ottawa, Canada

Learning is required to optimize behavioural choices. Synaptic plasticity mechanisms, such as Long-term potentiation (LTP), are widely believed to be cellular correlates of learning and memory. LTP can be induced by Spike-Timing-Dependent Plasticity protocols that typically require dozens of near-simultaneous (*i.e.,* tens of milliseconds) firing of pre- and postsynaptic neurons, a timescale fundamentally incompatible with that expected for supervised learning (200ms-2s), and a repetition requirement that is far from that of quasi one-shot learning (1-5x). Eligibility traces, an unknown biochemical process priming synapses to remain eligible for potentiation for an extended period of time (hundreds of milliseconds), have long been hypothesized to provide an appealing solution to this temporal credit assignment problem. However, their existence is unclear. Here, using cellular electrophysiology and 2-photon microscopy, we examined the ability of temporally separated pre- and postsynaptic events to induce potentiation in pyramidal neurons of mice prefrontal cortex. We observed that a few pairings of pre- and postsynaptic events at behaviourally relevant timescale (0.5s–1.5s) reliably and robustly potentiated synaptic strength. This form of plasticity followed unsuspected temporal rules that were dependent on bursting and that were modulated by norepinephrine, a neuromodulator believed to provide saliency signal. We are currently developing a model that captures the core aspects of these plasticity rules. The features of these plasticity rules support the existence of synaptic eligibility traces, and provide a potential avenue of solution to the temporal credit assignment problem.

POSTSYNAPTIC GABAB RECEPTORS INHIBIT SYNAPTIC PLASTICITY AT MOSSY FIBRE INPUT ONTO THE BASKET CELLS OF THE DENTATE GYRUS

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Rita Loureiro[1], Sam Booker[2], Imre Vida[1]
[1]Charité Universitätsmedizin Berlin, Institute Of Integrative Neuroanatomy, Berlin, Germany, [2]Simons Initiative for the Developing Brain, Centre For Discovery Brain Sciences, Edinburgh, United Kingdom

$GABA_B$ receptors are important modulators of synaptic plasticity in principal cells, promoting plasticity via disinhibition. In contrast, in inhibitory interneurons, $GABA_B$ receptors were recently found to inhibit plasticity (Booker et al., 2019). Thus, the modulatory role of $GABA_B$ receptor may differ in a cell type-specific manner. Here, we investigated the effects of tonic $GABA_B$ receptor activation on the induction of synaptic plasticity in basket cells of the dentate gyrus (DG). We performed whole-cell patch-clamp recordings from DG basket cells and induced long-term potentiation (LTP) at their mossy fibre input by non-associative theta burst stimulation (TBS) in acute slices of the rat hippocampus. Under control conditions, TBS resulted in a robust LTP of the EPSP amplitude to 226.2 ± 33.57% of preceding baseline (at 30 min). Pre-application of Baclofen (5 µM), a $GABA_B$ receptor agonist, to the bath massively reduced the LTP to 126.8±13.20% (p=0.0328, compared to control conditions). When baclofen was co-applied with SCH-23390, a Kir3.1 channel blocker, the inhibitory effect on plasticity was reversed (192.7±20.07%, p=0.5733, compared to control conditions), pointing to the involvement of these channels. Finally, intracellular perfusion of Gallein, an inhibitor of G-protein signaling, prior to induction partially reversed the inhibitory effect of $GABA_B$ receptor activation (163.6±26.76%, p=0.3046, compared to control conditions). These results show that at the excitatory input synapses of basket cells in the DG, GABA can modulate synaptic plasticity post-synaptically through $GABA_B$ receptor-Kir3.1 channel cascade, and inhibit LTP induction. At a network level, $GABA_B$ receptors may act to readjust excitation-inhibition balance.

MOTOR LEARNING SELECTIVELY STRENGTHENS CORTICAL AND STRIATAL SYNAPSES OF MOTOR ENGRAM NEURONS

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Fuu-Jiun Hwang, Richard Roth, Yu-Wei Wu, Yue Sun, Jun Ding
Stanford University School of Medicine, Neurosurgery, Stanford, United States of America

Learning and consolidation of new motor skills require adaptations of neuronal activity and connectivity in the motor cortex and striatum, two key motor regions of the brain. Yet, how neurons undergo synaptic changes and become recruited during motor learning to form a memory engram remains an open question. Here, we train mice on a single-pellet reaching motor learning task and use a genetic approach to identify and manipulate behavior-relevant neurons selectively in the primary motor cortex (M1). We find that the degree of reactivation of M1 engram neurons correlates strongly with motor performance. We further demonstrate that learning-induced dendritic spine reorganization specifically occurs in these M1 engram neurons. In addition, we find that motor learning leads to an increase in the number and strength of outputs from M1 engram neurons onto striatal spiny projection neurons (SPNs) and that these synapses form local clusters along SPN dendrites. These results identify a highly specific synaptic plasticity during the formation of long-lasting motor memory traces in the corticostriatal circuit.

Learning relies mainly on neuroplasticity, i.e. the ability of neuronal cells to perform structural and functional adaptations throughout life. Plasticity comes in two forms: synaptic plasticity (changes in synaptic strength), and structural plasticity (rewiring of synaptic networks). Plasticity events involve cellular components, including neurons and glial cells, and extracellular components such as the extracellular matrix. This resulted in a formulation of a concept called the tetrapartite synapse: pre and post synaptic elements, glial cells and the surrounding extracellular matrix. Around some neurons, proteins of the extracellular matrix are densely organised in a reticular pattern to form the perineuronal net (PNN). The PNN plays an important role in controlling neuroplasticity but the mechanisms by which the PNN acts remain unclear. The chemorepulsive axon guidance protein semaphorin3A (Sema3A) is highly expressed in PNNs. Our hypothesis is that Sema3A is a crucial functional component of PNNs, regulating learning and memory. To investigate this idea, we used 3-months-old mutant mice in which the ability of Sema3A to bind to its receptor complex is reduced and evaluated the cognitive changes with a discrimination and reversal learning test. The results indicate that impaired Sema3A signalling leads to an improvement of reversal learning. Potential sources of Sema3A in PNNs are certain classes of neurons and the choroid plexus. Therefore, we created tools to knock-out Sema3A in specific cell types using a CRE/LoxP approach and adeno-associated viral vectors. These tools will be employed to study the consequences of sema3A deletion for various types of neuroplasticity and learning.

EXPERIENCE-DEPENDENT PLASTICITY OF BURST ACTIVITY IN LATERAL HABENULA NEURONS

POSTER SESSION 02 - SECTION: SYNAPTIC PLASTICITY, LEARNING AND MEMORY

Sarah Mondoloni, Salvatorre Lecca, Arnaud Lalive, Mauro Congiu, Manuel Mameli
University of Lausanne, Department Of Fundamental Neuroscience, Lausanne, Switzerland

The lateral habenula (LHb) is a subcortical structure controlling monoamimergic systems contributing to valence processing. In contrast, its defective activity leads to the emergence of depressive like states typical of depression and addiction. This suggests that LHb neuronal dynamics adapt accordingly to the animal's affective state, although the underlying mechanism remains elusive. Burst activity in LHb neurons, defined as a transitory high-frequency spikes that mingles with regular firing, is a candidate substrate disrupted in depression. Yet its ionic substrate, plasticity and relevance in behavior remains understudied. We used ex-vivo and in-vivo electrophysiology together with an observational threat paradigm in mice in which animals observe a cage-mate undergoing a traumatic experience (i.e. foot shocks). First, we observed that bath application of T-type and Ca2+-dependent potassium (Sk) channels blockers as well as serotonin decreased the number of bursts, unraveling the conductances and neuromodulatory systems relevant for this activity modality. Then, we demonstrated that observational threat downregulates LHb burst activity. Finally, serotonin-induced bursts reduction was occluded after the observational threat paradigm. In conclusion, our evidence support that *i.* LHb bursts rely on specific ion-channels conductances, *ii.* bursts adapt after observing a conspecific under threat, and *iii.* this burst plasticity requires serotonin release. This supports that LHb neuronal activity is vulnerable to the affective state of individuals, which may in turn have repercussions on motivated behaviors.

Reward and aversion encoding in the lateral habenula for innate and learned behaviours.
Throughout life, individuals experience a vast array of positive and aversive events that trigger adaptive behavioural responses. These events are often unpredicted and engage actions that are likely anchored on innate behavioural programs expressed by each individual member of virtually all animal species. In a second step, environmental cues, that are initially neutral, acquire value through the association with external sensory stimuli, and become instrumental to predict upcoming positive or negative events. This process ultimately prompts learned goal-directed actions allowing the pursuit of rewarding experience or the avoidance of a danger. Both innate and learned behavioural programs are evolutionarily conserved and fundamental for survival. Among the brain structures participating in the encoding of positive/negative stimuli and contributing to innate and learned behaviours is the epithalamic lateral habenula (LHb). The LHb provides top-down control of monoaminergic systems, responds to unexpected appetitive/aversive stimuli as well as external cues that predict the upcoming rewards or punishments. Accordingly, the LHb controls a number of behaviours that are innate (originating from unpredicted stimuli), and learned (stemming from predictive cues). In this review, we will discuss the progresses that rodent's experimental work made in identifying how LHb activity governs these vital processes, and we will provide a view on how these findings integrate within a complex circuit connectivity.

Chronic nicotine increases midbrain dopamine neuron activity and biases individual strategies towards reduced exploration in mice.
Long-term exposure to nicotine alters brain circuits and induces profound changes in decision-making strategies, affecting behaviors both related and unrelated to drug seeking and consumption. Using an intracranial self-stimulation reward-based foraging task, we investigated in mice the impact of chronic nicotine on midbrain dopamine neuron activity and its consequence on the trade-off between exploitation and exploration. Model-based and archetypal analysis revealed substantial inter-individual variability in decision-making strategies, with mice passively exposed to nicotine shifting toward a more exploitative profile compared to non-exposed animals. We then mimicked the effect of chronic nicotine on the tonic

activity of dopamine neurons using optogenetics, and found that photo-stimulated mice adopted a behavioral phenotype similar to that of mice exposed to chronic nicotine. Our results reveal a key role of tonic midbrain dopamine in the exploration/exploitation trade-off and highlight a potential mechanism by which nicotine affects the exploration/exploitation balance and decision-making.

Biophysical and synaptic properties of NMDA receptors in the lateral habenula.
Excitatory synaptic transmission in the lateral habenula (LHb), an evolutionarily ancient subcortical structure, encodes aversive stimuli and affective states. Habenular glutamatergic synapses contribute to these processes partly through the activation of AMPA receptors. Yet, N-methyl-d-aspartate receptors (NMDARs) are also expressed in the LHb and support the emergence of depressive symptoms. Indeed, local NMDAR blockade in the LHb rescues anhedonia and behavioral despair in rodent models of depression. However, the subunit composition and biophysical properties of habenular NMDARs remain unknown, thereby hindering their study in the context of mental health. Here, we performed electrophysiological recordings and optogenetic-assisted circuit mapping in mice, to study pharmacologically-isolated NMDAR currents in LHb neurons that receive innervation from different brain regions (entopeduncular nucleus, lateral hypothalamic area, bed nucleus of the stria terminalis, or ventral tegmental area). This systematic approach revealed that habenular NMDAR currents are sensitive to TCN and ifenprodil - drugs that specifically inhibit GluN2A- and GluN2B-containing NMDARs, respectively. Whilst these pharmacological effects were consistently observed across inputs, we detected region-specific differences in the current-voltage relationship and decay time of NMDAR currents. Finally, inspired by the firing of LHb neurons in vivo, we designed a burst protocol capable of eliciting calcium-dependent long-term potentiation of habenular NMDAR transmission ex vivo. Altogether, we define basic biophysical and synaptic properties of NMDARs in LHb neurons, opening new avenues for studying their plasticity processes in physiological as well as pathological contexts.

Nicotine inhibits the VTA-to-amygdala dopamine pathway to promote anxiety.
Nicotine stimulates dopamine (DA) neurons of the ventral tegmental area (VTA) to establish and maintain reinforcement. Nicotine also induces anxiety through an as yet unknown circuitry. We found that nicotine injection drives opposite functional responses of two distinct populations of VTA DA neurons with anatomically segregated projections: it activates neurons that project to the nucleus accumbens (NAc), whereas it inhibits neurons that project to the amygdala nuclei (Amg). We further show that nicotine mediates anxiety-like behavior by acting on β2-subunit-containing nicotinic acetylcholine receptors of the VTA. Finally, using optogenetics, we bidirectionally manipulate the VTA-NAc and VTA-Amg pathways to dissociate their contributions to anxiety-like behavior. We show that inhibition of VTA-Amg DA neurons mediates anxiety-like behavior, while their activation prevents the anxiogenic effects of nicotine. These distinct subpopulations of VTA DA neurons with opposite responses to nicotine may differentially drive the anxiogenic and the reinforcing effects of nicotine.

Probing the ionotropic activity of glutamate GluD2 receptor in HEK cells with genetically-engineered photopharmacology.
Glutamate delta (GluD) receptors belong to the ionotropic glutamate receptor family, yet they don't bind glutamate and are considered orphan. Progress in defining the ion channel function of GluDs in neurons has been hindered by a lack of pharmacological tools. Here, we used a chemo-genetic approach to engineer specific and photo-reversible pharmacology in GluD2 receptor. We incorporated a cysteine mutation in the cavity located above the putative ion channel pore, for site-specific conjugation with a photoswitchable pore blocker. In the constitutively open GluD2 Lurcher mutant, current could be rapidly and reversibly decreased with light. We then transposed the cysteine mutation to the native receptor, to demonstrate with high pharmacological specificity that metabotropic glutamate receptor signaling triggers opening of GluD2. Our results assess the functional relevance of GluD2 ion channel and introduce an optogenetic tool that will provide a novel and powerful means for probing GluD2 ionotropic contribution to neuronal physiology.

Cell-Specific Neuropharmacology.
Neuronal communication involves a multitude of neurotransmitters and an outstanding diversity of receptors and ion channels. Linking the activity of cell surface receptors and ion channels in defined neural circuits to brain states and behaviors has been a key challenge in neuroscience, since cell targeting is not possible with traditional neuropharmacology. We review here recent technologies that enable the effect of drugs to be restricted to specific cell types, thereby allowing

acute manipulation of the brain's own proteins with circuit specificity. We highlight the importance of developing cell-specific neuropharmacology strategies for decoding the nervous system with molecular and circuit precision, and for developing future therapeutics with reduced side effects.

A Human Polymorphism in CHRNA5 Is Linked to Relapse to Nicotine Seeking in Transgenic Rats.
Tobacco addiction is a chronic and relapsing disorder with an important genetic component that represents a major public health issue. Meta-analysis of large-scale human genome-wide association studies (GWASs) identified a frequent non-synonymous SNP in the gene coding for the α5 subunit of nicotinic acetylcholine receptors (α5SNP), which significantly increases the risk for tobacco dependence and delays smoking cessation. To dissect the neuronal mechanisms underlying the vulnerability to nicotine addiction in carriers of the α5SNP, we created rats expressing this polymorphism using zinc finger nuclease technology and evaluated their behavior under the intravenous nicotine-self-administration paradigm. The electrophysiological responses of their neurons to nicotine were also evaluated. α5SNP rats self-administered more nicotine at high doses and exhibited higher nicotine-induced reinstatement of nicotine seeking than wild-type rats. Higher reinstatement was associated with altered neuronal activity in several discrete areas that are interconnected, including in the interpeduncular nucleus (IPN), a GABAergic structure that strongly expresses α5-containing nicotinic receptors. The altered reactivity of IPN neurons of α5SNP rats to nicotine was confirmed electrophysiologically. In conclusion, the α5SNP polymorphism is a major risk factor for nicotine intake at high doses and for relapse to nicotine seeking in rats, a dual effect that reflects the human condition. Our results also suggest an important role for the IPN in the higher relapse to nicotine seeking observed in α5SNP rats.

Manipulating midbrain dopamine neurons and reward-related behaviors with light-controllable nicotinic acetylcholine receptors.
Dopamine (DA) neurons of the ventral tegmental area (VTA) integrate cholinergic inputs to regulate key functions such as motivation and goal-directed behaviors. Yet the temporal dynamic range and mechanism of action of acetylcholine (ACh) on the modulation of VTA circuits and reward-related behaviors are not known. Here, we used a chemical-genetic approach for rapid and precise optical manipulation of nicotinic neurotransmission in VTA neurons in living mice. We provide direct evidence that the ACh tone fine-tunes the firing properties of VTA DA neurons through β2-containing (β2*) nicotinic ACh receptors (nAChRs). Furthermore, locally photo-antagonizing these receptors in the VTA was sufficient to reversibly switch nicotine reinforcement on and off. By enabling control of nicotinic transmission in targeted brain circuits, this technology will help unravel the various physiological functions of nAChRs and may assist in the design of novel therapies relevant to neuropsychiatric disorders.

[Optically dissecting brain nicotinic receptor function with photo-controllable designer receptors].
Nicotinic acetylcholine receptors (nAChRs) are pentameric ligand-gated ion channels widely expressed in the central nervous system and the periphery. They play an important modulatory role in learning, memory and attention, and have been implicated in various diseases such as Alzheimer's disease, Parkinson's disease, epilepsy, schizophrenia and addiction. These receptors are activated by the endogenous neurotransmitter acetylcholine, or by nicotine, the alkaloid found in tobacco leaves. Both molecules open the ion channel and cause the movement of cations across the membrane, which directly affects neuronal excitability and synaptic plasticity. nAChRs are very heterogeneous in their subunit composition (α2-10 et β2-4), in their brain distribution (cortex, midbrain, striatum…) and in their sub-cellular localization (pre- vs post-synaptic, axonal, dendritic…). This heterogeneity highly contributes to the very diverse roles these receptors have in health and disease. The ability to activate or block a specific nAChR subtype, at a defined time and space within the brain, would greatly help obtaining a clearer picture of these various functions. To this aim, we are developing novel optogenetic pharmacology strategies for optically controlling endogenous nAChR isoforms within the mouse brain. The idea is to tether a chemical photoswitch on the surface of a cysteine-modified nAChR, and use light for rapidly and reversibly turning that receptor mutant on and off. Here we will discuss the history of optogenetic pharmacology, and the recent advances for the optical control of brain nicotinic receptors in vivo.

Homeostatic synaptic plasticity (HSP) is a process by which neurons adjust synaptic strengths to compensate for various perturbations and which allows to stabilize neuronal activity. Yet, whether the highly diverse synapses harboring a neuron respond uniformly to a same perturbation is unclear and the underlying molecular determinants remain to be identified. Here, using patch-clamp recordings, immunolabeling and imaging approaches, we report that the ability of individual synapses to undergo HSP in response to activity-deprivation paradigms depends on the local expression of the spine apparatus related protein synaptopodin (SP) acting as a synaptic tag to promote AMPA receptors synaptic accumulation and spine growth. Gain and loss-of-function experiments indicate that this process relies on the local de-repression of SP translation by miR124 which supports both non-uniform and synapse-autonomous HSP induced by global or input specific activity deprivation, respectively. Our findings uncover an unexpected synaptic-tagging mechanism for HSP, whose molecular actors are intriguingly shared with Hebbian plasticity and linked to multiple neurological diseases.

LONGITUDINAL TRACKING OF SYNAPTIC STRUCTURAL HOMEOSTATIC MECHANISMS IN THE HIPPOCAMPAL CA1 REGION OF LIVE MICE USING TWO-PHOTON IMAGING

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Bhargavi Keerthana Boovaraga Murthy[1], Hannah Klimmt[1], Inna Slutsky[2], Alessio Attardo[1]

Experience induces specific neural activity patterns and plasticity of synaptic connections, thus enabling information storage. In addition, homeostatic mechanisms at the synaptic level ensure stability by diverse functional and structural modifications such as, change in dendritic spine density and size – as demonstrated in cortical brain regions *in vivo*. Owing to the hippocampus being buried deep in the brain, little is known on how homeostatic compensation affects long-term structural stability of synapses in the hippocampus of live mammals. The aim of this project is to investigate *in vivo*, if changes in the density and stability of excitatory and inhibitory synapses in the hippocampus, constitute adaptive mechanisms in response to perturbed neuronal activity. By employing deep-brain two-photon time lapse imaging in live mice, we are chronically tracking and measuring the synaptic dynamics of excitatory and inhibitory synapses on pyramidal neurons in the CA1 region, in response to chemogenetically manipulated neuronal activity. We image dendritic spines as a proxy for excitatory synapses and for inhibitory synapses, we image a fluorescent protein fused to Gephyrin, a postsynaptic protein in inhibitory synapses. Through this project, we will recognize the timescale required for synaptic structural homeostatic mechanisms to emerge in the hippocampus. The study results will contribute to bridging the gap between the properties of individual neurons and the emerging properties of neuronal populations, and lead to a deeper understanding of how neural circuits in the hippocampus maintain functional stability upon perturbation of activity.

DYNAMIC CHANGES IN MUNC13-1 DISTRIBUTION AT HIPPOCAMPAL MOSSY FIBER BOUTONS DURING SYNAPTIC PLASTICITY

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Olena Kim[1], Yuji Okamoto[1], Walter Kaufmann[2], Ryuichi Shigemoto[3], Peter Jonas[1]
[1]Institute of Science and Technology Austria, Cellular Neuroscience, Klosterneuburg, Austria, [2]Institute of Science and Technology Austria, Electron Microscopy Facility, Klosterneuburg, Austria, [3]Institute of Science and Technology Austria, Molecular Neuroscience, Klosterneuburg, Austria

Despite a large body of work on the morphological and physiological properties of synapses, the links between structure and function remain enigmatic. Although recent studies elucidated a potential correlation between physiological and morphological properties of synapses during synaptic plasticity (Vandael *et al.*, 2020, Neuron 107: 509–521), the corresponding molecular changes remain unknown. To pinpoint changes in the molecular architecture at hippocampal mossy fiber bouton (MFB) synapses during short- and long-term potentiation (STP and LTP), we combined chemical potentiation, by the adenylyl cyclase activator forskolin, and freeze-fracture replica immunolabeling of calcium channels and synaptic proteins in mouse hippocampus. This method allowed us to localize membrane-bound proteins with nanometer precision within the active zone (AZ), in particular, $Ca_V2.1$ calcium channels and Munc13-1 protein, a putative marker of primed vesicles. First, the mean number of clusters of Munc13-1 in the MFB active zone significantly increased from 2.4 in control to 3.3 clusters during STP (~5 min; 90 and 51 AZs respectively), but it decreased below the control value to 1.9 clusters during LTP (~30 min; 44 AZs). Secondly, although the mean pairwise distance between the $Ca_V2.1$s and Munc13-1s did not significantly change in the STP phase (113.5 nm; control: 105.8 nm), it shortened during LTP (80.8 nm). These results suggest the existence of two distinct mechanisms that govern STP and LTP at MFB synapses: an increase in the readily releasable pool in the case of STP and a potential increase in release probability during LTP.

Functional Electron Microscopy, "Flash and Freeze," of Identified Cortical Synapses in Acute Brain Slices.
How structural and functional properties of synapses relate to each other is a fundamental question in neuroscience. Electrophysiology has elucidated mechanisms of synaptic transmission, and electron microscopy (EM) has provided insight into morphological properties of synapses. Here we describe an enhanced method for functional EM ("flash and freeze"), combining optogenetic stimulation with high-pressure freezing. We demonstrate that the improved method can be applied to intact networks in acute brain slices and organotypic slice cultures from mice. As a proof of concept, we probed vesicle pool changes during synaptic transmission at the hippocampal mossy fiber-CA3 pyramidal neuron synapse. Our findings show overlap of the docked vesicle pool and the functionally defined readily releasable pool and provide evidence of fast endocytosis at this synapse. Functional EM with acute slices and slice cultures has the potential to reveal the structural and functional mechanisms of transmission in intact, genetically perturbed, and disease-affected synapses.

CKAMP44 MODULATES PROCESSING OF VISUAL INFORMATION BY DLGN RELAY NEURONS

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Sonia Ruggieri[1], Tim Gollisch[2], Xufeng Chen[3], Jakob Von Engelhardt[1]
[1]University Medical Center of the Johannes Gutenberg University Mainz, Institute Of Pathophysiology, Mainz, Germany, [2]University Medical Center Göttingen, Sensory Processing In The Retina, Goettingen, Germany, [3]Renaissance School od Medicine, Department Of Anesthesiology, Stony Brook, NY, United States of America

The dorsolateral geniculate nucleus (dLGN) is the first relay station for visual information. Relay cells in the dLGN receive excitatory inputs from retinal ganglion cells via retinogeniculate synapses. We showed previously that the AMPA receptors (AMPARs) auxiliary subunit CKAMP44 increases the number of AMPARs and reduces short-term depression in retinogeniculate synapses. The influence of CKAMP44 on short-term plasticity results from the slow rate of recovery from desensitization of AMPARs that contain CKAMP44. *In vivo* recordings showed that the alteration in short-term plasticity affects relay cell spike probability in response to visual input. To investigate in more detail how deletion of CKAMP44 alters computational properties of relay cells, I analyzed relay cell activity in response to diverse visual stimuli by performing *in-vivo* tetrode recordings in awake head-fixed mice. The results indicate that the influence of CKAMP44 on relay cells is particularly high when retinal ganglion cells respond to external input with high firing frequency. Furthermore, to understand the relevance of main mechanisms involved in short-term plasticity of retinogeniculate synapses and information processing in relay cells, I generated a computational model of relay cells with retinogeniculate synapses based on realistic anatomical and physiological parameters. Results from simulations revealed that input integration at retinogeniculate synapses depends strongly on the slow recovery from desensitization of AMPARs, but also on glutamate spillover. Taken together, these findings show that CKAMP44 via its influence on AMPAR gating has an important influence on processing of visual information.

C57BL/6 Background Attenuates mHTT Toxicity in the Striatum of YAC128 Mice.
Mouse models are frequently used to study Huntington's disease (HD). The onset and severity of neuronal and behavioral pathologies vary greatly between HD mouse models, which results from different huntingtin expression levels and different CAG repeat length. HD pathology appears to depend also on the strain background of mouse models. Thus, behavioral deficits of HD mice are more severe in the FVB than in the C57BL/6 background. Alterations in medium spiny neuron (MSN) morphology and function have been well documented in young YAC128 mice in the FVB background. Here, we tested the relevance of strain background for mutant huntingtin (mHTT) toxicity on the cellular level by investigating HD pathologies in YAC128 mice in the C57BL/6 background (YAC128/BL6). Morphology, spine density, synapse function and membrane properties were not or only subtly altered in MSNs of 12-month-old YAC128/BL6 mice. Despite the mild cellular phenotype, YAC128/BL6 mice showed deficits in motor performance. More pronounced alterations in MSN function were found in the HdhQ150 mouse model in the C57BL/6 background (HdhQ150/BL6). Consistent with the differences in HD pathology, the number of inclusion bodies was considerably lower in YAC128/BL6 mice than HdhQ150/BL6 mice. This study highlights the relevance of strain background for mHTT toxicity in HD mouse models.

Amyloid Beta-Mediated Changes in Synaptic Function and Spine Number of Neocortical Neurons Depend on NMDA Receptors.
Onset and progression of Alzheimer's disease (AD) pathophysiology differs between brain regions. The neocortex, for example, is a brain region that is affected very early during AD. NMDA receptors (NMDARs) are involved in mediating amyloid beta (Aβ) toxicity. NMDAR expression, on the other hand, can be affected by Aβ. We tested whether the high vulnerability of neocortical neurons for Aβ-toxicity may result from specific NMDAR expression profiles or from a particular regulation of NMDAR expression by Aβ. Electrophysiological analyses suggested that pyramidal cells of 6-months-old wildtype mice express mostly GluN1/GluN2A NMDARs. While synaptic NMDAR-mediated currents are unaltered in 5xFAD

mice, extrasynaptic NMDARs seem to contain GluN1/GluN2A and GluN1/GluN2A/GluN2B. We used conditional GluN1 and GluN2B knockout mice to investigate whether NMDARs contribute to Aβ-toxicity. Spine number was decreased in pyramidal cells of 5xFAD mice and increased in neurons with 3-week virus-mediated Aβ-overexpression. NMDARs were required for both Aβ-mediated changes in spine number and functional synapses. Thus, our study gives novel insights into the Aβ-mediated regulation of NMDAR expression and the role of NMDARs in Aβ pathophysiology in the somatosensory cortex.

ROLE OF PRESYNAPTIC PLASTICITY AT MOSSY FIBER-CA3 SYNAPSES: CONSEQUENCES OF SYT7 ABROGATION IN DG CELLS ON CA3 CIRCUITS AND MEMORY ENCODING

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Catherine Marneffe, Kyrian Nicolay-Kritter, Ashley Kees, Noelle Grosjean, Cécile Chatras, Evan Harrell, Christophe Mulle
Université de Bordeaux, Iins, Bordeaux, France

The hippocampus is known to play a major role in the storage and recall of information depending on different forms of activity dependent synaptic plasticity. Mossy fibers synapses between the axons of dentate gyrus (DG) cells and CA3 pyramidal cells (Mf-CA3 synapses) display a high dynamic range of presynaptic plasticity which endow these synaptic connections with detonator properties. The pattern of action potential firing, in the form of high frequency bursts in the DG strongly controls the amplitude of synaptic responses and information transfer to CA3. Presynaptic short-term plasticity is thought to play a major role in the process of spike transfer within local circuits. Here we aim at investigating the role of presynaptic facilitation at Mf- CA3 synapses in the operation of CA3 circuits *in vivo* and in memory encoding. Syt7 is a calcium sensor that has been showed to be necessary for a presynaptic facilitation. We have selectively abrogated Syt7 expression in DG granule cells using conditional Syt7 KO mice. We confirm that presynaptic facilitation is suppressed at Mf-CA3 synapses in the absence of presynaptic Syt7. We have next used simultaneous silicon probe recordings in DG and CA3 to understand how the network adapts to changes in presynaptic plasticity, in reference to brain states. Finally, we describe the behavioral consequences of DG-selective Syt7 deletion in DG-dependent tasks, with a focus on memory encoding. This approach will bring new understanding of the role in presynaptic facilitation and specifically on the detonator properties of DG-CA3 synapses.

ORGANIZATION AND DYNAMICS OF THE ENDOGENOUS CAV2.1 NANOCLUSTERS SHAPE THE SHORT-TERM PLASTICITY IN HIPPOCAMPAL SYNAPSES

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Abderazzaq El Khallouqi[1], Artur Bikbaev[1], Ana Carolina Palmeira Do Amaral[1], Melanie Mark[2], Stefan Herlitze[3], Martin Heine[1]
[1]Johannes Gutenberg-University Mainz, Institute For Developmental Biology And Neurobiology, Mainz, Germany, [2]Ruhr-University Bochum, Behavioral Neurobiology, Bochum, Germany, [3]Ruhr University Bochum, Department Of Zoology And Neurobiology, Bochum, Germany

The kinetic properties of presynaptic calcium channels, including the activation state and conductivity but also their spatial arrangement, are critical parameters shaping the release probability of synapses. $Ca_V2.1$ (P/Q-type channels) represent the main population of voltage-gated calcium channels in many synapses of the mammalian brain. Within the presynaptic membrane, the $Ca_V2.1$ were found to be clustered in the active zone (AZ). However, it remains unclear whether such clusters are synapse type-specific and whether they depend on the history of presynaptic activation. To address these questions, we used a Cacna1a-Citrine knock-in mouse model together with an anti-GFP nanobody in combination with super-resolution microscopy (STED and dSTORM) to directly target and characterize the nanocluster organization of the endogenous population of Cav2.1 in AZ. We found that the cluster size of calcium channels is smaller in inhibitory synapses as compared to excitatory synapses. Furthermore, we generated an anti-GFP intrabody expression vector to monitor the local dynamics of Cav2.1. Our mobility data suggests an ongoing rearrangement that depends on the network activity levels. Interestingly, the manipulation with presynaptic G protein-coupled receptors (GPCRs) also influenced the Cav2.1 dynamics. Artificial clustering of Cav2.1 by photoactivatable cross-linkers induced a shrinkage of nanoclusters, which affected the impact of GPCR modulation on the synaptic function that was evaluated by the glutamate and calcium imaging. Taken together, this data suggests that the short-term plasticity is influenced by the re-arrangement of Cav2.1 nanoclusters inside the AZ, which can serve as an initial step leading to sustained changes in synaptic transmission.

TAFA4 relieves injury-induced mechanical hypersensitivity through LDL receptors and modulation of spinal A-type K current.
Pain, whether acute or persistent, is a serious medical problem worldwide. However, its management remains unsatisfactory, and new analgesic molecules are required. We show here that TAFA4 reverses inflammatory, postoperative, and spared nerve injury (SNI)-induced mechanical hypersensitivity in male and female mice. TAFA4 requires functional low-density lipoprotein receptor-related proteins (LRPs) because their inhibition by RAP (receptor-associated protein) dose-dependently abolishes its antihypersensitive actions. SNI selectively decreases A-type K current (I) in spinal lamina II outer excitatory interneurons (L-IIo ExINs) and induces a concomitant increase in I and decrease in hyperpolarization-activated current (I) in lamina II inner inhibitory interneurons (L-IIi InhINs). Remarkably, SNI-induced ion current alterations in both IN subtypes were rescued by TAFA4 in an LRP-dependent manner. We provide insights into the mechanism by which TAFA4 reverses injury-induced mechanical hypersensitivity by restoring normal spinal neuron activity and highlight the considerable potential of TAFA4 as a treatment for injury-induced mechanical pain.

Endogenous β-neurexins on axons and within synapses show regulated dynamic behavior.
Neurexins are key organizer molecules that regulate synaptic function and are implicated in autism and schizophrenia. β-neurexins interact with numerous cell adhesion and receptor molecules, but their neuronal localization remains elusive. Using single-molecule tracking and high-resolution microscopy to detect neurexin1β and neurexin3β in primary hippocampal neurons from knockin mice, we demonstrate that endogenous β-neurexins are present in fewer than half of excitatory and inhibitory synapses. Moreover, we observe a large extrasynaptic pool of β-neurexins on axons and show that axonal β-neurexins diffuse with higher surface mobility than those transiently confined within synapses. Stimulation of neuronal activity further increases the mobility of synaptic and axonal β-neurexins, whereas inhibition causes the opposite. Blocking

ectodomain cleavage by metalloproteases also reduces β-neurexin mobility and enhances glutamate release. These findings suggest that the surface mobility of endogenous β-neurexins inside and outside of synapses is dynamically regulated and linked to neuronal activity.

More than a pore: How voltage-gated calcium channels act on different levels of neuronal communication regulation.
Voltage-gated calcium channels (VGCCs) represent key regulators of the calcium influx through the plasma membrane of excitable cells, like neurons. Activated by the depolarization of the membrane, the opening of VGCCs induces very transient and local changes in the intracellular calcium concentration, known as calcium nanodomains, that in turn trigger calcium-dependent signaling cascades and the release of chemical neurotransmitters. Based on their central importance as concierges of excitation-secretion coupling and therefore neuronal communication, VGCCs have been studied in multiple aspects of neuronal function and malfunction. However, studies on molecular interaction partners and recent progress in omics technologies have extended the actual concept of these molecules. With this review, we want to illustrate some new perspectives of VGCCs reaching beyond their function as calcium-permeable pores in the plasma membrane. Therefore, we will discuss the relevance of VGCCs as voltage sensors in functional complexes with ryanodine receptors, channel-independent actions of auxiliary VGCC subunits, and provide an insight into how VGCCs even directly participate in gene regulation. Furthermore, we will illustrate how structural changes in the intracellular C-terminus of VGCCs generated by alternative splicing events might not only affect the biophysical channel characteristics but rather determine their molecular environment and downstream signaling pathways.

PRIORITIZED DOCKING OF SYNAPTIC VESICLES PROVIDED BY A RAPID RECYCLING PATHWAY

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Le Thuy Van Tran[1], Alain Marty[2]
[1]Université de Paris, Sppin - Cnrs Umr8003, Paris cedex , France, [2]Université de Paris, Sppin - Cnrs Umr8003, Paris cedex, France

To manage computational demands of synaptic transmission, synaptic vesicles (SVs) are organised into multiple functional pools within a synapse. The readily releasable pool (RRP) is responsible for the immediate release of neurotransmitter in response to action potential stimulation. The RRP is replenished either by recycling fused SVs or by recruiting new SVs from an upstream pool. Collectively, all SVs that take part in synaptic transmission constitute the recycling pool. The remaining SVs, which form the reserve pool, only undergo exocytosis during intense and prolonged activity. **Aims:** We investigated the recycling of SVs during repeated train stimulation at cerebellar synapses formed by granule cells (GCs) onto molecular layer interneurons (MLIs). **Methods:** Electrophysiological recordings were obtained from individual MLIs while a single presynaptic GC was being stimulated. **Results:** We found evidence for a rapid route of SV recycling during repeated train stimulation with short inter-train intervals. This route, which requires activation of the myosin light chain kinase, uses recently endocytosed vesicles to delay the reduction in synaptic output. It has a limited capacity and contributes minimally during steady-state release with short intervals. Nonetheless, SVs that are recycled through this pathway are preferentially docked compared to those coming from the reserve pool. **Conclusions:** Prioritized docking reveals a functional link between specific recycling pathways and SV sorting within the RRP. During and after extended synaptic stimulation, prioritized docking enhances the synaptic response to the first stimulation in a train, thus protecting responses to scarce stimuli from depression.

IMPAIRED EXCITATORY AND INHIBITORY SYNAPTIC PLASTICITY IN THE NL3-R451C MOUSE MODEL OF AUTISM SPECTRUM DISORDER

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Martina Bruno[1,2], Stefka Stancheva[2], Loris Mannino[2], Massimo Ruben[2], Alice Polenghi[2], Francesco Colaci[2], Enrica Petrini[2], Andrea Barberis[2]
[1]Università degli Studi di Genova, Dinogmi, Genova, Italy, [2]Istituto italiano di Tecnologia, Neuroscience Area, Genova, Italy

Autistic spectrum disorder (ASD) has been associated to genetic alterations of proteins involved in synaptic function such as the point mutation R451C in neuroligin 3 (NLGN3), a postsynaptic adhesion molecule which binds its presynaptic partner neurexin at both excitatory and inhibitory synapses. In the present study, by exploiting the transgenic NL3R451C knock-in (KI) mice as an ASD animal model, we aimed at investigating the role of this mutation in the coordination of both excitatory and inhibitory synaptic plasticity. We found that, with respect to WT condition, the $NL3^{R451C}$ protein was less expressed at the neuronal surface and showed increased lateral diffusion at GABAergic synapses. In WT animals, we observed that, in response to a chemical protocol for the induction of synaptic plasticity (NMDA treatment), excitatory synaptic currents were depressed (LTD) whereas the inhibitory ones were potentiated (iLTP). Interestingly, such opposed synaptic plasticity was abolished in KI neurons. These effects were paralleled by changes in synaptic receptors and scaffold proteins at both excitatory and inhibitory synapses in WT and KI neurons. In addition, the quantification of NLGN3 clusters fluorescence intensity revealed that, after the NMDA treatment, surface NLGN3 decreased in WT neurons while it was unaffected in KI neurons. Collectively, our results reveal that the perturbed synaptic molecular composition of both glutamatergic and GABAergic synapses induced by the NL3 R451C mutation disrupts the coordination of excitatory and inhibitory synaptic plasticity thus potentially contributing to the pathophysiology of ASD.

Aims: AMPA receptors (AMPARs) are crucial ionotropic glutamate receptors directly involved in synaptic plasticity. The number of AMPARs at a synapse serves as a proxy for its synaptic strength. Experimental studies show that neurons can modulate the number of AMPARs locally in a synapse during synaptic plasticity by adjusting the surface mobility of the receptors or by altering the endocytosis/exocytosis frequency or both [1]. The active molecular motor-based transport is essential for the long-distance delivery of the receptors [2]. Recent advances in molecular and imaging techniques have improved our understanding of these trafficking mechanisms in dendrites and spines, and provided a careful characterization of the kinetic parameters involved in AMPAR trafficking. **Methods:** To keep up with this growing experimental data and to link changes in molecular mechanisms to changes in synaptic or dendritic receptor distributions, we developed a quantitative reaction diffusion model for local and long-range AMPAR trafficking. In parallel, we advanced the corresponding automated analysis of neural imaging data to obtain endogenous long-range mRNA and protein distributions in situ. **Results and Conclusions:** This allowed us to build a data-driven model framework describing the endogenous distribution of AMPA receptor subunits globally and locally. Next, we plan to study the temporal and spatial extent of heterosynaptic plasticity using our model. **References:** [1] Anggono & Huganir *Curr. Opin. Development and testing of a game-based digital intervention for working memory training in autism spectrum disorder.
Autism spectrum disorder (ASD) is prevalent globally, yet it lacks cost-effective treatment approaches. Deficits in executive functions occur frequently in autism spectrum disorder and present a target for intervention. Here we report the design and development of five smartphone-based games for training working memory in children with ASD. These open-source games, available free of cost to the community, were designed to match the behavioral preferences and sensorimotor abilities of children with ASD. We then conducted a preliminary trial to test the effectiveness of a month-long intervention using these games. Although we did not see a significant change in the working memory of all children with a month-long training, children who performed better on the games also showed more improvement in their working memory, suggesting that a longer intervention with the games might be useful in improving working memory. Using a Hindi translation of the autism treatment evaluation checklist, we also tested the collateral gains of the training in reducing autistic symptoms. We found no significant change in the autistic symptoms after the intervention. Further, there was no correlation between the change in the working memory and the change in the autistic symptoms.

REVERSE ENGINEERING OF THE SYNAPTIC TAGGING AND CAPTURE MECHANISMS

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Macarena Gomez De Salazar, Magnus Kjaergaard
Aarhus University, Molecular Biology And Genetics, Dandrite, Promemo, Aarhus C, Denmark

Memory and learning require fine-tuning of the connections between neurons. To strengthen a connection, a neuron needs to deliver hundreds of proteins from a range of different signaling pathways, but only to synapses that have been specifically stimulated. These proteins, known as plasticity-related proteins (PRP) can be locally recruited and produced in response to synaptic stimulation. Despite decades of research, molecules and signaling pathways that participate in this mechanism, known as "synaptic tagging" have not been categorically identified, possibly because there are many different tags. Instead of asking “What is the synaptic tag?”, we have focused on “What does it take to be a synaptic tag?” aiming to identify the biophysical characteristics PRPs should have. To address these questions, we have engineered artificial proteins, Synthetic PRPs (SynPRPs), to test mechanisms of activity-dependent targeting and determine how they collaborate to strengthen connections. We have demonstrated that these synPRPs are phosphorylated by CaMKII and consequently bind postsynaptic density protein 95 (PSD95) in a phospho-dependent manner. Additionally, we have tested if they are captured in activated synapses by expressing synPRPs in mouse hippocampal neuronal cultures. Subsequently, we have analyzed synaptic distribution and colocalization with PSD95 after an in vitro chemical long term potentiation (cLTP). We have observed that synaptic clusters of SynPRPs+PSD95 increase 2-fold their synaptic localization after cLTP in cultured hippocampal neurons. Our results could indicate that SynPRPs fulfill the criteria to be captured by a synaptic tag in activated synapses. Moreover, biophysically understanding synaptic tag and capture mechanisms could lead to prevent alterations of synaptic tagging in cognitive dysfunctions

L-Serine dietary supplementation is associated with clinical improvement of loss-of-function -related pediatric encephalopathy.
Autosomal dominant mutations in are associated with severe encephalopathy, but little is known about the pathophysiological outcomes and any potential therapeutic interventions. Genetic studies have described the association between de novo mutations of genes encoding the subunits of the -methyl-d-aspartate receptor (NMDAR) and severe neurological conditions. Here, we evaluated a missense mutation in , causing a proline-to-threonine switch (P553T) in the GluN2B subunit of NMDAR, which was found in a 5-year-old patient with Rett-like syndrome with severe encephalopathy. Structural molecular modeling predicted a reduced pore size of the mutant GluN2B-containing NMDARs. Electrophysiological recordings in a HEK-293T cell line expressing the mutated subunit confirmed this prediction and showed an associated reduced glutamate affinity. Moreover, GluN2B(P553T)-expressing primary murine hippocampal neurons showed decreased spine density, concomitant with reduced NMDA-evoked currents and impaired NMDAR-dependent insertion of the AMPA receptor subunit GluA1 at stimulated synapses. Furthermore, the naturally occurring coagonist d-serine restored function to GluN2B(P553T)-containing NMDARs. l-Serine dietary supplementation of the patient was hence initiated, resulting in the increased abundance of d-serine in the plasma and brain. The patient has shown notable improvements in motor and cognitive performance and communication after 11 and 17 months of l-serine dietary supplementation. Our data suggest that l-serine supplementation might ameliorate -related severe encephalopathy and other neurological conditions caused by glutamatergic signaling deficiency.

Phosphoproteomic Alterations of Ionotropic Glutamate Receptors in the Hippocampus of the Ts65Dn Mouse Model of Down Syndrome.
Down syndrome (DS), the main genetic cause of intellectual disability, is associated with an imbalance of excitatory/inhibitory

neurotransmitter systems. The phenotypic assessment and pharmacotherapy interventions in DS murine models strongly pointed out glutamatergic neurotransmission alterations (specially affecting ionotropic glutamate receptors [iGluRs]) that might contribute to DS pathophysiology, which is in agreement with DS condition. iGluRs play a critical role in fast-mediated excitatory transmission, a process underlying synaptic plasticity. Neuronal plasticity is biochemically modulated by post-translational modifications, allowing rapid and reversible adaptation of synaptic strength. Among these modifications, phosphorylation/dephosphorylation processes strongly dictate iGluR protein-protein interactions, cell surface trafficking, and subsynaptic mobility. Hence, we hypothesized that dysregulation of phosphorylation/dephosphorylation balance might affect neuronal function, which in turn could contribute to the glutamatergic neurotransmitter alterations observed in DS. To address this point, we biochemically purified subsynaptic hippocampal fractions from adult Ts65Dn mice, a trisomic mouse model recapitulating DS phenotypic alterations. Proteomic analysis showed significant alterations of the molecular composition of subsynaptic compartments of hippocampal trisomic neurons. Further, we characterized iGluR phosphopattern in the hippocampal glutamatergic synapse of trisomic mice. Phosphoenrichment-coupled mass spectrometry analysis revealed specific subsynaptic- and trisomy-associated iGluR phosphorylation signature, concomitant with differential subsynaptic kinase and phosphatase composition of Ts65Dn hippocampal subsynaptic compartments. Furthermore, biochemical data were used to build up a genotype-kinome-iGluR phosphopattern matrix in the different subsynaptic compartments. Overall, our results provide a precise profile of iGluR phosphopattern alterations in the glutamatergic synapse of the Ts65Dn mouse model and support their contribution to DS-associated synaptopathy. The alteration of iGluR phosphoresidues in Ts65Dn hippocampi, together with the kinase/phosphatase signature, identifies potential novel therapeutic targets for the treatment of glutamatergic dysfunctions in DS.

ACTIVITY-DEPENDENT REGULATION OF SYNAPTIC INTEGRATION IN PARVALBUMIN-POSITIVE INTERNEURONS

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Martijn Selten[1,2], Clémence Bernard[1,2], Fursham Hamid[1,2], Fazal Oozeer[1,2], Alicia Hanusz Godoy[1,2], Oscar Marín[1,2]

Neuronal networks require precise coordination of excitatory and inhibitory synaptic connectivity to function properly. Regulation of parvalbumin-positive (PV+) interneuron activity is especially important for network function, and changes in PV+ interneuron activity correlate with an animal's performance in learning tasks. Previously, changes in PV+ interneuron connectivity have been shown to regulate excitatory pyramidal cell activity. However, the mechanism via which PV+ interneurons control their own activity remains unknown. Here we used a chemogenetic approach to change the activity of PV+ interneurons and performed whole-cell electrophysiological recordings to assess compensatory changes in the excitatory and inhibitory inputs they received. We find that increasing or decreasing the activity of PV+ interneuron activity specifically leads to a cell-autonomous compensatory change in inhibitory, but not excitatory, synaptic connectivity. Further optogenetic experiments revealed that these synaptic changes originate exclusively from other PV+ interneurons. We next performed ribosome profiling experiments to identify the molecular mechanisms mediating the activity-dependent scaling of PV+ synapses onto PV+ interneurons. To this end, we combined chemogenetics with viral Translating Ribosome Affinity Purification (vTRAP) to isolate mRNAs that are specifically translated in activated PV+ interneurons. Subsequent RNA-sequencing revealed differentially regulated genes that are specifically induced following an increase in the activity of PV+ interneurons, some of which are specifically required for the compensatory synaptic changes induced by activity in these cells. Our experiments identify specific molecular programmes through which PV+ interneurons control their activity by regulating the amount of inhibition they receive from other PV+ interneurons.

Cadherin-13 is a critical regulator of GABAergic modulation in human stem-cell-derived neuronal networks.
Activity in the healthy brain relies on a concerted interplay of excitation (E) and inhibition (I) via balanced synaptic communication between glutamatergic and GABAergic neurons. A growing number of studies imply that disruption of this E/I balance is a commonality in many brain disorders; however, obtaining mechanistic insight into these disruptions, with translational value for the patient, has typically been hampered by methodological limitations. Cadherin-13 (CDH13) has been associated with autism and attention-deficit/hyperactivity disorder. CDH13 localizes at inhibitory presynapses, specifically of parvalbumin (PV) and somatostatin (SST) expressing GABAergic neurons. However, the mechanism by which CDH13 regulates the function of inhibitory synapses in human neurons remains unknown. Starting from human-induced pluripotent stem cells, we established a robust method to generate a homogenous population of SST and MEF2C (PV-precursor marker protein) expressing GABAergic neurons (iGABA) in vitro, and co-cultured these with glutamatergic neurons at defined E/I ratios on micro-electrode arrays. We identified functional network parameters that are most reliably affected by GABAergic modulation as such, and through alterations of E/I balance by reduced expression of CDH13 in iGABAs. We found that CDH13 deficiency in iGABAs decreased E/I balance by means of increased inhibition. Moreover, CDH13 interacts with Integrin-β1 and Integrin-β3, which play opposite roles in the regulation of inhibitory synaptic strength via this interaction. Taken together, this model allows for standardized investigation of the E/I balance in a human neuronal background and can be deployed to dissect the cell-type-specific contribution of disease genes to the E/I balance.

Distinct Pathogenic Genes Causing Intellectual Disability and Autism Exhibit a Common Neuronal Network Hyperactivity Phenotype.

Pathogenic mutations in either one of the epigenetic modifiers EHMT1, MBD5, MLL3, or SMARCB1 have been identified to be causative for Kleefstra syndrome spectrum (KSS), a neurodevelopmental disorder with clinical features of both intellectual disability (ID) and autism spectrum disorder (ASD). To understand how these variants lead to the phenotypic convergence in KSS, we employ a loss-of-function approach to assess neuronal network development at the molecular, single-cell, and network activity level. KSS-gene-deficient neuronal networks all develop into hyperactive networks with altered network organization and excitatory-inhibitory balance. Interestingly, even though transcriptional data reveal distinct regulatory mechanisms, KSS target genes share similar functions in regulating neuronal excitability and synaptic function, several of which are associated with ID and ASD. Our results show that KSS genes mainly converge at the level of neuronal network communication, providing insights into the pathophysiology of KSS and phenotypically congruent disorders.

Optimization of interneuron function by direct coupling of cell migration and axonal targeting.
Neural circuit assembly relies on the precise synchronization of developmental processes, such as cell migration and axon targeting, but the cell-autonomous mechanisms coordinating these events remain largely unknown. Here we found that different classes of interneurons use distinct routes of migration to reach the embryonic cerebral cortex. Somatostatin-expressing interneurons that migrate through the marginal zone develop into Martinotti cells, one of the most distinctive classes of cortical interneurons. For these cells, migration through the marginal zone is linked to the development of their characteristic layer 1 axonal arborization. Altering the normal migratory route of Martinotti cells by conditional deletion of Mafb-a gene that is preferentially expressed by these cells-cell-autonomously disrupts axonal development and impairs the function of these cells in vivo. Our results suggest that migration and axon targeting programs are coupled to optimize the assembly of inhibitory circuits in the cerebral cortex.

Inhibitory control of the excitatory/inhibitory balance in psychiatric disorders.
Neuronal networks consist of different types of neurons that all play their own role in order to maintain proper network function. The two main types of neurons segregate in excitatory and inhibitory neurons, which together regulate the flow of information through the network. It has been proposed that changes in the relative strength in these two opposing forces underlie the symptoms observed in psychiatric disorders, including autism and schizophrenia. Here, we review the role of alterations to the function of the inhibitory system as a cause of psychiatric disorders. First, we explore both patient and post-mortem evidence of inhibitory deficiency. We then discuss the function of different interneuron subtypes in the network and focus on the central role of a specific class of inhibitory neurons, parvalbumin-positive interneurons. Finally, we discuss genes known to be affected in different disorders and the effects that mutations in these genes have on the inhibitory system in cortex and hippocampus. We conclude that alterations to the inhibitory system are consistently identified in animal models of psychiatric disorders and, more specifically, that mutations affecting the function of parvalbumin-positive interneurons seem to play a central role in the symptoms observed in these disorders.

Ptchd1 deficiency induces excitatory synaptic and cognitive dysfunctions in mouse.
Synapse development and neuronal activity represent fundamental processes for the establishment of cognitive function. Structural organization as well as signalling pathways from receptor stimulation to gene expression regulation are mediated by synaptic activity and misregulated in neurodevelopmental disorders such as autism spectrum disorder (ASD) and intellectual disability (ID). Deleterious mutations in the PTCHD1 (Patched domain containing 1) gene have been described in male patients with X-linked ID and/or ASD. The structure of PTCHD1 protein is similar to the Patched (PTCH1) receptor; however, the cellular mechanisms and pathways associated with PTCHD1 in the developing brain are poorly determined. Here we show that PTCHD1 displays a C-terminal PDZ-binding motif that binds to the postsynaptic proteins PSD95 and SAP102. We also report that PTCHD1 is unable to rescue the canonical sonic hedgehog (SHH) pathway in cells depleted of PTCH1, suggesting that both proteins are involved in distinct cellular signalling pathways. We find that Ptchd1 deficiency in male mice (Ptchd1) induces global changes in synaptic gene expression, affects the expression of the immediate-early expression genes Egr1 and Npas4 and finally impairs excitatory synaptic structure and neuronal excitatory activity in the hippocampus, leading to cognitive dysfunction, motor disabilities and hyperactivity. Thus our results support that PTCHD1 deficiency induces a neurodevelopmental disorder causing excitatory synaptic dysfunction.

Reduced Inhibition within Layer IV of Sert Knockout Rat Barrel Cortex is Associated with Faster Sensory Integration.
Neural activity is essential for the maturation of sensory systems. In the rodent primary somatosensory cortex (S1), high extracellular serotonin (5-HT) levels during development impair neural transmission between the thalamus and cortical input layer IV (LIV). Rodent models of impaired 5-HT transporter (SERT) function show disruption in their topological organization of S1 and in the expression of activity-regulated genes essential for inhibitory cortical network formation. It remains unclear how such alterations affect the sensory information processing within cortical LIV. Using serotonin transporter knockout (Sert-/-) rats, we demonstrate that high extracellular serotonin levels are associated with impaired feedforward inhibition (FFI), fewer perisomatic inhibitory synapses, a depolarized GABA reversal potential and reduced expression of KCC2 transporters in juvenile animals. At the neural population level, reduced FFI increases the excitatory drive originating from LIV, facilitating evoked representations in the supragranular layers II/III. The behavioral consequence of these changes in network excitability is faster integration of the sensory information during whisker-based tactile navigation, as Sert-/- rats require fewer whisker contacts with tactile targets and perform object localization with faster reaction times. These results highlight the association of serotonergic homeostasis with formation and excitability of sensory cortical networks, and consequently with sensory perception.

Increased GABA receptor signaling in a rat model for schizophrenia.
Schizophrenia is a complex disorder that affects cognitive function and has been linked, both in patients and animal models, to dysfunction of the GABAergic system. However, the pathophysiological consequences of this dysfunction are not well understood. Here, we examined the GABAergic system in an animal model displaying schizophrenia-relevant features, the apomorphine-susceptible (APO-SUS) rat and its phenotypic counterpart, the apomorphine-unsusceptible (APO-UNSUS) rat at postnatal day 20-22. We found changes in the expression of the GABA-synthesizing enzyme GAD67 specifically in the prelimbic- but not the infralimbic region of the medial prefrontal cortex (mPFC), indicative of reduced inhibitory function in this region in APO-SUS rats. While we did not observe changes in basal synaptic transmission onto LII/III pyramidal cells in the mPFC of APO-SUS compared to APO-UNSUS rats, we report reduced paired-pulse ratios at longer inter-stimulus intervals. The GABA receptor antagonist CGP 55845 abolished this reduction, indicating that the decreased paired-pulse ratio was caused by increased GABA signaling. Consistently, we find an increased expression of the GABA receptor subunit in APO-SUS rats. Our data provide physiological evidence for increased presynaptic GABA signaling in the mPFC of APO-SUS rats, further supporting an important role for the GABAergic system in the pathophysiology of schizophrenia.

Histone Methylation by the Kleefstra Syndrome Protein EHMT1 Mediates Homeostatic Synaptic Scaling.
Homeostatic plasticity, a form of synaptic plasticity, maintains the fine balance between overall excitation and inhibition in developing and mature neuronal networks. Although the synaptic mechanisms of homeostatic plasticity are well characterized, the associated transcriptional program remains poorly understood. We show that the Kleefstra-syndrome-associated protein EHMT1 plays a critical and cell-autonomous role in synaptic scaling by responding to attenuated neuronal firing or sensory drive. Chronic activity deprivation increased the amount of neuronal dimethylated H3 at lysine 9 (H3K9me2), the catalytic product of EHMT1 and an epigenetic marker for gene repression. Genetic knockdown and pharmacological blockade of EHMT1 or EHMT2 prevented the increase of H3K9me2 and synaptic scaling up. Furthermore, BDNF repression was preceded by EHMT1/2-mediated H3K9me2 deposition at the Bdnf promoter during synaptic scaling up, both in vitro and in vivo. Our findings suggest that H3K9me2-mediated changes in chromatin structure govern a repressive program that controls synaptic scaling.

ARHGAP12 Functions as a Developmental Brake on Excitatory Synapse Function.
The molecular mechanisms that promote excitatory synapse development have been extensively studied. However, the molecular events preventing precocious excitatory synapse development so that synapses form at the correct time and place are less well understood. Here, we report the functional characterization of ARHGAP12, a previously uncharacterized Rho GTPase-activating protein (RhoGAP) in the brain. ARHGAP12 is specifically expressed in the CA1 region of the hippocampus, where it localizes to the postsynaptic compartment of excitatory synapses. ARHGAP12 negatively controls spine size via its RhoGAP activity and promotes, by interacting with CIP4, postsynaptic AMPA receptor endocytosis.

Arhgap12 knockdown results in precocious maturation of excitatory synapses, as indicated by a reduction in the proportion of silent synapses. Collectively, our data show that ARHGAP12 is a synaptic RhoGAP that regulates excitatory synaptic structure and function during development.

Cadherin-13, a risk gene for ADHD and comorbid disorders, impacts GABAergic function in hippocampus and cognition.
Cadherin-13 (CDH13), a unique glycosylphosphatidylinositol-anchored member of the cadherin family of cell adhesion molecules, has been identified as a risk gene for attention-deficit/hyperactivity disorder (ADHD) and various comorbid neurodevelopmental and psychiatric conditions, including depression, substance abuse, autism spectrum disorder and violent behavior, while the mechanism whereby CDH13 dysfunction influences pathogenesis of neuropsychiatric disorders remains elusive. Here we explored the potential role of CDH13 in the inhibitory modulation of brain activity by investigating synaptic function of GABAergic interneurons. Cellular and subcellular distribution of CDH13 was analyzed in the murine hippocampus and a mouse model with a targeted inactivation of Cdh13 was generated to evaluate how CDH13 modulates synaptic activity of hippocampal interneurons and behavioral domains related to psychopathologic (endo)phenotypes. We show that CDH13 expression in the cornu ammonis (CA) region of the hippocampus is confined to distinct classes of interneurons. Specifically, CDH13 is expressed by numerous parvalbumin and somatostatin-expressing interneurons located in the stratum oriens, where it localizes to both the soma and the presynaptic compartment. Cdh13(-/-) mice show an increase in basal inhibitory, but not excitatory, synaptic transmission in CA1 pyramidal neurons. Associated with these alterations in hippocampal function, Cdh13(-/-) mice display deficits in learning and memory. Taken together, our results indicate that CDH13 is a negative regulator of inhibitory synapses in the hippocampus, and provide insights into how CDH13 dysfunction may contribute to the excitatory/inhibitory imbalance observed in neurodevelopmental disorders, such as ADHD and autism.

THE KINESIN KIF21B REGULATES ACTIN DYNAMICS AT SPINE SYNAPSES AND CONTRIBUTES TO HOMEOSTATIC SYNAPTIC DOWNSCALING

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Kira Brune[1], Matthias Kneussel[2], Felix Lützenkirchen[2], Christine Gee[3], Yipeng Zhu[2], Michaela Schweizer[4]
[1]ZMNH, Molecular Neurogenetics, Hamburg, Germany, [2]Center for Molecular Neurobiology Hamburg - ZMNH, Institute Molecular Neurogenetics, Hamburg, Germany, [3]ZMNH, Department Of Synaptic Physiology, Hamburg, Germany, [4]ZMNH, Morphology Unit, Hamburg, Germany

Homeostatic regulation of synaptic strength preserves the balance of excitation and inhibition (E-I), which is critical for brain function and behavior. Accordingly, E-I imbalance contributes to neuronal pathology in neurodegenerative and neurodevelopmental disorders. Current evidence suggests that neurons counterbalance chronic activity changes by modulating glutamate receptor trafficking and adapting scaffold protein dynamics at postsynaptic sites. However, underlying molecular mechanisms and the potential contribution of actin remodeling at spines are barely understood. Here we report that the processive motor protein kinesin KIF21B plays a role in homeostatic synaptic downscaling. We demonstrate that KIF21B is localized to synaptic spines in a myosin-dependent manner and associates with postsynaptic densities. Furthermore, Kif21B regulates actin dynamics and interacts with scaffold proteins, essential for homeostatic plasticity. Our study provides novel insights into the role of kinesin motors in the homeostatic regulation of synaptic function.

HOMEOSTATIC CONTROL OF NEUROMUSCULAR SYNAPTIC TRANSMISSION

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Thierry Bal, Gilles Ouanounou
Université Paris-Saclay, CNRS,, Neuropsi, Institut Des Neurosciences Paris-saclay, Saclay, France

The neuromuscular synapse plays a relay function that requires a homeostatic control. This control adapts the neurotransmitter release to the post-synaptic excitability, resulting in a unity synaptic gain (one post-synaptic action potential for one pre-synaptic action potential). For this control process, the post-synaptic cell evaluates the synaptic efficacy and exercises a retrograde feedback on the pre-synaptic terminal. Our work focuses on the postsynaptic sensors that evaluate the synaptic efficacy. We have previously proposed (Ouanounou et al. eLife 2016;5:e12190) that postsynaptic calcium signaling reports distinctly the occurrence of the pre- and postsynaptic events, and that this dual detection is used to adjust the neurotransmitter release to a level matching the postsynaptic excitability. Here we confirm the calcium nature of the sensor of the synaptic efficacy, and we refine the understanding of its mechanism. We show that in addition to the detection of activities, the postsynaptic sensor precisely reports the synaptic strength. Contrary to the common belief, we discovered that this operation is not done by the quantification of the postsynaptic potential amplitude, masked by the action potential, but of the repolarization kinetics. We show that the sub-synaptic calcium build up, due to the nicotinic receptor permeability to calcium, strongly depends on repolarization kinetics and perfectly encodes the ratio between the synaptic conductance and the postsynaptic input conductance. This signal is used by the postsynaptic cell to balance homeostatic synaptic plasticity and to hold synaptic strength at a set point.

ENTORHINAL CORTEX LESION INDUCES HOMEOSTATIC SYNAPTIC PLASTICITY OF CA3 PYRAMIDAL NEURONS

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Pia Kruse[1], Andreas Vlachos[1,2,3], Maximilian Lenz[1]
[1]University of Freiburg, Department Of Neuroanatomy, Institute Of Anatomy And Cell Biology, Faculty Of Medicine, Freiburg, Germany, [2]University of Freiburg, Center For Basics In Neuromodulation (neuromodulbasics), Faculty Of Medicine, Freiburg, Germany, [3]University of Freiburg, Center Brain Links Brain Tools, Faculty Of Medicine, Freiburg, Germany

Aims: A common aspect of many neurological diseases is the denervation of brain regions as a result of either demyelination or cell death. Nonetheless, the underlying mechanisms involved in lesion-induced reorganization of neural networks warrant further investigation. In this study, we addressed the effects of a partial denervation of CA3 pyramidal neurons. **Methods:** Lesion of the entorhinal cortex in organotypic entorhino-hippocampal tissue cultures — prepared from wild type mice of both sexes — was used to denervate distal apical dendrites of hippocampal granule cells and CA3 pyramidal neurons. Changes in excitatory neurotransmission were assessed with single and paired whole-cell patch-clamp recordings and morphological alterations were analyzed with electron microscopy. Moreover, a region specific transcriptome analysis was performed. **Results:** Partial denervation resulted in homeostatic synaptic adaptions of dentate granule cells and CA3 pyramidal cells. These changes in excitatory neurotransmission occurred predominantly in the strongest synapses as shown by a hierarchical analysis of spontaneous excitatory postsynaptic currents. The homeostatic adjustment was accompanied by characteristic region-specific transcriptomic changes. Consistent with these findings, paired recordings of dentate granule cells and CA3 pyramidal neurons and ultrastructural analysis of mossy fiber synapses revealed denervation-induced homeostatic structural and functional changes at the single synapse level. **Conclusion:** Lesion-induced homeostatic synaptic plasticity of dentate granule cells and CA3 pyramidal neurons leads to hetero- and transsynaptic adaptations of hippocampal networks. All-trans retinoic acid induces synaptic plasticity in human cortical neurons.
A defining feature of the brain is the ability of its synaptic contacts to adapt structurally and functionally in an experience-dependent manner. In the human cortex, however, direct experimental evidence for coordinated structural and functional synaptic adaptation is currently lacking. Here, we probed synaptic plasticity in human cortical slices using the vitamin A derivative all-trans retinoic acid (atRA), a putative treatment for neuropsychiatric disorders such as Alzheimer's disease. Our experiments demonstrated that the excitatory synapses of superficial (layer 2/3) pyramidal neurons underwent coordinated structural and functional changes in the presence of atRA. These synaptic adaptations were accompanied by ultrastructural remodeling of the calcium-storing spine apparatus organelle and required mRNA translation. It was not observed in synaptopodin-deficient mice, which lack spine apparatus organelles. We conclude that atRA is a potent mediator of synaptic plasticity in the adult human cortex.

All-trans retinoic acid induces synaptopodin-dependent metaplasticity in mouse dentate granule cells.
Previously we showed that the vitamin A metabolite all-trans retinoic acid (atRA) induces synaptic plasticity in acute brain slices prepared from the mouse and human neocortex (Lenz et al., 2021). Depending on the brain region studied, distinct effects of atRA on excitatory and inhibitory neurotransmission have been reported. Here, we used intraperitoneal injections of atRA (10 mg/kg) in adult C57BL/6J mice to study the effects of atRA on excitatory and inhibitory neurotransmission in the mouse fascia dentata-a brain region implicated in memory acquisition. No major changes in synaptic transmission were observed in the ventral hippocampus while a significant increase in both spontaneous excitatory postsynaptic current frequencies and synapse numbers were evident in the dorsal hippocampus 6 hr after atRA administration. The intrinsic properties of hippocampal dentate granule cells were not significantly different and hippocampal transcriptome analysis revealed no essential neuronal changes upon atRA treatment. In light of these findings, we tested for the metaplastic effects of atRA, that is, for its ability to modulate synaptic plasticity expression in the absence of major changes in baseline synaptic

strength. Indeed, in vivo long-term potentiation (LTP) experiments demonstrated that systemic atRA treatment improves the ability of dentate granule cells to express LTP. The plasticity-promoting effects of atRA were not observed in synaptopodin-deficient mice, therefore, extending our previous results regarding the relevance of synaptopodin in atRA-mediated synaptic strengthening in the mouse prefrontal cortex. Taken together, our data show that atRA mediates synaptopodin-dependent metaplasticity in mouse dentate granule cells.

Interleukin 10 Restores Lipopolysaccharide-Induced Alterations in Synaptic Plasticity Probed by Repetitive Magnetic Stimulation.
Systemic inflammation is associated with alterations in complex brain functions such as learning and memory. However, diagnostic approaches to functionally assess and quantify inflammation-associated alterations in synaptic plasticity are not well-established. In previous work, we demonstrated that bacterial lipopolysaccharide (LPS)-induced systemic inflammation alters the ability of hippocampal neurons to express synaptic plasticity, i.e., the long-term potentiation (LTP) of excitatory neurotransmission. Here, we tested whether synaptic plasticity induced by repetitive magnetic stimulation (rMS), a non-invasive brain stimulation technique used in clinical practice, is affected by LPS-induced inflammation. Specifically, we explored brain tissue cultures to learn more about the direct effects of LPS on neural tissue, and we tested for the plasticity-restoring effects of the anti-inflammatory cytokine interleukin 10 (IL10). As shown previously, 10 Hz repetitive magnetic stimulation (rMS) of organotypic entorhino-hippocampal tissue cultures induced a robust increase in excitatory neurotransmission onto CA1 pyramidal neurons. Furthermore, LPS-treated tissue cultures did not express rMS-induced synaptic plasticity. Live-cell microscopy in tissue cultures prepared from a novel transgenic reporter mouse line [] confirms that LPS administration triggers microglial tumor necrosis factor alpha (TNFα) expression, which is ameliorated in the presence of IL10. Consistent with this observation, IL10 hampers the LPS-induced increase in TNFα, IL6, IL1β, and IFNγ and restores the ability of neurons to express rMS-induced synaptic plasticity in the presence of LPS. These findings establish organotypic tissue cultures as a suitable model for studying inflammation-induced alterations in synaptic plasticity, thus providing a biological basis for the diagnostic use of transcranial magnetic stimulation in the context of brain inflammation.

Aims: Homeostatic synaptic plasticity aims at compensating for perturbations in network activity, thereby keeping synaptic transmission in a dynamic range. Among the mechanisms that mediate and control homeostatic plasticity, mRNA translation in dendrites plays a crucial role for the local control of synaptic properties. Nevertheless, the precise regulatory mechanisms and the relevance of homeostatic plasticity in human cortical networks remain unknown. **Methods:** In this study, we investigated the impact of neural network silencing through pharmacological inhibition of voltage-gated sodium channels or glutamatergic neurotransmission (i.e., common targets of anticonvulsant substances) on functional and structural properties of murine and human cortical neurons. **Results:** Using mouse organotypic tissue cultures and adult human cortical slices we showed that network silencing promotes a compensatory functional reorganization of excitatory synapses consistent with a homeostatic synaptic adjustment. This form of homeostatic plasticity was accompanied by epitranscriptomic changes and required *de novo* protein synthesis. **Conclusion:** Our findings provide first experimental evidence for homeostatic synaptic plasticity in the adult human neocortex. They suggest an important role for epitranscriptomic modifications and protein synthesis in the regulation of synaptic homeostasis in murine and human cortical networks.

Neuronal networks are balanced by mechanisms of homeostatic plasticity, which adjust synaptic strength via molecular and morphological changes in the pre- and post-synapse. The perineuronal extracellular matrix (ECM) of the adult brain, which is mainly composed of chondroitin sulfate proteoglycans such as brevican stabilizes synapses and thereby reduces neuronal plasticity. Previous data indicate that brevican is cleaved during homoeostatic plasticity and thereby may facilitate synapse remodeling. The proteases ADAMTS4, -5 and the closely related ADAMTS8, -9 and -15 may share brevican as substrate and are presumably responsible for ECM regulation. In order to elucidate the role of ADAMTS family members in homeostatic plasticity we quantified ADAMTS expression by qPCR in dissociated neuronal cultures after prolonged network silencing. Further, we investigated substrate specificity of ADAMTS family members *in vitro*. We used siRNAs to knock-down selected ADAMTS in neuronal cultures and quantified abundance of specific synaptic proteins regulated during network silencing. We found ADAMTS4 and -5 mRNA regulated during homeostatic plasticity. In contrast to ADAMTS4 and -5, neither ADAMTS8 nor ADAMTS15 cleaved brevican *in vitro*. In line with this finding downregulation of ADAMTS4 and -5, but not ADAMTS8 diminished cleavage of brevican in neuronal cultures. Furthermore, homeostatic regulation of synaptic proteins was abolished when interfering with ADAMTS function. In conclusion we found that ECM remodeling via ADAMTS4 and -5 derived cleavage of brevican is necessary for homeostatic regulation of synaptic plasticity and thus adjustment of neuronal networks.

NCAM2 Regulates Dendritic and Axonal Differentiation through the Cytoskeletal Proteins MAP2 and 14-3-3.
Neural cell adhesion molecule 2 (NCAM2) is involved in the development and plasticity of the olfactory system. Genetic data have implicated the NCAM2 gene in neurodevelopmental disorders including Down syndrome and autism, although its role in cortical development is unknown. Here, we show that while overexpression of NCAM2 in hippocampal neurons leads to minor alterations, its downregulation severely compromises dendritic architecture, leading to an aberrant phenotype including shorter dendritic trees, retraction of dendrites, and emergence of numerous somatic neurites. Further, our data reveal alterations in the axonal tree and deficits in neuronal polarization. In vivo studies confirm the phenotype and reveal an unexpected role for NCAM2 in cortical migration. Proteomic and cell biology experiments show that NCAM2 molecules exert their functions through a protein complex with the cytoskeletal-associated proteins MAP2 and 14-3-3γ and ζ. We provide evidence that NCAM2 depletion results in destabilization of the microtubular network and reduced MAP2 signal. Our results demonstrate a role for NCAM2 in dendritic formation and maintenance, and in neural polarization and migration, through interaction of NCAM2 with microtubule-associated proteins.

RAPID HOMEOSTATIC MODULATION OF TRANSSYNAPTIC NANOCOLUMN RINGS

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Paola Muttathukunnel[1], Patrick Frei[1], Sarah Perry[2], Dion Dickman[2], Martin Müller[1]
[1]University of Zurich, Molecular Life Sciences, Zürich, Switzerland, [2]University of Southern California, Neurobiology, CA, United States of America

Robust neural information transfer relies on a delicate molecular architecture of chemical synapses and even subtle changes in the molecular organization of synapses may profoundly affect synaptic transmission and animal behavior. Neurotransmitter release is controlled by a specific arrangement of proteins within presynaptic active zones. How the specific presynaptic molecular architecture relates to postsynaptic organization, and how synaptic nano-architecture is transsynaptically regulated to achieve stable synaptic transmission remains enigmatic. Using STED microscopy, we here discovered that presynaptic nano-rings formed by the active-zone cytomatrix protein scaffold Bruchpilot (Brp) precisely align with glutamate receptors (GluRs) nano-rings composed of ~ 6 GluR clusters at the *Drosophila* NMJ. Individual rings harbor ~ 5 transsynaptically-aligned Brp-GluR 'nanocolumns'. Transsynaptic nanocolumn rings are partially masked by unaligned GluR clusters. Genetic manipulations of GluR subunits and the auxiliary GluR subunit Neto revealed a GluR subtype-specific nano-organization: While GluRs containing the GluRIIA subunit predominantly localize to nanorings, GluRIIB 'nanoclusters' can be found both, inside and outside of nanorings. Interestingly, acute GluR impairment rapidly triggers the formation of new transsynaptic nanocolumns on the minute time scale during homeostatic plasticity. We reveal distinct phases of structural transsynaptic homeostatic plasticity, with postsynaptic reorganization preceding presynaptic modulation. Finally, the auxiliary GluR subunit Neto promotes structural and functional homeostatic plasticity. Thus, transsynaptic nanocolumns arrange in stereotypic rings that are rapidly modulated during homeostatic plasticity to stabilize synaptic efficacy. We are in in the process of linking synaptic nano-architecture to synaptic physiology. Preliminary data suggest a correlation between nano-column number and miniature frequency

DENDRITIC SIGNALING PATHWAYS UNDERLYING ENDOCANNABINOID-MEDIATED INHIBITORY BOUTON GROWTH

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Lotte Herstel, Tom Coopmans, Hai Yin Hu, Dennis Kruijssen, Corette Wierenga
Utrecht University, Cell Biology, Neurobiology And Biophysics, Utrecht, Netherlands

Coordination between excitation and inhibition is essential for proper functioning of neuronal circuits. Inhibitory synapses can locally control the activity of excitatory inputs by their strategic placement on the same dendrite. We recently discovered that excitatory and inhibitory plasticity is regulated at the synaptic level. By repeated stimulation of excitatory synapses, the formation of a nearby inhibitory bouton onto the same dendrite can be triggered. Our findings show that this process is mediated by the dendritic production of the 2-AG which activates axonal CB1 receptors. In addition, we found that long-term structural plasticity of excitatory synapses was affected by manipulations of the endocannabinoid system.
We further explored the local dendritic signaling mechanism that underlies coordinated inhibitory plasticity. We found that NMDA receptor activation is required, but not sufficient, to induce bouton growth. We hypothesized that additional activation of mGluR5 is necessary. We used two-photon microscopy to image crossings between CA1 pyramidal cell dendrites and GFP-labeled GABAergic axons in organotypic hippocampal slices of GAD65-GFP mice. We stimulated multiple dendritic spines close to the crossing axon using two-photon glutamate uncaging (30x @0.5Hz) paired with somatic postsynaptic depolarization (0 mV, 100 msec). Pharmacological blockade of mGluR5 throughout the experiment did not prevent bouton growth, indicating that inhibitory bouton growth is independent of mGluR5 activation. To visualize the local dendritic activity upon two-photon uncaging we are now performing functional imaging experiments with an calcium indicator. Our results help to further unravel the activity-dependent signaling pathways that regulate coordination between excitatory and inhibitory synapses within dendrites.

Network control through coordinated inhibition.
Coordinated excitatory and inhibitory activity is required for proper brain functioning. Recent computational and experimental studies have demonstrated that activity patterns in recurrent cortical networks are dominated by inhibition. Whereas previous studies have suggested that inhibitory plasticity is important for homeostatic control, this new framework puts inhibition in the driver's seat. Complex neuronal networks in the brain comprise many configurations in parallel, controlled by external and internal 'switches'. Context-dependent modulation and plasticity of inhibitory connections play a key role in memory and learning. It is therefore important to realize that synaptic plasticity is often multisynaptic and that a proper balance between excitation and inhibition is not fixed, but depends on context and activity level.

Quantitative mapping of transcriptome and proteome dynamics during polarization of human iPSC-derived neurons.
The differentiation of neuronal stem cells into polarized neurons is a well-coordinated process which has mostly been studied in classical non-human model systems, but to what extent these findings are recapitulated in human neurons remains unclear. To study neuronal polarization in human neurons, we cultured hiPSC-derived neurons, characterized early developmental stages, measured electrophysiological responses, and systematically profiled transcriptomic and proteomic dynamics during these steps. The neuron transcriptome and proteome shows extensive remodeling, with differential expression profiles of ~1100 transcripts and ~2200 proteins during neuronal differentiation and polarization. We also identified a distinct axon developmental stage marked by the relocation of axon initial segment proteins and increased microtubule remodeling from the distal (stage 3a) to the proximal (stage 3b) axon. This developmental transition coincides with action potential maturation. Our comprehensive characterization and quantitative map of transcriptome and proteome dynamics provides a solid framework for studying polarization in human neurons.

M, MacGillavry HD, Wierenga CJ, Hoogenraad CC
Centrosome-mediated microtubule remodeling during axon formation in human iPSC-derived neurons.
Axon formation critically relies on local microtubule remodeling and marks the first step in establishing neuronal polarity. However, the function of the microtubule-organizing centrosomes during the onset of axon formation is still under debate. Here, we demonstrate that centrosomes play an essential role in controlling axon formation in human-induced pluripotent stem cell (iPSC)-derived neurons. Depleting centrioles, the core components of centrosomes, in unpolarized human neuronal stem cells results in various axon developmental defects at later stages, including immature action potential firing, mislocalization of axonal microtubule-associated Trim46 proteins, suppressed expression of growth cone proteins, and affected growth cone morphologies. Live-cell imaging of microtubules reveals that centriole loss impairs axonal microtubule reorganization toward the unique parallel plus-end out microtubule bundles during early development. We propose that centrosomes mediate microtubule remodeling during early axon development in human iPSC-derived neurons, thereby laying the foundation for further axon development and function.

DOES ENVIRONMENTAL ENRICHMENT OR MONOCULAR DEPRIVATION MODIFY THE DEVELOPMENT OF SYNAPTOME ARCHITECTURE?

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Hanan Woods[1], Zhen Qiu[1], Noboru Komiyama[1], Frank Sengpiel[2], Seth Grant[1]
[1]University of Edinburgh, Centre For Clinical Brain Sciences, Chancellor's Building, EDINBURGH, United Kingdom, [2]Cardiff University, School Of Biosciences, Cardiff, United Kingdom

The synaptome describes the diversity of brain synapses and the synaptome architecture describes the spatial distribution of these synapses in neurons, brain regions and the whole brain. Systematic mapping of the molecular and morphological properties of individual excitatory synapses on a brain-wide scale in the mouse reveals high synapse diversity (Zhu et al, *Neuron* 2018 doi.org/10.1016/j.neuron.2018.07.007). Excitatory synapse diversity expands during postnatal development and each brain region develops a unique signature of synapse composition (Cizeron et al, *Science* 2020 doi: 10.1126/science.aba3163). How much the synaptome architecture of excitatory synapses is controlled by activity and experience is poorly understood, especially for large parts of the brain that remain unexplored. We asked if the development of the synaptome architecture was modified in two well-established paradigms used to study how experience modifies synaptic properties, environmental enrichment (EE) and monocular deprivation (MD). PSD95$^{eGFP/eGFP}$/SAP102$^{MKO2/MKO2}$ mice expressing fluorescently labelled post-synaptic proteins underwent MD from P25-31 or EE rearing until P30 and P90 and synaptome mapping was performed on a brain-wide scale. Preliminary results indicate no significant differences in excitatory synapse number in any brain regions. Analysis of synapse types, subtypes and synapse diversity will be presented. These findings will help to clarify diverse, region-specific changes in excitatory synapse populations in response to experience-dependent activity.

GIRK CHANNELS ARE INVOLVED IN THE MODULATION OF DORSAL HIPPOCAMPUS METAPLASTICITY MECHANISMS THAT SUPPORT COGNITIVE HEALTH

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Souhail Djebari, Guillermo Iborra-Lázaro, Lydia Jiménez-Díaz, Juan Navarro-López
University of Castilla-La Mancha, Neurophysiology & Behavior Laboratory, Centro Regional De Investigaciones Biomédicas, Facultad De Medicina De Ciudad Real, Ciudad Real, Spain

GirK (G-protein-gated inwardly rectifying potassium) channels conductance is constitutively active in dorsal CA1 neurons, contributing to their resting membrane potential and ability to self-regulate their excitability in response to neuronal activity, a key aspect of homeostatic plasticity. This open a research avenue to explore GirK-mediated homeostatic regulation as a therapeutic tool in pathologies were hyperexcitabilitiy and altered synaptic plasticity are a hallmark. Here, we aimed to explore the role GirK-mediated basal activity in the regulation of metaplasticity mechanisms supporting hippocampal plasticity processes and dorsal hippocampus-dependent cognitive capabilities. Towards this aim, first, using mice dorsal hippocampal slice preparations, we examined pharmacological GirK channel activity modulation effect on the metaplasticity of long-term plasticity processes induction at CA3-CA1 synapse. Additionally, using an *in vivo* approach, we performed acute intracerebroventricular injections of GirK selective modulators to study their contribution to CA3-CA1 synaptic plasticity and subsequent learning and memory functions. Our data shows that GirK activity is required for the establishment of long-term synaptic plasticity processes in dorsal hippocampus, as its modulation can modify the metaplasticity of LTP/LTD induction threshold. Also, the disruption of such mechanism leads to a decline in hippocampal-dependent tasks performance. Together, these results provide evidence that GirK basal activity governs hippocampal synaptic plasticity direction, which has a significant impact on hippocampal-dependent cognitive functions. **Acknowledgements**: This work was supported by grants no. G-Protein-Gated Inwardly Rectifying Potassium (Kir3/GIRK) Channels Govern Synaptic Plasticity That Supports Hippocampal-Dependent Cognitive Functions in Male Mice.
The G-protein-gated inwardly rectifying potassium (Kir3/GIRK) channel is the effector of many G-protein-coupled receptors (GPCRs). Its dysfunction has been linked to the pathophysiology of Down syndrome, Alzheimer's and Parkinson's diseases, psychiatric disorders, epilepsy, drug addiction, or alcoholism. In the hippocampus, GIRK channels decrease excitability of the cells and contribute to resting membrane potential and inhibitory neurotransmission. Here, to elucidate the role of GIRK channels activity in the maintenance of hippocampal-dependent cognitive functions, their involvement in controlling neuronal excitability at different levels of complexity was examined in C57BL/6 male mice. For that purpose, GIRK activity in the dorsal hippocampus CA3-CA1 synapse was pharmacologically modulated by two drugs: ML297, a GIRK channel opener, and Tertiapin-Q (TQ), a GIRK channel blocker. , using dorsal hippocampal slices, we studied the effect of pharmacological GIRK modulation on synaptic plasticity processes induced in CA1 by Schaffer collateral stimulation. , we performed acute intracerebroventricular (i.c.v.) injections of the two GIRK modulators to study their contribution to electrophysiological properties and synaptic plasticity of dorsal hippocampal CA3-CA1 synapse, and to learning and memory capabilities during hippocampal-dependent tasks. We found that pharmacological disruption of GIRK channel activity by i.c.v. injections, causing either function gain or function loss, induced learning and memory deficits by a mechanism involving neural excitability impairments and alterations in the induction and maintenance of long-term synaptic plasticity processes. These results support the contention that an accurate control of GIRK activity must take place in the hippocampus to sustain cognitive functions. Cognitive processes of learning and memory that rely on hippocampal synaptic plasticity processes are critically ruled by a finely tuned neural excitability. G-protein-gated inwardly rectifying K (GIRK) channels play a key role in maintaining resting membrane potential, cell excitability and inhibitory neurotransmission. Here, we demonstrate that modulation of GIRK channels activity, causing either function gain or function loss, transforms high-frequency stimulation (HFS)-induced long-

term potentiation (LTP) into long-term depression (LTD), inducing deficits in hippocampal-dependent learning and memory. Together, our data show a crucial GIRK-activity-mediated mechanism that governs synaptic plasticity direction and modulates subsequent hippocampal-dependent cognitive functions.

Short-term plasticity after partial deafferentation in the oculomotor system.
Medial rectus motoneurons are innervated by two main pontine inputs. The specific function of each of these two inputs remains to be fully understood. Indeed, selective partial deafferentation of medial rectus motoneurons, performed by the lesion of either the vestibular or the abducens input, initially induces similar changes in motoneuronal discharge. However, at longer time periods, the responses to both lesions are dissimilar. Alterations on eye movements and motoneuronal discharge induced by vestibular input transection recover completely 2 months post-lesion, whereas changes induced by abducens internuclear lesion are more drastic and permanent. Functional recovery could be due to some kind of plastic process, such as reactive synaptogenesis, developed by the remaining intact input, which would occupy the vacant synaptic spaces left after lesion. Herein, by means of confocal microscopy, immunocytochemistry and retrograde labeling, we attempt to elucidate the possible plastic processes that take place after partial deafferentation of medial rectus motoneuron. 48 h post-injury, both vestibular and abducens internuclear lesions produced a reduced synaptic coverage on these motoneurons. However, 96 h after vestibular lesion, there was a partial recovery in the number of synaptic contacts. This suggests that there was reactive synaptogenesis. This recovery was preceded by an increase in somatic neurotrophin content, suggesting a role of these molecules in presynaptic axonal sprouting. The rise in synaptic coverage might be due to terminal sprouting performed by the remaining main input, i.e., abducens internuclear neurons. The present results may improve the understanding of this apparently redundant input system.

Hippocampal long-term synaptic depression and memory deficits induced in early amyloidopathy are prevented by enhancing G-protein-gated inwardly rectifying potassium channel activity.
Hippocampal synaptic plasticity disruption by amyloid-β (Aβ) peptides + thought to be responsible for learning and memory impairments in Alzheimer's disease (AD) early stage. Failures in neuronal excitability maintenance seems to be an underlying mechanism. G-protein-gated inwardly rectifying potassium (GirK) channels control neural excitability by hyperpolarization in response to many G-protein-coupled receptors activation. Here, in early in vitro and in vivo amyloidosis mouse models, we study whether GirK channels take part of the hippocampal synaptic plasticity impairments generated by Aβ . In vitro electrophysiological recordings from slices showed that Aβ alters synaptic plasticity by switching high-frequency stimulation (HFS) induced long-term potentiation (LTP) to long-term depression (LTD), which led to in vivo hippocampal-dependent memory deficits. Remarkably, selective pharmacological activation of GirK channels with ML297 rescued both HFS-induced LTP and habituation memory from Aβ action. Moreover, when GirK channels were specifically blocked by Tertiapin-Q, their activation with ML297 failed to rescue LTP from the HFS-dependent LTD induced by Aβ . On the other hand, the molecular analysis of the recorded slices by western blot showed that the expression of GIRK1/2 subunits, which form the prototypical GirK channel in the hippocampus, was not significantly regulated by Aβ . However, immunohistochemical examination of our in vivo amyloidosis model showed Aβ to down-regulate hippocampal GIRK1 subunit expression. Together, our results describe an Aβ-mediated deleterious synaptic mechanism that modifies the induction threshold for hippocampal LTP/LTD and underlies memory alterations observed in amyloidosis models. In this scenario, GirK activation assures memory formation by preventing the transformation of HFS-induced LTP into LTD.

32698467: Mayordomo-Cava J, Iborra-Lázaro G, Djebari S, Temprano-Carazo S, Sánchez-Rodríguez I, Jeremic D, Gruart A, Delgado-García JM, Jiménez-Díaz L, Navarro-López JD
Impairments of Synaptic Plasticity Induction Threshold and Network Oscillatory Activity in the Hippocampus Underlie Memory Deficits in a Non-Transgenic Mouse Model of Amyloidosis.
In early Alzheimer disease (AD) models synaptic failures and upstreaming aberrant patterns of network synchronous activity result in hippocampal-dependent memory deficits. In such initial stage, soluble forms of Amyloid- (A) peptides have been shown to play a causal role. Among different A species, A has been identified as the biologically active fragment, as induces major neuropathological signs related to early AD stages. Consequently, it has been extensively used to acutely explore the pathophysiological events related with neuronal dysfunction induced by soluble A forms. However, the synaptic mechanisms underlying its toxic effects on hippocampal-dependent memory remain unresolved. Here, in an in vivo model of amyloidosis generated by intracerebroventricular injections of A we studied the synaptic dysfunction mechanisms underlying hippocampal cognitive deficits. At the synaptic level, long-term potentiation (LTP) of synaptic excitation and inhibition was induced in CA1

region by high frequency simulation (HFS) applied to collaterals. A was found to alter metaplastic mechanisms of plasticity, facilitating long-term depression (LTD) of both types of LTP. In addition, aberrant synchronization of hippocampal network activity was found while at the behavioral level, deficits in hippocampal-dependent habituation and recognition memories emerged. Together, our results provide a substrate for synaptic disruption mechanism underlying hippocampal cognitive deficits present in A amyloidosis model.

Activation of G-protein-gated inwardly rectifying potassium (Kir3/GirK) channels rescues hippocampal functions in a mouse model of early amyloid-β pathology.
The hippocampus plays a critical role in learning and memory. Its correct performance relies on excitatory/inhibitory synaptic transmission balance. In early stages of Alzheimer's disease (AD), neuronal hyperexcitability leads to network dysfunction observed in cortical regions such as the hippocampus. G-protein-gated potassium (GirK) channels induce neurons to hyperpolarize, contribute to the resting membrane potential and could compensate any excesses of excitation. Here, we have studied the relationship between GirK channels and hippocampal function in a mouse model of early AD pathology. Intracerebroventricular injections of amyloid-β (Aβ) peptide-which have a causal role in AD pathogenesis-were performed to evaluate CA3-CA1 hippocampal synapse functionality in behaving mice. Aβ increased the excitability of the CA3-CA1 synapse, impaired long-term potentiation (LTP) and hippocampal oscillatory activity, and induced deficits in novel object recognition (NOR) tests. Injection of ML297 alone, a selective GirK activator, was also translated in LTP and NOR deficits. However, increasing GirK activity rescued all hippocampal deficits induced by Aβ due to the restoration of excitability values in the CA3-CA1 synapse. Our results show a synaptic mechanism, through GirK channel modulation, for the prevention of the hyperexcitability that causally contributes to synaptic, network, and cognitive deficits found in early AD pathogenesis.

MECHANICAL ACTIONS OF DENDRITIC-SPINE ENLARGEMENT ON THE PRESYNAPTIC TERMINAL AND THE DISCOVERY OF THE PRESSURE SENSATION AND TRANSDUCTION (PREST) MECHANISM.

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Hasan Ucar[1,2], Satoshi Watanabe[1,3], Jun Noguchi[1,3], Sho Yagishita[1,2], Noriko Takahashi[1,4], Haruo Kasai[1,2]

Dendritic spines in the CNS enlarge during learning. Within the compact brain tissue, this spine enlargement may have mechanical effects on the presynaptic terminals. In this work, we studied this phenomenon and we have identified a mechanosensory and transduction mechanism where presynaptic activity is enhanced by sensing the mechanical pressure emerging from spine enlargement. We used the Schaffer collateral (SC) in hippocampal slice cultures and we have found that fine and transient pushing of the boutons by a glass pipette markedly promoted the evoked neurotransmitter release and vesicle binding in the presynaptic terminals. To our surprise, both effects persisted over 20 min. Here, transmitter release was measured by presynaptic expression of iGluSnFR, and vesicle binding was estimated by the assembly of SNARE proteins, whose FRET between Syntaxin1A and VAMP2 was measured with fluorescence lifetime imaging (FLIM). Both effects were reproduced by a low hypertonic sucrose solution. Finally, we identified synapse candidates by labeling boutons (trans-SNARE or iGluSnFR probe) and dendritic spines (Alexa-dye by whole-cell patch-clamping). Here, the spine enlargement induced by two-photon glutamate uncaging enhanced evoked release and FRET only when the spines pushed the boutons by their elongation. In summary, we have found a PREST (Pressure Sensation and Transduction) mechanism in the boutons which enables boutons to sense mechanical forces for enhancing evoked release by increasing the ternary-SNARE formation. And we suggest that the spine enlargement, in addition to its roles in the well-recognized postsynaptic mechanisms, can potentiate the synaptic transmission by direct mechanical coupling of the presynaptic terminal.

In glutamatergic synapses of the mammalian brain, the sizes of synaptic structures are strongly correlated with each other and with synaptic strength. In particular the size of the post-synaptic density (PSD) correlates with that of the supporting spine. How this correlation is established and maintained is not clear. Spine size depends on the mechanical support and outward physical pressure exerted by the spine's actin cytoskeleton. Since some of the PSD proteins are also stabilized by binding to actin filaments, one possibility is that assembly of spine actin may directly control the extent of PSD growth.
To test this hypothesis, using cultured hippocampal neurons, we have investigated changes in the PSD component Homer 1c following pharmacological stabilization of actin filaments or direct optogenetic stimulation of actin filament nucleation in single spines.
We find that the effects of enhanced actin assembly are consistent with a homeostatic role of spine actin for regulating the size of the PSD at the single synapse level. The findings are discussed in the framework of structural plasticity.

LTP induced by a weak stimulus can be enhanced if it is preceded by LTP induced by a strong stimulus at neighbouring synapses due to a process known as synaptic tagging and capture (STC). Despite the importance of calcium in synaptic plasticity, there remains a large gap as to the exact mechanism by which this occurs and the source of calcium that govern different forms of synaptic plasticity. To study this, we performed a two-pathway experiment. In the first pathway (

BOARD NUMBER: S0), we induced LTP with a strong spaced TBS protocol (sTBS) and followed that with a weak TBS (wTBS) applied to an independent pathway (S1) 30 mins later. We recorded fEPSPs from stratum radiatum in response to stimulation of the Schaffer Collateral-Commissural pathway of 10-12 week old C57/BL6J M mice. We found that when Cyclopiazonic acid (CPA, 30 uM), Ryanodine (Ry, 10uM) and IEM (30 uM) a Calcium Permeable -AMPAR inhibitor were present during the strong TBS, LTP in both pathways were inhibited. However, when group 1 mGluRs inhibtors (1 uM YM 298198 and MTEP) were used, STC was unaffected. To see if the deficit was due to a disruption of setting of the synaptic tag, we washed on CPA 30 mins later during only the weak TBS and showed that LTP was inhibited in the second pathway but not the first. Together these results highlight the importance of intracellular calcium stores in the generation (during the sTBS in

BOARD NUMBER: S0) and setting of the synaptic tag (during wTBS in S1).

Aims: Neuropsychiatric disorders are on a steep rise in the last decades. With their complex etiology and poorly defined molecular basis, it is very difficult to aim for efficient treatment. Their pathology is usually connected to a dysregulation of neurotransmitters, disruption of neuroplasticity and neurogenesis. Cannabidiol (CBD) is a non-psychoactive compound harvested from *Cannabis sativa* with a considerable therapeutic potential for treating anxiety and depression. Proposed molecular mechanisms involved in its antidepressant and anxiolytic features are connected to cannabinoid (CB) and serotonin 5-HT_{1A} receptors. However, we still lack sufficient amount of clear scientific data proving these effects. Methods: First, we examined viability of embryonic rat cortical neuronal cultures (E18, DIV16) after CBD treatment in various concentrations (0.1 – 100 μM). Next, we examined the effect of CBD (0.1 – 10 μM) on synaptic plasticity with immunocytochemistry, using synapsin I and PSD-95 as presynaptic and postsynaptic markers, respectively, in dendrites of pyramidal neurons. Data were analysed using ImageJ software. Results: 24h treatment with 100 μM CBD significantly decreased viability of the cells, while lower doses did not affect it. Interestingly, CBD dose-dependently decreased numbers of both pre– and postsynaptic puncta and also number of synapses. Conclusions: CBD diminished number of synaptic proteins puncta. Our data show new insights into the molecular effects of CBD and indicate that further research on the actions of CBD is required to trace the basis of therapeutic potential of CBD.

The cellular prion protein (PrP^C) is highly expressed in the brain and in neurons. It is known for its role in transmissible spongiform encephalopathies and is suggested to be involved in the pathophysiology of other neurodegenerative diseases including Alzheimer's disease. Although PrP^C structure, misfolding, and mechanisms of pathogenesis have been extensively studied, its physiological functions in neurons largely remain elusive.
Recently, we have shown that the coordination of dynein- and kinesin-mediated bidirectional PrP^C vesicle trafficking impacts on prion disease progression. The regulation of motor protein complexes was found to operate as a critical switch for PrP^C lysosomal degradation versus its recycling and release in exosomes. In the current project, we aimed to investigate the role of PrP^C at hippocampal synapses and for activity-regulated processes. Our analysis revealed PrP^C localization at both excitatory and inhibitory synapses. Interestingly, we identified two cell adhesion molecules as novel interaction partners of PrP^C. Synaptically localized PrP^C only showed moderate response to different chemical stimulation protocols. In contrast, induction of chemical LTP or LTD triggered prominent changes in the vesicular PrP^C pool and in its active transport and targeting to endolysosomal compartments. Furthermore, neuronal live imaging revealed PrP^C and cell adhesion molecules to undergo cotransport within the same vesicles. Functionally, PrP^C facilitated the targeting of cell adhesion molecules to endolysosomes. Future experiments are planned to ask whether and how PrP^C neuronal turnover links to synaptic function.

Protein synthesis is a highly regulated process that is pivotal for long-term memory formation. Mutations in translation factors, or genes modulating translation initiation, have been associated with a wide range of neurological disorders, including cognitive disorders. Compared to the relatively well characterized AUG-mediated classical model of translation, little is known about the role of alternative translation that utilizes non-AUG start codons in mnemonic processing. Here we generated and characterized a new mouse model lacking the unconventional translation initiation factor eIF2A, which has been shown to regulate non-AUG translation initiation. Mice lacking eIF2A exhibit deficits in several long-term memory tasks. Interestingly, eIF2A deficient mice show specific deficits in protein synthesis-dependent mGluR long-term potentiation (LTP) and depression (LTD). Finally, using an in vivo ribosome profiling, we investigated the translation landscape controlled by eIF2A in the mammalian brain. Our findings suggest a crucial role for non-canonical translational control by eIF2A in long-term memory formation.

An ultrapotent synthetic nanobody neutralizes SARS-CoV-2 by stabilizing inactive Spike.
The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) virus enters host cells via an interaction between its Spike protein and the host cell receptor angiotensin-converting enzyme 2 (ACE2). By screening a yeast surface-displayed library of synthetic nanobody sequences, we developed nanobodies that disrupt the interaction between Spike and ACE2. Cryo-electron microscopy (cryo-EM) revealed that one nanobody, Nb6, binds Spike in a fully inactive conformation with its receptor binding domains locked into their inaccessible down state, incapable of binding ACE2. Affinity maturation and structure-guided design of multivalency yielded a trivalent nanobody, mNb6-tri, with femtomolar affinity for Spike and picomolar neutralization of SARS-CoV-2 infection. mNb6-tri retains function after aerosolization, lyophilization, and heat treatment, which enables aerosol-mediated delivery of this potent neutralizer directly to the airway epithelia.

Inhibition of Upf2-Dependent Nonsense-Mediated Decay Leads to Behavioral and Neurophysiological Abnormalities by Activating the Immune Response.
In humans, disruption of nonsense-mediated decay (NMD) has been associated with neurodevelopmental disorders (NDDs) such as autism spectrum disorder and intellectual disability. However, the mechanism by which deficient NMD leads to neurodevelopmental dysfunction remains unknown, preventing development of targeted therapies. Here we identified novel protein-coding UPF2 (UP-Frameshift 2) variants in humans with NDD, including speech and language deficits. In parallel, we

found that mice lacking Upf2 in the forebrain (Upf2 fb-KO mice) show impaired NMD, memory deficits, abnormal long-term potentiation (LTP), and social and communication deficits. Surprisingly, Upf2 fb-KO mice exhibit elevated expression of immune genes and brain inflammation. More importantly, treatment with two FDA-approved anti-inflammatory drugs reduced brain inflammation, restored LTP and long-term memory, and reversed social and communication deficits. Collectively, our findings indicate that impaired UPF2-dependent NMD leads to neurodevelopmental dysfunction and suggest that anti-inflammatory agents may prove effective for treatment of disorders with impaired NMD.

Microglia and amyloid precursor protein coordinate control of transient Candida cerebritis with memory deficits.
Bloodborne infections with Candida albicans are an increasingly recognized complication of modern medicine. Here, we present a mouse model of low-grade candidemia to determine the effect of disseminated infection on cerebral function and relevant immune determinants. We show that intravenous injection of 25,000 C. albicans cells causes a highly localized cerebritis marked by the accumulation of activated microglial and astroglial cells around yeast aggregates, forming fungal-induced glial granulomas. Amyloid precursor protein accumulates within the periphery of these granulomas, while cleaved amyloid beta (Aβ) peptides accumulate around the yeast cells. CNS-localized C. albicans further activate the transcription factor NF-κB and induce production of interleukin-1β (IL-1β), IL-6, and tumor necrosis factor (TNF), and Aβ peptides enhance both phagocytic and antifungal activity from BV-2 cells. Mice infected with C. albicans display mild memory impairment that resolves with fungal clearance. Our results warrant additional studies to understand the effect of chronic cerebritis on cognitive and immune function.

Aims: Psychostimulant substances, such as methamphetamine (Meth), affect the function and morphology of neuronal cells. Here, we aimed at uncovering the signalling pathways regulating this complex process, focusing on cdc42, a RhoGTPase important for the regulation of the actin cytoskeleton and synaptic function. **Methods:** Primary hippocampal neurons were exposed to Meth to assess alterations on morphology, function and to monitor cdc42 activation through FRET assays. Synaptoneurosomes from these cultures were used to evaluate cdc42 downstream proteins. Tying to prevent Meth effects on neuronal morphology, neurons were transfected with a miRNA to knockdown Intersectin1, a specific activator of cdc42, or treated with Zcl278, an inhibitor of cdc42/Intersectin1 interaction. Finally, WT mice received a binge pattern of Meth (4x5mg/kg, 2h intervals) and cdc42 activation and neuronal remodelling on the hippocampus were assessed. **Results:** Meth increased neurite outgrowth, dendritic spine density and decreased spontaneous neuronal activity. Cdc42 activity was increased at dendritic spines 5 min after drug exposure. Concurrently, the downstream pathway (N-Wasp, Arp3) was activated 15 min following Meth. Inhibition of Intersectin1, as well as Intersectin1 knockdown prevented Meth-induced effects on neuronal remodelling. In WT mice exposed to Meth, cdc42 activity was increased in hippocampal synaptoneurosomes 15 min after drug administration. Meth also increased neurite length and dendritic spine density *in vivo*. **Conclusions:** Collectively, our data demonstrate that Meth affects neuronal function and morphology in the hippocampus, which is driven, at least in part, by cdc42. Future work will determine the role of cdc42 on the development of addictive behaviour and relapse.

Neuron-Microglia Contact-Dependent Mechanisms Attenuate Methamphetamine-Induced Microglia Reactivity and Enhance Neuronal Plasticity.
Exposure to methamphetamine (Meth) has been classically associated with damage to neuronal terminals. However, it is now becoming clear that addiction may also result from the interplay between glial cells and neurons. Recently, we demonstrated that binge Meth administration promotes microgliosis and microglia pro-inflammation via astrocytic glutamate release in a TNF/IPR2-Ca-dependent manner. Here, we investigated the contribution of neuronal cells to this process. As the crosstalk between microglia and neurons may occur by contact-dependent and/or contact-independent mechanisms, we developed co-cultures of primary neurons and microglia in microfluidic devices to investigate how their interaction affects Meth-induced microglia activation. Our results show that neurons exposed to Meth do not activate microglia in a cell-autonomous way but require astrocyte mediation. Importantly, we found that neurons can partially prevent Meth-induced microglia activation via astrocytes, which seems to be achieved by increasing arginase 1 expression and strengthening the CD200/CD200r pathway. We also observed an increase in synaptic individual area, as determined by co-localization of pre- and post-synaptic markers.

The present study provides evidence that contact-dependent mechanisms between neurons and microglia can attenuate pro-inflammatory events such as Meth-induced microglia activation.

34400780: Canedo T, Portugal CC, Socodato R, Almeida TO, Terceiro AF, Bravo J, Silva AI, Magalhães JD, Guerra-Gomes S, Oliveira JF, Sousa N, Magalhães A, Relvas JB, Summavielle T
Astrocyte-derived TNF and glutamate critically modulate microglia activation by methamphetamine.
Methamphetamine (Meth) is a powerful illicit psychostimulant, widely used for recreational purposes. Besides disrupting the monoaminergic system and promoting oxidative brain damage, Meth also causes neuroinflammation, contributing to synaptic dysfunction and behavioral deficits. Aberrant activation of microglia, the largest myeloid cell population in the brain, is a common feature in neurological disorders triggered by neuroinflammation. In this study, we investigated the mechanisms underlying the aberrant activation of microglia elicited by Meth in the adult mouse brain. We found that binge Meth exposure caused microgliosis and disrupted risk assessment behavior (a feature that usually occurs in individuals who abuse Meth), both of which required astrocyte-to-microglia crosstalk. Mechanistically, Meth triggered a detrimental increase of glutamate exocytosis from astrocytes (in a process dependent on TNF production and calcium mobilization), promoting microglial expansion and reactivity. Ablating TNF production, or suppressing astrocytic calcium mobilization, prevented Meth-elicited microglia reactivity and re-established risk assessment behavior as tested by elevated plus maze (EPM). Overall, our data indicate that glial crosstalk is critical to relay alterations caused by acute Meth exposure.

Neuronal megalin mediates synaptic plasticity-a novel mechanism underlying intellectual disabilities in megalin gene pathologies.
Donnai-Barrow syndrome, a genetic disorder associated to LRP2 (low-density lipoprotein receptor 2/megalin) mutations, is characterized by unexplained neurological symptoms and intellectual deficits. Megalin is a multifunctional endocytic clearance cell-surface receptor, mostly described in epithelial cells. This receptor is also expressed in the CNS, mainly in neurons, being involved in neurite outgrowth and neuroprotective mechanisms. Yet, the mechanisms involved in the regulation of megalin in the CNS are poorly understood. Using transthyretin knockout mice, a megalin ligand, we found that transthyretin positively regulates neuronal megalin levels in different CNS areas, particularly in the hippocampus. Transthyretin is even able to rescue megalin downregulation in transthyretin knockout hippocampal neuronal cultures, in a positive feedback mechanism via megalin. Importantly, transthyretin activates a regulated intracellular proteolysis mechanism of neuronal megalin, producing an intracellular domain, which is translocated to the nucleus, unveiling megalin C-terminal as a potential transcription factor, able to regulate gene expression. We unveil that neuronal megalin reduction affects physiological neuronal activity, leading to decreased neurite number, length and branching, and increasing neuronal susceptibility to a toxic insult. Finally, we unravel a new unexpected role of megalin in synaptic plasticity, by promoting the formation and maturation of dendritic spines, and contributing for the establishment of active synapses, both in and hippocampal neurons. Moreover, these structural and synaptic roles of megalin impact on learning and memory mechanisms, since megalin heterozygous mice show hippocampal-related memory and learning deficits in several behaviour tests. Altogether, we unveil a complete novel role of megalin in the physiological neuronal activity, mainly in synaptic plasticity with impact in learning and memory. Importantly, we contribute to disclose the molecular mechanisms underlying the cognitive and intellectual disabilities related to megalin gene pathologies.

RNF10: A SYNAPTONUCLEAR MESSENGER LINKING NMDA RECEPTOR SYNAPTIC ACTIVITY AT CA1 SYNAPSES TO COGNITIVE FLEXIBILITY

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Fabrizio Gardoni[1], Carrano[1], Diego Scheggia[1], Ribeiro[1], Laura D'Andrea[2], Maria Italia[1], Elisa Zianni[1], La Greca[1], Ponzoni[3], Genova[1], Sala[3], Mitro[1], Monica Diluca[1], Marcello[1]

Background: Synaptonuclear protein messengers are fundamental players for the regulation of neuronal activation and morphology both in health and diseases. The Ring Finger Protein 10 (RNF10) is a synapse-to-nucleus signaling protein that specifically links activation of synaptic NMDA receptors to modulation of gene expression. *Aims:* To gain new insight into the *in vivo* functional and structural role of this synaptonuclear protein messenger in hippocampal neurons in orchestrating NMDA receptor-dependent signalling and learning behavior. *Methods:* We used an AAV-shRNA mediated strategy to decrease RNF10 expression selectively in CA1 region. 6 weeks after AAV-injection we performed *in vivo* behavioral evaluations of hippocampal dependent tasks and *ex-vivo* morphological and molecular (biochemistry, confocal imaging, RNAseq) analyses. RNF10 ko mice were also used for proof of concept experiments. *Results: In vivo* silencing of RNF10 in CA1 hippocampal neurons induced morphological and molecular alterations at dendritic spines strictly associated to its role as nuclear messenger. These events led to profound behavioral impairments in learning and cognitive flexibility tests. *Conclusions:* RNF10 activity as synaptonuclear messenger orchestrates the molecular composition, morphology and signalling at CA1 dendritic spines, playing also a key role in NMDAR-dependent learning and cognitive flexibility.

MMP-9 EXERTS CONTROL OVER INDIVIDUAL DENDRITIC SPINE PLASTICITY

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Diana Legutko[1,2], Piotr Michaluk[2], Ryohei Yasuda[1], Leszek Kaczmarek[3]
[1]Max Planck Florida Institute for Neuroscience, Neuronal Signal Transduction, Jupiter, United States of America, [2]Nencki Institute of Experimental Biology, Laboratory Of Neurobiology, Warsaw, Poland, [3]Nencki Institute of Experimental Biology, Polish Academy of Sciences, Braincity, Laboratory Of Neurobiology, Warsaw, Poland

Understanding molecular mechanisms of morphological and functional synaptic plasticity is a major research challenge. Matrix metalloproteinase-9 (MMP-9) has repeatedly been implicated in plasticity of excitatory synapses, however the exact mechanistic insight into its function is missing. To address this issue, we have followed glutamate uncaging protocol (uLTP) to produce long-term potentiation of individual synapses in organotypic hippocampal cultures. The cultures were incubated in the presence of MNI-glutamate with stimulation protocol of 30 laser pulses (0.5 Hz) delivered specifically at CA1 individual spines (harboring the excitatory synapses). Fluorescent lifetime imaging microscopy (FLIM) together with MMP-9 FRET sensor was used to measure MMP-9 activity. uLTP protocol resulted in a marked spine growth (up to 3-fold peak, followed by a 50% sustained increase lasting for at least 20 min.). The increase in spine volume was taken as a measure of a structural LTP of the synapses. Treatment with MMP-9 inhibitors (Inhibitor I and GM 6001) significantly impaired the spine growth both during its peak and sustained phase. Similarly, uLTP protocol induced significantly smaller spine growth in cultures derived from the MMP-9 KO mice in comparison to their WT littermates. This structural plasticity impairment was reversed by MMP-9 overexpression in KO cultures. Furthermore, we have shown a rapid local activity of MMP-9 during uLTP induction on dendritic spines. Our results suggest the MMP-9 involvement in dendritic spines plasticity from the onset of the LTP induction.

Inhibition of Matrix Metalloproteinase 9 Activity Promotes Synaptogenesis in the Hippocampus.
Information coding in the hippocampus relies on the interplay between various neuronal ensembles. We discovered that the application of a cholinergic agonist, carbachol (Cch), which triggers oscillatory activity in the gamma range, induces the activity of matrix metalloproteinase 9 (MMP-9)-an enzyme necessary for the maintenance of synaptic plasticity. Using electrophysiological recordings in hippocampal organotypic slices, we show that Cch potentiates the frequency of miniature inhibitory and excitatory postsynaptic currents (mIPSCs and mEPSCs, respectively) in CA1 neurons and this effect is MMP-9 dependent. Interestingly, though MMP-9 inhibition prevents the potentiation of inhibitory events, it further boosts the frequency of excitatory mEPSCs. Such enhancement of the frequency of excitatory events is a result of increased synaptogenesis onto CA1 neurons. Thus, the function of MMP-9 in cholinergically induced plasticity in the hippocampus is to maintain the fine-tuned balance between the excitatory and the inhibitory synaptic transmission.

Light-sheet microscopy imaging of a whole cleared rat brain with Thy1-GFP transgene.
Whole-brain imaging with light-sheet fluorescence microscopy and optically cleared tissue is a new, rapidly developing research field. Whereas successful attempts to clear and image mouse brain have been reported, a similar result for rats has proven difficult to achieve. Herein, we report on creating novel transgenic rat harboring fluorescent reporter GFP under control of neuronal gene promoter. We then present data on clearing the rat brain, showing that FluoClearBABB was found superior over passive CLARITY and CUBIC methods. Finally, we demonstrate efficient imaging of the rat brain using light-sheet fluorescence microscopy.

[Getting an insight into the brain - new optical clearing techniques and imaging using light-sheet microscope].
One of the biggest challenges in neuroscience is to understand how brain operates. For this, it would be the best to image the whole brain with at least cellular resolution, preserving the three-dimensional structure in order to capture the connections between different areas. Most currently available high-resolution imaging techniques are based on preparing thin brain sections that are next photographed one by one and subsequently bigger structures are reconstructed. These techniques are laborious and create artifacts. Recent optical clearing methods allow to obtain literally transparent brains that can be imaged using light-sheet microscope. The present review summarizes the most popular optical clearing techniques, describing their different mechanisms and comparing advantages and disadvantages of different approaches, and presents the principle of light-sheet microscopy and its use in imaging. Finally, it gives examples of application of optical tissue clearing and light-sheet imaging in neuroscience and beyond it.

Pax7 as molecular switch regulating early and advanced stages of myogenic mouse ESC differentiation in teratomas.
Pluripotent stem cells present the ability to self-renew and undergo differentiation into any cell type building an organism. Importantly, a lot of evidence on embryonic stem cell (ESC) differentiation comes from in vitro studies. However, ESCs cultured in vitro do not necessarily behave as cells differentiating in vivo. For this reason, we used teratomas to study early and advanced stages of in vivo ESC myogenic differentiation and the role of Pax7 in this process. Pax7 transcription factor plays a crucial role in the formation and differentiation of skeletal muscle precursor cells during embryonic development. It controls the expression of other myogenic regulators and also acts as an anti-apoptotic factor. It is also involved in the formation and maintenance of satellite cell population.

DESIGN OF AN ULTRAPOTENT GENETICALLY ENCODED BLOCKER OF THE POTASSIUM CHANNEL KV4.2 FOR GATING NEURAL PLASTICITY

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Michael Andreyanov, Shai Berlin
Technion, Department Of Physiology, Haifa, Israel

The voltage gated potassium channel Kv4.2 is critical in neuronal plasticity, learning and memory. However, the exact mechanism(s) by which Kv4.2 modulates neuronal plasticity are poorly understood and, at times, diverging. Current means to study the roles of Kv4.2, whether genetic or pharmacologic, are limited in specificity, spatial and temporal resolutions. To address the roles of Kv4.2 in neurons, we engineered a novel targeted tethered toxin, **Me**mbrane **t**ethered Hetero**Poda**toxin-2 (**MetaPoda**) and systematically characterized it. We found that MetaPoda is potent at inhibiting Kv4.2 currents and instigated a drastic reduction in the expression of Kv4.2. In neurons, MetaPoda shortened the action potential, but other intrinsic properties were unaffected. Using single cell RNA Sequencing of neurons expressing MetaPoda showed that inhibition of Kv4.2 causes very subtle changes in transcriptome, consistent with studies using Kv4.2-knock-out animals. However, we did observe an increase in cFOS and Arc/Arg3.1 which have been shown to increase during LTP and are necessary for it. cFos immunostaining showed an increase of 2.5-fold in MetaPoda infected neurons. This led us to suggest an additional role for Kv4.2 beyond its function as a potassium channel which negatively influences plasticity. Kv4.2 could act as a plasticity regulator with the following proposed mechanism: downregulation of Kv4.2 in neurons drives the neuron towards a post-potentiation state, as if potentiation has ensued. This post-potentiation state thereby hinders the ability of the neuron to further undergo potentiation which affects learning and memory. This counterintuitive role could help reveal the mechanisms through which Kv4.2 affects plasticity.

VASOPRESSIN ACTS AS A SYNAPSE ORGANIZER IN LIMBIC REGIONS BY BOOSTING PSD95 AND GLUA1 EXPRESSION

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Vito Hernandez[1], Mario Zetter-Salmon[1], Teresa Padilla[1], Lee Eiden[2], Limei Zhang[1]
[1]National Autonomous University of Mexico, Physiology Department, School Of Medicine, Mexico City, Mexico, [2]National Institute of Mental Health, Section On Molecular Neuroscience, Bethesda, United States of America

Previous results from our group have shown that AVP magnocellular neurons project to the hippocampus, extended amygdala, habenula, and locus coeruleus, with dense-core vesicles close to the active zone of excitatory synapses. The current study was conducted to determine whether AVP regulates excitatory synapse formation in those areas. Western blot analysis showed that 48-hour water deprivation increases the expression of PSD95 and GluA1 in the amygdala, lateral habenula, and ventral hippocampus, but not in the visual cortex. In *ex vivo* experiments with hippocampal brain slices incubated with AVP for 1-2 hours, we observed an upregulation of both PSD95 and GluA1. The co-incubation with the antagonists for the V1a (SR49059) or V1b (SSR149415) receptors blocked this AVP-induced increase in PSD95 and GLUA1. Using expansion microscopy, we showed that the density of PSD95 and GluA1 puncta in the dendrites of neurons innervated by vasopressinergic fibers is increased after 48-hours of water deprivation. These results suggest that vasopressin can act as a synapse organizer by modulating the synaptic strength in specific synapses of hypothalamic-limbic circuits.

Pre- and postsynaptic forms of long-term potentiation (LTP) are candidate synaptic mechanisms underlying learning and memory. A classical form of presynaptic LTP, referred to as synaptic redistribution, has been described for layer 5 pyramidal neurons. However, how this apparent increase in the release probability relates to recent advances in the understanding of priming of synaptic vesicles remains unclear. We therefore performed whole-cell recordings from layer 5 pyramidal neurons in acute cortical slices of rats in combination with extracellular stimulation of local excitatory inputs and analyzed the presynaptic function before and after the induction of LTP. LTP increased the EPSC amplitude by a median factor of 1.5 in half of the synapses. In these responder synapses, LTP increased synaptic depression during high-frequency transmission and slowed the recovery from depression by adding a second slow component to the time course of recovery. Analysis with a recently established two-step vesicle priming model indicates an increase in the number of fully-primed vesicles that recover slowly following stimulation. To further test this hypothesis, we pharmacologically stimulated the cyclic adenosine monophosphate (cAMP) and diacylglycerol (DAG) pathways, which are both known to promote synaptic vesicle priming. Both pharmacological manipulations indeed mimicked all features of electrically-induced LTP. Comparing presynaptic plasticity at various synapses revealed a general correlation that stronger synapses recover slower from synaptic depression, indicating that fully-primed vesicles rely on a slowly maturating release machinery. Our data show that LTP at layer 5 pyramidal neurons increases the synaptic strength by enlarging a subpool of fully-primed slowly-recovering vesicles.

GEPHYRIN E DOMAIN DIMERIZATION-DEPENDENT GLYCINE RECEPTOR BINDING

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Arthur Macha, Nele Burdina, Elmar Behrmann, Guenter Schwarz
University of Cologne, Institute For Biochemistry, Cologne, Germany

Gephyrin is the main scaffold protein at inhibitory synapses and interacts with γ-aminobutyric acid type A receptors ($GABA_AR$) or glycine receptors (GlyR), thus restricting their lateral movement and ensuring proper inhibitory signal transmission. Gephyrin is a three-domain protein which assembles as a trimer and adopts various conformations. High-affinity interaction towards GlyRs and $GABA_ARs$ is primarily mediated via the E domain (GephE), which forms dimers in solution and builds up a hydrophobic pocket for receptor binding. However, full-length gephyrin assembles as a homotrimer in which GephE was found in a monomeric state. In this work we utilized electron microscopy with single particle analysis (SPA) of gephyrin alone or in complex with 49 residue peptide derived from the GlyR β subunit (GlyR-bloop) harboring the gephyrin binding motif. In addition, we used a pentameric GlyR intracellular domain (ICD) mimicking protein to obtain structural insights of the GlyR-gephyrin complex. Analyzing those complexes revealed a ligand-induced GephE dimerization which formed within one gephyrin trimer, thus creating the previously observed binding pocket for high affinity receptor interaction. Consequently, gephyrin variants with altered GephE dimerization showed an impairment in GlyR binding *in vitro* and in neurons. Furthermore, the obtained structural data excluded the formation of GephE dimers between different gephyrin trimers, which argues against the formation of a previously proposed synapse spanning hexagonal lattice. Nonetheless, complex formation between gephyrin pentameric GlyR-ICD mimicking protein resulted in the formation of large assemblies suggesting a bridging function of gephyrin in connecting various receptors at the postsynaptic membrane.

BNDF MRNA TRACKING IN LIVE NEURONS

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Giorgia Bimbi, Enrico Tongiorgi
University of Trieste, Life Sciences, Trieste, Italy

The neurotrophin brain-derived neurotrophic factor (BDNF) plays a key role in neuronal survival and neurite out-growth, synaptogenesis and synaptic plasticity. BDNF mRNA can be transported in neuronal dendrites in an activity-dependent manner in particular, following seizures but also in response to antidepressants or physical activity. At present, a clear demonstration that BDNF mRNA is locally transported and translated at activated synapses in response to the induction of long-term potentiation (LTP) is still lacking. Here, we study the dynamics of BDNF mRNA trafficking during neuronal plasticity induced by chemical-LTP. The project explores the two hypotheses of selective vs. non-selective dendritic transport of BDNF transcripts after synaptic potentiation and the related methodological constrains using the MS2 system for mRNA visualization in living neurons.

ALL-OPTICAL INVESTIGATION OF LONG-TERM PLASTICITY IN THE HIPPOCAMPUS

POSTER SESSION 02 - SECTION: MECHANISMS OF SYNAPTIC PLASTICITY

Rui Wang, Margarita Anisimova, Thomas Oertner, Christine Gee
Institute of Synaptic Physiology, Center For Molecular Neurobiology Hamburg (zmnh), University Medical Center Hamburg-eppendorf, Hamburg, Germany

Synaptic plasticity, the long-lasting change in synaptic efficacy and structure, is a major mechanism of information storage in the brain. We took advantage of optogenetic tools to investigate the role of postsynaptic CaMKIIα in synaptic plasticity up to 3 days following induction. We induced spike-timing-dependent plasticity (STDP) at Schaffer collateral synapses in rat hippocampal slice cultures by pairing independent optogenetic stimulation of pre and postsynaptic neurons expressing spectrally separated channelrhodopsins. We found that optically induced STDP induces timing-dependent long-term potentiation (tLTP) of synaptic strength up to 30 minutes after stimulation. Even 3 days later, we could detect strengthened synaptic input onto tLTP neurons. When we optically inhibited the activity of CaMKIIα, one of the very important memory molecules that transform transient synaptic activity events into long-lasting synaptic plasticity, we observed a complete blockade of the acute tLTP. Unexpectedly, 3 days later, stimulated neurons received significantly stronger input than their neighbors, a potentiation that appears to be independent of CaMKIIα activity. We then tested the direct effects of CaMKIIα activation with a photoactivatable CaMKII. We found that optical activation of CaMKIIα is sufficient to acutely induce functional LTP. In line with the effects of acute CaMKII inhibition, this CaMKIIα activation-induced LTP returned to baseline after a couple of days. In conclusion, the potentiation of synaptic inputs seems to have two phases: CaMKIIα is necessary and sufficient to induce acute LTP. Whereas a second CaMKIIα independent mechanism is responsible for the selective strengthening of inputs days later.

REGULATION OF THE GABAERGIC SYNAPSE BY THE WNK PATHWAY.

POSTER SESSION 02 - SECTION: GABAERGIC TRANSMISSION AND SYNAPTIC FUNCTION

Zaha Merlaud, Marion Russeau, Juliette Gouhier, Sabine Levi
Institut du Fer à Moulin UMR-S1270, Inserm, Paris, France

We have shown that the chloride-sensing WNK kinase and its effector, SPAK, rapidly regulates neuronal Cl- homeostasis in mature hippocampal neurons by controlling the membrane dynamics and clustering of the chloride transporters KCC2 and NKCC1 near GABAergic synapses, thereby impacting the efficacy of GABAergic transmission. It is still unknown whether this pathway regulates the ionotropic $GABA_A$ receptor ($GABA_AR$) and/or its scaffolding protein gephyrin. Upon pharmacological blockade of the WNK/SPAK pathway, Single-Particle Tracking (SPT) experiments on live neurons show no effect of inhibitors on the lateral diffusion of the $GABA_AR$ α1 subunit ($GABA_AR\alpha1$) at synapses but a reduced diffusion and an increased confinement of the $GABA_AR\alpha1$ at extrasynaptic site. This effect was prevented by applying a peptide blocking clathrin-dependent endocytosis indicating that the restricted motion of $GABA_AR\alpha1$ upon WNK/SPAK inhibition was due to receptor undergoing endocytosis. Super-resolution microscopy upon WNK/SPAK inhibition reported an increase in the number of $GABA_AR\alpha1$ clusters with reduced size and density of detections, indicating cluster fragmentation. These results suggest that the WNK/SPAK pathway stabilizes $GABA_AR\alpha1$ at the plasma membrane. To confirm this hypothesis, we activated the pathway by lowering intracellular chloride levels and checked its impact on $GABA_AR\alpha1$ diffusion. Preliminary results show that activation of the pathway releases diffusion constraints on extrasynaptic GABAARα1 and confines GABAARα1 to synapses. This suggests increased receptor recruitment to synapses, which will need to be confirmed in super-resolution. Altogether, our data point toward a regulation of the GABAergic synapse by the WNK pathway.

PRESYNAPTIC LOCALIZATION OF ATG-9 IS REGULATED BY SCAMP5 ASSOCIATED WITH AP-4 COMPLEX

POSTER SESSION 02 - SECTION: GABAERGIC TRANSMISSION AND SYNAPTIC FUNCTION

Unghwi Lee, Seung Hyun Ryu, Jungmin Lee, Sunghoe Chang
Seoul National University College of Medicine, Biomedical Sciences, Seoul, Korea, Republic of

Autophagy is one of major cellular catabolic systems for regulating degradation of a wide range of damaged proteins and dysfunctional organelles. In neurons, autophagy is important for controlling turnover of synaptic proteins and removal of protein aggregates to maintain the neuronal activity and synaptic transmission. In recent studies, ATG-9 which is a transmembrane component of core autophagosome formation machineries has been suggested as a mediator of synaptic autophagy at presynaptic terminal. ATG-9 is known to be exported from *trans*-Golgi network (TGN) and transported to its destination via AP-4 complex, however, how ATG-9 trafficking to presynaptic bouton is regulated remains unknown despite its importance for adjusting the presynaptic autophagy and synaptic activity. Here, we found that secretory carrier membrane protein 5 (SCAMP5) enriched at TGN interacted with AP-4 complex to promote the recruitment of ATG-9 to presynaptic site for mediating autophagy process. Biochemical analysis and optical imaging revealed that the N-terminal region of SCAMP5 is associated with mu subunit of AP-4 complex and shRNA-mediated knockdown (KD) of SCAMP5 significantly impaired the localization of ATG-9 and autophagosome formation which led to the accumulation of excessive proteins at presynaptic terminal. Together, our results exhibit that the interaction between SCAMP5 and AP-4 complex is crucial for the export and transport of ATG-9 from TGN to presynaptic compartment. Since ATG-9 is one of core autophagic machinery members, understanding the localization mechanism of ATG-9 to synaptic boutons may propose a better insight about working system of synaptic autophagy and underpinning mechanisms of autophagy-related neuronal disease.

SCAMP5 plays a critical role in axonal trafficking and synaptic localization of NHE6 to adjust quantal size at glutamatergic synapses.
Glutamate uptake into synaptic vesicles (SVs) depends on cation/H exchange activity, which converts the chemical gradient (ΔpH) into membrane potential (Δψ) across the SV membrane at the presynaptic terminals. Thus, the proper recruitment of cation/H exchanger to SVs is important in determining glutamate quantal size, yet little is known about its localization mechanism. Here, we found that secretory carrier membrane protein 5 (SCAMP5) interacted with the cation/H exchanger NHE6, and this interaction regulated NHE6 recruitment to glutamatergic presynaptic terminals. Protein-protein interaction analysis with truncated constructs revealed that the 2/3 loop domain of SCAMP5 is directly associated with the C-terminal region of NHE6. The use of optical imaging and electrophysiological recording showed that small hairpin RNA-mediated knockdown (KD) of SCAMP5 or perturbation of SCAMP5/NHE6 interaction markedly inhibited axonal trafficking and the presynaptic localization of NHE6, leading to hyperacidification of SVs and a reduction in the quantal size of glutamate release. Knockout of NHE6 occluded the effect of SCAMP5 KD without causing additional defects. Together, our results reveal that as a key regulator of axonal trafficking and synaptic localization of NHE6, SCAMP5 could adjust presynaptic strength by regulating quantal size at glutamatergic synapses. Since both proteins are autism candidate genes, the reduced quantal size by interrupting their interaction may underscore synaptic dysfunction observed in autism.
Proc Natl Acad Sci U S A, 2021; 118
33663553: Lee U, Ryu SH, Chang S
SCAMP5 mediates activity-dependent enhancement of NHE6 recruitment to synaptic vesicles during synaptic plasticity.
Na(K)/H exchanger 6 (NHE6) on synaptic vesicle (SV) is critical for the presynaptic regulation of quantal size at the glutamatergic synapses by converting the chemical gradient (ΔpH) into membrane potential (Δψ) across the SV membrane. We recently found that NHE6 directly interacts with secretory carrier membrane protein 5 (SCAMP5), and SCAMP5-dependent recruitment of NHE6 to SVs controls the strength of synaptic transmission by modulation of quantal size of glutamate release at rest. It is, however, unknown whether NHE6 recruitment by SCAMP5 plays a role during synaptic plasticity. Here, we found that the number of NHE6-positive presynaptic boutons was significantly increased by the chemical long-term potentiation (cLTP). Since cLTP involves new synapse formation, our results indicated that NHE6 was recruited not

only to the existing presynaptic boutons but also to the newly formed presynaptic boutons. Knock down of SCAMP5 completely abrogated the enhancement of NHE6 recruitment by cLTP. Interestingly, despite an increase in the number of NHE6-positive boutons by cLTP, the quantal size of glutamate release at the presynaptic terminals remained unaltered. Together with our recent results, our findings indicate that SCAMP5-dependent recruitment of NHE6 plays a critical role in manifesting presynaptic efficacy not only at rest but also during synaptic plasticity. Since both are autism candidate genes, reduced presynaptic efficacy by interfering with their interaction may underlie the molecular mechanism of synaptic dysfunction observed in autism.

nArgBP2 regulates excitatory synapse formation by controlling dendritic spine morphology.
Neural Abelson-related gene-binding protein 2 (nArgBP2) was originally identified as a protein that directly interacts with synapse-associated protein 90/postsynaptic density protein 95-associated protein 3 (SAPAP3), a postsynaptic scaffolding protein critical for the assembly of glutamatergic synapses. Although genetic deletion of nArgBP2 in mice leads to manic/bipolar-like behaviors resembling many aspects of symptoms in patients with bipolar disorder, the actual function of nArgBP2 at the synapse is completely unknown. Here, we found that the knockdown (KD) of nArgBP2 by specific small hairpin RNAs (shRNAs) resulted in a dramatic change in dendritic spine morphology. Reintroducing shRNA-resistant nArgBP2 reversed these defects. In particular, nArgBP2 KD impaired spine-synapse formation such that excitatory synapses terminated mostly at dendritic shafts instead of spine heads in spiny neurons, although inhibitory synapse formation was not affected. nArgBP2 KD further caused a marked increase of actin cytoskeleton dynamics in spines, which was associated with increased Wiskott-Aldrich syndrome protein-family verprolin homologous protein 1 (WAVE1)/p21-activated kinase (PAK) phosphorylation and reduced activity of cofilin. These effects of nArgBP2 KD in spines were rescued by inhibiting PAK or activating cofilin combined with sequestration of WAVE. Together, our results suggest that nArgBP2 functions to regulate spine morphogenesis and subsequent spine-synapse formation at glutamatergic synapses. They also raise the possibility that the aberrant regulation of synaptic actin filaments caused by reduced nArgBP2 expression may contribute to the manifestation of the synaptic dysfunction observed in manic/bipolar disorder.

29562188: Park D, Lee U, Cho E, Zhao H, Kim JA, Lee BJ, Regan P, Ho WK, Cho K, Chang S
Impairment of Release Site Clearance within the Active Zone by Reduced SCAMP5 Expression Causes Short-Term Depression of Synaptic Release.
Despite being a highly enriched synaptic vesicle (SV) protein and a candidate gene for autism, the physiological function of SCAMP5 remains mostly enigmatic. Here, using optical imaging and electrophysiological experiments, we demonstrate that SCAMP5 plays a critical role in release site clearance at the active zone. Truncation analysis revealed that the 2/3 loop domain of SCAMP5 directly interacts with adaptor protein 2, and this interaction is critical for its role in release site clearance. Knockdown (KD) of SCAMP5 exhibited pronounced synaptic depression accompanied by a slower recovery of the SV pool. Moreover, it induced a strong frequency-dependent short-term depression of synaptic release, even under the condition of sufficient release-ready SVs. Super-resolution microscopy further proved the defects in SV protein clearance induced by KD. Thus, reduced expression of SCAMP5 may impair the efficiency of SV clearance at the active zone, and this might relate to the synaptic dysfunction observed in autism.
Cell Rep, 2018; 22

Activation of CaMKIV by soluble amyloid-β impedes trafficking of axonal vesicles and impairs activity-dependent synaptogenesis.
The prefibrillar form of soluble amyloid-β (sAβ) impairs synaptic function and is associated with the early phase of Alzheimer's disease (AD). We investigated how sAβ led to presynaptic defects using a quantum dot-based, single particle-tracking method to monitor synaptic vesicle (SV) trafficking along axons. We found that sAβ prevented new synapse formation induced by chemical long-term potentiation (cLTP). In cultured rat hippocampal neurons, nanomolar amounts of sAβ impaired Ca clearance from presynaptic terminals and increased the basal Ca concentration. This caused an increase in the phosphorylation of Ca/calmodulin-dependent protein kinase IV (CaMKIV) and its substrate synapsin, which markedly inhibited SV trafficking along axons between synapses. Neurons derived from a transgenic AD mouse model had similar defects, which were prevented by an inhibitor of CaMK kinase (CaMKK; which activates CaMKIV), by antibodies against Aβ, or by expression a phosphodeficient synapsin mutant. The CaMKK inhibitor also abolished the defects in activity-dependent synaptogenesis caused by sAβ Our results suggest that by disrupting SV reallocation between synapses, sAβ prevents neurons from forming new synapses or adjusting strength and activity among neighboring synapses. Targeting this mechanism might prevent synaptic dysfunction in AD patients.
Sci Signal, 2017; 10

Release Mode Dynamically Regulates the RRP Refilling Mechanism at Individual Hippocampal Synapses.
Synaptic strength and reliability are determined by the number of vesicles released per action potential and the availability of release-competent vesicles in the readily releasable pool (RRP). Compared with release of a single vesicle (univesicular release), multivesicular release (MVR) would speed up RRP depletion, yet whether the RRP is refilled differently during the two different release modes has not been investigated. Here, we address this question by quantitative optical imaging with an axon-targeting glutamate sensor, iGluSnFRpre. We found that hippocampal synapses preferentially release multiple vesicles per action potential at high extracellular calcium or by paired-pulse stimulation. When MVR prevails, the RRP is recovered very rapidly with a time constant of 430 ms. This rapid recovery is mediated by dynamin-dependent endocytosis followed by direct reuse of retrieved vesicles. Furthermore, our simulation proved that the portion of retrieved vesicles that directly refill the RRP increases dramatically (>70%) in MVR compared with that in univesicular release (<10%). These results suggest that the contribution of rapid and direct recruitment of retrieved vesicle to the RRP changes dynamically with release mode at the level of individual synapses, which suggests a form of presynaptic homeostatic plasticity for reliable synaptic transmission during various synaptic activity. The number of vesicles released in response to an action potential and the number of release competent vesicles in the readily releasable pool (RRP) are the fundamental determinants of synaptic efficacy. Despite its functional advantages, releasing multiple vesicles, especially at small synapses, can deplete the RRP after a couple of action potentials. To prevent failure of synaptic transmission, the RRP should be refilled rapidly, yet whether the RRP replenishment process is regulated by the release mode has not been investigated. Here, using quantitative optical glutamate imaging and simulation, we demonstrate that the contribution of the fast refilling mechanism changes with release mode at the level of individual synapses, suggesting a rapid form of presynaptic homeostatic plasticity during various synaptic activity.

SGIP1α functions as a selective endocytic adaptor for the internalization of synaptotagmin 1 at synapses.
Proper sorting of exocytosed synaptic vesicle (SV) proteins into individual SVs during endocytosis is of the utmost importance for the fidelity of subsequent neurotransmission. Recent studies suggest that each SV protein is sorted into individual SVs by its own dedicated adaptors as well as by association between SV proteins. The SH3-containing GRB2-like protein 3-interacting protein 1 (SGIP1), an ortholog of Fer/Cip4 homology domain-only (FCHo) proteins, contains a μ-homology domain (μHD) and binds AP-2 and Eps15, thus functioning as an endocytic regulator of clathrin-mediated endocytosis (CME). Its longest isoform SGIP1α is predominantly expressed in the brain but the functional significance of SGIP1 in SV recycling remains unknown. Here, we found that SGIP1α, a brain-specific long isoform of SGIP1 binds synaptotagmin1 (Syt1) via its μHD and promotes the internalization of Syt1 on the neuronal surface. The small hairpin RNA (shRNA)-mediated knockdown (KD) of SGIP1α caused selective impairment of Syt1 internalization at hippocampal synapses and it was fully rescued by coexpression of the shRNA-resistant form of SGIP1α in KD neurons. We further found that the μHD of SGIP1α is structurally similar to those of AP-2 and stonin2, and mutations at Trp771 and Lys781, which correspond to Syt1-recognition motifs of AP-2 and stonin2, to Ala bound less efficiently to Syt1 and failed to rescue the endocytic defect of Syt1 caused by KD. Our results indicate that SGIP1α is an endocytic adaptor dedicated to the retrieval of surface-stranded Syt1. Since endocytic sorting of Syt1 is also mediated by the overlapping activities of synaptic vesicle glycoprotein 2A/B (SV2A/B) and stonin2, our results suggest that complementary fail-safe mechanism by these proteins ensures high fidelity of Syt1 retrieval.

THE TIMING OF THE GABA SHIFT AFFECTS THE POSTNATAL DEVELOPMENT OF INHIBITORY SYNAPSES

POSTER SESSION 02 - SECTION: GABAERGIC TRANSMISSION AND SYNAPTIC FUNCTION

Carlijn Peerboom, Tessel Wijne, Marijn Rieter, Nikki Jonker, Corette Wierenga
Utrecht University, Cell Biology, Neurobiology, Biophysics, Utrecht, Netherlands

Chloride-mediated GABA signaling shifts from depolarizing to hyperpolarizing during the second postnatal week in rodents, due to increased activity of the chloride exporter KCC2 relative to the chloride importer NKCC1. The GABA shift is delayed in patients and mouse models for neurodevelopmental disorders. It is unclear whether a delayed GABA shift causes alterations in synaptic transmission . Here we assessed the consequences of mistimed GABA shift on synapse development in hippocampal slice cultures, in which we can follow the GABA shift between *day in vitro* (DIV) 2 and 22. We set out to delay the GABA shift by blocking KCC2 with VU0463271 or furosemide during DIV2-8 and assessed the consequences for inhibitory and excitatory postsynaptic currents (IPSCs and EPSCs) using patch clamp recordings at DIV9 and DIV21. As expected, blocking KCC2 with VU0463271 resulted in a depolarizing GABA reversal potential at DIV8, which normalized at DIV20. IPSCs and EPSCs were not affected at DIV9. However, at DIV21, when chloride levels were restored, the frequency of spontaneous IPSCs was increased. Unexpectedly, GABA signaling was strongly hyperpolarizing at DIV 8 after furosemide treatment. This was associated with a decrease in the frequency of spontaneous IPSCs at DIV9. We observed that IPSCs were suppressed in an activity-dependent manner, which was independent of BDNF and endocannabinoids. When chloride levels were restored at DIV 21, IPSC frequency was increased compared to control slices. Our results indicate that the timing of the GABA shift affects postnatal development of inhibitory synapses .

The postnatal GABA shift: A developmental perspective.
GABA is the major inhibitory neurotransmitter that counterbalances excitation in the mature brain. The inhibitory action of GABA relies on the inflow of chloride ions (Cl), which hyperpolarizes the neuron. In early development, GABA signaling induces outward Cl currents and is depolarizing. The postnatal shift from depolarizing to hyperpolarizing GABA is a pivotal event in brain development and its timing affects brain function throughout life. Altered timing of the postnatal GABA shift is associated with several neurodevelopmental disorders. Here, we argue that the postnatal shift from depolarizing to hyperpolarizing GABA represents the final shift in a sequence of GABA shifts, regulating proliferation, migration, differentiation, and finally plasticity of developing neurons. Each developmental GABA shift ensures that the instructive role of GABA matches the circumstances of the developing network. Sensory input may be a crucial factor in determining proper timing of the postnatal GABA shift. A developmental perspective is necessary to interpret the full consequences of a mismatch between connectivity, activity and GABA signaling during brain development.

TSPAN15 DEPLETION AFFECTS EXTRACELLULAR VESICLE UPTAKE BY RECIPIENT NEURONS

POSTER SESSION 02 - SECTION: GABAERGIC TRANSMISSION AND SYNAPTIC FUNCTION

Daniele Stajano[1], Franco Lombino[1], Kira Gromova[1], Paul Saftig[2], Matthias Kneussel[1]
[1]Center for Molecular Neurobiology Hamburg - ZMNH, Institute Molecular Neurogenetics, Hamburg, Germany, [2]Christian-Albrechts University of Kiel, Institute For Biochemistry, Kiel, Germany

Extracellular vesicles (EVs) provide a unique mode of intercellular communication. EVs serve as vehicles for transferring proteins, lipids, and RNAs between cells. They represent a heterogeneous population of membranous vesicles released by several cell types, such as glia or neurons. EVs are known to alter recipient cell physiology depending on their membrane and luminal cargoes and play critical roles in pathological processes. The functions of EVs have been extensively studied in the context of neurodegenerative diseases and their bioengineering provides great therapeutic potential. EVs are taken up by recipient cells through different modes. However, detailed molecular mechanisms and critical molecular players are presently barely understood. Using biochemical and cell biology techniques, we show that Tspan15 is an EV membrane protein. Fluorescent EV labeling demonstrates that TSPAN15 depletion does not affect EV release, but significantly impairs EV uptake by recipient neurons.

GABA EVOKES DEPOLARIZATIONS AND CALCIUM TRANSIENTS IN ADULT CEREBROSPINAL FLUID-CONTACTING NEURONS OF MOUSE SPINAL CORD

POSTER SESSION 02 - SECTION: GABAERGIC TRANSMISSION AND SYNAPTIC FUNCTION

Priscille Riondel, Nina Jurčić, Nicolas Wanaverbecq, Riad Seddik
Institut de Neurosciences de la Timone, Bouches-du-rhône, Marseille, France

Cerebrospinal fluid-contacting neurons (CSF-cNs) form an evolutionary conserved bipolar cells population localized in mammalian spinal cord. They lie at the interface between CSF and the parenchyma while their activity is modulated by extracellular pH and osmolarity variations, suggesting that CSF-cNs are polymodal sensory neurons able to carry information from the CSF to spinal neuronal network. Alongside their sensory features, CSF-cNs were shown to express molecular markers of neuronal immaturity during adulthood, though the functional relevance of their incomplete maturation is still unknown. Here, we used a combination of electrophysiology and calcium imaging to investigate the properties of $GABA_A$ receptors-dependent signaling in experimental conditions that maintain unchanged the concentration of intracellular chloride in CSF-cNs. We found that CSF-cNs of adult mice spinal cord respond by either depolarization or hyperpolarization of their membrane potential upon GABA application. Moreover, depolarizing-GABA responses trigger intracellular calcium elevations in CSF-cNs through the activation of voltage-gated calcium channels. Our findings represent the first evidence that a subpopulation of adult spinal CSF-cNs around the central canal maintain immature properties in their GABA signaling, with GABA-dependent depolarization and calcium modulation. Hence, GABAergic transmission in CSF-cNs may be part of mechanisms regulating their functional maturation and integration in spinal circuits.

SYNAPTOTAGMIN-11 CONTROLS GABAB RECEPTOR INTERNALIZATION

POSTER SESSION 02 - SECTION: GABAERGIC TRANSMISSION AND SYNAPTIC FUNCTION

Luca Trovò, Diego Fernandez-Fernandez, Txomin Lalanne, Martin Gassmann, Bernhard Bettler
University of Basel, Department Of Biomedicine, Basel, Switzerland

$GABA_B$ receptors (GBRs) regulate neurotransmitter release and postsynaptic inhibition. Proteomic approaches have revealed that the Amyloid Precursor Protein APP is required for axonal transport of GBRs (Dinamarca et al., Nature Communications 10, 2019). Synaptotagmin-11 (Syt11), an atypical member of the synaptotagmin family, was found to form a multi-protein complex with GBRs and APP (Schwenk et al., Nature Neuroscience 19, 2016). Using biochemical approaches, we characterized the interaction between Syt11, APP, and GBRs. We found that Syt11 interacts indirectly with GBRs through APP and the auxiliary receptor subunit KCTD16 (K^+ channel tetramerization-domain containing protein 16). We show that the GBR/Syt11 complex is transported in NPY^+ cargo vesicles in axons and dendrites and co-localizes with pre- and postsynaptic structures at the plasma membrane. Consistent with its reported role as a clamp for endocytosis (Wang et al., Embo reports 17, 2016), Syt11 inhibited GBR internalization from the cell surface. Accordingly, $Syt11^{-/-}$ neurons exhibit a reduced number of GBRs at the plasma membrane and a deficit in GBR-mediated inhibition of neurotransmitter release.

Symmetric signal transduction and negative allosteric modulation of heterodimeric mGlu1/5 receptors.
For a long time metabotropic glutamate receptors (mGluRs) were thought to regulate neuronal functions as obligatory homodimers. Recent reports, however, indicate the existence of heterodimers between group-II and -III mGluRs in the brain, which differ from the homodimers in their signal transduction and sensitivity to negative allosteric modulators (NAMs). Whether the group-I mGluRs, mGlu1 and mGlu5, form functional heterodimers in the brain is still a matter of debate. We now show that mGlu1 and mGlu5 co-purify from brain membranes and hippocampal tissue and co-localize in cultured hippocampal neurons. Complementation assays with mutants deficient in agonist-binding or G protein-coupling reveal that mGlu1/5 heterodimers are functional in heterologous cells and transfected cultured hippocampal neurons. In contrast to heterodimers between group-II and -III mGluRs, mGlu1/5 receptors exhibit a symmetric signal transduction, with both protomers activating G proteins to a similar extent. NAMs of either protomer in mGlu1/5 receptors partially inhibit signaling, showing that both protomers need to be able to reach an active conformation for full receptor activity. Complete heterodimer inhibition is observed when both protomers are locked in their inactive state by a NAM. In summary, our data show that mGlu1/5 heterodimers exhibit a symmetric signal transduction and thus intermediate signaling efficacy and kinetic properties. Our data support the existence of mGlu1/5 heterodimers in neurons and highlight differences in the signaling transduction of heterodimeric mGluRs that influence allosteric modulation.

The green tea polyphenol epigallocatechin-3-gallate (EGCG) restores CDKL5-dependent synaptic defects in vitro and in vivo.
CDKL5 deficiency disorder (CDD) is a rare X-linked neurodevelopmental disorder that is characterised by early-onset seizures, intellectual disability, gross motor impairment, and autistic-like features. CDD is caused by mutations in the cyclin-dependent kinase-like 5 (CDKL5) gene that encodes a serine/threonine kinase with a predominant expression in the brain. Loss of CDKL5 causes neurodevelopmental alterations in vitro and in vivo, including defective dendritic arborisation and spine maturation, which most likely underlie the cognitive defects and autistic features present in humans and mice. Here, we show that treatment with epigallatocathechin-3-gallate (EGCG), the major polyphenol of green tea, can restore defects in dendritic and synaptic development of primary Cdkl5 knockout (KO) neurons. Furthermore, defective synaptic maturation in the hippocampi and cortices of adult Cdkl5-KO mice can be rescued through the intraperitoneal administration of EGCG, which is however not sufficient to normalise behavioural CDKL5-dependent deficits. EGCG is a pleiotropic compound with numerous cellular targets, including the dual-specificity tyrosine-phosphorylation-regulated kinase 1A (DYRK1A) that is selectively inhibited by EGCG. DYRK1A controls dendritic development and spine formation and its deregulation has been

implicated in neurodevelopmental and degenerative diseases. Treatment with another DYRK1A inhibitor, harmine, was capable of correcting neuronal CDKL5-dependent defects; moreover, DYRK1A levels were upregulated in primary Cdkl5-KO neurons in concomitance with increased phosphorylation of Tau, a well-accepted DYRK1A substrate. Altogether, our results indicate that DYRK1A deregulation may contribute, at least in part, to the neurodevelopmental alterations caused by CDKL5 deficiency.

MOLECULAR MECHANISMS OF UNCONVENTIONAL NMDA RECEPTORS CONTAINING GLUN3A SUBUNITS

POSTER SESSION 02 - SECTION: GABAERGIC TRANSMISSION AND SYNAPTIC FUNCTION

Marco De Battista, Pierre Paoletti, David Stroebel
École normale supérieure, Ibens, PARIS, France

NMDA receptors (N-Methyl-D-Aspartate) are ligand gated ionotropic channels belonging to the ionotropic glutamate receptor (iGluR) family that drives excitatory transmission in the central nervous system (CNS). NMDARs assemble as tetramers, composed of two GluN1s with two GluN2 (GluN2A-D), or two GluN3 subunits (GluN3A-B). Among NMDARs, di-heteromeric GluN1/GluN3A NMDARs exhibit peculiar properties: i) they are activated by glycine alone and not glutamate; ii) they display atypical gating kinetics with glycine acting as an activator at GluN3A subunits and an antagonist as GluN1 subunits. In recent years, we and others have revealed that GluN1/GluN3A receptors are functionally expressed in the CNS where they form excitatory glycine receptors. Still, little is known about the molecular mechanisms of GluN1/GluN3A receptor function involved in neuronal excitability. In other iGluRs, it is well established that the Ligand Binding Domain (LBD) interfaces control important features of receptor gating. We thus aimed at characterizing the role of LBD interfaces in GluN3As. Structural modelling allowed us to highlight key residues located in these regions. Using two electrodes voltage clamp recordings in Xenopus oocytes, we studied the impact of mutating these residues on the main biophysical properties of GluN1/GluN3A receptors, among which current phenotypes, channel open probability, desensitization kinetics, and sensitivity to pharmacological agents. Some of these mutants display gain of function phenotypes unveiling distinct properties of the GluN3A receptor LBD interface. Altogether, our research individuates structural features underpinning the atypical behavior of glycine-gated GluN1/GluN3A receptors, representing a step forward in our understanding of their differences with canonical GluN1/GluN2 NMDARs.

COMPLEX REGULATION OF GEPHYRIN SPLICING IS A DETERMINANT OF INHIBITORY POSTSYNAPTIC DIVERSITY

POSTER SESSION 02 - SECTION: GABAERGIC TRANSMISSION AND SYNAPTIC FUNCTION

Fabrice Ango
INSERM U1298, Inm, Montpellier, France

Gephyrin (*GPHN*) regulates the clustering of postsynaptic components at inhibitory synapses and is involved in pathophysiology of neuropsychiatric disorders. Here, we uncover an extensive diversity of *GPHN* transcripts that are tightly controlled by splicing during mouse and human brain development. Proteomic analysis reveals at least a hundred isoforms of GPHN incorporated at inhibitory Glycine and GABA-A receptors containing synapses. They exhibit different localization and postsynaptic clustering properties, and altering the expression level of one isoform is sufficient to affect the number, size, and density of inhibitory synapses in cerebellar Purkinje cells. Furthermore, we discovered that splicing defects reported in neuropsychiatric disorders are carried by multiple alternative *GPHN* transcripts, demonstrating the need for a thorough analysis of the *GPHN* transcriptome in patients. Overall, we show that alternative splicing of *GPHN* is an important genetic variation to consider in neurological diseases and a determinant of the diversity of postsynaptic inhibitory synapses.

EFFECTS OF PKA-MEDIATED PHOSPHORYLATION IN THE GLYCINE RECEPTOR ALPHA 3K VARIANT.

POSTER SESSION 02 - SECTION: GABAERGIC TRANSMISSION AND SYNAPTIC FUNCTION

Katherine Fariña, Nicole Espinoza, David Flaig, Santiago Quintana, Paul Soto, Patricio Castro, Jorge Fuentealba, Carola Munoz Montesino, Gonzalo Yévenes, Gustavo Moraga-Cid
University of Concepción, Department Of Physiology, Concepción, Chile

Glycine receptors (GlyRs) are anion-permeable pentameric ligand-gated ion channels (pLGICs). Glycinergic neurotransmission is critical controlling key functions, such as motor coordination, respiratory control, muscle tone and pain processing. In this context, previous studies have shown that the functional inhibition of GlyRs containing the α3 subunit is a pivotal mechanism of pain hypersensitivity. In glycinergic neurons, two GlyRsα3 variants are generated by post-transcriptional processing; alpha 3K and alpha 3L, with the later containing a 15 amino acids insert located in the large intracellular domain (ICD). Interestingly, pain hypersensitivity has been associated to the inhibition of glycine activated currents by phosphorylation by PKA in the S346 residue located in the ICD of the α3L. This reduced activity of α3L is due to a diminished single channel conductance. Despite to the importance of the expression of both variants in glycinergic neurons, the effects of PKA phosphorylation in the α3K variant is still unknown. Here, using optogenetics and electrophysiological approach combined with site-directed mutagenesis we evaluated the effects of PKA activation in the unitary conductance of the wild type and phospomimetic mutants (S346E) α3K variant. Single channel currents obtained in cell attached configurations showed similar amplitude in both variants. PKA activation by a photoactivatable adenylyl cyclases (bPACs) or a phosphomimetic mutation (S346E) significantly reduced the unitary conductance in the α3K, similar to observed in the α3L variant. These results reveal that the activation of PKA and the subsequent phosphorylation of the S346 residue, have a similar functional impact on both GlyRsa3 variants.

ACTIVATION MECHANISMS OF THE ORPHAN RECEPTOR GPR158

POSTER SESSION 02 - SECTION: GABAERGIC TRANSMISSION AND SYNAPTIC FUNCTION

Thibaut Laboute, Dipak Patil, Kirill Martemyanov
Scripps Research Institute, Neurosciences, Jupiter, United States of America

G Protein Coupled Receptors (GPCR) are important receptor family for therapeutics development since a vast number of drugs in clinical use target GPCRs. Orphan GPCRs represent promising candidates for development of novel therapeutics. GPR158 is an orphan GPCR highly expressed in brain. It is enriched in the prefrontal cortex, and its genetic suppression in mice results in prominent antidepressant phenotype and stress resiliency making GPR158 an attractive target for development of novel anti-depressants. One of the biggest mysteries related to GPR158 biology is its ligand and mechanism of activation. In this work, we are addressing this challenge in several ways. First, we studied an ability of GPR158 to constitutively activate various heterotrimeric G proteins and detected none. We then analyzed whether it could modulate an activity of its intracellular partner – a GTPase activating complex consisting of RGS7 and Gb5 subunits. Indeed, we found that manipulations with an extracellular domain of GPR158 result in RGS7/Gb5-dependent regulation of G protein deactivation. This indicates that GPR158 may signal non-canonically to regulate activity of RGS proteins rather than activate G proteins. Finally, we determined a high-resolution structure of GPR158 in complex with RGS7/Gb5. In addition to showing how GPR158 engages RGS7/Gb5 complex, it revealed the presence of an extracellular Cache domain, a putative ligand-binding module. Work is underway to determine the nature of the ligand that binds to the Cache domain and activates GPR158 to result in modulation of RGS7/Gb5 activity. Collectively, these results offer new insights into exciting pharmacological target for intervention in depression.

Cryo-EM structure of human GPR158 receptor coupled to the RGS7-Gβ5 signaling complex.
GPR158 is an orphan G protein–coupled receptor (GPCR) highly expressed in the brain, where it controls synapse formation and function. GPR158 has also been implicated in depression, carcinogenesis, and cognition. However, the structural organization and signaling mechanisms of GPR158 are largely unknown. We used single-particle cryo–electron microscopy (cryo-EM) to determine the structures of human GPR158 alone and bound to an RGS signaling complex. The structures reveal a homodimeric organization stabilized by a pair of phospholipids and the presence of an extracellular Cache domain, an unusual ligand-binding domain in GPCRs. We further demonstrate the structural basis of GPR158 coupling to RGS7-Gβ5. Together, these results provide insights into the unusual biology of orphan receptors and the formation of GPCR-RGS complexes.

GPR88 is an orphan G-protein-coupled receptor (GPCR) highly expressed in striatal medium spiny neurons (MSN), also found in cortical neurons at low level. In MSN, GPR88 has a canonical GPCR plasma membrane/cytoplasmic expression, whereas in cortical neurons, we previously reported an atypical intranuclear localization. Molecular size analysis suggests that GPR88, expressed in plasma membrane of MSN or in nuclear compartment of cortical neurons, corresponds to the full-length protein. By transfection of cortical neurons, we showed that GPR88 fluorescent chimeras exhibit a nuclear localization. This localization is contingent on the third intracytoplasmic loop and C-terminus domains, even though these domains do not contain any known nuclear localization signals (NLS). Using yeast two-hybrid screening with these domains, we identified the nuclear proteins ATRX, TOP2B, and BAZ2B, all involved in chromatin remodeling, as potential protein partners of GPR88. We also validated the interaction of GPR88 with these nuclear proteins by proximity ligation assay on cortical neurons in culture and coimmunoprecipitation experiments on cortical extracts from GPR88 wild-type (WT) and knockout (KO) mice. The identification of GPR88 subcellular partners may provide novel functional insights for nonclassical modes of GPCR action that could be relevant in the maturating process of neocortical neurons.

AGE DIFFERENTIALLY MODULATES L-TYPE CALCIUM CHANNEL AND N-METHYL-D-ASPARTATE RECEPTOR EXPRESSIONS IN THE HIPPOCAMPUS AND PIRIFORM CORTEX

POSTER SESSION 02 - SECTION: GABAERGIC TRANSMISSION AND SYNAPTIC FUNCTION

Aida Maziar, Qi Yuan
Memorial University of Newfoundland, Faculty Of Medicine, St. John's, Canada

AIMS: Calcium signalling is essential for learning and memory, and its dysregulation is a key contributor in age-related cognitive decline. Ca^{2+} influx in neurons is mediated mainly by L-type calcium channels (LTCCs) and N-methyl-D-aspartate receptors (NMDARs). Here we measured LTCC and NMDAR expressions in Sprague-Dawley rats of various ages. We focused on the piriform cortex (PC) and the hippocampus, two areas integral to olfactory and spatial learning. **METHODS**: We measured synaptic and extrasynaptic levels of LTCCs (Cav1.2) and NMDAR subunits (GluN1, GluN2A, and GluN2B) in neonatal, adult and aged rats using western blot. We further investigated the somatic and dendritic expression of the Cav1.2 subunit using immunohistochemistry. Synaptic and extrasynaptic (PSD95 colocalizing and non-colocalizing) Cav1.2 subunit expressions in the dendritic layer were compared between adult and aged brains using confocal microscopy. **RESULTS**: In adults and aged hippocampus, there was a higher expression of synaptic, but not extrasynaptic NMDARs compared to neonates. However, GluN2A/2B ratios and synaptic:extrasynaptic ratios of NMDAR subunits were similar across age groups. In contrast, in the PC, GluN2A/2B and synaptic:extrasynaptic ratios were higher in adult PC compared to neonates. In hippocampal CA1 and PC, the soma:dendritic ratio of Cav1.2 expression increased with aging and extrasynaptic Cav1.2 (PSD95 non-colocalizing) expression was also found to have higher expression in the aged rats PC compared to adults. **CONCLUSIONS**: Hippocampus and PC differ in age-related channel expression. Higher somatic Cav1.2 expression in CA1 and higher extrasynaptic Cav1.2 in the PC may correlate with aging-associated disruption of calcium homeostasis and cognitive decline.

REDEFINING THE GABAERGIC TRANSPORTER SYSTEMS IN C. ELEGANS

POSTER SESSION 02 - SECTION: GABAERGIC TRANSMISSION AND SYNAPTIC FUNCTION

Elise Cheynet, Nalia Samba, Charlotte Tissot, Marie Gendrel
Institut de Biologie de l'Ecole Normale Supérieure (IBENS), Ecole Normale Supérieure (ENS), CNRS, INSERM, Université Paris Sciences et Lettres Research University (PSL), Biology, Paris, France

Functional neuronal circuits rely on a combination of both excitation and inhibition. In mature neurons, the main inhibitory neurotransmitter is GABA. Traditionally, neurons have been classified as GABAergic if they co-expressed three protein determinants: 1) GAD/UNC-25, which synthesizes GABA from glutamate, 2) VGAT/UNC-47, a vesicular transporter that packages GABA into synaptic vesicles, and 3) GAT/SNF-11, a plasma membrane transporter that recaptures extracellular GABA. In *C. elegans*, only 26 out of 302 neurons were considered GABAergic, until an improved immunostaining enabled the identification of 15 additional GABA-positive neurons. Although they stain for GABA and contact neurons expressing post synaptic $GABA_A$ receptors, they do not all coexpress GAD/UNC-25, VGAT/UNC-47 and GAT/SFN-11. In particular, three pairs of neurons express none of those. They are thus unable to synthesize, uptake or package GABA the way we know it. **We hypothesize that those neurons use unidentified transporters for GABA uptake and vesicular packaging. The present work aims to identify them.** Therefore, we are probing 51 putative amino acid transporters, analyzing both their expression pattern and how they affect GABA localisation. Currently, 18 available mutant strains are being characterized for GABA staining. For the other genes without any null allele available, we already found four out of nine to be neuronally expressed. One has been further characterized and is likely to be expressed in two of our neurons of interest. Using Crispr/Cas9 technology, we will generate a knockout allele of that candidate to test it for GABA transport.

ROLE OF THE ORGANIC ANION TRANSPORTER 1 IN MEMORY AND SYNAPTIC PLASTICITY

POSTER SESSION 02 - SECTION: GABAERGIC TRANSMISSION AND SYNAPTIC FUNCTION

Javier Sánchez Romero, Janina Kupke, Ana Oliveira, Daniela Mauceri
Heidelberg University, Izn Neurobiology, Heidelberg, Germany

The molecular mechanisms of synaptic plasticity have been extensively studied. Nevertheless, many events occurring at the synapse during physiological and pathological neuroadaptations are still unclear. New modulators of synaptic physiology are recurringly discovered. The organic anion transporter 1 (OAT1), a multi-specific kidney transporter involved in drug excretion and regulation of systemic metabolite levels, could belong to this category of newly identified plasticity modulators. Until recently, very little was known about OAT1 expression and function in the central nervous system. A few reports indicated its expression in the brain and choroid plexus. Our group recently showed that OAT1 expression in the mouse spinal cord is key to the establishment and maintenance of hypersensitivity in chronic inflammatory pain. Thus, a function for OAT1 as a mediator of maladaptive plasticity was identified for the first time. Whether OAT1 is involved in additional plasticity mechanisms has not been studied. Here, we systematically characterized OAT1 expression in the adult mouse brain. Using OAT1-knockout mice, we studied the involvement of OAT1 in hippocampus-dependent memory tasks. We found that OAT1 deficiency results in changes in several molecular players of synaptic plasticity and their downstream signaling events in both primary hippocampal cultures and hippocampal tissue. Furthermore, metabolomics analysis of the OAT1-KO hippocampus and cerebrospinal fluid revealed pathway alterations similar to those previously reported in the plasma, hinting at candidate OAT1 substrates that might explain the involvement of OAT1 in synaptic signaling. Taken together, our results suggest OAT1 as a novel regulator of plasticity in the central nervous system.

NON-CANONICAL ROLE OF NKCC1 IN NEURONS BY REGULATING KCC2 FUNCTION

POSTER SESSION 02 - SECTION: GABAERGIC TRANSMISSION AND SYNAPTIC FUNCTION

Erwan Pol[1,2], Marion Russeau[2], Christophe Piesse[3], Nicolas Pietrancosta[1,3], Sabine Levi[2]
[1]CNRS - Sorbonne Université, Laboratoire Des Biomolécules, PARIS, France, [2]Institut du Fer à Moulin UMR-S1270, Inserm, Paris, France, [3]Institut de Biologie Paris-Seine (IBPS) UPMC-CNRS, Plateforme Synthèse Peptidique, Interactions Moléculaires Et Pcr En Temps Réel, Paris, France

Chloride neuronal homeostasis, which is determined by the KCC2 and NKCC1 transporters, responsible for Cl- efflux and influx respectively, regulates the efficiency and polarity of GABAergic transmission in the brain. The dysfunction of these transporters leads to a pathological state by a build-up of chloride in neurons. Drugs aimed at reducing neuronal chloride levels therefore represent promising therapeutic strategies. We have shown in mature neurons that the regulation of the membrane trafficking/activity of KCC2 and NKCC1 involves the With-No-lysine-(K)-serine-threonine kinase WNK1 and its effector, Ste20-Proline-Asparagine-Rich-Kinase (SPAK). Once activated, SPAK is recruited below the plasma membrane allowing a local control of its activity. NKCC1 but not KCC2 directly binds SPAK. We propose that NKCC1 regulates KCC2 by recruiting SPAK near inhibitory synapses. We developed several peptides that prevent SPAK binding to NKCC1 and showed that they regulate KCC2 as a proof of concept. We want now to validate the SPAK scaffold hypothesis and identif new small compounds, through interdisciplinary approaches (chemistry/molecular modeling/cell biology/imaging/animal behavior), able to interact with the NKCC1/SPAK complex and inhibit SPAK activity and thus prevent KCC2 internalization and chloride build-up in neurons. This project will shed light on the virtually unknown role of a signaling pathway in the nervous system and may lead to the discovery of a non-canonical role for NKCC1 in neurons. It may also lead to the discovery of new therapeutic strategies in diseases with inhibition defects.

KCC2-MEDIATED REGULATION OF CHRONIC BENZODIAZEPINE ACTION

POSTER SESSION 02 - SECTION: GABAERGIC TRANSMISSION AND SYNAPTIC FUNCTION

Annika Schäfer, Teemu Aitta-Aho, Esa Korpi
University of Helsinki, Department Of Pharmacology, Faculty Of Medicine, Helsinki, Finland

Benzodiazepines remain to be routinely used as rapidly acting, short-term therapy for status epilepticus, anxiety, panic attacks and insomnia. However, limitations related to acute and chronic tolerance, leading to escalating doses and heightened risk of dependence, hampers their clinical usage. Adaptations in $GABA_A$Rs' subunit composition, intracellular mechanisms or changes in other neurotransmitter systems have been extensively studied as main components underlying such drug tolerance. In contrast, what happens to Cl^- homeostasis – the principal mechanisms of ensuring the inward, hyperpolarizing Cl^- gradient - has remained poorly understood. In this study, we aimed at exploring possible alterations in KCC2-mediated chloride homeostasis underlying tolerance development to diazepam. Mice were treated chronically with diazepam (elevating doses from 5 to 25 mg/kg, s.c.) or vehicle twice a day for 28 days. Tolerance development to motor-impairing effects was confirmed using the Rotarod performance and beam walking tests. Surprisingly, light-dark box measurements conducted at the end of the treatment period showed a strong anxiety-like phenotype in the diazepam-treated group, independent of the timing of the last drug administration (30 min or 11 h). Brain regions known to mediate the effects of diazepam, including the cerebellum and thalamus, were subjected to immunoblotting using antibodies against pan-KCC2 and its phosphorylated forms (S940 and T1007). Immunoblotting analysis did not show any statistically significant differences in brain regional KCC2 protein expression and phosphorylation between the diazepam- and vehicle-treated mice. These preliminary results should still be confirmed by additionally examining possible alterations in KCC2 transporter functionality.

A NEW MOLECULAR TOOLBOX FOR EXPLORING GEPHYRIN AND INHIBITORY SYNAPSE BIOLOGY

POSTER SESSION 02 - SECTION: GABAERGIC TRANSMISSION AND SYNAPTIC FUNCTION

Benjamin Campbell[1], Shiva Tyagarajan[1], Birgit Drier[2], Andreas Plückthun[2]
[1]University of Zurich, Institute Of Pharmacology And Toxicology, Zurich, Switzerland, [2]University of Zurich, Department Of Biochemistry, Zurich, Switzerland

Progress in neurobiology is often limited by the availability, tractability, and specificity of molecular tools. This especially concerns the use of antibodies to label synaptic marker proteins which define the number, size, and dynamics of synapses as a proxy for function. Gephyrin is the major post-synaptic scaffold at GABAergic and glycinergic synapses in the nervous system where it interacts with other synaptic organizing proteins and receptors to facilitate inhibitory neurotransmission. Gephyrin itself is modified by post-translational modifications including phosphorylation to control its synaptic function. Despite the importance of using gephyrin as a canonical inhibitory post-synaptic marker, there are currently no widely available tools that can probe gephyrin specifically across applications and independently of its modified state. We therefore employed a synthetic library screening approach to identify Designed Ankyrin Repeat Proteins (DARPins) which specifically interact with gephyrin. From this screen we discovered several DARPin clones which bind to gephyrin, and then characterised their morphological use to examine compartment-specific phosphorylation of gephyrin in neurons. We additionally used these anti-gephyrin DARPins as biochemical tools to determine the most comprehensive gephyrin protein interactome to date, revealing putative novel functions of gephyrin beyond synapses. These anti-gephyrin DARPins offer a new resource to the study of both gephyrin biology and inhibitory synapses in general.

Surfaceome dynamics reveal proteostasis-independent reorganization of neuronal surface proteins during development and synaptic plasticity.
Neurons are highly compartmentalized cells with tightly controlled subcellular protein organization. While brain transcriptome, connectome and global proteome maps are being generated, system-wide analysis of temporal protein dynamics at the subcellular level are currently lacking. Here, we perform a temporally-resolved surfaceome analysis of primary neuron cultures and reveal dynamic surface protein clusters that reflect the functional requirements during distinct stages of neuronal development. Direct comparison of surface and total protein pools during development and homeostatic synaptic scaling demonstrates system-wide proteostasis-independent remodeling of the neuronal surface, illustrating widespread regulation on the level of surface trafficking. Finally, quantitative analysis of the neuronal surface during chemical long-term potentiation (cLTP) reveals fast externalization of diverse classes of surface proteins beyond the AMPA receptor, providing avenues to investigate the requirement of exocytosis for LTP. Our resource (neurosurfaceome.ethz.ch) highlights the importance of subcellular resolution for systems-level understanding of cellular processes.

Spontaneous action potentials in retinal horizontal cells of goldfish () are dependent upon L-type Ca channels and ryanodine receptors.
Horizontal cells (HCs) are interneurons of the outer retina that undergo graded changes in membrane potential during the light response and provide feedback to photoreceptors. We characterized spontaneous Ca-based action potentials (APs) in isolated goldfish () HCs with electrophysiological and intracellular imaging techniques. Transient changes in intracellular Ca concentration ([Ca]) were observed with fura-2 and were abolished by removal of extracellular Ca or by inhibition of Ca channels by 50 µM Cd or 100 µM nifedipine. Inhibition of Ca release from stores with 20 µM ryanodine or 50 µM dantrolene abolished Ca transients and increased baseline [Ca]. This increased baseline was prevented by blocking L-type Ca channels with nifedipine, suggesting that Ca-induced Ca release from stores may be needed to inactivate membrane Ca channels. Caffeine (3 mM) increased the frequency of Ca transients, and the store-operated channel antagonist 2-aminoethyldiphenylborinate (100 µM) counteracted this effect. APs were detected with voltage-sensitive dye imaging

(FluoVolt) and current-clamp electrophysiology. In current-clamp recordings, regenerative APs were abolished by removal of extracellular Ca or in the presence of 5 mM Co or 100 µM nifedipine, and APs were amplified with 15 mM Ba. Collectively, our data suggest that during APs Ca enters through L-type Ca channels and that Ca stores (gated by ryanodine receptors) contribute to the rise in [Ca]. This work may lead to further understanding of the possible role APs have in vision, such as transitioning from light to darkness or modulating feedback from HCs to photoreceptors. Horizontal cells (HCs) are interneurons of the outer retina that provide inhibitory feedback onto photoreceptors. HCs respond to light via graded changes in membrane potential. We characterized spontaneous action potentials in HCs from goldfish and linked action potential generation to a rise in intracellular Ca via plasma membrane channels and ryanodine receptors. Action potentials may play a role in vision, such as transitioning from light to darkness, or in modulating feedback from HCs to photoreceptors.

Cellular Mechanisms Contributing to the Functional Heterogeneity of GABAergic Synapses.

GABAergic inhibitory neurotransmission contributes to diverse aspects of brain development and adult plasticity, including the expression of complex cognitive processes. This is afforded for in part by the dynamic adaptations occurring at inhibitory synapses, which show great heterogeneity both in terms of upstream signaling and downstream effector mechanisms. Single-particle tracking and live imaging have revealed that complex receptor-scaffold interactions critically determine adaptations at GABAergic synapses. Super-resolution imaging studies have shown that protein interactions at synaptic sites contribute to nano-scale scaffold re-arrangements through post-translational modifications (PTMs), facilitating receptor and scaffold recruitment to synaptic sites. Additionally, plasticity mechanisms may be affected by the protein composition at individual synapses and the type of pre-synaptic input. This mini-review article examines recent discoveries of plasticity mechanisms that are operational within GABAergic synapses and discusses their contribution towards functional heterogeneity in inhibitory neurotransmission.

The catalytic function of the gephyrin-binding protein IQSEC3 regulates neurotransmitter-specific matching of pre- and post-synaptic structures in primary hippocampal cultures.

In dissociated neuronal cultures the absence of spatial and temporal cues causes the emergence of mismatched synapses, where post-synaptic proteins of GABAergic synapses are in part apposed to glutamatergic pre-synaptic terminals and vice versa. This mismatch offers an opportunity to study the mechanisms that regulate correct apposition of pre- and post-synaptic elements. We report here that the IQ motif and Sec7 domain-containing protein 3 (IQSEC3; BRAG3; synArfGEF) specifically regulates the mislocalization of GABAergic post-synaptic density (PSD) proteins. Over-expression of IQSEC3 constructs harboring mutations that ablate Sec7 domain or IQ motif function revealed that IQSEC3 catalytic activity is involved in the control of apposition between the GABAergic PSD and glutamatergic terminals. Neurons co-expressing eGFP-gephyrin with IQSEC3 Sec7 mutant displayed a drastically increased fraction of mismatched eGFP-gephyrin clusters compared to other IQSEC3 constructs. Along with eGFP-gephyrin, endogenous GABA receptor cluster mismatching was increased by IQSEC3 Sec7 mutant over-expression. Conversely, GFP-PSD-95 clusters were unaffected by over-expression of any IQSEC3 construct. The GABAergic PSD mismatch phenotype was recapitulated by Arf6 dominant-negative mutant over-expression, suggesting that Arf6 activation by IQSEC3 is an essential step in this pathway. In addition, we provide biochemical evidence to confirm gephyrin/IQSEC3 interaction near the IQSEC3 IQ motif, which in turn binds calmodulin at low Ca concentrations. Taken together, our findings identify a post-synaptic protein which specifically regulates correct apposition of the GABAergic PSD to pre-synaptic terminals.

BENZODIAZEPINE DIAZEPAM INDUCES DENDRITIC SPINE LOSS VIA 18 KDA TRANSLOCATOR PROTEIN

POSTER SESSION 02 - SECTION: GABAERGIC TRANSMISSION AND SYNAPTIC FUNCTION

Mochen Cui[1,2,3], Yuan Shi[1,2,4], Jochen Herms[1,2,4]
[1]Ludwig Maximilian University of Munich, Center For Neuropathology, Munich, Germany, [2]German Center for Neurodegenerative Diseases (DZNE), Translational Brain Research, Munich, Germany, [3]Munich Medical Research School, Ludwig Maximilian University Of Munich, Munich, Germany, [4]Munich Cluster for Systems Neurology (SyNergy), Munich, Germany

Benzodiazepines are widely prescribed drugs to treat insomnia and anxiety. However, they have been long suspected of causing cognitive impairment and increasing the risk for dementia. Here we report that diazepam, a commonly used benzodiazepine, impairs the structural plasticity of dendritic spines and leads to cognitive impairment in mice. After daily administration of diazepam for one week (5mg/kg) or eight weeks (1mg/kg), we observed significant, yet reversible, reductions of cortical dendritic spines in mice, accompanied with behavioural alterations. Given that diazepam exerts sedative and anxiolytic effects primarily via $GABA_A$ receptors ($GABA_AR$), we blocked the binding of diazepam to $GABA_AR$ by employing *Gabra RRRR* transgenic mice, which lack the histidine residue necessary for diazepam binding. However, blocking of diazepam's binding to $GABA_AR$ failed to prevent diazepam-induced dendritic spine reduction or behavioural changes. We then extend our exploration to another binding site of diazepam in the central nervous system, the 18kDa translocator protein (TSPO), which is highly expressed in microglia – the brain resident macrophage. Interestingly, in the TSPO knockout mice, diazepam administration did not induce changes in dendritic spines and behaviours. Using *in vivo* imaging and super-resolution microscopy, we discovered that via TSPO, diazepam administration alters microglia functionally and morphologically. In diazepam-fed mice, we observed that microglia contacted dendritic spines more frequently, we also observed microglia became hypertrophic and engulfed more synaptic materials. Collectively, we discovered a benzodiazepine diazepam-induced microglial TSPO-mediated dendritic spine regulation, independent of the $GABA_AR$-mediated signalling pathway.

COOPERATIVE EFFECT OF GABA AND CA2+ FOR THE DIFFUSION AND TRAPPING OF GABAARS AT SYNAPSES: REGULATION OF RECEPTOR NUMBER

POSTER SESSION 02 - SECTION: GABAERGIC TRANSMISSION AND SYNAPTIC FUNCTION

Fumihiro Niwa, Antoine Triller
École normale supérieure, CNRS, INSERM, Université PSL, Institut De Biologie De L'École Normale Supérieure (ibens), Paris, France

$GABA_AR$s diffuse on the surface of neurons and are trapped by scaffold proteins at synapses. Receptor number at synapses determines the efficiency of neurotransmission. Thus, mechanisms regulating $GABA_AR$ diffusion and synaptic trapping are crucial for the tuning of GABAergic transmission. Bindings of agonists to $GABA_AR$ and its post-translational modification modify its trapping at synapses. Hence, precise regulation of pre-and post-synapse is involved in the regulation of $GABA_AR$ clustering. However, the cooperation of pre-and post-synaptic activity for the regulation of the diffusion-trapping of $GABA_AR$ is poorly understood due to technical difficulty for the simultaneous single-molecule imaging combined with uncaging and optogenetic stimulation. Actually, the UV photoconversion of dye/fluorescent protein could release the caged compound, we used a spontaneously blinking fluorophore (HMSiR) instead for the single-molecule-localization-microscopy (SMLM) to track $GABA_AR$s. Overexpression of tagged receptors is another issue because it biases the ratio of the number of synaptic-scaffolds vs receptors. This is why we raised a knock-in mouse whose $GABA_AR$g2-subunit contains a spot-tag recognized by a dye-coupled nanobody. We found in mature synapses from cultured (> 21 div) dissociated neurons that repetitive GABA uncaging combined with Ca^{2+} elevation induced a rapid and persistent reduction of $GABA_AR$g2-subunit-containing receptors from the stimulated synapse. Either sole Ca^{2+}-elevation or GABA-uncaging alone couldn't induce this phenomenon. Thus, both the binding of GABA which induce dissociation of $GABA_AR$s from scaffolds combined with neuronal activity, and Ca^{2+} elevation prevents re-accumulation of receptors to synaptic sites could be indispensable for the long-lasting loss of $GABA_AR$s from synapses and a subsequent dis-inhibition.

SINGLE MOLECULE CHARACTERISATION OF α3-CONTAINING GABAARS REVEALS A UNIQUE ROLE AT INHIBITORY SYNAPSES

POSTER SESSION 02 - SECTION: GABAERGIC TRANSMISSION AND SYNAPTIC FUNCTION

Parnayan Syed[1], Robert Harvey[2], Pankaj Sah[1], Joseph Lynch[1], Nela Durisic[1]
[1]Queensland Brain Institute, -, St Lucia, Australia, [2]University of Sunshine Coast, Biomedical Science, Sippy Downs, Australia

Aims: GABA-A receptors (GABAARs) are the main inhibitory receptors in the brain. They are pentameric oligomers comprised of combinations of 19 subunits. Of these, little is known about the α3 subunit despite significant expression in the brain. Mutations in α3 have been linked to epilepsy, anxiety and intellectual disabilities. We characterised synaptic properties of α3-containing GABAARs (α3-GABAARs) in comparison to α1-GABAARs (the most well-studied GABAARs), to understand the role of α3 in synaptic transmission. **Methods:** We recorded synaptic currents mediated by specific α3-GABAAR isoforms in heterosynapses of transfected HEK293 cells and neuronal presynaptic terminals, and used super-resolution microscopy to track receptor molecules in neurons. We characterised the shape and size of synaptic clusters, rate of receptor trapping at synapses, diffusion probability and diffusion state transitions at synapses. Distinct mobility patterns were identified using moment scaling spectrum analysis. **Results:** We found that α3-GABAARs cluster at synapses, and diffuse 10-fold faster than α1-GABAARs. Synaptic currents mediated by α3-GABAARs have longer decay times and altered frequency compared to α1. Per length of neuronal processes, α3-GABAARs are more abundant at synapses, but dwell for significantly shorter times. **Conclusions:** Synaptic α3-GABAARs mediate phasic neurotransmission. The slow decay times, fast diffusion and shorter dwell times indicate that unlike the stably-anchored α1-GABAARs, α3-GABAARs might be more mobile at synapses in response to neuronal activity, maintaining the excitatory/inhibitory balance at a synapse level. These results show the first functional characterisation of α3-GABAARs, their integration into synapses and provide unique insights into their specialised role in inhibitory synaptic plasticity.

THE GLUTAMATERGIC SYNAPSE: A CHAT ROOM FOR AMYLOID-BETA PEPTIDE AND THE NUCLEUS

POSTER SESSION 02 - SECTION: NEW PERSPECTIVES IN NEURODEGENERATION

Laura D'Andrea, Stefano Musardo, Nicolò Carrano, Silvia Pelucchi, Ramona Stringhi, Ana Ribeiro, Matteo Audano, Nico Mitro, Fabrizio Gardoni, Monica Di Luca, Elena Marcello
Università degli studi di Milano, Department Of Pharmacological An Biomolecular Sciences, Milano, Italy

Introduction: Synaptonuclear messengers translate specific synaptic signaling into gene expression, modulating synaptic dynamics. Alterations of such proteins lead to dendritic spine failure, indicating a contribution to synaptopathies. The synaptonuclear messenger RING Finger Protein 10 (RNF10) operates as a mobile hub that docks NMDAR-derived signalosomes to nuclear target sites, regulating genes involved in spine morphology and Alzheimer's disease (AD) pathogenesis, suggesting an implication in AD-synaptic dysfunction. *Methods:* RNF10 expression and subcellular localization, were investigated by biochemical and imaging approaches in AD patients autoptic specimens and primary hippocampal neurons exposed to Amyloid β (Aβ) oligomers. RNA-Seq analysis elucidated the impact of Aβ-triggered RNF10 trafficking on gene expression. Mitochondrial morphology and activity were examined by imaging techniques and oxygen consumption measurements. *Results:* RNF10 expression and localization are altered in AD patients' hippocampi at the earlier stages of the disease. Furthermore, Aβ oligomers trigger a calcium-dependent NMDAR-induced RNF10 nuclear translocation, in hippocampal neurons. RNA-Seq analysis in hippocampal neurons silenced for RNF10 and exposed to Aβ oligomers showed that Aβ-mediated RNF10 signaling pathway triggers mitochondrial dysfunctions in neurons. Importantly, the down-regulation of RNF10 prevents the Aβ-triggered mitochondrial defects. *Conclusions:* Several mitochondrial functions have been found severely compromised in AD models linked to Aβ, nevertheless the molecular mechanisms underlying such changes are still unclear. Here we show that RNF10 can play a key role in translating Aβ synaptotoxicity into mitochondrial dysfunction. Overall, our findings suggest that the RNF10-mediated signaling contributes to AD and provides new potential pharmacological tools and novel biomarkers of synaptic dysfunction in AD.

Looking at Alzheimer's Disease Pathogenesis from the Nuclear Side.
Alzheimer's disease (AD) is a neurodegenerative disorder representing the most common form of dementia. It is biologically characterized by the deposition of extracellular amyloid-β (Aβ) senile plaques and intracellular neurofibrillary tangles, constituted by hyperphosphorylated tau protein. The key protein in AD pathogenesis is the amyloid precursor protein (APP), which is cleaved by secretases to produce several metabolites, including Aβ and APP intracellular domain (AICD). The greatest genetic risk factor associated with AD is represented by the () allele. Importantly, all of the above-mentioned molecules that are strictly related to AD pathogenesis have also been described as playing roles in the cell nucleus. Accordingly, evidence suggests that nuclear functions are compromised in AD. Furthermore, modulation of transcription maintains cellular homeostasis, and alterations in transcriptomic profiles have been found in neurodegenerative diseases. This report reviews recent advancements in the AD players-mediated gene expression. Aβ, tau, AICD, and localize in the nucleus and regulate the transcription of several genes, part of which is involved in AD pathogenesis, thus suggesting that targeting nuclear functions might provide new therapeutic tools for the disease.

Fragile X mental retardation protein in intrahepatic cholangiocarcinoma: regulating the cancer cell behavior plasticity at the leading edge.
Intrahepatic cholangiocarcinoma (iCCA) is a rare malignancy of the intrahepatic biliary tract with a very poor prognosis. Although some clinicopathological parameters can be prognostic factors for iCCA, the molecular prognostic markers and potential mechanisms of iCCA have not been well investigated. Here, we report that the Fragile X mental retardation protein (FMRP), a RNA binding protein functionally absent in patients with the Fragile X syndrome (FXS) and also involved in several types of cancers, is overexpressed in human iCCA and its expression is significantly increased in iCCA metastatic tissues.

The silencing of FMRP in metastatic iCCA cell lines affects cell migration and invasion, suggesting a role of FMRP in iCCA progression. Moreover, we show evidence that FMRP is localized at the invasive front of human iCCA neoplastic nests and in pseudopodia and invadopodia protrusions of migrating and invading iCCA cancer cells. Here FMRP binds several mRNAs encoding key proteins involved in the formation and/or function of these protrusions. In particular, we find that FMRP binds to and regulates the expression of Cortactin, a critical regulator of invadopodia formation. Altogether, our findings suggest that FMRP could promote cell invasiveness modulating membrane plasticity and invadopodia formation at the leading edges of invading iCCA cells.

Altered mitochondrial function in cells carrying a premutation or unmethylated full mutation of the FMR1 gene.
Fragile X-related disorders are due to a dynamic mutation of the CGG repeat at the 5' UTR of the FMR1 gene, coding for the RNA-binding protein FMRP. As the CGG sequence expands from premutation (PM, 56-200 CGGs) to full mutation (> 200 CGGs), FMRP synthesis decreases until it is practically abolished in fragile X syndrome (FXS) patients, mainly due to FMR1 methylation. Cells from rare individuals with no intellectual disability and carriers of an unmethylated full mutation (UFM) produce slightly elevated levels of FMR1-mRNA and relatively low levels of FMRP, like in PM carriers. With the aim of clarifying how UFM cells differ from CTRL and FXS cells, a comparative proteomic approach was undertaken, from which emerged an overexpression of SOD2 in UFM cells, also confirmed in PM but not in FXS. The SOD2-mRNA bound to FMRP in UFM more than in the other cell types. The high SOD2 levels in UFM and PM cells correlated with lower levels of superoxide and reactive oxygen species (ROS), and with morphological anomalies and depolarization of the mitochondrial membrane detected through confocal microscopy. The same effect was observed in CTRL and FXS after treatment with MC2791, causing SOD2 overexpression. These mitochondrial phenotypes reverted after knock-down with siRNA against SOD2-mRNA and FMR1-mRNA in UFM and PM. Overall, these data suggest that in PM and UFM carriers, which have high levels of FMR1 transcription and may develop FXTAS, SOD2 overexpression helps to maintain low levels of both superoxide and ROS with signs of mitochondrial degradation.

Protein synthesis levels are increased in a subset of individuals with fragile X syndrome.
Fragile X syndrome (FXS) is a monogenic form of intellectual disability and autism spectrum disorder caused by the absence of the fragile X mental retardation protein (FMRP). In biological models for the disease, this leads to upregulated mRNA translation and as a consequence, deficits in synaptic architecture and plasticity. Preclinical studies revealed that pharmacological interventions restore those deficits, which are thought to mediate the FXS cognitive and behavioral symptoms. Here, we characterized the de novo rate of protein synthesis in patients with FXS and their relationship with clinical severity. We measured the rate of protein synthesis in fibroblasts derived from 32 individuals with FXS and from 17 controls as well as in fibroblasts and primary neurons of 27 Fmr1 KO mice and 20 controls. Here, we show that levels of protein synthesis are increased in fibroblasts of individuals with FXS and Fmr1 KO mice. However, this cellular phenotype displays a broad distribution and a proportion of fragile X individuals and Fmr1 KO mice do not show increased levels of protein synthesis, having measures in the normal range. Because the same Fmr1 KO animal measures in fibroblasts predict those in neurons we suggest the validity of this peripheral biomarker. Our study offers a potential explanation for the comprehensive drug development program undertaken thus far yielding negative results and suggests that a significant proportion, but not all individuals with FXS, may benefit from the reduction of excessive levels of protein synthesis.

Reducing eIF4E-eIF4G interactions restores the balance between protein synthesis and actin dynamics in fragile X syndrome model mice.
Fragile X syndrome (FXS) is the most common form of inherited intellectual disability and autism spectrum disorder. FXS is caused by silencing of the gene, which encodes fragile X mental retardation protein (FMRP), an mRNA-binding protein that represses the translation of its target mRNAs. One mechanism by which FMRP represses translation is through its association with cytoplasmic FMRP-interacting protein 1 (CYFIP1), which subsequently sequesters and inhibits eukaryotic initiation factor 4E (eIF4E). CYFIP1 shuttles between the FMRP-eIF4E complex and the Rac1-Wave regulatory complex, thereby connecting translational regulation to actin dynamics and dendritic spine morphology, which are dysregulated in FXS model mice that lack FMRP. Treating FXS mice with 4EGI-1, which blocks interactions between eIF4E and eIF4G, a critical interaction partner for translational initiation, reversed defects in hippocampus-dependent memory and spine morphology. We also found that 4EGI-1 normalized the phenotypes of enhanced metabotropic glutamate receptor (mGluR)-mediated long-

term depression (LTD), enhanced Rac1-p21-activated kinase (PAK)-cofilin signaling, altered actin dynamics, and dysregulated CYFIP1/eIF4E and CYFIP1/Rac1 interactions in FXS mice. Our findings are consistent with the idea that an imbalance in protein synthesis and actin dynamics contributes to pathophysiology in FXS mice, and suggest that targeting eIF4E may be a strategy for treating FXS.

Impaired GABAergic inhibition in the hippocampus of Fmr1 knockout mice.
Many clinical and molecular features of the fragile X syndrome, a common form of intellectual disability and autism, can be modeled by deletion of the Fmr1 protein (Fmrp) in mice. Previous studies showed a decreased expression of several components of the GABAergic system in Fmr1 knockout mice. Here, we used this mouse model to investigate the functional consequences of Fmrp deletion on hippocampal GABAergic inhibition in the CA1-region of the hippocampus. Whole-cell patch-clamp recordings demonstrated a significantly reduced amplitude of evoked inhibitory postsynaptic currents (eIPSCs) and a decrease in the amplitude and frequency of spontaneous IPSCs. In addition, miniature IPSCs were reduced in amplitude and frequency and decayed significantly slower than mIPSCs in controls. Quantitative real-time PCR revealed a significantly lower expression of α2, β1 and δ GABA receptor subunits in the hippocampus of the juvenile mice (P22) compared to wild-type littermates. Correspondingly, we found also at the protein level reduced amounts of α2, β1 and δ subunits in Fmr1 knockout mice. Overall, these results demonstrate that the reduction in several components of the GABAergic system is already present at young age and that this reduction results in measurable abnormalities on GABA receptor-mediated phasic inhibition. These abnormalities might contribute to the behavioral and cognitive deficits of this fragile X mouse model.

Dysregulated ADAM10-Mediated Processing of APP during a Critical Time Window Leads to Synaptic Deficits in Fragile X Syndrome.
The Fragile X mental retardation protein (FMRP) regulates neuronal RNA metabolism, and its absence or mutations leads to the Fragile X syndrome (FXS). The β-amyloid precursor protein (APP) is involved in Alzheimer's disease, plays a role in synapse formation, and is upregulated in intellectual disabilities. Here, we show that during mouse synaptogenesis and in human FXS fibroblasts, a dual dysregulation of APP and the α-secretase ADAM10 leads to the production of an excess of soluble APPα (sAPPα). In FXS, sAPPα signals through the metabotropic receptor that, activating the MAP kinase pathway, leads to synaptic and behavioral deficits. Modulation of ADAM10 activity in FXS reduces sAPPα levels, restoring translational control, synaptic morphology, and behavioral plasticity. Thus, proper control of ADAM10-mediated APP processing during a specific developmental postnatal stage is crucial for healthy spine formation and function(s). Downregulation of ADAM10 activity at synapses may be an effective strategy for ameliorating FXS phenotypes.

Two-stage translational control of dentate gyrus LTP consolidation is mediated by sustained BDNF-TrkB signaling to MNK.
BDNF signaling contributes to protein-synthesis-dependent synaptic plasticity, but the dynamics of TrkB signaling and mechanisms of translation have not been defined. Here, we show that long-term potentiation (LTP) consolidation in the dentate gyrus of live rodents requires sustained (hours) BDNF-TrkB signaling. Surprisingly, this sustained activation maintains an otherwise labile signaling pathway from TrkB to MAP-kinase-interacting kinase (MNK). MNK activity promotes eIF4F translation initiation complex formation and protein synthesis in mechanistically distinct early and late stages. In early-stage translation, MNK triggers release of the CYFIP1/FMRP repressor complex from the 5'-mRNA cap. In late-stage translation, MNK regulates the canonical translational repressor 4E-BP2 in a synapse-compartment-specific manner. This late stage is coupled to MNK-dependent enhanced dendritic mRNA translation. We conclude that LTP consolidation in the dentate gyrus is mediated by sustained BDNF signaling to MNK and MNK-dependent regulation of translation in two functionally and mechanistically distinct stages.

Autism Spectrum Disorders: Translating human deficits into mouse behavior.
Autism Spectrum Disorders are a heterogeneous group of neurodevelopmental disorders, with rising incidence but little effective therapeutic intervention available. Currently two main clinical features are described to diagnose ASDs: impaired social interaction and communication, and repetitive behaviors. Much work has focused on understanding underlying causes of ASD by generating animal models of the disease, in the hope of discovering signaling pathways and cellular targets for drug intervention. Here we review how ASD behavioral phenotypes can be modeled in the mouse, the most common animal

model currently in use in this field, and discuss examples of genetic mouse models of ASD with behavioral features that recapitulate various symptoms of ASD.

Aims. Transposable elements (TEs) are emerging as novel unsuspected culprits in neurodegenerative diseases. The effects of a derepression of young, coding TEs from the LINE-1 family are not well known but include genomic instability and inflammation. We are studying the mechanisms through which LINE-1 RNA and proteins are linked to age-related neurodegenerative diseases like Parkinson's and Alzheimer's disease. **Methods**. We are using a human dopaminergic neuron cell line (LUHMES) as a model in which we induce oxidative stress or an aging-like condition by arsenite treatment (NaAsO2) or multiple passaging, respectively. Levels of LINE-1 RNA and proteins (ORF1p/ORF2p) were analyzed by immunofluorescence (IF), Western blot and RT-qPCR. Nuclear envelope (NE) integrity (LaminB1/RAN/KPNB/Nup153), heterochromatin (H3K9me3, H4K20me3, HP1) and DNA damage (yH2aX) were analyzed by IF. Direct interaction of ORF1p with NE proteins was analyzed by proximal ligation assay (PLA) and IF colocalization. **Results and Conclusion**. LINE-1 expression in neurons increased upon oxidative stress or multiple passaging. Upon stress, ORF1p translocated to the nucleus and co-localized with NE proteins (LaminB1/RAN). This was accompanied by NE distortion as revealed by LaminB1 staining. NE proteins (e.g. LaminB1, RAN, PIN1, KPNB, Nup153) were also identified as ORF1p partners (mass spectroscopy/co-immunoprecipitation). Direct interaction of ORF1p with LaminB1 and Nup153 was confirmed by PLA. ORF1p could thus potentially sequester NE proteins, compromising NE integrity and function, altering nucleocytoplasmic transport and induce genomic instability (DNA damage and cytosolic leakage) and inflammation events. NE distortion also resulted in heterochromatin disorganisation, with potential consequences on gene expression.

Modeling late-onset disorders using induced pluripotent stem cells (iPSCs) technology holds a challenge due to iPSCs cellular rejuvenation during reprogramming. Hallmarks of aging are often difficult to distinguish from disease-related degenerative processes but are usually associated with a gradual deterioration in structure and function. Extreme perturbations of cellular ageing occur in the context of genetic progeria syndromes, especially in Hutchison-Gilford Progeria Syndrome (HGPS). These provide unique opportunities to investigate the ageing program. Our aim is to generate a cellular model system of human ageing based on progerin overexpression. To that end, we have harnessed our inducible reprogramming system, OptiOX, and engineered human iPSCs to overexpress progerin in parallel with neurogenin 2 (NGN2). This enables direct conversion of iPSCs into cortical glutamatergic neurons by overexpressing NGN2, while ageing the cells by overexpressing progerin. Aged induced neurons (iNs) show phenotypic changes in neuronal process outgrowth, connectivity, and in morphology. Selected hallmarks of physiological ageing were observed, among these downregulation of peripheral heterochromatin markers and increased double strand DNA breaks. In addition, the epigenetic clock of the aged iNs was studied. These findings confirm our base hypothesis that our system enables independent control of progerin expression and cellular reprogramming. The resulting neurons remain viable and demonstrate select hallmarks of ageing, which provides a cellular model for both physiological and chronological

ageing.

Comparing Transcriptome Profiles of Neurons Interfacing Adjacent Cells and Nanopatterned Substrates Reveals Fundamental Neuronal Interactions.
Developing neuronal axons are directed by chemical and physical signals toward a myriad of target cells. According to current dogma, the resulting network architecture is critically shaped by electrical interconnections, the synapses; however, key mechanisms translating neuronal interactions into neuronal growth behavior during network formation are still unresolved. To elucidate these mechanisms, we examined neurons interfacing nanopatterned substrates and compared them to natural interneuron interactions. We grew similar neuronal populations under three connectivity conditions, (1) the neurons are isolated, (2) the neurons are interconnected, and (3) the neurons are connected only to artificial substrates, then quantitatively compared both the cell morphologies and the transcriptome-expression profiles. Our analysis shows that whereas axon-guidance signaling pathways in isolated neurons are predominant, in isolated neurons interfacing nanotopography, these pathways are downregulated, similar to the interconnected neurons. Moreover, in nanotopography, interfacing neuron genes related to synaptogenesis and synaptic regulation are highly expressed, that is, again resembling the behavior of interconnected neurons. These molecular findings demonstrate that interactions with nanotopographies, although not leading to electrical coupling, play a comparable functional role in two major routes, neuronal guidance and network formation, with high relevance to the design of regenerative interfaces.

Interactions of Neurons with Physical Environments.
Nerve growth strongly relies on multiple chemical and physical signals throughout development and regeneration. Currently, a cure for injured neuronal tissue is an unmet need. Recent advances in fabrication technologies and materials led to the development of synthetic interfaces for neurons. Such engineered platforms that come in 2D and 3D forms can mimic the native extracellular environment and create a deeper understanding of neuronal growth mechanisms, and ultimately advance the development of potential therapies for neuronal regeneration. This progress report aims to present a comprehensive discussion of this field, focusing on physical feature design and fabrication with additional information about considerations of chemical modifications. We review studies of platforms generated with a range of topographies, from micro-scale features

down to topographical elements at the nanoscale that demonstrate effective interactions with neuronal cells. Fabrication methods are discussed as well as their biological outcomes. This report highlights the interplay between neuronal systems and the important roles played by topography on neuronal differentiation, outgrowth, and development. The influence of substrate structures on different neuronal cells and parameters including cell fate, outgrowth, intracellular remodeling, gene expression and activity is discussed. Matching these effects to specific needs may lead to the emergence of clinical solutions for patients suffering from neuronal injuries or brain-machine interface (BMI) applications.

Iron oxide nanoparticles for neuronal cell applications: uptake study and magnetic manipulations.
The ability to direct and manipulate neuronal cells has important potential in therapeutics and neural network studies. An emerging approach for remotely guiding cells is by incorporating magnetic nanoparticles (MNPs) into cells and transferring the cells into magnetic sensitive units. Recent developments offer exciting possibilities of magnetic manipulations of MNPs-loaded cells by external magnetic fields. In the present study, we evaluated and characterized uptake properties for optimal loading of cells by MNPs. We examined the interactions between MNPs of different cores and coatings, with primary neurons and neuron-like cells.

Gold Nanoparticle-Decorated Scaffolds Promote Neuronal Differentiation and Maturation.
Engineered 3D neuronal networks are considered a promising approach for repairing the damaged spinal cord. However, the lack of a technological platform encouraging axonal elongation over branching may jeopardize the success of such treatment. To address this issue we have decorated gold nanoparticles on the surface of electrospun nanofiber scaffolds, characterized the composite material, and investigated their effect on the differentiation, maturation, and morphogenesis of primary neurons and on an immature neuronal cell line. We have shown that the nanocomposite scaffolds have encouraged a longer outgrowth of the neurites, as judged by the total length of the branching trees and the length and total distance of neurites. Moreover, neurons grown on the nanocomposite scaffolds had less neurites originating out of the soma and lower number of branches. Taken together, these results indicate that neurons cultivated on the gold nanoparticle scaffolds prefer axonal elongation over forming complex branching trees. We envision that such cellular constructs may be useful in the future as implantable cellular devices for repairing damaged neuronal tissues, such as the spinal cord.

In-vitro Optimization of Nanoparticle-Cell Labeling Protocols for In-vivo Cell Tracking Applications.
Recent advances in theranostic nanomedicine can promote stem cell and immune cell-based therapy. Gold nanoparticles (GNPs) have been shown to be promising agents for in-vivo cell-tracking in cell-based therapy applications. Yet a crucial challenge is to develop a reliable protocol for cell upload with, on the one hand, sufficient nanoparticles to achieve maximum visibility of cells, while on the other hand, assuring minimal effect of particles on cell function and viability. Previous studies have demonstrated that the physicochemical parameters of GNPs have a critical impact on their efficient uptake by cells. In the current study we have examined possible variations in GNP uptake, resulting from different incubation period and concentrations in different cell-lines. We have found that GNPs effectively labeled three different cell-lines - stem, immune and cancer cells, with minimal impairment to cell viability and functionality. We further found that uptake efficiency of GNPs into cells stabilized after a short period of time, while GNP concentration had a significant impact on cellular uptake, revealing cell-dependent differences. Our results suggest that while heeding the slight variations within cell lines, modifying the loading time and concentration of GNPs, can promote cell visibility in various nanoparticle-dependent in-vivo cell tracking and imaging applications.

The effect of nanoparticle size on the probability to cross the blood-brain barrier: an in-vitro endothelial cell model.
During the last decade nanoparticles have gained attention as promising drug delivery agents that can transport through the blood brain barrier. Recently, several studies have demonstrated that specifically targeted nanoparticles which carry a large payload of therapeutic agents can effectively enhance therapeutic agent delivery to the brain. However, it is difficult to draw definite design principles across these studies, owing to the differences in material, size, shape and targeting agents of the nanoparticles. Therefore, the main objective of this study is to develop general design principles that link the size of the nanoparticle with the probability to cross the blood brain barrier. Specifically, we investigate the effect of the nanoparticle size on the probability of barbiturate coated GNPs to cross the blood brain barrier by using bEnd.3 brain endothelial cells as an in vitro blood brain barrier model.

Neuronal growth on L- and D-cysteine self-assembled monolayers reveals neuronal chiral sensitivity.
Studying the interaction between neuronal cells and chiral molecules is fundamental for the design of novel biomaterials and drugs. Chirality influences all biological processes that involve intermolecular interaction. One common method used to study cellular interactions with different enantiomeric targets is the use of chiral surfaces. Based on previous studies that demonstrated the importance of cysteine in the nervous system, we studied the effect of L- and D-cysteine on single neuronal growth. L-Cysteine, which normally functions as a neuromodulator or a neuroprotective antioxidant, causes damage at elevated levels, which may occur post trauma. In this study, we grew adult neurons in culture enriched with L- and D-cysteine as free compounds or as self-assembled monolayers of chiral surfaces and examined the effect on the neuronal morphology and adhesion. Notably, we have found that exposure to the L-cysteine enantiomer inhibited, and even prevented, neuronal attachment more severely than exposure to the D-cysteine enantiomer. Atop the L-cysteine surfaces, neuronal growth was reduced and degenerated. Since the cysteine molecules were attached to the surface via the thiol groups, the neuronal membrane was exposed to the molecular chiral site. Thus, our results have demonstrated high neuronal chiral sensitivity, revealing chiral surfaces as indirect regulators of neuronal cells and providing a reference for studying chiral drugs.

Interactions of neurons with topographic nano cues affect branching morphology mimicking neuron-neuron interactions.
We study the effect of topographic nano-cues on neuronal growth-morphology using invertebrate neurons in culture. We use photolithography to fabricate substrates with repeatable line-pattern ridges of nano-scale heights of 10-150 nm. We plate leech neurons atop the patterned-substrates and compare their growth pattern to neurons plated atop non-patterned substrates. The model system allows us the analysis of single neurite-single ridge interactions. The use of high resolution electron microscopy reveals small filopodia processes that attach to the line-pattern ridges. These fine processes, that cannot be detected in light microscopy, add anchoring sites onto the side of the ridges, thus additional physical support. These interactions of the neuronal process dominantly affect the neuronal growth direction. We analyze the response of the entire neuronal branching tree to the patterned substrates and find significant effect on the growth patterns compared to non-patterned substrates. Moreover, interactions with the nano-cues trigger a growth strategy similarly to interactions with other neuronal cells, as reflected in their morphometric parameters. The number of branches and the number of neurites originating from the soma decrease following the interaction demonstrating a tendency to a more simplified neuronal branching tree. The effect of the nano-cues on the neuronal function deserves further investigation and will strengthen our understanding of the interplay between function and form.

Topographic cues of nano-scale height direct neuronal growth pattern.
We study the role of nano-scale cues in controlling neuronal growth. We use photolithography to fabricate substrates with repeatable line-pattern ridges of nano-scale heights. We find that neuronal processes, which are of micron size, have strong interactions with ridges even as low as 10 nm. The interaction between the neuronal process and the ridge leads to a deflection of growth direction and a preferred alignment with the ridges. The interaction strength clearly depends on the ridges' height. For 25 nm ridges approximately half of the neuronal processes are modified, while at 100 nm the majority of neurites change their original growth direction post interaction. In addition, the effect on growth correlates with the incoming angle between the neuronal process and the ridge. We underline the adhesion as a key mechanism in directing neuronal growth. Our study highlights the sensitivity of growing neurites to nano-scale cues thus opens a new avenue of research for pre-designed neuronal growth and circuitry.

Conditional inactivation of the NBS1 gene in the mouse central nervous system leads to neurodegeneration and disorganization of the visual system.
Nijmegen breakage syndrome (NBS) is a genomic instability disease caused by hypomorphic mutations in the NBS1 gene encoding the Nbs1 (nibrin) protein. Nbs1 is a component of the Mre11/Rad50/Nbs1 (MRN) complex that acts as a sensor of double strand breaks (DSBs) in the DNA and is critical for proper activation of the broad cellular response to DSBs. Conditional disruption of the murine ortholog of the human NBS1, Nbs1, in the CNS of mice was previously reported to cause microcephaly, severe cerebellar atrophy and ataxia. Here we report that conditional targeted disruption of the murine NBS1 gene in the CNS results in mal-development, degeneration, disorganization and dysfunction of the murine visual system, especially in the optic nerve. Nbs1 deletion resulted in reduced diameters of Nbs1-CNS-Delta eye and optic nerve. MRI

analysis revealed defective white matter development and organization. Nbs1 inactivation altered the morphology and organization of the glial cells. Interestingly, at the age of two-month-old the levels of the axonal guidance molecule semaphorin-3A and its receptor neuropilin-1 were up-regulated in the retina of the mutant mice, a typical injury response. Electroretinogram analysis revealed marked reduction in a- and b-waves, indicative of decreased retinal function. Our study points to a novel role for Nbs1 in the development, organization and function of the visual system.

SPG7 biallelic mutations are the most frequent cause of autosomal recessive spastic paraplegia. The associated clinical picture is either a pure spastic paraplegia, or a complex phenotype encompassing mitochondrial features, optic atrophy, and cerebellar signs. In the recent years, the phenotype has been widened to cerebellar ataxia more generally, with or without pyramidal signs; and to clinical presentations associating extrapyramidal features, mimicking Parkinson's disease or Multisystemic Atrophy of the cerebellar type in some cases. In 731 patients with cerebellar ataxia, we sequenced known ataxia genes, either with amplicon-based panel sequencing (n=412) or whole exome sequencing (n=319). We found biallelic mutations in 23 patients (3.1%), often associating spastic or mitochondrial presentations. We also identified 19 heterozygous carriers of loss of function or previously described missense variants in *SPG7*, without a second mutation. Dominant transmission has been discussed in the literature. While it is suggested in some patients, a recent report described a deep intronic change responsible for an alteration of *SPG7* expression, in trans with a missense mutation, advising genetic reexamination of heterozygous carriers. We included 19 index cases with a phenotype characteristic of *SPG7*-related cerebellar ataxia, associating either spasticity or parkinsonism, and an established causative but monoallelic *SPG7* variant. We performed short-read Whole Genome Sequencing in those patients and their relatives, when available, and report our results on missing heritability identification.

Transient expression of the *ATOH7* gene in the embryonic neural retina is required for the genesis of retinal ganglion cells (RGC), hence for optic nerve (ON) development. Different *ATOH7* disease alleles could result in different degrees of optic nerve abnormalities; from optic nerve aplasia (ONA) to a wide spectrum of optic nerve hypoplasia (ONH). We have previously shown that the deletion of a cis controlling element upstream of *ATOH7* results in nonsyndromic congenital retinal non-attachment (NCRNA) and congenital blindness with no perception of light. In this study, we investigate the histology of optic pathways in a 16-week NCRNA (*ATOH7*-/-) fetus and an age-matched *ATOH7*+/+ fetus as control. We reported this phenotype as a case of ONA. However, because, in the magnetic resonance images of an NCRNA patient, thin linear structures were present in his orbital cones, and the MR images did not allow us to resolve the components of these structures, we could not rule out the presence of thin atrophic/hypoplastic optic nerves. In this report, we describe the histopathological differences between optic pathways in these fetuses.

Imipramine alleviates memory impairment and hippocampal apoptosis in STZ-induced sporadic Alzheimer's rat model: Possible contribution of MAPKs and insulin signaling.
Alzheimer's disease (AD) is the most common age-related neurodegenerative disease, associated with several pathophysiological complaints. Impaired insulin signaling in the brain, is one of the important characteristic features of AD which is accompanied by cognitive deficits. According to the multifactorial and complicated pathology of AD, no modifying therapy has been approved yet. Imipramine is a kind of tricyclic antidepressant with reported anti-inflammatory and anti-oxidant effects in the brain. There are controversial studies about the effect of this drug on spatial memory. This study investigates the effect of imipramine on streptozotocin (STZ) induced memory impairment in rats. Pursuing this objective, rats were treated with imipramine 10 or 20 mg/kg i.p. once a day for 14 days. 24 h after the last injection, memory function was evaluated by the Morris water maze (MWM) test in 4 consecutive days. Then, hippocampi were removed and the activity of caspase-3, mitogen activated protein kinases (MAPKs) family and inhibitory phosphorylation of insulin receptor substrate-1 (IRS-1) were analyzed using Western blotting. Results showed that imipramine prevents memory impairment in STZ induced rats and this improvement was accompanied with an increase in ERK activity, reduction of caspase-3 and JNK activity, as well as partial restoration of P38 and IRS-1 activity. In conclusion, our study demonstrated that at least some members of the MAPK family are involved in the neuroprotective effect of imipramine.

Neurodegenerative diseases affect millions of people worldwide. Until now no effective treatment have been developed and currently available options are targeted to help reduce symptoms and relieve patient's pain. C terminus of HSC70-Interacting Protein (CHIP) is acknowledged as a protector of neurons and cells of central nervous system (CNS) from oxidative stress which plays fundamental role in a common pathophysiology of neurodegenerative diseases. Previous studies have shown that CHIP regulates cellular membrane integrity under conditions of acute stress, at the same time acting as a proteostasis sensor that models the proteome. Protein misfolding and aggregation are hallmarks of age-related proteinopathies. To determine the role of CHIP in the process of neurodegeneration, we proposed 'network level' view on signalling in SH-SY5Y cell models. Our team investigated protein homeostasis inside the WT and CHIP KO SH-SY5Y cell models. The key readout of changes in proteostasis obtained with use of liquid chromatography mass spectrometry (LC-MS) showed overexpression of Pro-neuropeptide Y (NPY) and Neurofilament medium polypeptide (NEFM) in the SH-SY5Y CHIP KO cells when compared to SH-SY5Y WT. Results were confirmed by SDS-PAGE. Both proteins play an important role in neurodevelopmental processes. This study could be fundamental for development of effective anti-neurodegeneration treatment therapies.

[Molecular mechanisms of genistein action in the light of therapies for genetic and immunological diseases].
Genetic and immunological diseases, despite many attempts to develop effective treatments, still remain a great challenge for medicine. Current therapies of these diseases consist of pharmacological alleviation of symptoms, rehabilitation and psychological help which, although very important, are not sufficient. Therefore, searching for new therapeutics which could remove the major causes of these diseases is of particular importance for the society. Natural compounds reveal many biological activities which makes them candidates for drugs in such diseases. One of them is genistein, a compound from the group of flavonoids. As it affects multiple processes, genistein has become in the center of interest of many scientists working on diseases of various etiology, course and inheritance. It was used in experimental therapies of some genetic diseases (Huntington's disease, amyotrophic lateral sclerosis Parkinson disease, cystic fibrosis), as well as autoimmunological diseases and allergies. Clinical trials with the use of genistein in treatment of patients suffering from Alzheimer's diseases and mucopolysaccharidosis type III are ongoing. The employment of differential properties of genistein in attempts to treat each of these diseases is of special interest. In this review, detailed molecular mechanisms of genistein action are summarized in the light of therapies of the above mentioned genetic and immunological diseases, including description of therapeutic potentials of each activity of this isoflavone, efficiency of its action, and its potential use as a drug in the future.

Alzheimer´s disease (AD) is clinically characterized by cognitive deficits. Neuropathologically, AD brains accumulate deposits of amyloid-β and tau proteins. Furthermore, these misfolded proteins can propagate cell-to-cell in a prion-like manner and induce native proteins to become pathological. Particularly, the entorhinal cortex (EC) is the earliest affected area by tau accumulation. Previous proteomic study in our lab revealed very interesting up- (S100A6, PPP1R1B, BAG3 and PRDX6) and downregulated (GSK3B, SYN1, DLG4 and RAB3A) proteins related with neurodegeneration and astrogliosis in the human EC in AD. However, several relevant proteins were neglected. Therefore, the aim of this work was to characterize additional different proteins between AD and non-AD cases in the human EC.
Post-mortem tissue, including 12 AD and 10 non-AD age-matched cases, was provided by IDIBAPS, BTCIEN, BIOBANC-MUR, BPA and NAVARRABIOMED Spanish National Biobanks. Experimental procedures were approved by the Ethical Committee of Clinical Research at Ciudad Real University Hospital (PID2019-108659RB-I00). Metaboanalyst, Reactome and STRING databases were used for bioinformatic analysis. Immunofluorescence and western blot were performed to evaluate selected proteins.
Data analysis indicate several pathological pathways involving synaptic processes, neuroinflammatory and chaperone response, as well as identify proteins that could constitute potential biomarkers in AD such as HSP90AA1, PTK2B and ANXA2. These results provide new insights on proteomic changes in the human entorhinal cortex in AD.
Sponsored by the UCLM/ERDF (2020-GRIN-31233), the Spanish Ministries of Economy and Competitiveness/ERDF (SAF2016-75768-R) and Science and Innovation (PID2019-108659RB-I00) and the Autonomous Government of Castilla-La Mancha/ERDF (SBPLY/17/180501/000430). SVC and MGR held a predoctoral fellowship UCLM/ESF.

Neurodegeneration and astrogliosis in the entorhinal cortex in Alzheimer's disease: Stereological layer-specific assessment and proteomic analysis.
The entorhinal cortex is among the earliest areas involved in Alzheimer's disease. Volume reduction and neural loss in this area have been widely reported. Human entorhinal cortex atrophy is, in part, due to neural loss, but microglial and/or astroglial involvement in the different layers remains unclear. Additionally, -omic approaches in the human entorhinal cortex are scarce.

ACCELERATED COGNITIVE DECLINE IN OBESE MOUSE MODEL OF ALZHEIMER'S DISEASE IS LINKED TO SIALIC ACID-DRIVEN IMMUNE DEREGULATION

POSTER SESSION 02 - SECTION: NEW PERSPECTIVES IN NEURODEGENERATION

Systemic immunity supports healthy brain homeostasis. Accordingly, conditions causing systemic immune deregulation may accelerate onset of neurodegeneration in predisposed individuals. Here we show that, in the 5xFAD mouse model of Alzheimer's disease (AD), high-fat diet-induced obesity accelerated cognitive decline, which was associated with immune deviations comprising increased splenic frequencies of exhausted $CD4^+$ T effector memory cells and $CD4^+FOXP3^+$ regulatory T cells (Tregs). Non-targeted plasma metabolomics identified *N*-acetylneuraminic acid (NANA), the predominant sialic acid, as the major obesity-induced metabolite in 5xFAD mice, the levels of which directly correlated with Tregs abundance and inversely correlated with cognitive performance. Visceral adipose tissue macrophages were identified by sNuc-Seq as one potential source of NANA. Exposure to NANA led to immune deregulation in middle-aged wild-type mice, and *ex vivo* in human T cells. Our study identified diet-induced immune deregulation, potentially via sialic acid, as a previously unrecognized link between obesity and AD.

Deletion of lrrk2 causes early developmental abnormalities and age-dependent increase of monoamine catabolism in the zebrafish brain.
LRRK2 gain-of-function is considered a major cause of Parkinson's disease (PD) in humans. However, pathogenicity of LRRK2 loss-of-function in animal models is controversial. Here we show that deletion of the entire zebrafish lrrk2 locus elicits a pleomorphic transient brain phenotype in maternal-zygotic mutant embryos (mzLrrk2). In contrast to lrrk2, the paralog gene lrrk1 is virtually not expressed in the brain of both wild-type and mzLrrk2 fish at different developmental stages. Notably, we found reduced catecholaminergic neurons, the main target of PD, in specific cell populations in the brains of mzLrrk2 larvae, but not adult fish. Strikingly, age-dependent accumulation of monoamine oxidase (MAO)-dependent catabolic signatures within mzLrrk2 brains revealed a previously undescribed interaction between LRRK2 and MAO biological activities. Our results highlight mzLrrk2 zebrafish as a tractable tool to study LRRK2 loss-of-function in vivo, and suggest a link between LRRK2 and MAO, potentially of relevance in the prodromic stages of PD.

Temporal dynamics of hippocampal neurogenesis in chronic neurodegeneration.
The study of neurogenesis during chronic neurodegeneration is crucial in order to understand the intrinsic repair mechanisms of the brain, and key to designing therapeutic strategies. In this study, using an experimental model of progressive chronic neurodegeneration, murine prion disease, we define the temporal dynamics of the generation, maturation and integration of new neurons in the hippocampal dentate gyrus, using dual pulse-chase, multicolour γ-retroviral tracing, transmission electron microscopy and patch-clamp. We found increased neurogenesis during the progression of prion disease, which partially counteracts the effects of chronic neurodegeneration, as evidenced by blocking neurogenesis with cytosine arabinoside, and helps to preserve the hippocampal function. Evidence obtained from human post-mortem samples, of both variant

Creutzfeldt-Jakob disease and Alzheimer's disease patients, also suggests increased neurogenic activity. These results open a new avenue into the exploration of the effects and regulation of neurogenesis during chronic neurodegeneration, and offer a new model to reproduce the changes observed in human neurodegenerative diseases.

Regulation of microglial proliferation during chronic neurodegeneration.
An important component of chronic neurodegenerative diseases is the generation of an innate inflammatory response within the CNS. Microglial and astroglial cells play a key role in the development and maintenance of this inflammatory response, showing enhanced proliferation and activation. We studied the time course and regulation of microglial proliferation, using a mouse model of prion disease. Our results show that the proliferation of resident microglial cells accounts for the expansion of the population during the development of the disease. We identify the pathway regulated by the activation of CSF1R and the transcription factors PU.1 and C/EBPα as the molecular regulators of the proliferative response, correlating with the chronic human neurodegenerative conditions variant Creutzfeldt-Jakob disease and Alzheimer's disease. We show that targeting the activity of CSF1R inhibits microglial proliferation and slows neuronal damage and disease progression. Our results demonstrate that microglial proliferation is a major component in the evolution of chronic neurodegeneration, with direct implications for understanding the contribution of the CNS innate immune response to disease progression.

THE APOE ε4 GENETIC POLYMORPHISM ALTERS CHOLESTEROL METABOLISM AND CHOLINERGIC SIGNALLING PATHWAY PROMOTING NEUROTOXIC EFFECTS

POSTER SESSION 02 - SECTION: NEW PERSPECTIVES IN NEURODEGENERATION

University of Pisa, Department Of Pharmacy, Pisa, Italy

Background. Physiologically, ApoE is produced by astrocytes and microglia in the central nervous system and is involved in the maintenance of normal brain functions, promoting neuronal integrity/repair and cholesterol redistribution. In neuropathological conditions, ApoE is also produced by neurons, in response to neuronal damage/stress; however, when ε4 isoform is expressed, the ApoE neuroprotective/repairing role is lost. Indeed, ApoEε4 promotes neurotoxic effects, increasing the APP transcription and Aβ production/accumulation, and leads to Alzheimer's Disease (AD), a neurodegenerative disorder characterized by cholinergic synapses alterations. Despite the cholinergic neurotransmission changes and ApoE-dependent pathogenic mechanisms in AD development have been extensively investigated, their cause-effect connection remains elusive. **Aim.** The current study aimed to explore the ApoEε4-induced neurotoxic effects in relation to cholesterol metabolism and cholinergic neurotransmission alterations. **Results.** A cholinergic neuron cell model overexpressing ApoEε4 was performed, thus reproducing a neuronal damage model. It showed increased intracellular cholesterol accumulation given by dysregulation of cholesterol metabolism genes (increased PLIN2; decreased HMGCR, PLIN2, NCEH, and CYP46A1). Furthermore, the overexpression of ApoEε4 altered ACh homeostasis (increased ChAT protein expression; increased VChAT and reduced AChE genes expression), leading to extracellular accumulation of ACh and intracellular accumulation of IP_3 and Ca^{2+}. This mediates apoptotic effects by reducing the expression/activation of PKCε, which in turn leads to higher APP/Aβ accumulation and GSK-3β expression and increased cleaved Cas-3 protein production. **Conclusions.** Overall, the obtained data suggest a possible involvement of ApoEε4-dependent cholesterol metabolism dysregulation in the alteration of cholinergic synapses and neurotoxicity. Further experiments are ongoing to investigate this crucial aspect.

Potential Diagnostic Value of Red Blood Cells α-Synuclein Heteroaggregates in Alzheimer's Disease.
A plethora of complex misfolded protein combinations have been found in Alzheimer disease (AD) brains besides the classical pathological hallmarks. Recently, α-synuclein (α-syn) and its heterocomplexes with amyloid-β (Aβ) and tau have been suggested to be involved in the pathophysiological processes of neurodegenerative diseases. These pathological features are not limited to the brain, but can be also found in peripheral fluids. In this respect, red blood cells (RBCs) have been suggested as a good model to investigate the biochemical alterations of neurodegeneration. Our aim is to find whether RBC concentrations of α-syn and its heterocomplexes (i.e., α-syn/Aβ and α-syn/tau) were different in AD patients compared with healthy controls (HC). The levels of homo- and heteroaggregates of α-syn, Aβ and tau, were analyzed in a cohort of AD patients at early stage either with dementia or prodromal symptoms (N = 39) and age-matched healthy controls (N = 39). All AD patients received a biomarker-based diagnosis (low cerebrospinal fluid levels of Aβ peptide combined with high cerebrospinal fluid concentrations of total tau and/or phospho-tau proteins; alternatively, a positivity to cerebral amyloid-PET scan). Our results showed lower concentrations of α-syn and its heterocomplexes (i.e., α-syn/Aβ and α-syn/tau) in RBCs of AD patients with respect to HC. RBC α-syn/Aβ as well as RBC α-syn/tau heterodimers discriminated AD participants from HC with fair accuracy, whereas RBC α-syn concentrations differentiated poorly the two groups. Although additional investigations are required, these data suggest α-syn heteroaggregates in RBCs as potential tool in the diagnostic work-up of early AD diagnosis.

High Levels of -Amyloid, Tau, and Phospho-Tau in Red Blood Cells as Biomarkers of Neuropathology in Senescence-Accelerated Mouse.
Alzheimer's Disease (AD) is the most common Neurodegenerative Disease (ND), primarily characterised by

neuroinflammation, neuronal plaques of -amyloid (A), and neurofibrillary tangles of hyperphosphorylated tau. -Synuclein (-syn) and its heteroaggregates with A and tau have been recently included among the neuropathological elements of NDs. These pathological traits are not restricted to the brain, but they reach peripheral fluids as well. In this sense, Red Blood Cells (RBCs) are emerging as a good model to investigate the biochemical alterations of aging and NDs. Herein, the levels of homo- and heteroaggregates of ND-related proteins were analysed at different stages of disease progression. In particular, a validated animal model of AD, the SAMP8 (Senescence-Accelerated Mouse-Prone) and its control strain SAMR1 (Senescence-Accelerated Mouse-Resistant) were used in parallel experiments. The levels of the aforementioned proteins and of the inflammatory marker interleukin-1 (IL-1) were examined in both brain and RBCs of SAMP8 and SAMR1 at 6 and 8 months. Brain A, tau, and phospho-tau (p-tau) were higher in SAMP8 mice than in control mice and increased with AD progression. Similar accumulation kinetics were found in RBCs, even if slower. By contrast, -syn and its heterocomplexes (-syn-A and -syn-tau) displayed different accumulation kinetics between brain tissue and RBCs. Both brain and peripheral IL-1 levels were higher in SAMP8 mice, but increased sooner in RBCs, suggesting that inflammation might initiate at a peripheral level before affecting the brain. In conclusion, these results confirm RBCs as a valuable model for monitoring neurodegeneration, suggesting peripheral A, tau, and p-tau as potential early biomarkers of AD.

Impact of ApoE Polymorphism and Physical Activity on Plasma Antioxidant Capability and Erythrocyte Membranes.
The allele epsilon 4 (ε4) of apolipoprotein E (ApoE) is the strongest genetic risk factor for Alzheimer's disease (AD). ApoE protein plays a pivotal role in the synthesis and metabolism of amyloid beta (Aβ), the major component of the extracellular plaques that constitute AD pathological hallmarks. Regular exercise is an important preventive/therapeutic tool in aging and AD. Nevertheless, the impact of physical exercise on the well-being of erythrocytes, a good model of oxidative stress and neurodegenerative processes, remains to be investigated, particularly depending on ApoE polymorphism. Herein, we evaluate the oxidative status, Aβ levels, and the membrane's composition of erythrocytes in a cohort of human subjects. In our hands, the plasma antioxidant capability (AOC), erythrocytes membrane fluidity, and the amount of phosphatidylcholine (PC) were demonstrated to be significantly decreased in the ApoE ε4 genotype and non-active subjects. In contrast, erythrocyte Aβ content and lipid peroxidation increased in ε4 carriers. Regular physical exercise was associated with an increased plasma AOC and membrane fluidity, as well as to a reduced amount of erythrocytes Aβ. Altogether, these data highlight the influence of the ApoE genotype on erythrocytes' well-being and confirm the positive impact of regular physical exercise.

Prodromal Intestinal Events in Alzheimer's Disease (AD): Colonic Dysmotility and Inflammation Are Associated with Enteric AD-Related Protein Deposition.
Increasing evidence suggests that intestinal dysfunctions may represent early events in Alzheimer's disease and contribute to brain pathology. This study examined the relationship between onset of cognitive impairment and colonic dysfunctions in a spontaneous AD model before the full development of brain pathology. SAMP8 mice underwent Morris water maze and assessment of faecal output at four, six and eight months of age. In vitro colonic motility was examined. Faecal and colonic Aβ, tau proteins, α-synuclein and IL-1β were assessed by ELISA. Colonic citrate synthase activity was assessed by spectrophotometry. Colonic NLRP3, caspase-1 and ASC expression were evaluated by Western blotting. Colonic eosinophil density and claudin-1 expression were evaluated by immunohistochemistry. The effect of Aβ on NLRP3 signalling and mitochondrial function was tested in cultured cells. Cognitive impairment and decreased faecal output occurred in SAMP8 mice from six months. When compared with SAMR1, SAMP8 animals displayed: (1) impaired in vitro colonic contractions; (2) increased enteric AD-related proteins, IL-1β, active-caspase-1 expression and eosinophil density; and (3) decreased citrate synthase activity and claudin-1 expression. In THP-1 cells, Aβ promoted IL-1β release, which was abrogated upon incubation with caspase-1 inhibitor or in ASC cells. Aβ decreased mitochondrial function in THP-1 cells. In SAMP8, enteric AD-related proteins deposition, inflammation and impaired colonic excitatory neurotransmission, occurring before the full brain pathology development, could contribute to bowel dysmotility and represent prodromal events in AD.

Comparative study of the stabilities of synthetic and natural transthyretin amyloid fibrils.
Systemic amyloidosis caused by extracellular deposition of insoluble fibrils derived from the pathological aggregation of circulating proteins, such as transthyretin, is a severe and usually fatal condition. Elucidation of the molecular pathogenic

mechanism of the disease and discovery of effective therapies still represents a challenging medical issue. The preparation of amyloid fibrils that exhibit structural and biochemical properties closely similar to those of natural fibrils is central to improving our understanding of the biophysical basis of amyloid formation and may offer an important tool for drug discovery. Here, we compared the morphology and thermodynamic stability of natural transthyretin fibrils with those of fibrils generated either using the common acidification procedure or primed by limited selective cleavage by plasmin. The free energies for fibril formation were -12.36, -8.10, and -10.61 kcal mol, respectively. The fibrils generated via plasmin cleavage were more stable than those prepared at low pH and were thermodynamically and morphologically similar to natural fibrils extracted from human amyloidotic tissue. Determination of thermodynamic stability is an important tool that is complementary to other methods of structural comparison between fibrils and fibrils generated Our finding that fibrils created via an amyloidogenic pathway are structurally similar to human amyloid fibrils does not necessarily establish that the fibrillogenic pathway is the same for both, but it narrows the current knowledge gap between models and pathophysiology.

Apolipoprotein E Polymorphism and Oxidative Stress in Human Peripheral Blood Cells: Can Physical Activity Reactivate the Proteasome System through Epigenetic Mechanisms?
Alzheimer's disease (AD) is characterized by proteasome activity impairment, oxidative stress, and epigenetic changes, resulting in -amyloid (A) production/degradation imbalance. Apolipoprotein E (ApoE) is implicated in A clearance, and particularly, the ApoE 4 isoform predisposes to AD development. Regular physical activity is known to reduce AD progression. However, the impact of ApoE polymorphism and physical exercise on A production and proteasome system activity has never been investigated in human peripheral blood cells, particularly in erythrocytes, an emerging peripheral model used to study biochemical alteration. Therefore, the influence of ApoE polymorphism on the antioxidant defences, amyloid accumulation, and proteasome activity was here evaluated in human peripheral blood cells depending on physical activity, to assess putative peripheral biomarkers for AD and candidate targets that could be modulated by lifestyle. Healthy subjects were enrolled and classified based on the ApoE polymorphism (by the restriction fragment length polymorphism technique) and physical activity level (Borg scale) and grouped into ApoE 4/non-4 carriers and active/non-active subjects. The plasma antioxidant capability (AOC), the erythrocyte A production/accumulation, and the nuclear factor erythroid 2-related factor 2 (Nrf2) mediated proteasome functionality were evaluated in all groups by the chromatographic and immunoenzymatic assay, respectively. Moreover, epigenetic mechanisms were investigated considering the expression of histone deacetylase 6, employing a competitive ELISA, and the modulation of two key miRNAs (miR-153-3p and miR-195-5p), through the miRNeasy Serum/Plasma Mini Kit. ApoE 4 subjects showed a reduction in plasma AOC and an increase in the Nrf2 blocker, miR-153-3p, contributing to an enhancement of the erythrocyte concentration of A. Physical exercise increased plasma AOC and reduced the amount of A and its precursor, involving a reduced miR-153-3p expression and a miR-195-5p enhancement. Our data highlight the impact of the ApoE genotype on the amyloidogenic pathway and the proteasome system, suggesting the positive impact of physical exercise, also through epigenetic mechanisms.

Palmitoylethanolamide Counteracts Enteric Inflammation and Bowel Motor Dysfunctions in a Mouse Model of Alzheimer's Disease.
Palmitoylethanolamide (PEA), an endogenous lipid mediator, is emerging as a promising pharmacological agent in multiple neurodegenerative disorders for its anti-inflammatory and neuroprotective properties. However, its effects on enteric inflammation and colonic dysmotility associated with Alzheimer's disease (AD) are lacking. This study was designed to investigate the beneficial effect of PEA administration in counteracting the enteric inflammation and relieving the bowel motor dysfunctions in an AD mouse model, SAMP8 mice. In addition, the ability of PEA in modulating the activation of enteric glial cells (EGCs), pivotally involved in the pathophysiology of bowel dysfunctions associated with inflammatory conditions, has also been examined. SAMP8 mice at 4 months of age were treated orally with PEA (5 mg/kg/day) for 2 months. SAMR1 animals were employed as controls. At the end of treatment, parameters dealing with colonic motility, inflammation, barrier

integrity and AD protein accumulation were evaluated. The effect of PEA on EGCs was tested in cultured cells treated with lipopolysaccharide (LPS) plus β-amyloid 1-42 (Aβ). SAMP8 treated with PEA displayed: 1) an improvement of colonic motor activity, citrate synthase activity and intestinal epithelial barrier integrity and 2) a decrease in colonic Aβ and α-synuclein (α-syn) accumulation, S100-β expression as well as enteric IL-1β and circulating LPS levels, as compared with untreated SAMP8 mice. In EGCs, treatment with PEA counteracted the increment of S100-β, TLR-4, NF-κB p65 and IL-1β release induced by LPS and Aβ. These results suggest that PEA, under a condition of cognitive decline, prevents the enteric glial hyperactivation, reduces AD protein accumulation and counteracts the onset and progression of colonic inflammatory condition, as well as relieves intestinal motor dysfunctions and improves the intestinal epithelial barrier integrity. Therefore, PEA represents a viable approach for the management of the enteric inflammation and motor contractile abnormalities associated with AD.

Pulmonary fibrosis from molecular mechanisms to therapeutic interventions: lessons from post-COVID-19 patients.
Pulmonary fibrosis (PF) is characterised by several grades of chronic inflammation and collagen deposition in the interalveolar space and is a hallmark of interstitial lung diseases (ILDs). Recently, infectious agents have emerged as driving causes for PF development; however, the role of viral/bacterial infections in the initiation and propagation of PF is still debated. In this context, the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the virus responsible for the current coronavirus disease 2019 (COVID-19) pandemic, has been associated with acute respiratory distress syndrome (ARDS) and PF development. Although the infection by SARS-CoV-2 can be eradicated in most cases, the development of fibrotic lesions cannot be precluded; furthermore, whether these lesions are stable or progressive fibrotic events is still unknown. Herein, an overview of the main molecular mechanisms driving the fibrotic process together with the currently approved and newly proposed therapeutic solutions was given. Then, the most recent data that emerged from post-COVID-19 patients was discussed, in order to compare PF and COVID-19-dependent PF, highlighting shared and specific mechanisms. A better understanding of PF aetiology is certainly needed, also to develop effective therapeutic strategies and COVID-19 pathology is offering one more chance to do it. Overall, the work reported here could help to define new approaches for therapeutic intervention in the diversity of the ILD spectrum.

TARGETING OF H3K4 DEMETHYLASES AS A THERAPEUTIC STRATEGY TO TREAT ALZHEIMER'S DISEASE

POSTER SESSION 02 - SECTION: NEW PERSPECTIVES IN NEURODEGENERATION

Jiayin Zhou, Lalit Kaurani, Susanne Burkhardt, Andre Fischer
DZNE, Department For Systems Medicine And Epigenetics, Goettingen, Germany

Aim: Mutations in genes that control epigenetic gene-expression, especially the machinery that controls Histone 3 lysine 4 (H3K4me) methylation, are over-represented in intellectual disability disorders. Moreover, there is evidence that H3K4me3 levels decrease in neurodegenerative diseases such as Alzheimer's disease. Methods: In this study, we have analyzed H3K4me3 levels in Alzheimer's disease and tested the therapeutic potential of H3K4me demethylases (KDMs) in *vitro* and in *vivo.* Results: Our data suggest that decreasing the levels of H3K4 KMDs can improve neuronal synapse plasticity and reduce inflammatory responses. Furthermore, inhibition of KDMs in mouse models for age-associated memory decline or amyloid deposition ameliorated memory impairment. Conclusion: Our data suggest that the H3K4me demethylases are therapeutic targets to treat cognitive diseases.

Introduction: Alzheimer's disease (AD) is a neurodegenerative disorder characterized by Amyloid β(Aβ)-driven synaptic dysfunction in the early phases of pathogenesis. In addition to spine loss, cytoskeletal abnormalities, such as cofilin-actin rods, have been reported in AD patients and animal models. We have recently demonstrated that the actin-binding protein Cyclase-associated protein 2 (CAP2) is a master regulator of cofilin localization and activity, through the Cys32-dependent CAP2 dimerization. These mechanisms are altered in AD, suggesting an involvement of CAP2/cofilin pathway in AD pathogenesis. *Aims:* This work aims to explore the involvement of CAP2 in Aβ-induced actin rods formation during the early phases of AD pathogenesis. *Methods:* Experiments were mainly carried out using imaging and biochemical approaches, in order to evaluate the effect of Aβ oligomers treatment on CAP2/cofilin pathway. In particular, three-dimensional imaging analysis was performed to identify CAP2 as a core component of Aβ-induced actin rods. *Results:* Firstly, we demonstrated that Aβ oligomers impair CAP2/cofilin pathway both after a short exposure and when cofilin-actin rods are generated, although the resulting effects are different. Then, we found that CAP2 accumulates in actin rods, when specifically induced by Aβ exposure, but not when neurons are exposed to a different stressor. Finally, we show that CAP2 overexpression can prevent rods formation and spine loss, through a mechanism that requires CAP2 capability to form Cys32-dependent dimers. *Conclusions:* Overall, our data support the involvement of cofilin/CAP2 cooperation in different biological aspects of AD pathogenesis in neuronal cells, thus providing novel potential therapeutic target for AD.

Looking at Alzheimer's Disease Pathogenesis from the Nuclear Side.
Alzheimer's disease (AD) is a neurodegenerative disorder representing the most common form of dementia. It is biologically characterized by the deposition of extracellular amyloid-β (Aβ) senile plaques and intracellular neurofibrillary tangles, constituted by hyperphosphorylated tau protein. The key protein in AD pathogenesis is the amyloid precursor protein (APP), which is cleaved by secretases to produce several metabolites, including Aβ and APP intracellular domain (AICD). The greatest genetic risk factor associated with AD is represented by the () allele. Importantly, all of the above-mentioned molecules that are strictly related to AD pathogenesis have also been described as playing roles in the cell nucleus. Accordingly, evidence suggests that nuclear functions are compromised in AD. Furthermore, modulation of transcription maintains cellular homeostasis, and alterations in transcriptomic profiles have been found in neurodegenerative diseases. This report reviews recent advancements in the AD players-mediated gene expression. Aβ, tau, AICD, and localize in the nucleus and regulate the transcription of several genes, part of which is involved in AD pathogenesis, thus suggesting that targeting nuclear functions might provide new therapeutic tools for the disease.

Dendritic Spines in Alzheimer's Disease: How the Actin Cytoskeleton Contributes to Synaptic Failure.
Alzheimer's disease (AD) is a neurodegenerative disorder characterized by Aβ-driven synaptic dysfunction in the early phases of pathogenesis. In the synaptic context, the actin cytoskeleton is a crucial element to maintain the dendritic spine architecture and to orchestrate the spine's morphology remodeling driven by synaptic activity. Indeed, spine shape and synaptic strength are strictly correlated and precisely governed during plasticity phenomena in order to convert short-term alterations of synaptic strength into long-lasting changes that are embedded in stable structural modification. These functional and structural modifications are considered the biological basis of learning and memory processes. In this review we discussed the existing evidence regarding the role of the spine actin cytoskeleton in AD synaptic failure. We revised the physiological function of the actin cytoskeleton in the spine shaping and the contribution of actin dynamics in the endocytosis

mechanism. The internalization process is implicated in different aspects of AD since it controls both glutamate receptor membrane levels and amyloid generation. The detailed understanding of the mechanisms controlling the actin cytoskeleton in a unique biological context as the dendritic spine could pave the way to the development of innovative synapse-tailored therapeutic interventions and to the identification of novel biomarkers to monitor synaptic loss in AD.

HIGH-CONTENT SCREENING OF ALZHEIMER'S DISEASE GENETIC RISK FACTORS BASED ON SYNAPTIC DENSITY ANALYSIS

POSTER SESSION 02 - SECTION: NEW PERSPECTIVES IN NEURODEGENERATION

Audrey Coulon, Tiago Mendes, Devrim Kilinc, Julie Dumont, Julien Chapuis, Jean-Charles Lambert
Institut Pasteur de Lille, Umr1167, Lille, France

Objectives: Synaptic loss is one of the earliest pathological hallmarks and the strongest marker of cognitive decline in Alzheimer's disease (AD). A strong genetic predisposition is linked to AD, and genome-wide association studies have pointed out hundreds of genes associated with the risk of developing the disease. With this background, our objective is to develop a cell-based screen to assess the impact of each genetic risk factor on synaptic density. **Methods**: We screened a lentiviral shRNA library targeting 200 AD genetic risk factors using primary rat hippocampal neurons in 384-wells plates. Immunofluorescence was performed to reveal pre- and post-synaptic compartments and the neuronal network. Synaptic density was then assessed through high content analysis by assigning each post-synaptic structure to the nearest pre-synaptic structure using *Columbus* and *Matlab* software. **Results**: We identified 9 shRNAs targeting AD risk genes which strongly impacted synaptic density in our model. These results could help us to point out a role for some unexpected AD genetic risk factors in synaptic function. **Conclusion**: We have developed a high-content screening approach which allows us to define the genetic risk factors that are susceptible to be involved in synaptic dysregulation observed in the early stages of AD.

The Neuronal Ceroid Lipofuscinoses (NCL) are the most common neurodegenerative disorders of childhood and presently 13 different genetic NCL variants are known. The CLN5 variant is caused by mutations in the *CLN5* gene and is associated with variable types of dementias ranging from late infantile epileptic encephalopathy to familial Alzheimer's disease. Cln5 shows no significant homology to other proteins by primary amino acid sequence, and the molecular functions of Cln5 have not been previously demonstrated. We crystallized the glycosylated human Cln5 protein, determined its protein structure and revealed unexpected thioesterase activity of Cln5. We demonstrated complete loss of enzymatic activity for mutations affecting the catalytic H166 and C280 as well as for the two patient mutations Y258D and D279N and discovered that Cln5-deficient neuronal progenitor cells showed reduced thioesterase activity. These findings represent an important step toward understanding the neurodegenerative disease mechanisms associated with *CLN5* mutations and opens new avenues for developing causative therapies against this fatal disorder.

Introduction: In Alzheimer's disease (AD), the neuroprotective BDNF/TrkB-FL system is impaired due to an amyloid-beta-mediated TrkB-FL receptor cleavage and subsequent formation of an intracellular fragment (TrkB-ICD). TrkB-ICD retains its kinase activity, promotes cognitive impairments, and modifies gene expression, contributing to intracellular toxicity. Interestingly, AD pathological features may be disseminated by small (sEVs) or large (lEVs) extracellular vesicles, but also by soluble factors on the secretome, causing cell-to-cell toxicity. Importantly, previous studies have already detected TrkB-ICD in cerebrospinal fluid of humans, raising the possibility of its secretion. **Aims:** Accordingly, this work aims to assess TrkB-ICD presence in EVs and secretome. **Methods**: EVs were isolated from media of control (non-transduced, CTR), GFP- and TrkB-ICD-V5-transduced (ICD-V5) differentiated SH-SY5Y cells. After purification, lEVs and sEVs were characterized regarding their morphology, size, and protein cargo using transmission electron microscopy (TEM), dynamic light scattering (DLS) and western-blot (WB) methods, respectively. **Results**: TEM and DLS analysis showed that isolated EVs exhibited a cup-shaped morphology and expected size profile for both lEVs and sEVs. WB experiments confirmed the presence of typical EV protein markers. Interestingly, we were able not only to confirm the existence of ICD-V5 in both EV types, but also the presence of the endogenous TrkB-ICD fragment. Additionally, this fragment was also detected in the EV-depleted cell secretome. **Conclusions**: Altogether, both EV populations were correctly isolated and the detection of TrkB-ICD in both lEVs and sEVs, and in the secretome soluble fraction, strongly suggest the paracrine dissemination of this fragment from cell-to-cell, propagating its putative toxicity.

Activity-dependent neuroprotective protein (ADNP) is essential for brain formation and function. As such, de novo mutations in ADNP lead to the autistic ADNP syndrome and somatic ADNP mutations may drive Alzheimer's disease (AD) tauopathy. Sirtuin 1 (SIRT1) is positively associated with aging, the major risk for AD. Here, we revealed DNA/chromatin interaction site for ADNP and SIRT1, with yin yang 1, histone deacetylase 2, and ADNP, sharing a DNA binding motif and regulating SIRT1, ADNP, and EB1 (MAPRE1). This interaction was linked to sex- and age-dependent altered histone modification, associated with ADNP/SIRT1/WD repeat-containing protein 5, which mediates the assembly of histone modification complexes. Single-cell RNA and protein expression analyses as well as gene expression correlations placed SIRT1–ADNP and either MAPRE1 (EB1), MAPRE3 (EB3), or both in the same mouse and human cell; however, while MAPRE1 seemed to be similarly regulated to ADNP and SIRT1, MAPRE3 seemed to deviate. Finally, we demonstrated an extremely tight correlation for the gene transcripts described above, including related gene products. This correlation was specifically abolished in affected postmortem AD and Parkinson's disease brain select areas compared to matched controls, while being maintained in blood samples. Thus, we identified an ADNP–SIRT1 complex that may serve as a new target for the understanding of brain degeneration. Introducing ADNP and SIRT1 as new partners regulating microtubules and histone methylation.
Activity-dependent neuroprotective protein (ADNP) is essential for brain formation and function. As such, de novo mutations in ADNP lead to the autistic ADNP syndrome and somatic ADNP mutations may drive Alzheimer's disease (AD) tauopathy. Sirtuin 1 (SIRT1) is positively associated with aging, the major risk for AD. Here, we revealed two key interaction sites for ADNP and SIRT1. One, at the microtubule end-binding protein (EB1 and EB3) Tau level, with EB1/EB3 serving as amplifiers for microtubule dynamics, synapse formation, axonal transport, and protection against tauopathy. Two, on the DNA/chromatin site, with yin yang 1, histone deacetylase 2, and ADNP, sharing a DNA binding motif and regulating SIRT1, ADNP, and EB1 (MAPRE1). This interaction was linked to sex- and age-dependent altered histone modification, associated with ADNP/SIRT1/WD repeat-containing protein 5, which mediates the assembly of histone modification complexes. Single-cell RNA and protein expression analyses as well as gene expression correlations placed SIRT1-ADNP and either MAPRE1 (EB1), MAPRE3 (EB3), or both in the same mouse and human cell; however, while MAPRE1 seemed to be similarly regulated to ADNP and SIRT1, MAPRE3 seemed to deviate. Finally, we demonstrated an extremely tight correlation for the gene transcripts described above, including related gene products. This correlation was specifically abolished in affected postmortem AD and Parkinson's disease brain select areas compared to matched controls, while being maintained in blood samples. Thus, we identified an ADNP-SIRT1 complex that may serve as a new target for the understanding of brain degeneration.

Single Cell ADNP Predictive of Human Muscle Disorders: Mouse Knockdown Results in Muscle Wasting.
Activity-dependent neuroprotective protein (ADNP) mutations are linked with cognitive dysfunctions characterizing the autistic-like ADNP syndrome patients, who also suffer from delayed motor maturation. We thus hypothesized that ADNP is deregulated in versatile myopathies and that local ADNP muscle deficiency results in myopathy, treatable by the ADNP fragment NAP. Here, single-cell transcriptomics identified as a major constituent of the developing human muscle. transcript concentrations further predicted multiple human muscle diseases, with concentrations negatively correlated with the ADNP target interacting protein, microtubule end protein 1 (EB1). Reverting back to modeling at the single-cell level of the male mouse transcriptome, mRNA concentrations age-dependently correlated with motor disease as well as with sexual maturation gene transcripts, while expressing limb muscle cells significantly decreased with aging. Mouse heterozygous deficiency exhibited muscle microtubule reduction and myosin light chain () deregulation coupled with motor dysfunction. CRISPR knockdown of adult gastrocnemius muscle Adnp in a Cas9 mouse resulted in treadmill (male) and gait (female) dysfunctions that were specifically ameliorated by treatment with the ADNP snippet, microtubule interacting, -regulating, NAP (CP201). Taken together, our studies provide new hope for personalized diagnosis/therapeutics in versatile myopathies.

Age and Sex-Dependent ADNP Regulation of Muscle Gene Expression Is Correlated with Motor Behavior: Possible Feedback Mechanism with PACAP.
The activity-dependent neuroprotective protein (ADNP), a double-edged sword, sex-dependently regulates multiple genes and was previously associated with the control of early muscle development and aging. Here we aimed to decipher the involvement of ADNP in versatile muscle gene expression patterns in correlation with motor function throughout life. Using quantitative RT-PCR we showed that heterozygous deficiency in mice resulted in aberrant gastrocnemius (GC) muscle, tongue and bladder gene expression, which was corrected by the Adnp snippet, drug candidate, NAP (CP201). A significant sexual dichotomy was discovered, coupled to muscle and age-specific gene regulation. As such, Adnp was shown to regulate myosin light chain () in the gastrocnemius (GC) muscle, the language acquisition gene forkhead box protein P2 () in the tongue and the pituitary-adenylate cyclase activating polypeptide (PACAP) receptor PAC1 mRNA () in the bladder, with PACAP linked to bladder function. A tight age regulation was observed, coupled to an extensive correlation to muscle function (gait analysis), placing ADNP as a muscle-regulating gene/protein.

Discovery of autism/intellectual disability somatic mutations in Alzheimer's brains: mutated ADNP cytoskeletal impairments and repair as a case study.
With Alzheimer's disease (AD) exhibiting reduced ability of neural stem cell renewal, we hypothesized that de novo mutations controlling embryonic development, in the form of brain somatic mutations instigate the disease. A leading gene presenting heterozygous dominant de novo autism-intellectual disabilities (ID) causing mutations is activity-dependent neuroprotective protein (ADNP), with intact ADNP protecting against AD-tauopathy. We discovered a genomic autism ADNP mutation (c.2188C>T) in postmortem AD olfactory bulbs and hippocampi. RNA-Seq of olfactory bulbs also identified a novel ADNP hotspot mutation, c.2187_2188insA. Altogether, 665 mutations in 596 genes with 441 mutations in AD patients (389 genes, 38% AD-exclusive mutations) and 104 genes presenting disease-causing mutations (OMIM) were discovered. OMIM AD mutated genes converged on cytoskeletal mechanisms, autism and ID causing mutations (about 40% each). The number and average frequencies of AD-related mutations per subject were higher in AD subjects compared to controls. RNA-seq datamining (hippocampus, dorsolateral prefrontal cortex, fusiform gyrus and superior frontal gyrus-583 subjects) yielded similar results. Overlapping all tested brain areas identified unique and shared mutations, with ADNP singled out as a gene associated with autism/ID/AD and presenting several unique aging/AD mutations. The large fusiform gyrus library (117 subjects) with high sequencing coverage correlated the c.2187_2188insA ADNP mutation frequency to Braak stage (tauopathy) and showed more ADNP mutations in AD specimens. In cell cultures, the ADNP-derived snippet NAP inhibited mutated-ADNP-microtubule (MT) toxicity and enhanced Tau-MT association. We propose a paradigm-shifting concept in the perception of AD whereby accumulating mosaic somatic mutations promote brain pathology.

Peripheral transcriptomic biomarkers for early detection of sporadic Alzheimer disease?
Alzheimer disease (AD) is the major epidemic of the 21 century, its prevalence rising along with improved human longevity. Early AD diagnosis is key to successful treatment, as currently available therapeutics only allow small benefits for diagnosed

AD patients. By contrast, future therapeutics, including those already in preclinical or clinical trials, are expected to afford neuroprotection prior to widespread brain damage and dementia. Brain imaging technologies are developing as promising tools for early AD diagnostics, yet their high cost limits their utility for screening at-risk populations. Blood or plasma transcriptomics, proteomics, and/or metabolomics may pave the way for cost-effective AD risk screening in middle-aged individuals years ahead of cognitive decline. This notion is exemplified by data mining of blood transcriptomics from a published dataset. Consortia blood sample collection and analysis from large cohorts with mild cognitive impairment followed longitudinally for their cognitive state would allow the development of a reliable and inexpensive early AD screening tool.

SIRT1, miR-132 and miR-212 link human longevity to Alzheimer's Disease.
Alzheimer's Disease (AD) is the most common cause of dementia in the elderly. Centenarians - reaching the age of >100 years while maintaining good cognitive skills - seemingly have unique biological features allowing healthy aging and protection from dementia. Here, we studied the expression of SIRT1 along with miR-132 and miR-212, two microRNAs known to regulate SIRT1, in lymphoblastoid cell lines (LCLs) from 45 healthy donors aged 21 to 105 years and 24 AD patients, and in postmortem olfactory bulb and hippocampus tissues from 14 AD patients and 20 age-matched non-demented individuals. We observed 4.0-fold ($P = 0.001$) lower expression of SIRT1, and correspondingly higher expression of miR-132 (1.7-fold; $P = 0.014$) and miR-212 (2.1-fold; $P = 0.036$), in LCLs from AD patients compared with age-matched healthy controls. Additionally, SIRT1 expression was 2.2-fold ($P = 0.001$) higher in centenarian LCLs compared with LCLs from individuals aged 56-82 years; while centenarian LCLs miR-132 and miR-212 indicated 7.6-fold and 4.1-fold lower expression, respectively. Correlations of SIRT1, miR-132 and miR-212 expression with cognitive scores were observed for AD patient-derived LCLs and postmortem AD olfactory bulb and hippocampus tissues, suggesting that higher SIRT1 expression, possibly mediated by lower miR-132 and miR-212, may protect aged individuals from dementia and is reflected in their peripheral tissues.

RNA sequencing of bipolar disorder lymphoblastoid cell lines implicates the neurotrophic factor HRP-3 in lithium's clinical efficacy.
Lithium remains the oldest and most effective treatment for mood stabilisation in bipolar disorder (BD), even though at least half of patients are only partially responsive or do not respond. This study aimed to identify biomarkers associated with lithium response in BD, based on comparing RNA sequencing information derived from lymphoblastoid cell lines (LCLs) of lithium-responsive (LR) versus lithium non-responsive (LNR) BD patients, to assess gene expression variations that might bear on treatment outcome. RNA sequencing was carried out on 24 LCLs from female BD patients (12 LR and 12 LNR) followed by qPCR validation in two additional independent cohorts (41 and 17 BD patients, respectively). Fifty-six genes showed nominal differential expression comparing LR and LNR ($FC \geq |1.3|$, ≤ 0.01). The differential expression of and was validated by qPCR in the independent cohorts. We observed higher expression levels of and in BD patients who favourably respond to lithium. Both of these genes are involved in neurogenesis, and has been suggested to be a neurotrophic factor. Additional studies in larger BD cohorts are needed to confirm the potential of and expression levels in blood cells as tentative favourable lithium response biomarkers.

RGS2 expression predicts amyloid-β sensitivity, MCI and Alzheimer's disease: genome-wide transcriptomic profiling and bioinformatics data mining.
Alzheimer's disease (AD) is the most frequent cause of dementia. Misfolded protein pathological hallmarks of AD are brain deposits of amyloid-β (Aβ) plaques and phosphorylated tau neurofibrillary tangles. However, doubts about the role of Aβ in AD pathology have been raised as Aβ is a common component of extracellular brain deposits found, also by in vivo imaging, in non-demented aged individuals. It has been suggested that some individuals are more prone to Aβ neurotoxicity and hence more likely to develop AD when aging brains start accumulating Aβ plaques. Here, we applied genome-wide transcriptomic profiling of lymphoblastoid cells lines (LCLs) from healthy individuals and AD patients for identifying genes that predict sensitivity to Aβ. Real-time PCR validation identified 3.78-fold lower expression of RGS2 (regulator of G-protein signaling 2; $P=0.0085$) in LCLs from healthy individuals exhibiting high vs low Aβ sensitivity. Furthermore, RGS2 showed 3.3-fold lower expression ($P=0.0008$) in AD LCLs compared with controls. Notably, RGS2 expression in AD LCLs correlated with the patients' cognitive function. Lower RGS2 expression levels were also discovered in published expression data sets from

postmortem AD brain tissues as well as in mild cognitive impairment and AD blood samples compared with controls. In conclusion, Aβ sensitivity phenotyping followed by transcriptomic profiling and published patient data mining identified reduced peripheral and brain expression levels of RGS2, a key regulator of G-protein-coupled receptor signaling and neuronal plasticity. RGS2 is suggested as a novel AD biomarker (alongside other genes) toward early AD detection and future disease modifying therapeutics.

Insulin-like Growth Factor 1 Differentially Affects Lithium Sensitivity of Lymphoblastoid Cell Lines from Lithium Responder and Non-responder Bipolar Disorder Patients.
Bipolar disorder (BD) is a chronic psychiatric illness with an unknown etiology. Lithium is considered the cornerstone in the management of BD, though about 50-60 % of patients do not respond sufficiently to chronic treatment. Insulin-like growth factor 1 (IGF1) has been identified as a candidate gene for BD susceptibility, and its low expression has been suggested as a putative biomarker for lithium unresponsiveness. In this study, we examined the in vitro effects of insulin-like growth factor 1 (IGF-1) on lithium sensitivity in lymphoblastoid cell lines (LCLs) from lithium responder (R) and non-responder (NR) bipolar patients. Moreover, we evaluated levels of microRNA let-7c, a small RNA predicted to target IGF1. We found that exogenous IGF-1 added to serum-free media increased lithium sensitivity selectively in LCLs from NR BD patients. However, no significant differences were observed when comparing let-7c expression in LCLs from R vs. NR BD patients. Our data support a key role for IGF-1 in lithium resistance/response in the treatment of bipolar disorder.

REGULATION OF THE DNA DAMAGE RESPONSE BY E2F4 PHOSPHORYLATION IN ITS T249/T251 CONSERVED MOTIF AND ALZHEIMER'S DISEASE

POSTER SESSION 02 - SECTION: NEW PERSPECTIVES IN NEURODEGENERATION

Aina Maria Llabrés Mas, Alberto Garrido-García, José Frade
Instituto Cajal (CSIC), Molecular, Cellular And Developmental Neurobiology, Madrid, Spain

Alzheimer's disease (AD) has a multifactorial etiology that includes DNA damage in neurons. The transcription factor E2F4, which can potentially regulate DNA repair, has two conserved threonines (T249/T251 in the mouse) that can be phosphorylated by $p38^{MAPK}$ (p38). The expression *in vivo* of the T249A/T251A E2F4 mutant form (E2F4DN) has been shown to be a multifactorial therapeutic agent against AD. In this work, we have analyzed the effects of E2F4 phosphorylation in T249/T251 on the DNA repair response (DDR). To this aim, we used N2a mouse neuroblastoma cells treated with 10 µM camptothecin (CPT), a treatment known to induce *Cited2* expression and subsequent cell death. In this paradigm, the repression of *Cited2* by E2F4 is abolished upon CPT treatment, thus allowing its E2F1-dependent expression followed by cell death. While E2F4 can be detected in both the nucleus and cytoplasm of N2a cells, phosphoT249-E2F4-specific immunoreactivity is specifically observed in the nucleus 4 h after treatment with CPT. Therefore, the known activation of p38 in response to CPT could lead to T249 phosphorylation of E2F4, thus suppressing its inhibition on E2F1 activity and allowing *Cited2* expression. This hypothesis, is being tested in CPT-treated N2a cells co-transduced with adenoviral vectors expressing E2F1 together with either wild-type E2F4 or E2F4DN, in either the presence or absence of p38 inhibitors. In summary, our work provides support for a novel mechanism used by E2F4 to regulate the response to DNA damage in pathological situations, which could participate in the therapeutic capacity of E2F4DN against AD.

Sporadic Alzheimer's disease (sAD), familial AD with duplication of the Amyloid Precursor Protein gene (Dup-APP), and Down Syndrome (DS) with three copies of *APP*, share common hallmarks including amyloid and tau pathologies. However, the amount of Aβ peptides deposits in the walls of cerebral blood vessels leading to cerebral amyloid angiopathy (CAA) vary. Our aim is to characterize and understand the role of endothelial cells (ECs) forming the blood brain barrier (BBB) in CAA severity. For this purpose, we used human iPSC-derived ECs (hiPSC-EC) from patients with Dup-APP and from mosaic DS. We found that hiPSC-EC with Dup-APP and DS secreted higher levels of Aβ compared to their isogenic controls using MesoScaleDiscovery Aβ triplex assay. In addition, staining of adherent and tight junction proteins using immunofluorescence, showed changes in expression and distribution of these proteins at the cell surface of ECs. To better understand these changes, we analyzed hiPSC-ECs transcripts using RNAseq and revealed multiple dysregulated genes linked to cell adhesion and tight junction proteins between Dup-APP, DS and their isogenic controls. A monolayer of iPSC-EC was cultivated on Transwell microporous membranes to study the alteration of permeability in Dup-APP and DS. Our results suggest that APP duplication may intrinsically alter ECs properties, possibly leading to differential CAA and BBB alterations in AD patients carrying Dup-APP and in individuals with DS.

POSSIBLE NEUROENDOCRINE MODULATIONS IN HIPPOCAMPI OF 3XTG-AD MICE MODEL OF ALZHEIMER'S DISEASE

POSTER SESSION 02 - SECTION: NEW PERSPECTIVES IN NEURODEGENERATION

Arif Kamil Salihoglu
Karadeniz Technical University Faculty of Medicine, Department Of Physiology, Trabzon, Turkey

AIM: Alzheimer's disease (AD) is the most common neurodegenerative disease all over the world. However, cellular mechanism of AD is not fully understood yet. The aim of this study was to detect possible pathophysiological factors in AD on examining differentially expressed genes in 3xTg-AD mice model by using *in silico* tools. **METHODS:** GSE144459 dataset downloaded from Gene Expression Omnibus (GEO) database was re-examined for this research. In the dataset, 3xTg-AD male mice (n=8 at 12 weeks-old-age (woa); n=8 at 52 woa) and B6129SF2 male mice (n=8 at 12 woa.; n=8 at 52 woa) were examined and gene expression profiles of their hippocampi were re-analyzed in R program, based on Benjamini-Hochberg correction, adjusted *p*-values <0.05 were accepted as significant. Gene set enrichment analyses were performed in Gene Ontology and ENRICHR tools. **RESULTS:** Gene expression levels indicated that prolactin receptor (PRLR), periostin (POSTN), gonadotropin-releasing hormone (GNRH1), galectin (LGALS-2,3,9), diazepam binding inhibitor (DBIL5), resistin (RETN), period circadian clock (PER1-2), insulin receptor (INSR) were upregulated ($p<0.05$); and arginine vasopressin receptor (AVPR1A), gastrin (GAST), glucagon (GCG), leptin (LEP), neuropeptid Y receptor (NPY-1R,4R), galanin (GAL), parathyroid hormone (PTH2), orexin receptor (HCRTR1), nerve growth factor (NGF), urotensin-2 receptor (UTS2R) were downregulated ($p<0.05$) in AD group, compared with control group. **CONCLUSION:** Results indicate imbalances in the expression levels (up- and down-regulation) of genes known to be involved in many neuroendocrine signaling in hippocampal cells during the developmental process of AD. **Keywords:** Alzheimer's disease, neuroendocrine signaling, bioinformatics. ***Acknowledgements:*** Thanks to my dear supervisor, Prof.Dr. Ahmet AYAR, for his scientific and spiritual support.

THE CDK5-CDH1-ROCK2 SIGNALLING AXIS MEDIATES AMYLOID-ß NEUROTOXICITY

POSTER SESSION 02 - SECTION: NEW PERSPECTIVES IN NEURODEGENERATION

Aims Alzheimer's disease (AD) is the main cause of dementia and one of the most lethal and burdening diseases. The main mechanisms responsible for the cognitive decline developed by the patients are synaptic and neuronal loss, triggered by Amyloid-beta (Aβ). Cdh1, the main APC/C cofactor in neurons, is essential for neuronal survival both by preserving neuronal homeostasis as well as by avoiding apoptosis. Neuronal survival is highly dependent on the maintenance of dendritic stability. One key protein involved in dendritic integrity regulation is ROCK2. Previous studies of our group demonstrate that APC/C-Cdh1 complex maintains dendritic integrity in cortex and hippocampus by regulating ROCK2 levels, preserving cognitive function. We have also demonstrated that Cdk5 hyperactivation directly phosphorylates and inactivates Cdh1. Our working hypothesis is that CDK5-APC/C-Cdh1-ROCK2 pathway regulates neuronal apoptosis against Aβ. Methods To assess this issue, we used an $A\beta_{25-35}$toxicity model in primary neurons, and in intracerebroventricularly-injected mice. Results We demonstrate that Aβ induces Cdk5 activation, which in turn, promotes Cdh1 phosphorylation and its disassembly from APC. This Cdh1 inactivation triggers Rock2 stabilization and activation, mediating amyloid-β neurotoxicity. Moreover, using a ROCK2 selective inhibitor, we were able to reduce the Aβ-induced memory impairment in vivo. Conclusions These results demonstrate that Cdk5-APC/C-Cdh1-ROCK2 axis actively modulates the neuronal response to Aβ damage, making them potential molecular targets for AD therapy. PSEN1 EXPRESSION IS REPRESSED IN ADULT TGCRND8 MICE VIA PERINATAL S-ADENOSYLMETHIONINE SUPPLEMENTATION AFFECTING ON CPG AND NON-CPG METHYLATION.

POSTER SESSION 02 - SECTION: NEW PERSPECTIVES IN NEURODEGENERATION

Tiziana Raia, Federica Armeli, Rosaria Cavallaro, Rita Businaro, Marco Lucarelli, Andrea Fuso
Sapienza University, Department Of Experimental Medicine, Roma, Italy

AIMS: The metabolic Homocysteine (Hcy) pathway, also called the “one-carbon metabolism”, leads to the production of S-adenosylmethionine (SAM), the first endogenous methyl donor in methylation reactions, and is modulated by B vitamins. The pathophysiology of neurodegenerative diseases is considerably affected by DNA methylation, the main epigenetic gene expression regulator. Specifically, previous evidence indicates that promoter hypomethylation of PSEN1, a gene involved in the amyloidogenic pathway in AD, increases the Alzheimer’s Disease-like phenotype in transgenic TgCRND8 mice. On the contrary, supplementation with S-adenosylmethionine, reverts the pathological phenotype. A large body of evidence indicates that epigenetic signatures driving the drift between the normal-diseased aging can be acquired during the first stage of life, even in utero, and becoming manifest later on. METHODS: In this study we compared the effect of post-weaning and perinatal SAM treatment in TgCRND8 mice, assessing PSEN1 methylation and expression. DNA from mice brain samples is modified by the sodium bisulfite reaction and amplified by PCR. PCR products are ligated in plasmids that are sequenced by Sanger method. The PSEN1 gene expression is assessed by Real-time PCR. Histological techniques have allowed the study of amyloid plaque spreading. RESULTS: The results show that short term perinatal supplementation is more effective than post-weaning chronic supplementation in repressing PSEN1 expression in adult mice, with comparable effect in reducing amyloid deposition. CONCLUSIONS: These results point out the importance of methyl-donors availability during the early life in order to promote healthy aging.

The inter-talk between and the epigenetic mechanisms.
Epigenetics regulate gene function without any alteration in the DNA sequence. The epigenetics represent one of the most important regulators in different cellular processes and have initially been developed in microorganisms as a protective strategy. The evaluation of the epigenetic mechanisms is also important in achieving an efficient control strategy in tuberculosis (TB). TB is one of the most significant epidemiological concerns in human history. Despite several and studies that have evaluated different epigenetic modifications in TB, many aspects of the association between epigenetics and TB are not fully understood. The current paper is aimed at reviewing our knowledge on histone modifications and DNA methylation modifications, as well as miRNAs regulation in TB.

The complex interplay between DNA methylation and miRNAs in gene expression regulation.
The short, non-coding RNAs, also called microRNAs (miRNAs) can bind complementary sequences on cellular mRNAs. The consequence of this binding is generally the degradation of mRNA and the inhibition of its translation. For this reason, miRNAs are included among the epigenetic factors acting as a modulator of gene expression. How miRNAs expression is, in turn, regulated is still the object of active investigation, but DNA methylation, another epigenetic modification, seems to play a central role in this sense. The "one-carbon" metabolism is responsible for the metabolic regulation of trans-methylation reactions and, therefore, DNA methylation. For this reason, to investigate the possible correlations between alterations of the one-carbon metabolism and differential DNA methylation sounds interesting. Moreover, recent evidence indicates that, vice-versa, miRNAs are associated with DNA methylation modulation, in a mutual cross-talk. The present review will discuss the interplay between miRNAs and DNA methylation and its fall-out on gene expression regulation.

CpG and non-CpG Presenilin1 methylation pattern in course of neurodevelopment and neurodegeneration is associated with

gene expression in human and murine brain.
The Presenilin1 () gene encodes the catalytic peptide of the γ-secretase complex, a key enzyme that cleaves the amyloid-β protein precursor (AβPP), to generate the amyloid-β (Aβ) peptides, involved in Alzheimer's Disease (AD). Other substrates of the γ-secretase, such as E-cadherin and Notch1, are involved in neurodevelopment and haematopoiesis. Gene-specific DNA methylation influences expression in AD animal models. Here we evaluated canonical and non-canonical cytosine methylation patterns of the 5'-flanking during brain development and AD progression, in DNA extracted from the frontal cortex of AD transgenic mice (TgCRND8) and post-mortem human brain. Mapping CpG and non-CpG methylation revealed different methylation profiles in mice and humans. expression only correlated with DNA methylation in adult female mice. However, in post-mortem human brain, lower methylation, both at CpG and non-CpG sites, correlated closely with higher expression during brain development and in disease progression. methylation in blood DNA was significantly lower in AD patients than in controls. The present study is the first to demonstrate a temporal correlation between dynamic changes in CpG and non-CpG methylation patterns and mRNA expression during neurodevelopment and AD neurodegeneration. These observations were made possible by the use of an improved bisulphite methylation assay employing primers that are not biased towards non-CpG methylation. Our findings deepen the understanding of γ-secretase regulation and support the hypothesis that epigenetic changes can promote the pathophysiology of AD. Moreover, they suggest that DNA methylation in peripheral blood may provide a biomarker for AD.

Active Demethylation of Non-CpG Moieties in Animals: A Neglected Research Area.
The functional role of cytosine methylation in the CpG moieties of DNA, is well established in several biological functions. The interplay between CpG methylation and hypomethylation is a well-known mechanism of modulation of gene expression. However, the role of non-CpG methylation and active dynamics of demethylation is not clearly recognized. Although some evidence exists of a role of active non-CpG demethylation in the fast dynamics of transcriptional activation in animals, few studies deal with this topic. At present, active demethylation of non-CpG moieties is a neglected research area, in spite of the promise of significant novelties.

Exploring the brain tissue proteome of TgCRND8 Alzheimer's Disease model mice under B vitamin deficient diet induced hyperhomocysteinemia by LC-MS top-down platform.
The multifactorial nature of Late Onset Alzheimer's Disease (LOAD), the AD form of major relevance on epidemiological and social aspects, has driven the original investigation by LC-MS and top-down proteomics approach of the protein repertoire of the brain tissue of TgCRND8 model mice fed with a diet deficient in B vitamins. The analysis of the acid-soluble fraction of brain tissue homogenates identified a list of proteins and peptides, proteoforms and PTMs. In order to disclose possible modulations, their relative quantification in wild type and AD model mice under both B vitamin deficient and control diets was performed. The levels of metallothionein III, guanine nucleotide-binding protein G(I)/G(S)/G(O) subunit gamma-2 and brain acid soluble protein 1 showed statistically significant alterations depending on genotype, diet or both effects, respectively. Particularly, metallothionein III exhibited increased levels in TgCRND8 mice under B vitamin deficient diet with respect to wild type mice under both diets. Brain acid soluble protein 1 showed the opposite, revealing decreased levels in all diet groups of AD model mice with respect to wild type mice in control diet. Lower levels of brain acid soluble protein 1 were also observed in wild type mice under deficiency of B vitamins. These results, besides contributing to increase the knowledge of AD at molecular level, give new suggestions for deeply investigating metallothionein III and brain acid soluble protein 1 in AD.

S-Adenosylmethionine and Superoxide Dismutase 1 Synergistically Counteract Alzheimer's Disease Features Progression in TgCRND8 Mice.
Recent evidence emphasizes the role of dysregulated one-carbon metabolism in Alzheimer's Disease (AD). Exploiting a nutritional B-vitamin deficiency paradigm, we have previously shown that PSEN1 and BACE1 activity is modulated by one-carbon metabolism, leading to increased amyloid production. We have also demonstrated that S-adenosylmethionine (SAM)

supplementation contrasted the AD-like features, induced by B-vitamin deficiency. In the present study, we expanded these observations by investigating the effects of SAM and SOD (Superoxide dismutase) association. TgCRND8 AD mice were fed either with a control or B-vitamin deficient diet, with or without oral supplementation of SAM + SOD. We measured oxidative stress by lipid peroxidation assay, PSEN1 and BACE1 expression by Real-Time Polymerase Chain Reaction (PCR), amyloid deposition by ELISA assays and immunohistochemistry. We found that SAM + SOD supplementation prevents the exacerbation of AD-like features induced by B vitamin deficiency, showing synergistic effects compared to either SAM or SOD alone. SAM + SOD supplementation also contrasts the amyloid deposition typically observed in TgCRND8 mice. Although the mechanisms underlying the beneficial effect of exogenous SOD remain to be elucidated, our findings identify that the combination of SAM + SOD could be carefully considered as co-adjuvant of current AD therapies.

Type-I interferon (IFN-I) signaling at the choroid plexus (CP) negatively affects brain function in aging and Alzheimer's disease (AD). Emerging evidence shows that oxidized cholesterol metabolites control immune responses. Here, we hypothesized that 24-hydroxycholesterol (24-OH), produced by the brain-specific enzyme cholesterol 24-hydroxylase (CYP46A1), affects the inflammatory state of the CP, and that the CP itself expresses this enzyme. Transcriptomic analysis of primary mouse CP cultures exposed to 24-OH revealed down-regulation of IFN-I signaling. Using single-cell published transcriptomic data, we could demonstrate that epithelial cells within the CP express CYP46A1. We further verified that CYP46A1 is expressed in both mice and human postmortem CP samples at the protein level, and that its levels are reduced with AD in both an AD mouse model (5xFAD) and human patients. We further found that *Cyp46a1* gene expression at the CP is reduced by tumor necrosis factor alpha (TNFα), an inflammatory signature of the brain in AD, known to also induce IFN-I signaling at the CP. In addition, systemic PD-L1 blockade, which transiently elevates IFN-II signaling at the CP , induced *Cyp46a1* gene expression at the CP. Finally, overexpression of *Cyp46a1* at the CP in 5xFAD mice, reduced the expression of IFN-I associated genes and attenuated cognitive loss and neuroinflammation. Our results suggest that CP CYP46A1 provides a safeguard against chronic inflammation that is lost with disease, but amenable to rescue.

Breaking immune tolerance by targeting Foxp3(+) regulatory T cells mitigates Alzheimer's disease pathology.
Alzheimer's disease (AD) is a neurodegenerative disorder in which chronic neuroinflammation contributes to disease escalation. Nevertheless, while immunosuppressive drugs have repeatedly failed in treating this disease, recruitment of myeloid cells to the CNS was shown to play a reparative role in animal models. Here we show, using the 5XFAD AD mouse model, that transient depletion of Foxp3(+) regulatory T cells (Tregs), or pharmacological inhibition of their activity, is followed by amyloid-β plaque clearance, mitigation of the neuroinflammatory response and reversal of cognitive decline. We further show that transient Treg depletion affects the brain's choroid plexus, a selective gateway for immune cell trafficking to the CNS, and is associated with subsequent recruitment of immunoregulatory cells, including monocyte-derived macrophages and Tregs, to cerebral sites of plaque pathology. Our findings suggest targeting Treg-mediated systemic immunosuppression for treating AD.

PD-1/PD-L1 checkpoint blockade harnesses monocyte-derived macrophages to combat cognitive impairment in a tauopathy mouse model.
Alzheimer's disease (AD) is a heterogeneous disorder with multiple etiologies. Harnessing the immune system by blocking the programmed cell death receptor (PD)-1 pathway in an amyloid beta mouse model was shown to evoke a sequence of immune responses that lead to disease modification. Here, blocking PD-L1, a PD-1 ligand, was found to have similar efficacy to that of PD-1 blocking in disease modification, in both animal models of AD and of tauopathy. Targeting PD-L1 in a tau-driven disease model resulted in increased immunomodulatory monocyte-derived macrophages within the brain parenchyma. Single cell RNA-seq revealed that the homing macrophages expressed unique scavenger molecules including

macrophage scavenger receptor 1 (MSR1), which was shown here to be required for the effect of PD-L1 blockade in disease modification. Overall, our results demonstrate that immune checkpoint blockade targeting the PD-1/PD-L1 pathway leads to modification of common factors that go awry in AD and dementia, and thus can potentially provide an immunotherapy to help combat these diseases.

PD-1 immune checkpoint blockade reduces pathology and improves memory in mouse models of Alzheimer's disease. Systemic immune suppression may curtail the ability to mount the protective, cell-mediated immune responses that are needed for brain repair. By using mouse models of Alzheimer's disease (AD), we show that immune checkpoint blockade directed against the programmed death-1 (PD-1) pathway evokes an interferon (IFN)-γ-dependent systemic immune response, which is followed by the recruitment of monocyte-derived macrophages to the brain. When induced in mice with established pathology, this immunological response leads to clearance of cerebral amyloid-β (Aβ) plaques and improved cognitive performance. Repeated treatment sessions were required to maintain a long-lasting beneficial effect on disease pathology. These findings suggest that immune checkpoints may be targeted therapeutically in AD.
Nat Med, 2016; 22

Mef2C restrains microglial inflammatory response and is lost in brain ageing in an IFN-I-dependent manner.
During ageing, microglia acquire a phenotype that may negatively affect brain function. Here we show that ageing microglial phenotype is largely imposed by interferon type I (IFN-I) chronically present in aged brain milieu. Overexpression of IFN-β in the CNS of adult wild-type mice, but not of mice lacking IFN-I receptor on their microglia, induces an ageing-like transcriptional microglial signature, and impairs cognitive performance. Furthermore, we demonstrate that age-related IFN-I milieu downregulates microglial myocyte-specific enhancer factor 2C (Mef2C). Immune challenge in mice lacking Mef2C in microglia results in an exaggerated microglial response and has an adverse effect on mice behaviour. Overall, our data indicate that the chronic presence of IFN-I in the brain microenvironment, which negatively affects cognitive function, is mediated via modulation of microglial activity. These findings may shed new light on other neurological conditions characterized by elevated IFN-I signalling in the brain.Microglia cells in the brain regulate immune responses, but in ageing can negatively affect brain function. Here the authors show that the chronic presence of type I interferon in aged mouse brain impedes cognitive ability by altering microglia transcriptome and limiting Mef2C, a microglia 'off' signal.

ROLE OF THE TYROSINE KINASE PYK2 IN SYNAPTIC FUNCTION AND IN THE PATHOPHYSIOLOGY OF ALZHEIMER'S DISEASE

POSTER SESSION 02 - SECTION: NEW PERSPECTIVES IN NEURODEGENERATION

Quentin Rodriguez, Eve Borel, Sylvie Boisseau, Muriel Jaquier-Sarlin, Karina Vargas-Baron, Fabien Lanté, Floriane Payet, Alain Buisson
Univ. Grenoble Alpes, Inserm U1216, Grenoble Institut Neurosciences, Grenoble, France

Aims: A genome wild association study has identified PTK2B, a gene which encodes for Pyk2, a neuronal Ca^{2+}-activated non-receptor tyrosine kinase implicated in synaptic function, as a major risk factor for Alzheimer's disease (AD). Several studies have validated the implication of Pyk2 in the pathophysiology of AD but contradictory findings have been reported. The objective of this project is to further understand the role of Pyk2 in physiological and pathophysiological synaptic functions in the context of AD. Methods: Murine primary neuronal culture (DIV 14) were transfected with Life-actin GFP and Pyk2 plasmids with altered kinase activity to assess the influence of PyK2 kinase activity on dendritic spines density and morphology. Furthermore, we measured Pyk2 expression and phosphorylation profile in the hippocampus and cortex of APPxPS1-21 transgenic mice, a model of AD. Results: Pyk2 overexpression leads to a decrease in synaptic density when it is overexpressed in neurons. This effect does not appear to be related to its kinase activity since this decrease is also observed with the inactive mutant Y402F of Pyk2. In APPxPS1 mice, we observed a strong decrease of Pyk2 phosphorylation in the cortex at 6 and 9 months. Conclusions: Together these results highlight the physiological role of PyK2 in the structural features of excitatory synapses. Because PyK2 phosphorylation displays a long lasting reduction in APPxPS1-21 mouse model of AD, we will study further the consequences of an altered PyK2 activity on excitatory neurotransmission in the context of AD.

FORMULATING NOVEL RESEARCH QUESTIONS TO INVESTIGATE A MECHANISTIC RELATIONSHIP BETWEEN THE BRAIN GLYMPHATIC SYSTEM AND ALZHEIMER'S DISEASE

POSTER SESSION 02 - SECTION: NEW PERSPECTIVES IN NEURODEGENERATION

Iva Durdanovic
Auburn University, Harrison College of Pharmacy, Drug Design And Discovery, Auburn, United States of America

Since it was first described in 1906, Alzheimer's disease (AD) has remained one of the most insidious brain diseases to claim the lives of the aging population. Despite the progress in drug development, an efficacious approach to preventing and treating AD is still needed. Although amyloid-beta and tau protein aggregation have been highly investigated for their roles in the pathogenesis of AD, little is still known regarding how dysfunction in the brain's microenvironment may result in conditions conducive to neuronal and glial cell dysfunction. An essential mechanism for homeostatic regulation of the brain microenvironment is the glymphatic system, comprised of multicellular and interstitial components that efficiently clear potential neurotoxins from the brain. The glymphatic system, most active during sleep, facilitates the elimination of waste macromolecules via fluid flux through paraventricular channels formed by glial cells, particularly astrocytes. Although the anatomical and physiological properties of the glymphatic system have been well-characterized, its potential role in AD is newly emerging. We performed a systematic literature review using the PubMed, Google Scholar, and NIH REPORTER databases using the keywords: sleep, glymphatic system, and AD. Forty-seven separate articles collectively suggested strong correlations between glymphatic function, sleep, and AD as of February-2022, with a small subset of studies dedicated to elucidating potential mechanistic relationships. Therefore, the existing rigor of the prior research indicates a premise to propose and conduct future studies elucidating the mechanisms of AD as it involves alterations in the brain microenvironment secondary to glymphatic system effects.

INTEGRATED NETWORK-BASED AND DIFFERENTIAL GENE EXPRESSION ANALYSIS IDENTIFIES POTENTIAL THERAPEUTIC TARGETS BASED ON ENDOTHELIAL AND MYELOID CELL TRANSCRIPTOME CHANGES IN PATIENTS WITH ALZHEIMER'S DISEASE

POSTER SESSION 02 - SECTION: NEW PERSPECTIVES IN NEURODEGENERATION

Kamelija Horvatović[1], Andrea Gelemanović[2]
[1]Faculty of Science, Univeristy of Zagreb, Department Of Molecular Biology, Zagreb, Croatia, [2]Mediterranean Institute for Life Sciences, Biology Of Robustness, Split, Croatia

Aims: Etiopathology of Alzheimer's dementia (AD) comprises complex interactions, including the interplay of disrupted neurovasculature and inflammatory processes. This *in silico* study investigates the transcriptomic changes in endothelial (EC) and myeloid cells (MC) obtained from superior frontal lobe. **Methods:** RNA-seq dataset GSE125050 was acquired from NCBI GEO database. Differentially expressed genes (DEGs) were identified with *DESeq2*, while weighted gene co-expression network analysis (WGCNA) pipeline was applied to identify highly correlated gene modules and key genes. Functional enrichment analysis was performed on DEGs and modules of interest. Transcriptomics-based drug repurposing approach using LINCS connectivity map was applied to identify drug candidates. **Results:** Distinct cell-type-specific transcriptomic changes were observed using different approaches. Six modules with 1695 key genes were significantly correlated with AD MC, while two modules with 378 key genes with AD EC, respectively. FZD3 was recognized as hub gene in both cell types, supporting evidence that Wnt signaling pathway is disrupted in AD. 53 and 1384 DEGs were identified in AD MC and EC, respectively, of which UVRAG was upregulated, and ANKRD26P3 and GLT1D1 were downregulated in both cell types. AD EC revealed altered cell adhesion and organization, whereas pathways related to synaptic modulation and immune response activation were more prominent in MC. 17 drug candidates, including temsirolimus, exhibited potential to reverse the AD transcriptomic signature. **Conclusions:** This integrated study identified several cell-specific genes that may serve as biomarkers or therapeutic targets and supports further investigations of rapamycin and its derivatives which exhibit protective effects in animal AD models.

THE NEURONAL SEIZURE PROTEIN 6 (SEZ6) IS A SUBSTRATE OF THE ALZHEIMER PROTEASE BACE1 AND A LIGAND FOR THE LDL-RELATED PROTEIN 1 (LRP1)

POSTER SESSION 02 - SECTION: NEW PERSPECTIVES IN NEURODEGENERATION

Xiao Feng[1], Stephan Müller[1], Cui[2], Gao[1], Kathryn Munro[3], Jenny Gunnersen[3], Stefan Lichtenthaler[1]
[1]DZNE, German Centre For Neurodegenerative Diseases, Munich, Germany, [2]Faculty of Medicine, Munich Medical Research School (mmrs), Lmu, Munich, Germany, [3]Department of Anatomy and Neuroscience, University Of Melbourne, Victoria, Australia

The protease BACE1 has fundamental functions in the nervous system, including in myelination, but also is a major drug target for Alzheimer's disease, because it generates the pathogenic amyloid beta peptide. However, BACE1-targeted inhibitors induced side effects in clinical trials, including cognitive worsening. While the underlying mechanism is not yet known, the side effects are assumed to be mechanism-based and to results from inhibition of one or several of the numerous BACE1 substrates in the nervous system. One key substrate for BACE1, that we identified, is the transmembrane protein seizure protein 6 (SEZ6), which controls dendritic branching, kainate receptor signaling, dendritic spine density and LTP. The BACE1-cleaved soluble SEZ6 ectodomain (sSEZ6) may act as a ligand and contribute to these neuronal processes, but a receptor for sSEZ6 has not yet been identified. Using mass spectrometry and biochemical strategies, we identified and validated the LDL receptor-related protein 1 (LRP1) as a receptor for sSEZ6. We provide evidence that sSEZ6 binding to LRP1 contributes to neurite arborization and spine morphology. Taken together, our study identifies a receptor for sSEZ6, demonstrates a molecular function for the sSEZ6-LRP1 interaction in the nervous system and may help to better understand the mechanistic basis of the side effects observed in BACE inhibitor trials.

Alzheimer's disease (AD) is pathologically characterised by the presence of amyloid-β plaques, neurofibrillary tangles containing hyperphosphorylated Tau protein, neuroinflammation and neuronal death leading to progressive cognitive impairment. The ε4 allele of the gene encoding apolipoprotein E (APOE), which is mainly expressed in glial cells, is the strongest genetic risk factor for sporadic AD. Increasing evidence has shown that APOE4 may disrupt normal astrocyte activity, potentially contributing to AD pathology, but the impact of different APOE alleles on astrocyte differentiation, maturation and function is not yet fully understood. To go in depth on these questions, we obtained induced pluripotent stem cells (iPSCs) from fibroblasts of AD patients carrying ε3 and ε4 alleles (in homozygosis) and from healthy patients. We also used gene-edited iPSC lines homozygous for the main APOE variants and an APOE knock-out line. iPSC-derived human astrocytes were generated by establishing a differentiation protocol through the consecutive addition of small molecules and growth factors, and the expression of typical markers (GFAP, GLT1, AQP4 and S100β) and APOE was confirmed. In addition, astrocytes exhibited functional features like glutamate uptake capacity and calcium waves production. They also responded to an inflammatory stimulus (IL-1β and TNF-α) or to the presence of amyloid-β 1-42 peptide by changing their morphology and increasing the expression levels of pro-inflammatory factors and cytokines. Our results shed light on the potential dual role of APOE polymorphism and the individual´s genetic background in favouring or perhaps preventing AD pathology.

Preconditioning-Activated AKT Controls Neuronal Tolerance to Ischemia through the MDM2-p53 Pathway.
One of the most important mechanisms of preconditioning-mediated neuroprotection is the attenuation of cell apoptosis, inducing brain tolerance after a subsequent injurious ischemia. In this context, the antiapoptotic PI3K/AKT signaling pathway plays a key role by regulating cell differentiation and survival. Active AKT is known to increase the expression of murine double minute-2 (MDM2), an E3-ubiquitin ligase that destabilizes p53 to promote the survival of cancer cells. In neurons, we recently showed that the MDM2-p53 interaction is potentiated by pharmacological preconditioning, based on subtoxic stimulation of NMDA glutamate receptor, which prevents ischemia-induced neuronal apoptosis. However, whether this mechanism contributes to the neuronal tolerance during ischemic preconditioning (IPC) is unknown. Here, we show that IPC induced PI3K-mediated phosphorylation of AKT at Ser, which in turn phosphorylated MDM2 at Ser. This phosphorylation triggered the nuclear stabilization of MDM2, leading to p53 destabilization, thus preventing neuronal apoptosis upon an ischemic insult. Inhibition of the PI3K/AKT pathway with wortmannin or by AKT silencing induced the accumulation of cytosolic MDM2, abrogating IPC-induced neuroprotection. Thus, IPC enhances the activation of PI3K/AKT signaling pathway and promotes neuronal tolerance by controlling the MDM2-p53 interaction. Our findings provide a new mechanistic pathway involved in IPC-induced neuroprotection via modulation of AKT signaling, suggesting that AKT is a potential therapeutic target against ischemic injury.

The Neuronal Ischemic Tolerance Is Conditioned by the Tp53 Arg72Pro Polymorphism.
Cerebral preconditioning (PC) confers endogenous brain protection after stroke. Ischemic stroke patients with a prior transient ischemic attack (TIA) may potentially be in a preconditioned state. Although PC has been associated with the

activation of pro-survival signals, the mechanism by which preconditioning confers neuroprotection is not yet fully clarified. Recently, we have described that PC-mediated neuroprotection against ischemic insult is promoted by p53 destabilization, which is mediated by its main regulator MDM2. Moreover, we have previously described that the human Tp53 Arg72Pro single nucleotide polymorphism (SNP) controls susceptibility to ischemia-induced neuronal apoptosis and governs the functional outcome of patients after stroke. Here, we studied the contribution of the human Tp53 Arg72Pro SNP on PC-induced neuroprotection after ischemia. Our results showed that cortical neurons expressing the Pro72-p53 variant exhibited higher PC-mediated neuroprotection as compared with Arg72-p53 neurons. PC prevented ischemia-induced nuclear and cytosolic p53 stabilization in Pro72-p53 neurons. However, PC failed to prevent mitochondrial p53 stabilization, which occurs in Arg72-p53 neurons after ischemia. Furthermore, PC promoted neuroprotection against ischemia by controlling the p53/active caspase-3 pathway in Pro72-p53, but not in Arg72-p53 neurons. Finally, we found that good prognosis associated to TIA within 1 month prior to ischemic stroke was restricted to patients harboring the Pro72 allele. Our findings demonstrate that the Tp53 Arg72Pro SNP controls PC-promoted neuroprotection against a subsequent ischemic insult by modulating mitochondrial p53 stabilization and then modulates TIA-induced ischemic tolerance.

The MDM2-p53 pathway is involved in preconditioning-induced neuronal tolerance to ischemia.
Brain preconditioning (PC) refers to a state of transient tolerance against a lethal insult that can be evoked by a prior mild event. It is thought that PC may induce different pathways responsible for neuroprotection, which may involve the attenuation of cell damage pathways, including the apoptotic cell death. In this context, p53 is a stress sensor that accumulates during brain ischemia leading to neuronal death. The murine double minute 2 gene (MDM2), a p53-specific E3 ubiquitin ligase, is the main cellular antagonist of p53, mediating its degradation by the proteasome. Here, we study the role of MDM2-p53 pathway on PC-induced neuroprotection both in cultured neurons (in vitro) and rat brain (in vivo). Our results show that PC increased neuronal MDM2 protein levels, which prevented ischemia-induced p53 stabilization and neuronal death. Indeed, PC attenuated ischemia-induced activation of the p53/PUMA/caspase-3 signaling pathway. Pharmacological inhibition of MDM2-p53 interaction in neurons abrogated PC-induced neuroprotection against ischemia. Finally, the relevance of the MDM2-p53 pathway was confirmed in rat brain using a PC model in vivo. These findings demonstrate the key role of the MDM2-p53 pathway in PC-induced neuroprotection against a subsequent ischemic insult and poses MDM2 as an essential target in ischemic tolerance.

Regulation of Bcl-xL-ATP Synthase Interaction by Mitochondrial Cyclin B1-Cyclin-Dependent Kinase-1 Determines Neuronal Survival.
The survival of postmitotic neurons needs continuous degradation of cyclin B1, a mitotic protein accumulated aberrantly in the damaged brain areas of Alzheimer's disease and stroked patients. Degradation of cyclin B1 takes place in the proteasome after ubiquitylation by the anaphase-promoting complex/cyclosome (APC/C)-cadherin 1 (Cdh1), an E3 ubiquitin ligase that is highly active in neurons. However, during excitotoxic damage-a hallmark of neurological disorders-APC/C-Cdh1 is inactivated, causing cyclin B1 stabilization and neuronal death through an unknown mechanism. Here, we show that an excitotoxic stimulus in rat cortical neurons in primary culture promotes cyclin B1 accumulation in the mitochondria, in which it binds to, and activates, cyclin-dependent kinase-1 (Cdk1). The cyclin B1-Cdk1 complex in the mitochondria phosphorylates the anti-apoptotic protein B-cell lymphoma extra-large (Bcl-xL), leading to its dissociation from the β subunit of F1Fo-ATP synthase. The subsequent inhibition of ATP synthase activity causes complex I oxidative damage, mitochondrial inner membrane depolarization, and apoptotic neuronal death. These results unveil a previously unrecognized role for mitochondrial cyclin B1 in the oxidative damage associated with neurological disorders.

Olfactory dysfunction manifests early in several neurodegenerative disorders including Alzheimer's disease (AD), however, disease-related alterations to olfactory mucosal (OM) cells remain poorly described. Furthermore, biometals functionally influence to olfaction and are altered in AD-affected brains. We harvested OM biopsies from cognitively healthy individuals and patients with late-onset AD to first profile disease-linked transcriptomic alterations at single-cell level. The single-cell RNA sequencing (scRNA-seq) unveiled 240 differentially expressed disease-associated genes in AD OM cells compared to the controls, and five distinct cell populations. Furthermore, the alterations in gene expression of mitochondrially located genes in AD OM cells were verified by functional assays. AD OM cells displayed increased secretion of beta-amyloid. Since alterations in the balance of metal ions are linked to the deposition of beta-amyloid, total RNA sequencing was applied to larger cohort of samples to discover transcriptional changes related to metals in AD and control OM cells. Furthermore, analysis of the elemental content by inductively coupled plasma mass spectrometry (ICP-MS) was performed. Consequently, the levels of zinc, calcium and sodium were observed to be significantly increased in the AD OM cells concomitantly with alterations to 17 genes associated with a metal-related function. A significant elevation in alpha-2-macroglobulin, a known metal-binding biomarker correlated with brain disease burden, was observed on the gene and protein level in the OM cells of AD patients. Our results reveal disease-related changes of OM cells in AD and suggest that impairments in biometal homeostasis in the OM can recapitulate the alterations observed in the disease affected brain.

Single-Cell RNA-Seq Analysis of Olfactory Mucosal Cells of Alzheimer's Disease Patients.
Olfaction is orchestrated by olfactory mucosal cells located in the upper nasal cavity. Olfactory dysfunction manifests early in several neurodegenerative disorders including Alzheimer's disease, however, disease-related alterations to the olfactory mucosal cells remain poorly described. The aim of this study was to evaluate the olfactory mucosa differences between cognitively healthy individuals and Alzheimer's disease patients. We report increased amyloid-beta secretion in Alzheimer's disease olfactory mucosal cells and detail cell-type-specific gene expression patterns, unveiling 240 differentially expressed disease-associated genes compared to the cognitively healthy controls, and five distinct cell populations. Overall, alterations of RNA and protein metabolism, inflammatory processes, and signal transduction were observed in multiple cell populations, suggesting their role in Alzheimer's disease-related olfactory mucosa pathophysiology. Furthermore, the single-cell RNA-sequencing proposed alterations in gene expression of mitochondrially located genes in AD OM cells, which were verified by functional assays, demonstrating altered mitochondrial respiration and a reduction of ATP production. Our results reveal disease-related changes of olfactory mucosal cells in Alzheimer's disease and demonstrate the utility of single-cell RNA

sequencing data for investigating molecular and cellular mechanisms associated with the disease.

Urban air particulate matter induces mitochondrial dysfunction in human olfactory mucosal cells.
The adverse effects of air pollutants including particulate matter (PM) on the central nervous system is increasingly reported by epidemiological, animal and post-mortem studies in the last decade. Oxidative stress and inflammation are key consequences of exposure to PM although little is known of the exact mechanism. The association of PM exposure with deteriorating brain health is speculated to be driven by PM entry via the olfactory system. How air pollutants affect this key entry site remains elusive. In this study, we investigated effects of urban size-segregated PM on a novel cellular model: primary human olfactory mucosal (hOM) cells.

Olfactory cell cultures to investigate health effects of air pollution exposure: Implications for neurodegeneration.
Air pollution is a major, global public health concern. A growing body of evidence shows that exposure to air pollutants may impair the brain. Living in highly polluted areas has been linked to several neurodegenerative diseases, where exposure to complex mixtures of air pollutants in urban environments may have harmful effects on brain function. These harmful effects are thought to originate from elevated inflammation and oxidative stress. The olfactory epithelium is a key entry site of air pollutants into the brain as the particles are deposited in the upper airways and the nasal region. A potential source of patient-derived cells for study of air pollutant effects is the olfactory mucosa, which constitutes a central part of the olfactory epithelium. This review first summarizes the current literature on the available in vitro models of the olfactory epithelium. It then describes how alterations of the olfactory mucosa are linked to neurodegeneration and discusses potential therapeutic applications of these cells for neurodegenerative diseases. Finally, it reviews the research performed on the effects of air pollutant exposure in cells of the olfactory epithelium. Patient-derived olfactory epithelial models hold great promise for not only elucidating the molecular and cellular pathophysiology of neurodegenerative disorders, but for providing key understanding about air pollutant particle entry and effects at this key brain entry site.

PPARβ/δ-agonist GW0742 ameliorates dysfunction in fatty acid oxidation in PSEN1ΔE9 astrocytes.
Astrocytes are the gatekeepers of neuronal energy supply. In neurodegenerative diseases, bioenergetics demand increases and becomes reliant upon fatty acid oxidation as a source of energy. Defective fatty acid oxidation and mitochondrial dysfunctions correlate with hippocampal neurodegeneration and memory deficits in Alzheimer's disease (AD), but it is unclear whether energy metabolism can be targeted to prevent or treat the disease. Here we show for the first time an impairment in fatty acid oxidation in human astrocytes derived from induced pluripotent stem cells of AD patients. The impairment was corrected by treatment with a synthetic peroxisome proliferator activated receptor delta (PPARβ/δ) agonist GW0742 which acts to regulate an array of genes governing cellular metabolism. GW0742 enhanced the expression of CPT1a, the gene encoding for a rate-limiting enzyme of fatty acid oxidation. Similarly, treatment of a mouse model of AD, the APP/PS1-mice, with GW0742 increased the expression of Cpt1a and concomitantly reversed memory deficits in a fear conditioning test. Although the GW0742-treated mice did not show altered astrocytic glial fibrillary acidic protein-immunoreactivity or reduction in amyloid beta (Aβ) load, GW0742 treatment increased hippocampal neurogenesis and enhanced neuronal differentiation of neuronal progenitor cells. Furthermore, GW0742 prevented Aβ-induced impairment of long-term potentiation in hippocampal slices. Collectively, these data suggest that PPARβ/δ-agonism alleviates AD related deficits through increasing fatty acid oxidation in astrocytes and improves cognition in a transgenic mouse model of AD.

Targeting Nrf2 to Suppress Ferroptosis and Mitochondrial Dysfunction in Neurodegeneration.
Ferroptosis is a newly described form of regulated cell death, distinct from apoptosis, necroptosis and other forms of cell death. Ferroptosis is induced by disruption of glutathione synthesis or inhibition of glutathione peroxidase 4, exacerbated by iron, and prevented by radical scavengers such as ferrostatin-1, liproxstatin-1, and endogenous vitamin E. Ferroptosis terminates with mitochondrial dysfunction and toxic lipid peroxidation. Although conclusive identification of ferroptosis is challenging, several salient and very well established features of neurodegenerative diseases are consistent with ferroptosis, including lipid peroxidation, mitochondrial disruption and iron dysregulation. Accordingly, interest in the role of ferroptosis in neurodegeneration is escalating and specific evidence is rapidly emerging. One aspect that has thus far received little attention is the antioxidant transcription factor nuclear factor erythroid 2-related factor 2 (Nrf2). This transcription factor

regulates hundreds of genes, of which many are either directly or indirectly involved in modulating ferroptosis, including metabolism of glutathione, iron and lipids, and mitochondrial function. This potentially positions Nrf2 as a key deterministic component modulating the onset and outcomes of ferroptotic stress. The minimal direct evidence currently available is consistent with this and indicates that Nrf2 may be critical for protection against ferroptosis. In contrast, abundant evidence demonstrates that enhancing Nrf2 signaling is potently neuroprotective in models of neurodegeneration, although the exact mechanism by which this is achieved is unclear. Further studies are required to determine to extent to which the neuroprotective effects of Nrf2 activation involve the prevention of ferroptosis.

Agonist-specific Protein Interactomes of Glucocorticoid and Androgen Receptor as Revealed by Proximity Mapping.
Glucocorticoid receptor (GR) and androgen receptor (AR) are steroid-inducible transcription factors (TFs). The GR and the AR are central regulators of various metabolic, homeostatic and differentiation processes and hence important therapeutic targets, especially in inflammation and prostate cancer, respectively. Hormone binding to these steroid receptors (SRs) leads to DNA binding and activation or repression of their target genes with the aid of interacting proteins, coregulators. However, protein interactomes of these important drug targets have remained poorly defined. We used proximity-dependent biotin identification to map the protein interaction landscapes of GR and AR in the presence and absence of their cognate agonist (dexamethasone, 5α-dihydrotestosterone) and antagonist (RU486, enzalutamide) in intact human cells. We reproducibly identified more than 30 proteins that interacted with the GR in an agonist-specific manner and whose interactions were significantly influenced by the DNA-binding function of the receptor. Interestingly, the agonist-dependent interactome of the GR overlapped considerably with that of the AR. In addition to known coactivators, corepressors and components of BAF (SWI/SNF) chromatin-remodeling complex, we identified a number of proteins, including lysine methyltransferases and demethylases that have not been previously linked to glucocorticoid or androgen signaling. A substantial number of these novel agonist-dependent GR/AR-interacting proteins, BCOR, IRF2BP2, RCOR1, and TLE3, have previously been implicated in transcription repression. This together with our data on the effect of BCOR, IRF2BP2, and RCOR1 on GR target gene expression suggests multifaceted functions and roles for SR coregulators. These first high confidence SR interactomes will aid in therapeutic targeting of the GR and the AR.

COLLAGEN XVIII KNOCKOUT MICE AS A MODEL FOR EARLY CEREBRAL SMALL VESSEL DISEASE

POSTER SESSION 02 - SECTION: NEW PERSPECTIVES IN NEURODEGENERATION

Mahsima Khoshneviszadeh[1], Solveig Jandke[2], Rahul Kaushik[1], Anne Heikkinen[3], Philipp Ulbrich[2], Alexander Dityatev[1], Stefanie Schreiber[2]
[1]German Center for Neurodegenerative Disease (DZNE), Molecular Neuroplasticity, Magdeburg, Germany, [2]Otto-von-Guericke University, Magdeburg, Germany, Department Of Neurology, Magdeburg, Germany, [3]University of Oulu, Finland, Faculty Of Biochemistry And Molecular Medicine, oulu, Finland

Aims: The pathological alterations of small arteries and capillaries defined as cerebral small vessel disease (CSVD) are characterized by age-dependent blood-brain barrier (BBB) breakdown and vessel wall remodeling related to small vessel occlusions and perivascular bleeds. As collagen XVIII (Col18a1) is an abundant heparan sulfate proteoglycan in vascular basement membranes, here we focused on studying the role of Col18a1 in the vascular integrity and neurovascular unit maintenance in the context of CSVD. Methods: In this study, using qPCR we compared the expression levels of genes encoding tight junction and basement membrane proteins, inflammatory markers, neural ECM proteins and proteinases in 12-month-old Col18a1-/- andCol18a1+/+ mice. Furthermore, we examined the BBB breakdown and pre/peri-synaptic proteins alterations using immunohistochemistry. Results: Our immunohistochemical analysis revealed a progression of small vessel leakage in Col18a1-/- mice between 5 and 12 months. A large fraction (60%) of small vessel area was mouse IgG-immunopositive in the hippocampus and retrosplenial cortex of 12-month-old Col18a1-/- mice. However, none of Col18a1-/- mice displayed hallmarks typical of more advanced stages of CSVD, such as perivascular or large bleeds or infarcts. Col18a1 deficiency-induced BBB leakage was accompanied by activation of microglia and astrocytes, leading to perivascular ECM remodeling, upregulation of TIMP3 and accumulation of perisynaptic ECM proteoglycan brevican and complement protein C1q, which may underlie impaired synaptic plasticity and loss of synapses. Conclusion: Our findings highlight that Col18a1-/- mice represent a valuable model of early CSVD and call for more mechanistic analysis of underlying mechanisms and cognitive dysfunction in this model.

DECIPHERING PROK2 IMPLICATION IN THE DEVELOPMENT OF DEMENTIA RELATED TO ALZHEIMER'S DISEASE

POSTER SESSION 02 - SECTION: NEW PERSPECTIVES IN NEURODEGENERATION

Hadi Younes, Zineb Mahrougui, Marie Amourette, Nadia Alfaidy-Benharougua, Christel Marquette
CEA, Drf/irig/u1292-biosanté/bci, GRENOBLE, France

A broad consensus is emerging that neuroinflammation and cerebrovascular dysfunction are central processes in the blood-brain barrier (BBB) disruption and dementia-related Alzheimer's disease (AD) pathogenesis. AD is the most common cause of dementia, with progressive and irreversible mental decline related to loss of cognitive abilities and memory functions, as well as cognitive impairment, and increasing neuroinflammation. Important inflammatory factors include prokineticin 2 (PROK2), a chemokine-like molecule that appears to mediate Aβ cytotoxicity in an acute model of AD. PROK2 acts through specific G protein-coupled receptors, the PROK receptor 2 (PROKR2) to control multiple biological functions, including circadian rhythm, angiogenesis, olfactory bulb neurogenesis, neuronal survival, reproduction, and inflammation. PROK2 increases in inflamed tissues and exacerbates local inflammation. Therefore, the objective of this study is to decipher PROK2's actions in the early vascular inflammatory steps leading to Aβ deposition and ultimately AD. Methods: First, PROK2/PROK2 antagonists' effects on vascular permeability and tight junction protein expression were investigated using in vitro BBB co-culture systems including endothelial/astrocytic cells and neurons. In parallel, using AD transgenic mice (APP/PSENdE9), which develop the pathology throughout their lives, we determined PROKR2 expression at different stages of the disease using WB, immunohistochemistry and Elisa assay to measure circulating PROK2 levels. We demonstrate that PROK2/PROKR2 are regulated during the development of the disease and notably as a neuroinflammatory agent at the vascular level. This is important to understand other neuroinflammatory cases related to cognitive dysfunction and the development of dementia, such as in preeclampsia, following hypertensive complications and vascular dysfunction.

TRANSCRIPTIONAL MODULATION OF ER-MITOCHONDRIA CROSSTALK IN ALZHEIMER'S DISEASE – ROLE OF HISTONE DEACETYLASES

POSTER SESSION 02 - SECTION: NEW PERSPECTIVES IN NEURODEGENERATION

Daniela Marinho, Ildete Luisa Ferreira, Ana Cristina Rego
Center for Neuroscience and Cell Biology, Neuroscience And Disease, Coimbra, Portugal

Background: Several molecular mechanisms have been described in Alzheimer's disease (AD), including repressed gene transcription and mitochondrial and endoplasmic reticulum (ER) dysfunction. Chromatin remodeling by class I histone deacetylases (HDACs) inhibitors was recently reported to rescue AD-like phenotype, highlighting transcription regulation as a potential therapeutic approach. **Aims**: In this study, we aimed to evaluate the potential efficacy of transcriptional modifications exerted by class I HDACs inhibition or knockdown in ameliorating ER-mitochondria crosstalk in AD hippocampal neural cells. **Methods**: We investigated changes in intracellular Ca^{2+} homeostasis following HDAC inhibitor tacedinaline (Tac) treatment in HT22 cells exposed to Abeta1-42 oligomers (AbetaO). We also evaluated the expression of proteins involved in Ca^{2+} signaling at mitochondrial-associated ER membranes (MAMs) and ER-mitochondria contacts (MERCs) by electron microscopy. To study the selective effect of class I HDACs on ER-mitochondria crosstalk, we silenced HDAC2 or HDAC3. **Results**: We show that Tac prevents enhanced ER-Ca^{2+} retention and mitochondrial Ca^{2+} accumulation induced by AbetaO. Concomitantly, exposure to AbetaO leads to increased mRNA levels of IP3R1, VDAC1, Sig1R and Grp75, associated with increased MERCs length and a narrower gap between the two organelles, which are prevented after Tac treatment. Moreover, HDAC2 siRNA ameliorates mitochondrial-Ca^{2+} retention and ER-mitochondria Ca^{2+} transfer, whereas HDAC3 silencing reverts ER-Ca^{2+} accumulation in AbetaO-treated cells, suggesting differential epigenetic regulation of ER-mitochondrial communication and ER function. Interestingly, knockdown of HDAC2 or HDAC3 reverts mitochondrial depolarization induced by AbetaO. **Conclusions**: These findings support ER/mitochondrial-related transcriptional regulation as a promising target for innovative therapeutics in AD.

Boldine Attenuates Synaptic Failure and Mitochondrial Deregulation in Cellular Models of Alzheimer's Disease.
Alzheimer's disease (AD) is the most common cause of senile dementia worldwide, characterized by both cognitive and behavioral deficits. Amyloid beta peptide (Aβ) oligomers (AβO) have been found to be responsible for several pathological mechanisms during the development of AD, including altered cellular homeostasis and synaptic function, inevitably leading to cell death. Such AβO deleterious effects provide a way for identifying new molecules with potential anti-AD properties. Available treatments minimally improve AD symptoms and do not extensively target intracellular pathways affected by AβO. Naturally-derived compounds have been proposed as potential modifiers of Aβ-induced neurodysfunction and cytotoxicity based on their availability and chemical diversity. Thus, the aim of this study was to evaluate boldine, an alkaloid derived from the bark and leaves of the Chilean tree , and its capacity to block some dysfunctional processes caused by AβO. We examined the protective effect of boldine (1-10 μM) in primary hippocampal neurons and HT22 hippocampal-derived cell line treated with AβO (24-48 h). We found that boldine interacts with Aβ affecting its aggregation and protecting hippocampal neurons from synaptic failure induced by AβO. Boldine also normalized changes in intracellular Ca levels associated to mitochondria or endoplasmic reticulum in HT22 cells treated with AβO. In addition, boldine completely rescued the decrease in mitochondrial membrane potential (ΔΨm) and the increase in mitochondrial reactive oxygen species, and attenuated AβO-induced decrease in mitochondrial respiration in HT22 hippocampal cells. We conclude that boldine provides neuroprotection in AD models by both direct interactions with Aβ and by preventing oxidative stress and mitochondrial dysfunction. Additional studies are required to evaluate the effect of boldine on cognitive and behavioral deficits induced by Aβ .

Defects in Coenzyme Q (CoQ) metabolism have been associated to primary mitochondrial disorders, neurodegenerative diseases and metabolic conditions. The consequences of CoQ deficiency have not been fully addressed, and the therapeutic approaches remain challenging. Here, we carried out multi-omics, molecular and morphologic analyses and we demonstrate that CoQ deficiency induces reactive gliosis, which mediates a neuroinflammatory response, both leading to a fatal encephalopathic phenotype in the *Coq9*^{R239X} mouse model. Also, CoQ deficiency profoundly alters the Q-junction, which lead to a major remodelling of the mitochondrial proteome and metabolism in the kidneys, and to a lesser extent in the brain. Importantly, the treatment with either vanillic acid (VA) or β-resorcylic acid (β-RA), two analogs of the natural precursor for CoQ biosynthesis, partially restores CoQ metabolism, particularly in the kidneys and liver, and induce a profound normalization of the mitochondrial proteome and metabolism, ultimately leading to the reduction of gliosis, neuroinflammation and spongiosis and, consequently, rescuing the phenotype. Together, these results add key mechanistic insights about defects in CoQ metabolism, and identify potential disease biomarkers. Furthermore, our findings are not only important for the use of analogs of the CoQ biosynthetic precursor in the treatment of mitochondrial encephalopathies associated with CoQ deficiency but also for the therapeutic use of those compounds in more common neurodegenerative and metabolic diseases that occur with secondary CoQ deficiency.

Coenzyme Q10 modulates sulfide metabolism and links the mitochondrial respiratory chain to pathways associated to one carbon metabolism.
Abnormalities of one carbon, glutathione and sulfide metabolisms have recently emerged as novel pathomechanisms in diseases with mitochondrial dysfunction. However, the mechanisms underlying these abnormalities are not clear. Also, we recently showed that sulfide oxidation is impaired in Coenzyme Q10 (CoQ10) deficiency. This finding leads us to hypothesize that the therapeutic effects of CoQ10, frequently administered to patients with primary or secondary mitochondrial dysfunction, might be due to its function as cofactor for sulfide:quinone oxidoreductase (SQOR), the first enzyme in the sulfide oxidation pathway. Here, using biased and unbiased approaches, we show that supraphysiological levels of CoQ10 induces an increase in the expression of SQOR in skin fibroblasts from control subjects and patients with mutations in Complex I subunits genes or CoQ biosynthetic genes. This increase of SQOR induces the downregulation of the cystathionine β-synthase and cystathionine γ-lyase, two enzymes of the transsulfuration pathway, the subsequent downregulation of serine biosynthesis and the adaptation of other sulfide linked pathways, such as folate cycle, nucleotides metabolism and glutathione system. These metabolic changes are independent of the presence of sulfur aminoacids, are confirmed in mouse models, and are recapitulated by overexpression of SQOR, further proving that the metabolic effects of CoQ10 supplementation are mediated by the overexpression of SQOR. Our results contribute to a better understanding of how sulfide metabolism is integrated in one carbon metabolism and may explain some of the benefits of CoQ10 supplementation observed in mitochondrial diseases.

Animal Models of Coenzyme Q Deficiency: Mechanistic and Translational Learnings.
Coenzyme Q (CoQ) is a vital lipophilic molecule that is endogenously synthesized in the mitochondria of each cell. The CoQ biosynthetic pathway is complex and not completely characterized, and it involves at least thirteen catalytic and regulatory proteins. Once it is synthesized, CoQ exerts a wide variety of mitochondrial and extramitochondrial functions thank to its

redox capacity and its lipophilicity. Thus, low levels of CoQ cause diseases with heterogeneous clinical symptoms, which are not always understood. The decreased levels of CoQ may be primary caused by defects in the CoQ biosynthetic pathway or secondarily associated with other diseases. In both cases, the pathomechanisms are related to the CoQ functions, although further experimental evidence is required to establish this association. The conventional treatment for CoQ deficiencies is the high doses of oral CoQ supplementation, but this therapy is not effective for some specific clinical presentations, especially in those involving the nervous system. To better understand the CoQ biosynthetic pathway, the biological functions linked to CoQ and the pathomechanisms of CoQ deficiencies, and to improve the therapeutic outcomes of this syndrome, a variety of animal models have been generated and characterized in the last decade. In this review, we show all the animal models available, remarking on the most important outcomes that each model has provided. Finally, we also comment some gaps and future research directions related to CoQ metabolism and how the current and novel animal models may help in the development of future research studies.

β-RA Targets Mitochondrial Metabolism and Adipogenesis, Leading to Therapeutic Benefits against CoQ Deficiency and Age-Related Overweight.
Primary mitochondrial diseases are caused by mutations in mitochondrial or nuclear genes, leading to the abnormal function of specific mitochondrial pathways. Mitochondrial dysfunction is also a secondary event in more common pathophysiological conditions, such as obesity and metabolic syndrome. In both cases, the improvement and management of mitochondrial homeostasis remain challenging. Here, we show that beta-resorcylic acid (β-RA), which is a natural phenolic compound, competed in vivo with 4-hydroxybenzoic acid, which is the natural precursor of coenzyme Q biosynthesis. This led to a decrease in demethoxyubiquinone, which is an intermediate metabolite of CoQ biosynthesis that is abnormally accumulated in mice. As a consequence, β-RA rescued the phenotype of mice, which is a model of primary mitochondrial encephalopathy. Moreover, we observed that long-term treatment with β-RA also reduced the size and content of the white adipose tissue (WAT) that is normally accumulated during aging in wild-type mice, leading to the prevention of hepatic steatosis and an increase in survival at the elderly stage of life. The reduction in WAT content was due to a decrease in adipogenesis, an adaptation of the mitochondrial proteome in the kidneys, and stimulation of glycolysis and acetyl-CoA metabolism. Therefore, our results demonstrate that β-RA acted through different cellular mechanisms, with effects on mitochondrial metabolism; as such, it may be used for the treatment of primary coenzyme Q deficiency, overweight, and hepatic steatosis.

Metabolic Targets of Coenzyme Q10 in Mitochondria.
Coenzyme Q10 (CoQ) is classically viewed as an important endogenous antioxidant and key component of the mitochondrial respiratory chain. For this second function, CoQ molecules seem to be dynamically segmented in a pool attached and engulfed by the super-complexes I + III, and a free pool available for complex II or any other mitochondrial enzyme that uses CoQ as a cofactor. This CoQ-free pool is, therefore, used by enzymes that link the mitochondrial respiratory chain to other pathways, such as the pyrimidine de novo biosynthesis, fatty acid β-oxidation and amino acid catabolism, glycine metabolism, proline, glyoxylate and arginine metabolism, and sulfide oxidation metabolism. Some of these mitochondrial pathways are also connected to metabolic pathways in other compartments of the cell and, consequently, CoQ could indirectly modulate metabolic pathways located outside the mitochondria. Thus, we review the most relevant findings in all these metabolic functions of CoQ and their relations with the pathomechanisms of some metabolic diseases, highlighting some future perspectives and potential therapeutic implications.

The Paradox of Coenzyme Q in Aging.
Coenzyme Q (CoQ) is an essential endogenously synthesized molecule that links different metabolic pathways to mitochondrial energy production thanks to its location in the mitochondrial inner membrane and its redox capacity, which also provide it with the capability to work as an antioxidant. Although defects in CoQ biosynthesis in human and mouse models cause CoQ deficiency syndrome, some animals models with particular defects in the CoQ biosynthetic pathway have shown an increase in life span, a fact that has been attributed to the concept of mitohormesis. Paradoxically, CoQ levels decline in some tissues in human and rodents during aging and coenzyme Q (CoQ) supplementation has shown benefits as an anti-aging agent, especially under certain conditions associated with increased oxidative stress. Also, CoQ has shown therapeutic benefits in aging-related disorders, particularly in cardiovascular and metabolic diseases. Thus, we discuss the paradox of health benefits due to a defect in the CoQ biosynthetic pathway or exogenous supplementation of CoQ.

Rapamycin administration is not a valid therapeutic strategy for every case of mitochondrial disease.
The vast majority of mitochondrial disorders have limited the clinical management to palliative care. Rapamycin has emerged as a potential therapeutic drug for mitochondrial diseases since it has shown therapeutic benefits in a few mouse models of mitochondrial disorders. However, the underlying therapeutic mechanism is unclear, the minimal effective dose needs to be defined and whether this therapy can be generally used is unknown.

PATIENT-DERIVED IPSCS AND CORTICAL DIFFERENTIATION: A NOVEL MODEL FOR CEREBRAL METHYLMALONIC ACIDURIA

POSTER SESSION 02 - SECTION: NEW PERSPECTIVES IN NEURODEGENERATION

Matthew Denley, Sean Froese, Matthias Baumgartner
Division of Metabolism, University Children's Hospital Zurich, Zürich, Switzerland

Methylmalonic aciduria (MMA) is an autosomal recessive disorder commonly caused by deficiency of the enzyme methylmalonyl-CoA mutase (MMUT) or production of its vitamin B12 derived cofactor (adenosyl-cobalamin). Although MMA affects multiple organs through impaired anaplerosis and energetic depletion; the pathomechanisms causing cerebral symptoms, such as lesions to the globus pallidus and developmental delay remain unclear. Patient-derived iPSCs were generated from fibroblasts with non-incorporating Sendai-delivered Yamanaka factors. A dual-SMAD inhibition approach was used to generate neural stem cells (NSCs) and patterning towards dorsal telencephalon was achieved with N2-B27 medium. We demonstrate that control and patient iPSCs progressively adopt PAX6, EOMES, TBR1 and NeuN. However, patient-derived neurons adopt excitatory markers (EOMES) at an accelerated rate. Throughout, we characterised the cellular location of MMUT. We identify heterogeneous populations of patient mitochondria, those with localized and with mis-localized MMUT. Mis-localisation of MMUT is associated to decreased mitochondrial membrane potential (assessed through TMRM) and increased mitochondrial superoxide production (assessed through mitoSOX). In neurons we demonstrate increased autophagy in patient cells using p62 and LC3-I/II. In NSCs, we identified the opposite effect - decreased autophagy. Whilst Caspase-3 was elevated in all time-points of patient cells, the relative increase in NSCs was more pronounced. In this project we have generated and characterised the first physiologically relevant, human neuronal model for MMA. Additionally, we can demonstrate a mitochondrial phenotype that may be associated with MMUT mis-localisation, as well as impaired autophagy and apoptosis.

Estradiol and the Development of the Cerebral Cortex: An Unexpected Role?
The cerebral cortex undergoes rapid folding in an "inside-outside" manner during embryonic development resulting in the establishment of six discrete cortical layers. This unique cytoarchitecture occurs via the coordinated processes of neurogenesis and cell migration. In addition, these processes are fine-tuned by a number of extracellular cues, which exert their effects by regulating intracellular signaling pathways. Interestingly, multiple brain regions have been shown to develop in a sexually dimorphic manner. In many cases, estrogens have been demonstrated to play an integral role in mediating these sexual dimorphisms in both males and females. Indeed, 17β-estradiol, the main biologically active estrogen, plays a critical organizational role during early brain development and has been shown to be pivotal in the sexually dimorphic development and regulation of the neural circuitry underlying sex-typical and socio-aggressive behaviors in males and females. However, whether and how estrogens, and 17β-estradiol in particular, regulate the development of the cerebral cortex is less well understood. In this review, we outline the evidence that estrogens are not only present but are engaged and regulate molecular machinery required for the fine-tuning of processes central to the cortex. We discuss how estrogens are thought to regulate the function of key molecular players and signaling pathways involved in corticogenesis, and where possible, highlight if these processes are sexually dimorphic. Collectively, we hope this review highlights the need to consider how estrogens may influence the development of brain regions directly involved in the sex-typical and socio-aggressive behaviors as well as development of sexually dimorphic regions such as the cerebral cortex.

Brain-synthesized oestrogens regulate cortical migration in a sexually divergent manner.
Oestrogens play an important role in brain development where they have been implicated in controlling various cellular processes. Several lines of evidence have been presented showing that oestrogens can be synthesized locally within the brain. Studies have demonstrated that aromatase, the enzyme responsible for the conversion of androgens to oestrogens, is expressed during early development in both male and female cortices. Furthermore, 17β-oestradiol has been measured in

foetal brain tissue from multiple species. 17β-oestradiol regulates neural progenitor proliferation as well as the development of early neuronal morphology. However, what role locally derived oestrogens play in regulating cortical migration and, moreover, whether these effects are the same in males and females are unknown. Here, we investigated the impact of knockdown expression of Cyp19a1, which encodes aromatase, between embryonic day (E) 14.5 and postnatal day 0 (P0) had on neural migration within the cortex. Aromatase was expressed in the developing cortex of both sexes, but at significantly higher levels in male than female mice. Under basal conditions, no obvious differences in cortical migration between male and female mice were observed. However, knockdown of Cyp19a1 resulted in an increase in cells within the cortical plate, and a concurrent decrease in the subventricular zone/ventricular zone in P0 male mice. Interestingly, the opposite effect was observed in females, who displayed a significant reduction in cells migrating to the cortical plate. Together, these findings indicate that brain-derived oestrogens regulate radial migration through distinct mechanisms in males and females.

Mitochondrial disease, mitophagy, and cellular distress in methylmalonic acidemia.
Mitochondria-the intracellular powerhouse in which nutrients are converted into energy in the form of ATP or heat-are highly dynamic, double-membraned organelles that harness a plethora of cellular functions that sustain energy metabolism and homeostasis. Exciting new discoveries now indicate that the maintenance of this ever changing and functionally pleiotropic organelle is particularly relevant in terminally differentiated cells that are highly dependent on aerobic metabolism. Given the central role in maintaining metabolic and physiological homeostasis, dysregulation of the mitochondrial network might therefore confer a potentially devastating vulnerability to high-energy requiring cell types, contributing to a broad variety of hereditary and acquired diseases. In this Review, we highlight the biological functions of mitochondria-localized enzymes from the perspective of understanding-and potentially reversing-the pathophysiology of inherited disorders affecting the homeostasis of the mitochondrial network and cellular metabolism. Using methylmalonic acidemia as a paradigm of complex mitochondrial dysfunction, we discuss how mitochondrial directed-signaling circuitries govern the homeostasis and physiology of specialized cell types and how these may be disturbed in disease. This Review also provides a critical analysis of affected tissues, potential molecular mechanisms, and novel cellular and animal models of methylmalonic acidemia which are being used to develop new therapeutic options for this disease. These insights might ultimately lead to new therapeutics, not only for methylmalonic acidemia, but also for other currently intractable mitochondrial diseases, potentially transforming our ability to regulate homeostasis and health.

Major depressive disorder (MDD) is a leading cause of disability. Although the precise pathomechanisms underlying MDD development are still not completely understood, mitochondria and energy metabolism have been increasingly considered to be involved in the pathomechanisms of depression. Cells from a cohort of MDD patients and non-depressed controls were previously analyzed and provide a data pool, which we now use as a reference to conduct case studies. Our purpose is to confront unique patients to our reference cohort, and unravel their specificities. The case study consists of a patient diagnosed with a mitochondriopathy, but whose precise pathology is still unclear, and of an anti-depressant (AD) resistant patient. We investigated cellular and mitochondrial functions in the peripheral, neural and neuronal lineage. In those different cell types, bioenergetic functions and Ca^{2+} homeostasis were assessed. In addition, mitochondrial content and cell size were evaluated. iNeurons were analyzed by whole-cell voltage- and current-clamp recording. In the AD-resistant patient, we found hyperactive oxidative phosphorylation and increased oxidative stress. iNeurons showed a more negative resting membrane potential (RMP). In the mitochondriopathy patient, we observed generally impaired bioenergetics functions and higher RMP in iNeurons. Interestingly, in both patients and across all cell types, as well as in the full cohort, patients cells were significantly smaller. Our findings reveal an interesting physiology in both case study patients, which is also consistent across reprogramming and further neural and neuronal differentiation. The case studies offer a singular perspective on MDD and mitochondrial dysfunctions, and how they relate to each other.

BRAIN PENETRATION OF CAMELID SINGLE-DOMAIN ANTIBODIES (VHH) : A PRIVILEGE OR A MORE COMMON TRAIT ?

POSTER SESSION 02 - SECTION: NEW PERSPECTIVES IN NEURODEGENERATION

Mireille Tsitokana, Philippe Rondard, Jean-Philippe Pin, Laurent Prezeau
Université de Montpellier, Institut De Génomique Fonctionnelle, Montpellier, France

Monoclonal antibodies have been increasingly used over the last decades in several pathologies such as inflammation and cancers. However, their use for the treatment of neurological and neurodegenerative diseases is not common yet. Their delivery into the brain parenchyma is challenging because of the blood-brain barrier (BBB). It makes the development of immunotherapy for brain diseases difficult. In the past few years, camelid single-domain antibodies (also known as Nanobody® or VHH) have gained interest in the biomedical field. Their small size (15kDa), conformational specificity, easy engineering, low immunogenicity and low cost production make them a good alternative to conventional antibodies. Besides, some VHHs have been reported to naturally cross the BBB (Wouters J. et al., 2020 ; Ruiz-Lopez E. and Schumacher A. J., 2021, ; Pothin E. et al., 2020). The present work describes the discovery of the first brain-penetrating VHHs specific to one metabotropic receptor subtype. An approach based on immunohistochemistry showed labelling in brain parenchyma after their peripheral administration in wild-type mice. Our results suggest that such VHH may be of interest for therapeutic intervention into the brain.

INCREASED EEG ALPHA POWER IS ASSOCIATED WITH HIGHER VITAMIN D3 AND LOWER IL-8 LEVELS IN BORNA-POSITIVE DEPRESSED PATIENTS

POSTER SESSION 02 - SECTION: NEW PERSPECTIVES IN NEURODEGENERATION

Anna Josefine Torner[1], Detlef E. Dietrich[2,3], Bernhard T. Baune[4,5,6], Kristian Folta-Schoofs[1]
[1]University of Hildesheim, Institute For Psychology, Hildesheim, Germany, [2]AMEOS Clinical Center Hildesheim, Department Of Psychiatry And Psychotherapy, Hildesheim, Germany, [3]Center for Systems Neuroscience Hannover, Hannover Medical School, Hannover, Germany, [4]University of Münster, Department Of Psychiatry, Münster, Germany, [5]Melbourne Medical School, The University of Melbourne, Department Of Psychiatry, Melbourne, Australia, [6]The University of Melbourne, The Florey Institute Of Neuroscience And Mental Health, Parkville, Australia

Borna Disease Virus (BDV) is a neurotropic, negative single-stranded RNA virus that induces inflammation in olfactory and limbic structures within a broad range of warm-blooded animals. Yet, there is no conclusive evidence that BDV is infecting man nor that it might constitute a co-factor in the etiology of human psychiatric disorders, although increases in BDV-specific RNA and BDV antibodies were observed in the blood of patients suffering from Major Depressive Disorder (MDD). Some studies indicate that human reactive antibodies exhibit low avidity for BDV antigens, offering the possibility that they might have been produced by exposure to a related cellular immunogen, which is up-regulated in MDD. The aim of the present study was to examine possible associations between MDD patient´s BDV-status (positive vs. negative), vitamin D3 level, plasma level of proinflammatory Interleukin 8 (IL-8), and resting-state EEG activity. We demonstrated a higher fronto-central EEG alpha power and lower IL-8 level in BDV-positive compared to BDV-negative patients. Both groups do not differ in their severity of depression. In BDV-positive patients a negative correlation between concentrations of proinflammatory IL-8 and anti-inflammatory vitamin D3 was observed. Thus, lower IL-8 levels are accompanied by high concentrations of vitamin D3. To summarize, our results suggest that MDD patients show BDV-dependent alterations in their immune and neural system. We suggest that in BDV-positive MDD patients, high levels of vitamin D3 serve to protect from a long-lasting overreaction of the immune system by inhibition of the NF-κB signaling pathway, which is responsible for an up-regulation of IL-8.

NR2F1 HAPLOINSUFFICIENCY ALTERS THE MORPHOLOGY OF ADULT-BORN NEURONS IN THE HIPPOCAMPUS OF A MOUSE MODEL OF THE NEURODEVELOPMENTAL DISORDER BBSOAS

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Eleonora Dallorto[1,2], Sara Bonzano[1,2], Alessia Pattaro[1,2], Michèle Studer[3], Silvia De Marchis[1,2]
[1]University of Turin, Department Of Life Sciences And Systems Biology (dbios), Torino, Italy, [2]University of Turin, Neuroscience Institute Cavalieri Ottolenghi (nico), Orbassano (TO), Italy, [3]Institute of Biology Valrose, iBV, Cnrs 7277-Inserm 1091, Nice, France

Intellectual disability (ID) is a neurodevelopmental pathological condition characterised by limitations in intellectual functioning and adaptive behaviour. Although the causes are highly heterogeneous, genetic factors take a large part in the etiology of ID. The Bosch-Boonstra-Schaaf optic atrophy-intellectual syndrome (BBSOAS; OMIN#615722), is a rare disorder caused by mutations in the NR2F1 gene, characterized by ID associated to global developmental delay, optic nerve atrophy, hypotonia, seizure and autistic traits. The transcriptional regulator Nr2f1 (i.e., COUP-TFI) is a key player in multiple cellular processes during brain development. Interestingly, alterations in postnatal hippocampal neurogenesis have been reported in animal models of ID and recent findings suggest that a deficit in hippocampal plasticity may contribute to BBSOAS. Here, to investigate the possible effects of Nr2f1 haploinsufficiency on the hippocampal circuit we took advantage of a recently validated BBSOAS mouse model (i.e., constitutive Nr2f1-heterozygous mice) and focussed on the adult hippocampal dentate gyrus (DG). Although, no differences were found in the density of newly generated doublecortin (DCX)-positive immature neurons, data from 3D morphometric reconstruction strongly suggests that Nr2f1 haploinsufficiency influences dendritic architecture and proper development of adult-born DG neurons, leading to the appearance of atypical and peculiar neuronal morphologies that are usually associated with pathological conditions and aberrant hippocampal circuitry rearrangements. Interestingly, preliminary data on the expression of the neuronal activity-dependent gene Npas4 started to depict altered recruitment of neuronal ensemble in the DG of Nr2f1-heterozygous mice. Ongoing and future investigations are aimed at elucidating the mechanisms underlying of the observed defects.

Neurodevelopmental disorders affect 2-5% of children at birth. Most have a genetic origin and are caused by *de novo* mutations affecting a restricted number of genes. We studied the functional consequences of mutations affecting the presynaptic protein Munc18-1 (encoded by *STXBP1*) because of its high prevalence in intellectual disabilities (ID), epilepsy, autism, and movement disorders. Munc18-1 chaperones the formation of the SNARE-complex, which is necessary to fuse synaptic vesicles. Most currently studied human disease mutations result in an unstable protein and in haploinsufficiency. Therefore, the disease can be modeled in mice by disrupting one of the two alleles (*STXBP1* heterozygotes). *STXBP1*$^{+/-}$ mice show cortical hyperexcitability and intermittent epilepsy, but the underlying synaptic deficits are not understood, since Munc18-1 is essential for both excitatory and inhibitory synapses and haploinsufficiency is, in principle, expected to affect both equally. We investigated the underlying synaptic deficits by simultaneously recording the activity of parvalbumin (PV) expressing interneurons and connected pyramidal cells. Our results demonstrate that inhibition is deficient in feedforward inhibition microcircuits in the neocortex of *STXBP1*$^{+/-}$ animals. Surprisingly, we found that inhibitory synapses are almost unaffected by the mutation. Instead, the deficit in inhibition is caused by the inability of excitatory synapses to recruit PV interneurons, which results in a lack of feedforward inhibition leading to the hyperexcitability of principal cells. The data show that deficits in excitatory synapses are the main explanation for cortical hyperexcitability in mouse models for STXBP1 syndrome, which may shift the focus of therapy design for human patients.

ANALYSIS OF THE SYNAPTIC CONTRIBUTION OF THE DPYSL5 GENE INVOLVED IN NEURODEVELOPMENTAL DISORDERS

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Florence Desprez[1], Sylviane Marouillat[1], Devina Ung[1], Roger Besançon[2], Jérôme Honnorat[2], Frederic Laumonnier[1,3]
[1]iBrain UMR1253, Inserm, University Of Tours, Tours, France, [2]Institut Neuromyogène (INMG), Inserm U1314 - CNRS UMR 5284, University Claude Bernard, Lyon, France, [3]Service de Génétique, Centre Hospitalier Régional Universitaire, Tours, France

The *DPYSL5* (Dihydropyrimidinase like 5) gene encodes a cytosolic protein strongly expressed in the developing brain and which plays a role in neuronal migration, axonal guidance and neuritic growth. We recently described missense mutations (p.E41K, recurrent ; p.G47R) in nine individuals presenting intellectual disability and brain malformations (agenesis of corpus callosum, cerebellar hypoplasia), causing abnormal dendritic development and impaired interaction with the cytoskeleton. Interestingly, various studies showed the presence of DPYSL5 in synaptic fractions, suggesting a role in the mature neuron. Here, our main objective was to clarify the physiological and pathological role of DPYSL5 at the synapse. We studied primary cultures of mouse hippocampal neurons transfected with normal (WT) and mutated variants of DPYSL5-GFP to evaluate their impact on synapse development and maturation. In parallel, we analyzed brains lysates from adult mouse models (*Dpysl5*$^{-/-}$, *Dpysl5*$^{+/-}$) to assess the consequences of *Dpysl5* inactivation on the expression of synaptic proteins. We found that the overexpression of both WT and mutated forms of DPYSL5 increased the synaptic density in vitro. However, while WT DPYSL5-GFP caused an increased number of mature spines when compared to GFP neurons, this effect was absent for both variants (i.e. similar to GFP neurons). Our study also revealed a significant alteration of the expression of excitatory synaptic protein (PSD95, vGLUT1) in *Dpysl5*$^{-/-}$ mice compared to WT mice. Taken together, these results suggest an involvement of DPYSL5 in synapse formation and maturation of excitatory neuronal networks, and they further highlight the contribution of glutamatergic synapse dysfunction in neurodevelopmental disorders.

CONTRIBUTION OF THE ADIPOCYTE HORMONE LEPTIN IN THE PATHOGENESIS OF RETT SYNDROME

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Yasmine Belaidouni[1], Diabé Diabira[1], Jean-Charles Graziano[1], Clément Menuet[1], Gary A. Wayman[2], Jean-Luc Gaïarsa[1]
[1]INMED, Inserm U1249, Marseille, France, [2]Program in Neuroscience, Integrative Physiology & Neuroscience, Washington, United States of America

Rett syndrome (RTT) is an X-linked neurodevelopmental disorder characterized by a loss of acquired speech, hand stereotypies, gait abnormalities, breathing difficulties and seizures appearing after an apparently normal postnatal development. This syndrome is caused by mutations in the X-linked chromosome gene *Methyl-CpG-binding protein 2* (*MECP2*) encoding a transcriptional regulator. Currently there are no cures for this disease. In spite of different causative mutated gene and biological pathways affected, epidemiological and animal studies revealed abnormally elevated circulating levels of the adipocyte hormone leptin in patients with RTT and *Mecp2*-deficient mice. Besides its canonical role in the control of satiety and energy expenditure, leptin acts on many brain areas modulating cognitive functions, anxiety, breathing and more. Consequently, altered leptin levels may contribute to the RTT-associated neuronal network dysfunctions. In the present study, we show that serum leptin levels are elevated in early (postnatal day (P) 30) and late symptomatic (P60) male *Mecp2-null* mice. We also show that daily subcutaneous injections of a validated leptin antagonist (Peg-SMLA, a competitive inhibitor of leptin BBB transport), during 10 days from P40, prevent the body weight loss, restore the hippocampal excitatory/inhibitory (E/I) balance, slows down the progression of breathing dysfunctions in the symptomatic male *Mecp2-null* mice. Conversely, leptin-treatment of wild type mice mimics some of the phenotypic manifestations observed in *Mecp2-null* mice, i.e. increased hippocampal E/I balance and increased number of apneas. These data provide further insights on the possible contribution of leptin in RTT pathogenesis and offer therapeutic perspective to alleviate RTT symptoms.

MULTI-SCALE ANALYSIS OF A NOVEL KNOCK-IN MOUSE MODEL REVEALS NEW PATHOGENIC MECHANISMS UNDERLYING SEVERE PAK3-LINKED NEURODEVELOPMENTAL DISORDERS.

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Manon Dobrigna[1], Kevin Duarte[1], Sandrone Poëa-Guyon[1], Véronique Rousseau[1], Laurine Gonzalez[2], Cyrille Vaillend[2], Glenn Dallérac[3], Roseline Poirier[2], Jean-Vianney Barnier[1]
[1]CNRS, Neuropsi, Saclay, France, [2]Paris-Saclay institute of neurosciences, Cognitive & Network Neuroscience, Saclay, France, [3]Paris-Saclay Institute for Neurosciences, CNRS UMR 9197, Astrocytes & Cognition, Saclay, France

The aetiology of neurodevelopmental diseases is complex, involving environmental and genetic factors: numerous genes were identified in several pathologies such as intellectual disability (ID) and autism spectrum disorder (ASD). *PAK3*, one of the first genes identified in X-linked ID, is involved in brain development and plasticity. Mutations in the *PAK3* gene are responsible for a large clinical spectrum, including ID, ASD, microcephaly or macrocephaly, epilepsy, and other neuropsychiatric symptoms. The pathogenic mechanisms underlying these symptoms are not well-known. Consequently, uncovering the precise genotype/phenotype correlation associated with *PAK3* mutations is challenging. We are deciphering the biochemical properties of PAK3 variants using *in-vitro* analyses of a broad mutation collection responsible for ID of varying severity. Our results helped us hypothesise that the biochemical anomalies of PAK3 variants affecting protein expression and stability, kinase activity, and protein-protein interactions are at the core of *PAK3* mutation pathogenicity. To go further, we generated a knock-in mouse expressing the *PAK3*-G424R mutation responsible for a severe clinical case. The *PAK3*-G424R mouse presents hyperactivity, stereotypies, microcephaly and cognitive defects, reminiscent of the patient's clinical data, confirming the relevance of this new model. Our results helped us put forward a new molecular pathogenic mechanism that could be at the root of the behavioural symptoms, electrophysiological dysfunctions and developmental defects observed in severe disease cases. Advances in our understanding of the pathophysiology of *PAK3*-linked disorders will pave the way for substantial advances in personalised treatment. CHARACTERIZATION OF DE NOVO GABAB2 VARIANTS LINKED TO RETT SYNDROME AND ENCEPHALOPATHIC EPILEPSY

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Diego Fernandez-Fernandez[1], Michal Stawarski[1], Murim Choi[2], Martin Gassmann[1], Bernhard Bettler[1]

Dysfunction of $GABA_B$ receptor (GBR) signaling has long been associated with neurological and psychiatric conditions, including epilepsy, spasticity, chronic pain, depression and schizophrenia. Recently, several *de novo* monoallelic variants have been identified in the $GABA_{B2}$ transmembrane domain 3 (TM3) of Rett Syndrome (RTT/A567T) and TM6 of Epileptic Encephalopathy (EE1/S695I, EE2/I705N) patients. In biochemical assays with heterologous cells, GABA exhibited decreased efficacy at the variant receptors (Yoo et al., 2017), presumably relating to increased constitutive receptor activity (Vuillaume et al., 2018). Using electrophysiology with transfected HEK293 cells, we now confirm increased constitutive activity of the variant receptors, which in turn causes an increase in tonic activity of Kir3-type effector potassium channels. Mutant receptors expressed in HEK293 cells also showed decreased responses to saturating concentrations of GABA. Patients carrying these mutations suffer from epileptic seizures and intellectual disability. To study the synaptic effects of a $GABA_{B2}$ variant in the brain, we developed a mouse line carrying the amino acid substitution corresponding to the human EE2 variant in the mouse gene (EE2/I704N). We have started to analyze these mice for electrophysiological phenotypes. Preliminary data indicate that the induction of LTP in hippocampal slices of EE2/I704N mice is compromised. We will provide an update on the characterization of homozygous and heterozygous EE2/I704N mice. References: Vuillaume et al. IDENTIFYING NEW MOLECULES TARGETING BKCA CHANNELS FOR THE TREATMENT OF AUDITORY IMPAIRMENTS IN TWO MOUSE MODELS OF NEURODEVELOPMENTAL DISORDERS

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Celeste Ferraguto[1], Thibault Peineau[2], Yohan Bouleau[2], Didier Dulon[2], Susanna Pietropaolo[1]

Auditory impairments, such as hearing loss and hyperacusis (i.e. increased perception of sounds), affect a large part of the human population with a dramatic impact on life quality. These auditory dysfunctions are commonly described in patients with neurodevelopmental disorders (NDDs) and often exacerbate the communication and social deficits typical of these conditions. In subjects with two major NDDs characterized by auditory abnormalities – namely, Fragile X syndrome (FXS) and Williams-Beuren syndrome (WBS) - a reduction in the expression and functionality of a specific population of ion channels, the Big conductance calcium-activated potassium (BK_{Ca}) channels, has been reported. This reduction could be linked to the hearing disorders manifested by these patients. Indeed, BK_{Ca} channels are highly expressed in the auditory pathway and play a key role in regulating the membrane potential of cochlear hair cells as well as neurons. BK_{Ca} channels are therefore potential major therapeutic candidates for auditory impairments in the context of NDDs. Here we tested the effects of a BK_{Ca} channel opener molecule (Chlorzoxazone) on the abnormal auditory phenotypes of two mouse models of FXS and WBS, i.e., respectively the Fmr1-KO and CD mouse lines. To this end, we combined acute injections of Chlorzoxazone with behavioural, electrophysiological and molecular analyses, in order to elucidate the role of these ion channels in the etiopathology of acoustic dysfunction. Our results clearly demonstrate that acting on BK_{Ca} channels is a valuable therapeutic strategy to treat acoustic dysfunction in these NDDs.

The monocarboxylate transporter 8 (MCT8) transports thyroid hormones across brain barriers. Inactivating mutations in the gene encoding for MCT8 (*SLC16A2)* results in MCT8 deficiency also known as Allan-Herndon-Dudley syndrome (AHDS). AHDS is an important cause of X-linked intellectual and motor disability. While thyroid hormone analogues improve peripheral changes of MCT8 deficiency, no treatment of the neurological symptoms is available so far. Therefore, we developed a gene replacement therapy in *Mct8*- and *Oatp1c1*-deficient mice, a well-established animal model for AHDS. In our study we show that targeting brain endothelial cells by intravenous injection of AAV-BR1-*Mct8* in neonatal mice increased the T3 levels in the brain and ameliorated morphological and functional parameters associated with the disease. This gene replacement therapy also resulted in long-lasting improvement in motor coordination. Together, our results support the concept that MCT8 mediates the transport of thyroid hormones into the brain and indicates that a readily accessible vascular target can help overcome the consequences of the severe disability associated with MCT8 deficiency.

Down syndrome (DS) is a genetic disease characterized by a supernumerary chromosome 21. Intellectual deficiency (ID) is one of the most prominent features of DS. Central nervous system defects lead to learning disabilities, motor and language delays and memory impairments. Previous studies showed a decrease in neurogenesis and proliferation, an increase of neuron apoptosis and astrogliogenesis, deregulations related to chronic neuroinflammation. So far, there is no prenatal treatment that is targeting the ID in DS. A natural treatment, based on the administration of a small molecule, has showed some neuroprotective effects such as decreased apoptosis with anti-inflammatory properties. We therefore evaluated the administration of this treatment during the gestation in a mouse model, the Dp1(16)Yey mice, that carry a duplication of a relevant orthologous region of the human chromosome 21 (HSA21). The effect of the treatment on mice brain is studied at a juvenile stage and adult stage by molecular and histological analysis and behavioral tests. Our results at postnatal day 11 (P11) show beneficial effects on microglia and astrocytes markers as well on a marker of HSA21, the Dual Specificity Tyrosine Phosphorylation Regulated Kinase 1A (DYRK1A) which is overexpressed and contributes to the specific cognitive defects in DS. Taken together, our results show that this treatment could represent a clinical candidate for cognitive deficits in DS patients and an alternative for parents to decide the fate of the pregnancy of a fetus with a DS.

ELECTROPHYSIOLOGICAL CHARACTERISTICS OF HUMAN INDUCED PLURIPOTENT STEM CELL-DERIVED NEURONS WITH CACNA1A VARIANTS

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Marina Hommersom[1], Bart Van De Warrenburg[2], Nael Nadif Kasri[1], Hans Van Bokhoven[1]

Episodic ataxia type 2 (EA2) is an autosomal dominant disorder in which patients experience recurrent episodes, characterized by ataxia, slurred speech, interictal nystagmus and vertigo. Also, chronic progressive ataxia can manifest in patients, both with and without previous episodic ataxia, carrying these variants. EA2 is caused by loss-of-function variants in *CACNA1A*, encoding the pore-forming α1 subunit ($Ca_V2.1$) of the P/Q-type voltage-gated calcium channel. $Ca_V2.1$ is widely expressed in the central nervous system, and one of its most important functions is the coupling of Ca^{2+} influx to neurotransmitter release in presynaptic terminals. As this channel has never been investigated in a human model, we aimed to study the electrophysiological phenotype of human induced pluripotent stem cell (hiPSC)-derived neurons with *CACNA1A* variants. We have derived hiPSCs from three ataxia patients with heterozygous loss-of-function variants in *CACNA1A*, and edited the *CACNA1A* gene by CRISPR/Cas9 in one control and one patient cell line to form isogenic pairs. These hiPSCs were differentiated to neurons and recorded on micro electrode arrays (MEAs). Upon development of an *in vitro* neuronal network, patient and control lines showed a regular pattern of network bursts and no distinct electrophysiological phenotype of the patient neurons was detected. However, when synaptic plasticity was induced, neurons with complete *CACNA1A* loss-of-function, showed a distinct MEA pattern. Our data show that basal neuronal network activity is not affected by loss-of-function of *CACNA1A*, but that a phenotype can be induced by triggering the network. This MEA phenotype offers opportunities for diagnostic pipelines and drug screens in *CACNA1A*.

The complexities of CACNA1A in clinical neurogenetics.
Variants in CACNA1A are classically related to episodic ataxia type 2, familial hemiplegic migraine type 1, and spinocerebellar ataxia type 6. Over the years, CACNA1A has been associated with a broader spectrum of phenotypes. Targeted analysis and unbiased sequencing of CACNA1A result not only in clear molecular diagnoses, but also in large numbers of variants of uncertain significance (VUS), or likely pathogenic variants with a phenotype that does not directly match the CACNA1A spectrum. Over the last years, targeted and clinical exome sequencing in our center has identified 41 CACNA1A variants. Ultimately, variants were considered pathogenic or likely pathogenic in 23 cases, with most phenotypes ranging from episodic or progressive ataxia to more complex ataxia syndromes, as well as intellectual disability and epilepsy. In two cases, the causality of the variant was discarded based on non-segregation or an alternative diagnosis. In the remaining 16 cases, the variant was classified as uncertain, due to lack of opportunities for segregation analysis or uncertain association with a non-classic phenotype. Phenotypic variability and the large number of VUS make CACNA1A a challenging gene for neurogenetic diagnostics. Accessible functional read-outs are clearly needed, especially in cases with a non-classic phenotype.

Imbalanced autophagy causes synaptic deficits in a human model for neurodevelopmental disorders.
Macroautophagy (hereafter referred to as autophagy) is a finely tuned process of programmed degradation and recycling of proteins and cellular components, which is crucial in neuronal function and synaptic integrity. Mounting evidence implicates chromatin remodeling in fine-tuning autophagy pathways. However, this epigenetic regulation is poorly understood in neurons. Here, we investigate the role in autophagy of KANSL1, a member of the nonspecific lethal complex, which

acetylates histone H4 on lysine 16 (H4K16ac) to facilitate transcriptional activation. Loss-of-function of KANSL1 is strongly associated with the neurodevelopmental disorder Koolen-de Vries Syndrome (KdVS). Starting from KANSL1-deficient human induced-pluripotent stem cells, both from KdVS patients and genome-edited lines, we identified SOD1 (superoxide dismutase 1), an antioxidant enzyme, to be significantly decreased, leading to a subsequent increase in oxidative stress and autophagosome accumulation. In KANSL1-deficient neurons, autophagosome accumulation at excitatory synapses resulted in reduced synaptic density, reduced GRIA/AMPA receptor-mediated transmission and impaired neuronal network activity. Furthermore, we found that increased oxidative stress-mediated autophagosome accumulation leads to increased MTOR activation and decreased lysosome function, further preventing the clearing of autophagosomes. Finally, by pharmacologically reducing oxidative stress, we could rescue the aberrant autophagosome formation as well as synaptic and neuronal network activity in KANSL1-deficient neurons. Our findings thus point toward an important relation between oxidative stress-induced autophagy and synapse function, and demonstrate the importance of H4K16ac-mediated changes in chromatin structure to balance reactive oxygen species- and MTOR-dependent autophagy.: APO: apocynin; ATG: autophagy related; BAF: bafilomycin A; BSO: buthionine sulfoximine; CV: coefficient of variation; DIV: days in vitro; H4K16ac: histone 4 lysine 16 acetylation; iPSC: induced-pluripotent stem cell; KANSL1: KAT8 regulatory NSL complex subunit 1; KdVS: Koolen-de Vries Syndrome; LAMP1: lysosomal associated membrane protein 1; MAP1LC3/LC3: microtubule associated protein 1 light chain 3; MEA: micro-electrode array; MTOR: mechanistic target of rapamycin kinase; NSL complex: nonspecific lethal complex; 8-oxo-dG: 8-hydroxydesoxyguanosine; RAP: rapamycin; ROS: reactive oxygen species; sEPSCs: spontaneous excitatory postsynaptic currents; SOD1: superoxide dismutase 1; SQSTM1/p62: sequestosome 1; SYN: synapsin; WRT: wortmannin.

Bi-allelic variants in the ER quality-control mannosidase gene EDEM3 cause a congenital disorder of glycosylation.
EDEM3 encodes a protein that converts ManGlcNAc isomer B to ManGlcNAc. It is involved in the endoplasmic reticulum-associated degradation pathway, responsible for the recognition of misfolded proteins that will be targeted and translocated to the cytosol and degraded by the proteasome. In this study, through a combination of exome sequencing and gene matching, we have identified seven independent families with 11 individuals with bi-allelic protein-truncating variants and one individual with a compound heterozygous missense variant in EDEM3. The affected individuals present with an inherited congenital disorder of glycosylation (CDG) consisting of neurodevelopmental delay and variable facial dysmorphisms. Experiments in human fibroblast cell lines, human plasma, and mouse plasma and brain tissue demonstrated decreased trimming of ManGlcNAc isomer B to ManGlcNAc, consistent with loss of EDEM3 enzymatic activity. In human cells, ManGlcNAc to ManGlcNAc conversion is also diminished with an increase of GlcManGlcNAc. Furthermore, analysis of the unfolded protein response showed a reduced increase in EIF2AK3 (PERK) expression upon stimulation with tunicamycin as compared to controls, suggesting an impaired unfolded protein response. The aberrant plasma N-glycan profile provides a quick, clinically available test for validating variants of uncertain significance that may be identified by molecular genetic testing. We propose to call this deficiency EDEM3-CDG.

Human Induced Pluripotent Stem Cell-Based Modelling of Spinocerebellar Ataxias.
Dominant spinocerebellar ataxias (SCAs) constitute a large group of phenotypically and genetically heterogeneous disorders that mainly present with dysfunction of the cerebellum as their main hallmark. Although animal and cell models have been highly instrumental for our current insight into the underlying disease mechanisms of these neurodegenerative disorders, they do not offer the full human genetic and physiological context. The advent of human induced pluripotent stem cells (hiPSCs) and protocols to differentiate these into essentially every cell type allows us to closely model SCAs in a human context. In this review, we systematically summarize recent findings from studies using hiPSC-based modelling of SCAs, and discuss what knowledge has been gained from these studies. We conclude that hiPSC-based models are a powerful tool for modelling SCAs as they contributed to new mechanistic insights and have the potential to serve the development of genetic therapies. However, the use of standardized methods and multiple clones of isogenic lines are essential to increase validity and reproducibility of the insights gained.

Mutations in *Ankyrin 2* (*ANK2*), previously known to cause cardiac arrythmia, may also cause epilepsy. In this study we delineate epilepsy phenotypes in patients with pathogenic variants in *ANK2*, and explore the effects on neuronal network dynamics and homeostatic plasticity in human neurons to explain the pathophysiological mechanism of epilepsy in these patients. We collected clinical data of twelve patients with heterozygous *de novo* loss-of-function (LoF) variants in *ANK2*. In addition, we generated a heterozygous LoF allele of *ANK2*using CRISPR/Cas9 in human induced pluripotent stem cells (hiPSCs). hiPSCs were differentiated towards excitatory neurons of which we characterized axon initial segment (AIS) structure and plasticity, somatodendritic morphology, and measured spontaneous electrophysiological responses using micro-electrode arrays (MEAs). We found epilepsy in seven of twelve (58%) of patients, all with early onset and variable severity of epilepsy. Autism spectrum disorder and intellectual disability were also frequently reported. Using MEAs, we found that hiPSCs-derived neurons with heterozygous LoF of *ANK2* show a hyperactive and desynchronized neuronal network. *ANK2* deficient neurons also showed altered AIS structure and plasticity of which is impaired upon activity-dependent modulation. The altered AIS structure may contribute to the observed increased neuronal network excitability. In conclusion, early onset epilepsy with variable severity is an important phenotype of *ANK2* LoF variants. Functional *in vitro* data of *ANK2*-deficient human neurons show a specific neuronal phenotype in which reduced ANKB disrupts AIS structure and thereby impairs activity-dependent plasticity of the AIS, resulting in increased neuronal excitability.

A REPROGRAMMING-BASED STRATEGY FOR DRUG REPOSITIONING IN MITOCHONDRIAL DNA-ASSOCIATED LEIGH SYNDROME

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Jesper Bergmans[1], Nael Nadif Kasri[2], Werner Koopman[1], Merel Adjobo-Hermans[3]
[1]Radboud University Medical Center, Pediatrics, Nijmegen, Netherlands, [2]Donders Institute for Brain, Cognition and Behavior, Radboud University Medical Center, Human Genetics, Nijmegen, Netherlands, [3]Radboud University Medical Center, Biochemistry, Nijmegen, Netherlands

Mitochondrial DNA (mtDNA)-associated Leigh syndrome (MILS) is an untreatable brain disease affecting 1/100,000 newborns. MILS is typically caused by mtDNA mutations in the *MT-ATP6* gene encoding the a-subunit of ATP-synthase, a vital part of the mitochondrial oxidative phosphorylation system. Drug discovery is particularly challenging for MILS. The limited access to patient neural tissue and the challenges in mtDNA engineering hinder the development of the cellular and animal models needed for intervention development. Here we will show our consortium's reprogramming-based strategy for large-scale phenotype-driven screening of repurposable drugs in cells derived from MILS patients, allowing the identification of novel therapeutics. This strategy includes screening a large library of repurposable compounds, followed by validation of the top hits. This validation will include both mitochondrial profiling of induced pluripotent stem cell (iPSC)-derived neural progenitor cells and electrophysiological characterization of iPSC-derived neuronal cultures on micro-electrode arrays, as well as multi-omics analysis and subsequent computation-based modeling. A proof-of-concept study already demonstrated that this approach is feasible and relevant [1]. By extending this approach, our consortium aims to identify existing drugs suited for repositioning as interventions in MILS, laying the foundation for a multi-national clinical trial and a concrete path towards a treatment for MILS. Moreover, we will establish a paradigmatic working pipeline for reprogramming-driven drug discovery in rare neurological disorders. [1] Lorenz, C., et al., *Human iPSC-Derived Neural Progenitors Are an Effective Drug Discovery Model for Neurological mtDNA Disorders.* Cell Stem Cell, 2017. **20**(5): p. 659-674.e9.

SIALIC ACID BIOSYNTHESIS IS ESSENTIAL FOR NETWORK FORMATION OF IPSC-DERIVED EXCITATORY NEURONS

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Rachel Mijdam[1], Raisa Veizaj[1], Hanneke Kwast[2], Marek Noga[2], Eline Van Hugte[3], Chantal Schoenmaker[3], Emma Dyke[3], Thomas Boltje[4], Dirk Schubert[5], Nael Nadif Kasri[3], Dirk Lefeber[1]
[1]Radboudumc, Neurology, Nijmegen, Netherlands, [2]Radboudumc, Translational Metabolic Laboratory, Nijmegen, Netherlands, [3]Radboudumc, Donders Institute for Brain, Cognition, and Behaviour, Human Genetics, Nijmegen, Netherlands, [4]Radboud University, Institute for Molecules and Materials, Department Of Organic Chemistry, Nijmegen, Netherlands, [5]Donders Institute for Brain, Cognition and Behavior, Department Of Cognitive Neuroscience, Nijmegen, Netherlands

Multiple congenital disorders of glycosylation (CDG) are linked to sialic acid, a sugar commonly found in all human tissues, with the highest expression in the brain. Of these, only NANS-CDG is characterized by severe neurological symptoms. How changes in sialic acid biosynthesis lead to neurological symptoms is poorly understood. Here, we studied how the sialic acid biosynthesis pathway (SBP) influences neuronal network formation. To assess the requirement of sialic acid and the effect of disease causing variants in this pathway, excitatory neurons (iNeurons) were derived from control induced pluripotent stem cells (iPSC) treated with the sialyltransferase inhibitor (SiaFEt) and from three NANS-CDG patient-derived iPSC lines. Changes in sugar metabolite levels were followed by mass spectrometry-based metabolomics and spontaneous electrophysiological activity was monitored with micro electrode arrays. We found that SiaFEt inhibits the entire SBP and disturbs network formation in iNeurons, leading to a lower firing rate and shorter but more frequent bursts. NANS-CDG iNeurons presented with a delayed network formation. Metabolomics revealed high ManNAc-6P levels, but no reduction in sialic acid. Surprisingly, also the hexosamine biosynthesis pathway was affected, since GlcNAc-1P, GalNAc-1P and UDP-HexNAc levels were decreased. In conclusion, we demonstrate that disturbances in the SBP lead to abnormal neuronal network formation, but in NANS-CDG this cannot directly be related to a lack of sialic acid.

Underreported and unknown student harassment at the Faculty of Science.
Reports of sexual harassment at medical faculties throughout the world, including the Radboud University, raised the question how prevalent this is at the Faculty of Science. We performed a survey among students to assess their experiences with harassment. This questionnaire consisted of questions from the EGERA survey, a questionnaire held among staff of multiple European Universities. We found that 9% of the respondents had observed or experienced harassment at the Faculty. Hardly any of these cases were reported to one of the institutional services. Moreover, most students did not now any of the provided services. We therefore suggest raising awareness on harassment and to make students more familiar with the trust person.

IDENTIFYING DEREGULATED AUTOPHAGY AS UNDERLYING MECHANISM OF NEURODEVELOPMETNAL DISORDERS

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Katrin Linda[1], Elly Lewerissa[1], Ummi Ciptasari[1], Shan Wang[2], Hans Van Bokhoven[1], Dirk Schubert[2], Nael Nadif Kasri[1]

Autophagy is an evolutionary highly conserved, catabolic process, that is important for the clearance of cytosolic contents to maintain cellular homeostasis and survival. Recent findings point towards a critical role for autophagy in brain function, not only by preserving neuronal health, but especially by controlling different aspects of neuronal development and functioning. More precisely, knockdown of different autophagy genes showed to affect neural stem cell proliferation and differentiation. Furthermore, reduced autophagic activity revealed to result in structural neuronal changes, like decreased synaptic pruning. In line with this, mutations in autophagy regulating genes could be linked to various key characteristics and symptoms of neurodevelopmental disorders, including autism, micro-/ macrocephaly, and epilepsy. Given the importance of tightly regulated autophagic activity for neuronal development and functioning, we questioned, whether deregulated autophagy is a more widely shared underlying mechanism among neurodevelopental disorders. To examine this, we focused on a group of neurological disorders that are caused by mutations in epigenetic modifier genes, so-called chromatinopathies. We made use of CRISPR/Cas9 genome editing and created different chromatinopathy-associated mutations in iPSC control cells. Subsequently, we performed a battery of standardized autophagy assays to compare autophagic protein expression and activity to isogenic control cells. Results indicate deregulated autophagy in most of our mutated iPSC lines, which provides an auspicious new approach to a better understanding of disease pathology and, more importantly, might help to develop more targeted therapies for a larger group of neuropsychiatric disorders.

Human neuronal networks on micro-electrode arrays are a highly robust tool to study disease-specific genotype-phenotype correlations in vitro.
Micro-electrode arrays (MEAs) are increasingly used to characterize neuronal network activity of human induced pluripotent stem cell (hiPSC)-derived neurons. Despite their gain in popularity, MEA recordings from hiPSC-derived neuronal networks are not always used to their full potential in respect to experimental design, execution, and data analysis. Therefore, we benchmarked the robustness of MEA-derived neuronal activity patterns from ten healthy individual control lines, and uncover comparable network phenotypes. To achieve standardization, we provide recommendations on experimental design and analysis. With such standardization, MEAs can be used as a reliable platform to distinguish (disease-specific) network phenotypes. In conclusion, we show that MEAs are a powerful and robust tool to uncover functional neuronal network phenotypes from hiPSC-derived neuronal networks, and provide an important resource to advance the hiPSC field toward the use of MEAs for disease phenotyping and drug discovery.

Furthermore, we found that increased oxidative stress-mediated autophagosome accumulation leads to increased MTOR activation and decreased lysosome function, further preventing the clearing of autophagosomes. Finally, by pharmacologically reducing oxidative stress, we could rescue the aberrant autophagosome formation as well as synaptic and neuronal network activity in KANSL1-deficient neurons. Our findings thus point toward an important relation between oxidative stress-induced autophagy and synapse function, and demonstrate the importance of H4K16ac-mediated changes in chromatin structure to balance reactive oxygen species- and MTOR-dependent autophagy.: APO: apocynin; ATG: autophagy related; BAF: bafilomycin A; BSO: buthionine sulfoximine; CV: coefficient of variation; DIV: days in vitro; H4K16ac: histone 4 lysine 16 acetylation; iPSC: induced-pluripotent stem cell; KANSL1: KAT8 regulatory NSL complex subunit 1; KdVS: Koolen-de Vries Syndrome; LAMP1: lysosomal associated membrane protein 1; MAP1LC3/LC3: microtubule associated protein 1 light chain 3; MEA: micro-electrode array; MTOR: mechanistic target of rapamycin kinase; NSL complex: nonspecific lethal complex; 8-oxo-dG: 8-hydroxydesoxyguanosine; RAP: rapamycin; ROS: reactive oxygen species; sEPSCs: spontaneous excitatory postsynaptic currents; SOD1: superoxide dismutase 1; SQSTM1/p62: sequestosome 1; SYN: synapsin; WRT: wortmannin.

Cadherin-13 is a critical regulator of GABAergic modulation in human stem-cell-derived neuronal networks.

Activity in the healthy brain relies on a concerted interplay of excitation (E) and inhibition (I) via balanced synaptic communication between glutamatergic and GABAergic neurons. A growing number of studies imply that disruption of this E/I balance is a commonality in many brain disorders; however, obtaining mechanistic insight into these disruptions, with translational value for the patient, has typically been hampered by methodological limitations. Cadherin-13 (CDH13) has been associated with autism and attention-deficit/hyperactivity disorder. CDH13 localizes at inhibitory presynapses, specifically of parvalbumin (PV) and somatostatin (SST) expressing GABAergic neurons. However, the mechanism by which CDH13 regulates the function of inhibitory synapses in human neurons remains unknown. Starting from human-induced pluripotent stem cells, we established a robust method to generate a homogenous population of SST and MEF2C (PV-precursor marker protein) expressing GABAergic neurons (iGABA) in vitro, and co-cultured these with glutamatergic neurons at defined E/I ratios on micro-electrode arrays. We identified functional network parameters that are most reliably affected by GABAergic modulation as such, and through alterations of E/I balance by reduced expression of CDH13 in iGABAs. We found that CDH13 deficiency in iGABAs decreased E/I balance by means of increased inhibition. Moreover, CDH13 interacts with Integrin-β1 and Integrin-β3, which play opposite roles in the regulation of inhibitory synaptic strength via this interaction. Taken together, this model allows for standardized investigation of the E/I balance in a human neuronal background and can be deployed to dissect the cell-type-specific contribution of disease genes to the E/I balance.

Distinct Pathogenic Genes Causing Intellectual Disability and Autism Exhibit a Common Neuronal Network Hyperactivity Phenotype.

Pathogenic mutations in either one of the epigenetic modifiers EHMT1, MBD5, MLL3, or SMARCB1 have been identified to be causative for Kleefstra syndrome spectrum (KSS), a neurodevelopmental disorder with clinical features of both intellectual disability (ID) and autism spectrum disorder (ASD). To understand how these variants lead to the phenotypic convergence in KSS, we employ a loss-of-function approach to assess neuronal network development at the molecular, single-cell, and

network activity level. KSS-gene-deficient neuronal networks all develop into hyperactive networks with altered network organization and excitatory-inhibitory balance. Interestingly, even though transcriptional data reveal distinct regulatory mechanisms, KSS target genes share similar functions in regulating neuronal excitability and synaptic function, several of which are associated with ID and ASD. Our results show that KSS genes mainly converge at the level of neuronal network communication, providing insights into the pathophysiology of KSS and phenotypically congruent disorders.

Neuronal network dysfunction in a model for Kleefstra syndrome mediated by enhanced NMDAR signaling.
Kleefstra syndrome (KS) is a neurodevelopmental disorder caused by mutations in the histone methyltransferase EHMT1. To study the impact of decreased EHMT1 function in human cells, we generated excitatory cortical neurons from induced pluripotent stem (iPS) cells derived from KS patients. Neuronal networks of patient-derived cells exhibit network bursting with a reduced rate, longer duration, and increased temporal irregularity compared to control networks. We show that these changes are mediated by upregulation of NMDA receptor (NMDAR) subunit 1 correlating with reduced deposition of the repressive H3K9me2 mark, the catalytic product of EHMT1, at the GRIN1 promoter. In mice EHMT1 deficiency leads to similar neuronal network impairments with increased NMDAR function. Finally, we rescue the KS patient-derived neuronal network phenotypes by pharmacological inhibition of NMDARs. Summarized, we demonstrate a direct link between EHMT1 deficiency and NMDAR hyperfunction in human neurons, providing a potential basis for more targeted therapeutic approaches for KS.

The promise of induced pluripotent stem cells for neurodevelopmental disorders.
A major challenge in clinical genetics and medicine is represented by genetically and phenotypically highly diverse neurodevelopmental disorders, like for example intellectual disability and autism. Intellectual disability is characterized by substantial limitations in cognitive function and adaptive behaviour. At the cellular level, this is reflected by deficits in synaptic structure and plasticity and therefore has been coined as a synaptic disorder or "synaptopathy". In this review, we summarize the findings from recent studies in which iPSCs have been used to model specific neurodevelopmental syndromes, including Fragile X syndrome, Rett syndrome, Williams-Beuren syndrome and Phelan-McDermid syndrome. We discuss what we have learned from these studies and what key issues need to be addressed to move the field forward.

Rapid Neuronal Differentiation of Induced Pluripotent Stem Cells for Measuring Network Activity on Micro-electrode Arrays.
Neurons derived from human induced Pluripotent Stem Cells (hiPSCs) provide a promising new tool for studying neurological disorders. In the past decade, many protocols for differentiating hiPSCs into neurons have been developed. However, these protocols are often slow with high variability, low reproducibility, and low efficiency. In addition, the neurons obtained with these protocols are often immature and lack adequate functional activity both at the single-cell and network levels unless the neurons are cultured for several months. Partially due to these limitations, the functional properties of hiPSC-derived neuronal networks are still not well characterized. Here, we adapt a recently published protocol that describes production of human neurons from hiPSCs by forced expression of the transcription factor neurogenin-2. This protocol is rapid (yielding mature neurons within 3 weeks) and efficient, with nearly 100% conversion efficiency of transduced cells (>95% of DAPI-positive cells are MAP2 positive). Furthermore, the protocol yields a homogeneous population of excitatory neurons that would allow the investigation of cell-type specific contributions to neurological disorders. We modified the original protocol by generating stably transduced hiPSC cells, giving us explicit control over the total number of neurons. These cells are then used to generate hiPSC-derived neuronal networks on micro-electrode arrays. In this way, the spontaneous electrophysiological activity of hiPSC-derived neuronal networks can be measured and characterized, while retaining interexperimental consistency in terms of cell density. The presented protocol is broadly applicable, especially for mechanistic and pharmacological studies on human neuronal networks.

Mutations linked to neurodevelopmental disorders, such as intellectual disability (ID), are frequently found in genes that encode for proteins of the excitatory synapse. Transmembrane AMPA receptor regulatory proteins (TARPs) are AMPA receptor auxiliary proteins that regulate crucial aspects of receptor function. Here, we investigate a mutant form of the TARP family member stargazin, described in an ID patient. Our data revealed that the ID-associated stargazin variant, V143L, presents increased cell surface mobility and disrupts synaptic AMPA receptor trafficking in cultured neurons. Knock-in mice harboring the V143L stargazin mutation manifest cognitive and social deficits and hippocampal synaptic transmission defects, resembling phenotypes displayed by ID patients. In the hippocampus of stargazin V143L mice, CA1 neurons show impaired spine maturation, abnormal synaptic transmission and long-term potentiation specifically in basal dendrites, and synaptic ultrastructural alterations. These observations indicate that stargazin has a specific role in maintaining spine structure and synaptic function and plasticity in CA1 basal dendrites, which agrees with the higher expression levels of stargazin in the hippocampal *stratum oriens*, where basal dendrites are located, compared with the *stratum radiatum*, where apical dendrites are located. These data suggests that apart from the well-described brain region- and cell type-specific roles of TARPs, there may be subfield-specific roles that are determined by the subcellular distribution pattern of different TARPs. Altogether, our results point to a causal role for mutated stargazin in the pathogenesis of ID and unveil a new role for stargazin in the development and function of hippocampal synapses.

Hepatitis E virus genotype 3 in echinoderms: First report of sea urchin (Paracentrotus lividus) contamination.
Hepatitis E virus (HEV) deriving from manure application runoffs and faecal waste spill over of swine and human origin bypass wastewater treatment plants and contaminate coastal waters. Shellfish bioaccumulate enteric viruses such as HEV from fecally contaminated coastal waters and under current European Regulations, shellfish sanitary status surveillance is mandatory but only by means of bacterial faecal indicators. The sea urchins are under the same regulations and their vulnerability to fecal contamination has been pointed out. Since they are consumed raw and with no steps to control/reduce hazards, sea urchin contamination with enteric viruses can represent a food safety risk. Hence, the aim of the present study was to screen sea urchin gonads destined for human consumption for the presence of HEV. HEV was detected and quantified in gonads of sea urchins collected in north Portugal by a reverse transcription-quantitative PCR (RT-qPCR) assay targeting the ORF3 region, followed by genotyping by a nested RT-PCR targeting the ORF2 region. Sequencing and phylogenetic analysis clustered the HEV sequence within genotype 3, subgenotype e. This the first study reporting HEV contamination of sea urchins. We hypothesize that like shellfish, sea urchins can also be a food vehicle for HEV transmission to humans.

Occurrence of mcr-1 in Escherichia coli from rabbits of intensive farming.
The emergence of mobile colistin resistance genes (mcr) is yet another challenge in the fight against antimicrobial resistance, with reports proving the dissemination of these genes in different countries and different environments being of great concern. In the present study, we describe the recovery of three E. coli strains with mcr-1 gene in IncHI2 plasmids from intestinal content of necropsied meat rabbits reared in two intensive production systems in Portugal. Our findings are

worrisome, given the high level of dependence on the usage of antibiotics in rabbit rearing and call for the development and implementation of an active surveillance system in this species.

Lichen Xanthones as Models for New Antifungal Agents.
Due to the emergence of multidrug-resistant pathogenic microorganisms, the search for new antimicrobial compounds plays an important role in current medicinal chemistry research. Inspired by lichen antimicrobial xanthones, a series of novel chlorinated xanthones was prepared using five chlorination methods (Methods A⁻E) to obtain different patterns of substitution in the xanthone scaffold. All the synthesized compounds were evaluated for their antimicrobial activity. Among them, 3-chloro-4,6-dimethoxy-1-methyl-9-xanthen-9-one showed promising antibacterial activity against (ATCC 29212 and 29213) and ATCC 29213. 2,7-Dichloro-3,4,6-trimethoxy-1-methyl-9-xanthen-9-one revealed a potent fungistatic and fungicidal activity against dermatophytes clinical strains (, , and (MIC = 4⁻8 µg/mL)). Moreover, when evaluated for its synergistic effect for , compound exhibited synergy with fluconazole (ΣFIC = 0.289). These results disclosed new hit xanthones for both antibacterial and antifungal activity.

Bis-Indolyl Benzenoids, Hydroxypyrrolidine Derivatives and Other Constituents from Cultures of the Marine Sponge-Associated Fungus Aspergillus candidus KUFA0062.
A previously unreported -indolyl benzenoid, candidusin D () and a new hydroxypyrrolidine alkaloid, preussin C () were isolated together with fourteen previously described compounds: palmitic acid, clionasterol, ergosterol 5,8-endoperoxides, chrysophanic acid (), emodin (), six -indolyl benzenoids including asterriquinol D dimethyl ether (), petromurin C (), kumbicin B (), kumbicin A (), 2″-oxoasterriquinol D methyl ether (), kumbicin D (), the hydroxypyrrolidine alkaloid preussin (), (3, 6)-3,6-dibenzylpiperazine-2,5-dione () and 4-(acetylamino) benzoic acid (), from the cultures of the marine sponge-associated fungus KUFA 0062. Compounds , , , , , and were tested for their antibacterial activity against Gram-positive and Gram-negative reference and multidrug-resistant strains isolated from the environment. Only exhibited an inhibitory effect against ATCC 29213 and ATCC29212 as well as both methicillin-resistant (MRSA) and vancomycin-resistant enterococci (VRE) strains. Both and also reduced significant biofilm formation in ATCC 25922. Moreover, and revealed a synergistic effect with oxacillin against MRSA 66/1 while exhibited a strong synergistic effect with the antibiotic colistin against 1410/1. Compound , , , , , and were also tested, together with the crude extract, for cytotoxic effect against eight cancer cell lines: HepG2, HT29, HCT116, A549, A 375, MCF-7, U-251, and T98G. Except for , , , and , all the compounds showed cytotoxicity against all the cancer cell lines tested.

In Vitro Activity of Quaternary Ammonium Surfactants against Streptococcal, Chlamydial, and Gonococcal Infective Agents.
Quaternary ammonium compounds (QAC) are widely used, cheap, and chemically stable disinfectants and topical antiseptics with wide-spectrum antimicrobial activities. Within this group of compounds, we recently showed that there are significant differences between the pharmacodynamics of n-alkyl quaternary ammonium surfactants (QAS) with a short (C12) alkyl chain when in vitro toxicities toward bacterial and mammalian epithelial cells are compared. These differences result in an attractive therapeutic window that justifies studying short-chain QAS as prophylactics for sexually transmitted infections (STI) and perinatal vertically transmitted urogenital infections (UGI). We have evaluated the antimicrobial activities of short-chain (C12) n-alkyl QAS against several STI and UGI pathogens as well as against commensal Lactobacillus species. Inhibition of infection of HeLa cells by Neisseria gonorrhoeae and Chlamydia trachomatis was studied at concentrations that were not toxic to the HeLa cells. We show that the pathogenic bacteria are much more susceptible to QAS toxic effects than the commensal vaginal flora and that QAS significantly attenuate the infectivity of N. gonorrhoeae and C. trachomatis without affecting the viability of epithelial cells of the vaginal mucosa. N-Dodecylpyridinium bromide (C12PB) was found to be the most effective QAS. Our results strongly suggest that short-chain (C12) n-alkyl pyridinium bromides and structurally similar compounds are promising microbicide candidates for topical application in the prophylaxis of STI and perinatal vertical transmission of UGI.

Quaternary ammonium surfactant structure determines selective toxicity towards bacteria: mechanisms of action and clinical implications in antibacterial prophylaxis.
Broad-spectrum antimicrobial activity of quaternary ammonium surfactants (QAS) makes them attractive and cheap topical

prophylactic options for sexually transmitted infections and perinatal vertically transmitted urogenital infections. Although attributed to their high affinity for biological membranes, the mechanisms behind QAS microbicidal activity are not fully understood. We evaluated how QAS structure affects antimicrobial activity and whether this can be exploited for use in prophylaxis of bacterial infections.

Mitochondrial dysfunction is the focus of quaternary ammonium surfactant toxicity to mammalian epithelial cells.
Surfactants have long been known to have microbicidal action and have been extensively used as antiseptics and disinfectants for a variety of general hygiene and clinical purposes. Among surfactants, quaternary ammonium compounds (QAC) are known to be the most useful antiseptics and disinfectants. However, our previous toxicological studies showed that QAC are also the most toxic surfactants for mammalian cells. An understanding of the mechanisms that underlie QAC toxicity is a crucial first step in their rational use and in the design and development of more effective and safer molecules. We show that QAC-induced toxicity is mediated primarily through mitochondrial dysfunction in mammalian columnar epithelial cell cultures in vitro. Toxic effects begin at sublethal concentrations and are characterized by mitochondrial fragmentation accompanied by decreased cellular energy charge. At very low concentrations, several QAC act on mitochondrial bioenergetics through a common mechanism of action, primarily by inhibiting mitochondrial respiration initiated at complex I and, to a lesser extent, by slowing down coupled ADP phosphorylation. The result is a reduction of cellular energy charge which, when reduced below 50% of its original value, induces apoptosis. The lethal effects are shown to be primarily a result of this process. At higher doses (closer to the critical micellar concentration), QAC induce the complete breakdown of cellular energy charge and necrotic cell death.

Nitric oxide stimulates the proliferation of neural stem cells bypassing the epidermal growth factor receptor.
Nitric oxide (NO) was described to inhibit the proliferation of neural stem cells. Some evidence suggests that NO, under certain conditions, can also promote cell proliferation, although the mechanisms responsible for a potential proliferative effect of NO in neural stem cells have remained unaddressed. In this work, we investigated and characterized the proliferative effect of NO in cell cultures obtained from the mouse subventricular zone. We found that the NO donor NOC-18 (10 microM) increased cell proliferation, whereas higher concentrations (100 microM) inhibited cell proliferation. Increased cell proliferation was detected rapidly following exposure to NO and was prevented by blocking the mitogen-activated kinase (MAPK) pathway, independently of the epidermal growth factor (EGF) receptor. Downstream of the EGF receptor, NO activated p21Ras and the MAPK pathway, resulting in a decrease in the nuclear presence of the cyclin-dependent kinase inhibitor 1, p27(KIP1), allowing for cell cycle progression. Furthermore, in a mouse model that shows increased proliferation of neural stem cells in the hippocampus following seizure injury, we observed that the absence of inducible nitric oxide synthase (iNOS(-/-) mice) prevented the increase in cell proliferation observed following seizures in wild-type mice, showing that NO from iNOS origin is important for increased cell proliferation following a brain insult. Overall, we show that NO is able to stimulate the proliferation of neural stem cells bypassing the EGF receptor and promoting cell division. Moreover, under pathophysiological conditions in vivo, NO from iNOS origin also promotes proliferation in the hippocampus.

Differential contribution of the guanylyl cyclase-cyclic GMP-protein kinase G pathway to the proliferation of neural stem cells stimulated by nitric oxide.
Nitric oxide (NO) is an important inflammatory mediator involved in the initial boost in the proliferation of neural stem cells following brain injury. However, the mechanisms underlying the proliferative effect of NO are still unclear. The aim of this work was to investigate whether cyclic GMP (cGMP) and the cGMP-dependent kinase (PKG) are involved in the proliferative effect triggered by NO in neural stem cells. For this purpose, cultures of neural stem cells isolated from the mouse subventricular zone (SVZ) were used. We observed that long-term exposure to the NO donor (24 h), NOC-18, increased the proliferation of SVZ cells in a cGMP-dependent manner, since the guanylate cyclase inhibitor, ODQ, prevented cell proliferation. Similarly to NOC-18, the cGMP analogue, 8-Br-cGMP, also increased cell proliferation. Interestingly, shorter exposures to NO (6 h) increased cell proliferation in a cGMP-independent manner via the ERK/MAP kinase pathway. The selective inhibitor of PKG, KT5823, prevented the proliferative effect induced by NO at 24 h but not at 6 h. In conclusion, the proliferative effect of NO is initially mediated by the ERK/MAPK pathway, and at later stages by the GC/cGMP/PKG pathway. Thus, our work shows that NO induces neural stem cell proliferation by targeting these two pathways in a biphasic manner.

Changes in calcium dynamics following the reversal of the sodium-calcium exchanger have a key role in AMPA receptor-mediated neurodegeneration via calpain activation in hippocampal neurons.

Proteolytic cleavage of the Na(+)/Ca(2+) exchanger (NCX) by calpains impairs calcium homeostasis, leading to a delayed calcium overload and excitotoxic cell death. However, it is not known whether reversal of the exchanger contributes to activate calpains and trigger neuronal death. We investigated the role of the reversal of the NCX in Ca(2+) dynamics, calpain activation and cell viability, in alpha-amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA) receptor-stimulated hippocampal neurons. Selective overactivation of AMPA receptors caused the reversal of the NCX, which accounted for approximately 30% of the rise in intracellular free calcium concentration ([Ca(2+)](i)). The NCX reverse-mode inhibitor, 2-[2-[4-(4-nitrobenzyloxy)phenyl]ethyl]isothiourea (KB-R7943), partially inhibited the initial increase in [Ca(2+)](i), and prevented a delayed increase in [Ca(2+)](i). In parallel, overactivation of AMPA receptors strongly activated calpains and led to the proteolysis of NCX3. KB-R7943 prevented calpain activation, cleavage of NCX3 and was neuroprotective. Silencing of NCX3 reduced Ca(2+) uptake, calpain activation and was neuroprotective. Our data show for the first time that NCX reversal is an early event following AMPA receptor stimulation and is linked to the activation of calpains. Since calpain activation subsequently inactivates NCX, causing a secondary Ca(2+) entry, NCX may be viewed as a new suicide substrate operating in a Ca(2+)-dependent loop that triggers cell death and as a target for neuroprotection.

THE X-LINKED PTCHD1 GENE ASSOCIATED WITH ID AND/OR ASD INTERACTS AS A PROTEIN RECEPTOR WITH RAC1 A KEY REGULATOR OF CYTOSKELETON REMODELING AND SYNAPSE PLASTICITY.

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Devina Ung, Sylviane Marouillat, Judith Halewa, Frederic Laumonnier
Universite de Tours, Umr1253, Ibrain, Inserm, Tours, France

Intellectual disability (ID) is a prevalent neurodevelopmental condition with enormous burden for patients and families and without effective treatment. Deleterious mutations in the *PTCHD1* (Patched domain containing 1) gene have been described in male patients with X-linked ID and/or ASD (Autism Spectrum Disorders) and accounting for up to 1% of diagnoses in males. I have used neurobiology and molecular biology techniques, applied to mouse models, to discover that genetically deleting *Ptchd1* affects the synaptic transcriptome and impairs synaptic structure and activity, leading to cognitive dysfunction, motor disabilities and hyperactivity (Ung et al., *MolPsych*, 2018). I have also identified a PDZ-binding motif at the C-terminal end of synaptic receptor PTCHD1 that binds to the major postsynaptic scaffolding proteins PSD-95 and SAP102. Recently, we characterized 13 novel missense variants in the *PTCHD1* gene (Halewa et al, 2021) causing alteration of its membrane subcellular localization and leading to ID and/or ASD in patients. Nevertheless several novel missense mutations have not been studied yet. We therefore continue our effort by focusing on additional variants (L38Q, N152E, G303R, F420L, P605L) by studying protein expression and subcellular localization in HEK293T cell line and in mouse hippocampal primary neuronal cultures. In parallel using specific protein interaction assays, I determined that the C-terminal region of PTCHD1 interacts with Rac1, a RhoGTPase associated with ID, essential for cytoskeleton remodeling and synapse plasticity. Highlighting PTCHD1 novel interacting proteins and *PTCHD1* mutations functional impact will allow a better understanding of those neurodevelopmental disorders and give potential answers to patients and families.

LOSS-OF-FUNCTION VARIANTS IN THE SCHIZOPHRENIA RISK GENE SETD1A ALTER NEURONAL NETWORK ACTIVITY IN HUMAN NEURONS THROUGH CAMP/PKA PATHWAY

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Shan Wang[1], Jon-Ruben Van Rhijn[1], Ibrahim Akkouh[2], Srdjan Djurovic[2], Hans Van Bokhoven[1,3], Tjitske Kleefstra[3], Nael Nadif Kasri[1,3], Dirk Schubert[1]

Heterozygous loss-of-function (LoF) mutations in *SETD1A*, which encodes a subunit of histone H3 lysine 4 methyltransferase, were shown to cause a novel neurodevelopmental syndrome and increase the risk for schizophrenia. We generated *in vitro* excitatory/inhibitory neuronal networks from human induced pluripotent stem cells with a *SETD1A* heterozygous LoF mutation (*SETD1A*$^{+/-}$) using CRISPR/Cas9. Our data show that *SETD1A* haploinsufficiency resulted in morphologically increased dendritic complexity and functionally increased bursting activity. This network phenotype was primarily driven by *SETD1A* haploinsufficiency in glutamatergic neurons. In accordance with the functional changes, transcriptomic profiling revealed perturbations in gene sets associated with glutamatergic synaptic function. At the molecular level, we identified specific changes in the cAMP/PKA pathway pointing toward a hyperactive cAMP pathway in *SETD1A*$^{+/-}$ neurons. Finally, by pharmacologically targeting the cAMP pathway we were able to rescue major aspects of the network deficits in *SETD1A*$^{+/-}$ cultures. Our results demonstrate a link between SETD1A and the cAMP-dependent pathway in human neurons.

Cadherin-13 is a critical regulator of GABAergic modulation in human stem-cell-derived neuronal networks.
Activity in the healthy brain relies on a concerted interplay of excitation (E) and inhibition (I) via balanced synaptic communication between glutamatergic and GABAergic neurons. A growing number of studies imply that disruption of this E/I balance is a commonality in many brain disorders; however, obtaining mechanistic insight into these disruptions, with translational value for the patient, has typically been hampered by methodological limitations. Cadherin-13 (CDH13) has been associated with autism and attention-deficit/hyperactivity disorder. CDH13 localizes at inhibitory presynapses, specifically of parvalbumin (PV) and somatostatin (SST) expressing GABAergic neurons. However, the mechanism by which CDH13 regulates the function of inhibitory synapses in human neurons remains unknown. Starting from human-induced pluripotent stem cells, we established a robust method to generate a homogenous population of SST and MEF2C (PV-precursor marker protein) expressing GABAergic neurons (iGABA) in vitro, and co-cultured these with glutamatergic neurons at defined E/I ratios on micro-electrode arrays. We identified functional network parameters that are most reliably affected by GABAergic modulation as such, and through alterations of E/I balance by reduced expression of CDH13 in iGABAs. We found that CDH13 deficiency in iGABAs decreased E/I balance by means of increased inhibition. Moreover, CDH13 interacts with Integrin-β1 and Integrin-β3, which play opposite roles in the regulation of inhibitory synaptic strength via this interaction. Taken together, this model allows for standardized investigation of the E/I balance in a human neuronal background and can be deployed to dissect the cell-type-specific contribution of disease genes to the E/I balance.

SETD1A Mediated H3K4 Methylation and Its Role in Neurodevelopmental and Neuropsychiatric Disorders.
Posttranslational modification of histones and related gene regulation are shown to be affected in an increasing number of neurological disorders. SETD1A is a chromatin remodeler that influences gene expression through the modulation of mono- di- and trimethylation marks on Histone-H3-Lysine-4 (H3K4me1/2/3). H3K4 methylation is predominantly described to result in transcriptional activation, with its mono- di- and trimethylated forms differentially enriched at promoters or enhancers. Recently, dominant mostly variants in have clinically been linked to developmental delay, intellectual disability (DD/ID), and

schizophrenia (SCZ). Affected individuals often display both developmental and neuropsychiatric abnormalities. The primary diagnoses are mainly dependent on the age at which the individual is assessed. Investigations in mouse models of SETD1A dysfunction have been able to recapitulate key behavioral features associated with ID and SCZ. Furthermore, functional investigations suggest disrupted synaptic and neuronal network function in these mouse models. In this review, we provide an overview of pre-clinical studies on the role of SETD1A in neuronal development. A better understanding of the pathobiology underlying these disorders may provide novel opportunities for therapeutic intervention. As such, we will discuss possible strategies to move forward in elucidating the genotype-phenotype correlation in associated disorders.

Protective Effects of L-3-n-Butylphthalide Against HO-Induced Injury in Neural Stem Cells by Activation of PI3K/Akt and Mash1 Pathway.
It has been reported that oxidative stress could result in damage to the developing brain. L-3-n-butylphthalide (L-NBP) could inhibit neuronal cell apoptosis and has neurogenesis effect in different animal and cellular models. However, whether L-NBP could protect the process of neurogenesis in neural stem cells (NSCs) against oxidative stress injury is still unclear. Here, in the present study, we evaluated the neuroprotective effect of L-NBP in NSCs against HO-induced injury and the possible mechanisms. The results showed that L-NBP elevated the proliferation of NSCs by upregulating cyclin D1, and PI3K/Akt might be a possible target in this process. Subsequently, L-NBP was found to promote the migration of NSCs and N-cadherin might be involved in. NSC differentiation was measured using immunofluorescence staining and the results demonstrated that L-NBP could promote the NSCs to differentiate more into neurons. The elevation of achaete-scute homolog1 (Mash1) expression might be a key factor as attenuation of endogenous Mash1 expression by short-interfering RNA could block L-NBP-promoted neuronal differentiation. In summary, L-NBP exerts protective effects in NSCs against HO-induced injury by promoting the proliferation, migration and neural differentiation of NSCs, indicating that L-NBP might be a potential therapeutic agent for the neurogenesis-based treatment for some brain diseases, such as Alzheimer's disease (AD).

Dl-3-n-Butylphthalide (NBP): A Promising Therapeutic Agent for Ischemic Stroke.
Stroke is a leading cause of morbidity and mortality in both developed and developing countries all over the world. The only drug for ischemic stroke approved by FDA is recombinant tissue plasminogen activator (rtPA). However, only 2-5% stroke patients receive rtPAs treatment due to its strict therapeutic time window. As ischemic stroke is a complex disease involving multiple mechanisms, medications with multi-targets may be more powerful compared with single-target drugs. Dl-3-n-Butylphthalide (NBP) is a synthetic compound based on l-3-n- Butylphthalide that is isolated from seeds of Apium graveolens. The racemic 3-n-butylphthalide (dl- NBP) was approved by Food and Drug Administration of China for the treatment of ischemic stroke in 2002. A number of clinical studies indicated that NBP not only improved the symptoms of ischemic stroke, but also contributed to the long-term recovery. The potential mechanisms of NBP for ischemic stroke treatment may target different pathophysiological processes, including anti-oxidant, antiinflammation, anti-apoptosis, anti-thrombosis, and protection of mitochondria et al. Conclusion: In this review, we have summarized the research progress of NBP for the treatment of ischemic stroke during the past two decades.

From stroke to neurodegenerative diseases: The multi-target neuroprotective effects of 3-n-butylphthalide and its derivatives.
Discovering effective agents to slow or stop neurodegeneration is a challenging task. Over decades, only a few drugs were approved by Food and Drug Administration (FDA) and most ended in failure. The lessons learned have switched the strategy of drug discovery from designing highly selective ligands to a network pharmacology approach. This enables many natural products like butylphthalide (NBP) once again to be regarded as a valuable source of leads for drug discovery. In this review, we first start with the neuroprotective effects of NBPs on acute ischemic stroke, and later spread to their applications in major neurodegenerative diseases. The underlying mechanisms are also discussed in order to provide a direction for further study. Hopefully, this review could bring some new insights for drug development in this struggling field.

Dammarane-type saponins from the leaves of Panax notoginseng and their neuroprotective effects on damaged SH-SY5Y cells.
Seven dammarane-type saponins previously undescribed (notoginsenosides Fh1-Fh7) were isolated from the aqueous extract leaves of Panax notoginseng (Burk.) F.H.Chen (Araliaceae), together with eleven known saponins. Their structures of were elucidated by spectroscopic analysis (NMR, UV, IR, ect.), HR-ESI-MS techniques and chemical methods. Screening results indicated that compounds 4, 5, 12, 13 showed moderate neuroprotective effects on HO-induced cellular damage in

human neuroblastoma SH-SY5Y cells (10 μM).

Hsp90β inhibitors prevent GLT-1 degradation but have no beneficial efficacy on absence epilepsy.
The loss of glutamate transporter-1 (GLT-1) is associated with temporal lobe epilepsy (TLE). A recent study reported that Hsp90β interacted with GLT-1 and recruited it to 20S proteasome for degradation. Therefore, inhibiting Hsp90β may be a new strategy for treating epilepsy. So far, no studies have shown whether the inhibition of Hsp90β had therapeutic effects on absence epilepsy. Using a model of absence epilepsy, we demonstrated that 17-allylamino-17-demethoxygeldanamycin (17AAG) and Ganetespib (STA9090) had no therapeutic effect. Although this is a negative result, it also has a meaningful exploration value for whether Hsp90 inhibitors have therapeutic effects on other epilepsy types.

Dravet syndrome (DS) is a severe epileptic encephalopathy, characterized by (febrile) seizures and neurological problems. 80% of DS patients have a mutation in *SCN1A*, encoding $Na_v1.1$. While there are over 1500 different *SCN1A* mutations known, the clinical predictive value remains challenging, even if one mutation is inherited within one family. Both this clinical and genetic heterogeneity complicate tailored prescription of anti-epileptic drugs (AEDs). Moreover, it is currently debated if excitatory neurons contribute to the DS phenotype, it could either depend on the patient clinical phenotype, or to the type of mutation studied. Studies sometimes only investigate a few *SCN1A* mutations, often in isolation of the patient background, or do not include multiple clinical phenotypes. Therefore, we investigated a panel of hiPSC-derived lines from patients with different phenotypes, harboring different mutations in *SCN1A*, including members of a family where the same mutation leads to different clinical phenotypes. Using Micro-electrode arrays, we provide further evidence that excitatory neurons are implicated in DS syndrome. The excitatory networks are affected by different *SCN1A* mutations to different extend, and show altered neuronal network organization upon febrile temperatures. However, the network phenotypes could not be distinguished based on patient clinical severity. Interestingly, the network phenotype could be partially rescued with valproic acid, the main AED prescribed for DS, while carbamazepine, a contraindicated AED, leads to aggrevation of the phenotype. In conclusion, our results indicate a mutation-specific excitatory neuronal network phenotype, which responds to the main DS-linked triggers, suggesting a useful platform for precision therapies for DS.

Early postnatal development of pyramidal neurons across layers of the mouse medial prefrontal cortex.
Mammalian neocortex is a highly layered structure. Each layer is populated by distinct subtypes of principal cells that are born at different times during development. While the differences between principal cells across layers have been extensively studied, it is not known how the developmental profiles of neurons in different layers compare. Here, we provide a detailed morphological and functional characterisation of pyramidal neurons in mouse mPFC during the first postnatal month, corresponding to known critical periods for synapse and neuron formation in mouse sensory neocortex. Our data demonstrate similar maturation profiles of dendritic morphology and intrinsic properties of pyramidal neurons in both deep and superficial layers. In contrast, the balance of synaptic excitation and inhibition differs in a layer-specific pattern from one to four postnatal weeks of age. Our characterisation of the early development and maturation of pyramidal neurons in mouse mPFC not only demonstrates a comparable time course of postnatal maturation to that in other neocortical circuits, but also implies that consideration of layer- and time-specific changes in pyramidal neurons may be relevant for studies in mouse models of neuropsychiatric and neurodevelopmental disorders.

Modeling Psychiatric Diseases with Induced Pluripotent Stem Cells.
Neuropsychiatric disorders are a heterogeneous group of disorders that are challenging to model and treat, due to their underlying complex genetic architecture and clinical variability. Presently, increasingly more studies are making use of induced pluripotent stem cell (iPSC)-derived neurons, reprogrammed from patient somatic cells, to model neuropsychiatric disorders. iPSC-derived neurons offer the possibility to recapitulate relevant disease biology in the context of the individual patient genetic background. In addition to disease modeling, iPSC-derived neurons offer unprecedented opportunities in drug screening. In this chapter, the current status of iPSC disease modeling for neuropsychiatric disorders is presented. Both 2D and 3D disease modeling approaches are discussed as well as the generation of different neuronal cell types that are

relevant for studying neuropsychiatric disorders. Moreover, the advantages and limitations are highlighted in addition to the future perspectives of using iPSC-derived neurons in the uncovering of robust cellular phenotypes that consecutively have the potential to lead to clinical developments.

Human neuronal networks on micro-electrode arrays are a highly robust tool to study disease-specific genotype-phenotype correlations in vitro.
Micro-electrode arrays (MEAs) are increasingly used to characterize neuronal network activity of human induced pluripotent stem cell (hiPSC)-derived neurons. Despite their gain in popularity, MEA recordings from hiPSC-derived neuronal networks are not always used to their full potential in respect to experimental design, execution, and data analysis. Therefore, we benchmarked the robustness of MEA-derived neuronal activity patterns from ten healthy individual control lines, and uncover comparable network phenotypes. To achieve standardization, we provide recommendations on experimental design and analysis. With such standardization, MEAs can be used as a reliable platform to distinguish (disease-specific) network phenotypes. In conclusion, we show that MEAs are a powerful and robust tool to uncover functional neuronal network phenotypes from hiPSC-derived neuronal networks, and provide an important resource to advance the hiPSC field toward the use of MEAs for disease phenotyping and drug discovery.

Neuron-Glia Interactions Increase Neuronal Phenotypes in Tuberous Sclerosis Complex Patient iPSC-Derived Models.
Tuberous sclerosis complex (TSC) is a rare neurodevelopmental disorder resulting from autosomal dominant mutations in the TSC1 or TSC2 genes, leading to a hyperactivated mammalian target of rapamycin (mTOR) pathway, and gray and white matter defects in the brain. To study the involvement of neuron-glia interactions in TSC phenotypes, we generated TSC patient induced pluripotent stem cell (iPSC)-derived cortical neuronal and oligodendrocyte (OL) cultures. TSC neuron mono-cultures showed increased network activity, as measured by calcium transients and action potential firing, and increased dendritic branching. However, in co-cultures with OLs, neuronal defects became more apparent, showing cellular hypertrophy and increased axonal density. In addition, TSC neuron-OL co-cultures showed increased OL cell proliferation and decreased OL maturation. Pharmacological intervention with the mTOR regulator rapamycin suppressed these defects. Our patient iPSC-based model, therefore, shows a complex cellular TSC phenotype arising from the interaction of neuronal and glial cells and provides a platform for TSC disease modeling and drug development.

m.3243A > G-Induced Mitochondrial Dysfunction Impairs Human Neuronal Development and Reduces Neuronal Network

Activity and Synchronicity.
Epilepsy, intellectual and cortical sensory deficits, and psychiatric manifestations are the most frequent manifestations of mitochondrial diseases. How mitochondrial dysfunction affects neural structure and function remains elusive, mostly because of a lack of proper in vitro neuronal model systems with mitochondrial dysfunction. Leveraging induced pluripotent stem cell technology, we differentiated excitatory cortical neurons (iNeurons) with normal (low heteroplasmy) and impaired (high heteroplasmy) mitochondrial function on an isogenic nuclear DNA background from patients with the common pathogenic m.3243A > G variant of mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS). iNeurons with high heteroplasmy exhibited mitochondrial dysfunction, delayed neural maturation, reduced dendritic complexity, and fewer excitatory synapses. Micro-electrode array recordings of neuronal networks displayed reduced network activity and decreased synchronous network bursting. Impaired neuronal energy metabolism and compromised structural and functional integrity of neurons and neural networks could be the primary drivers of increased susceptibility to neuropsychiatric manifestations of mitochondrial disease.

MOLECULAR AND CELLULAR STUDY OF THE IMPACT OF NR2F1 MISSENSE VARIANTS BY USING STRUCTURAL BIOLOGY AND THE GENETIC CODE EXPANSION (GCE) APPROACH

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Wanchana Phromkrasae[1], Valerio Marino[2], Michele Bertacchi[1], Krittalak Chakrabandhu[1], Daniele Dell'Orco[2], Michèle Studer[1]
[1]Institute of Biology Valrose, iBV, Cnrs 7277- Inserm 1091, Nice, France, [2]Department of Neurosciences, Biomedicine and Movement Sciences Section of Biological Chemistry, University Of Verona, Verona, Italy

Bosch-Boonstra-Schaaf optic atrophy syndrome (BBSOAS) is a rare neurodevelopmental disorder caused by mutations in the *NR2F1* gene. NR2F1 acts as a transcriptional regulator and plays an important role in brain development. Several pathogenic mutations were reported in *NR2F1* leading to variable clinical severities among patients. However, the way single mutations affect protein structural stability and neuronal function is still poorly understood. By modeling *NR2F1* missense variants *in silico*, we found that several mutations destabilize the structure of the isolated functional domains and have a negative effect on either the affinity or the stability of the complexes. By using a synthetic biology technique, called genetic code expansion (GCE), that incorporates the photo-crosslinker azido-L-phenylalanine (AzF) at pre-determined sites within the NR2F1 protein, and transient transfections *in vitro*, we unravelled a whole series of putative co-factor protein complexes of different sizes. GCE-captured protein complexes were abolished in the presence of the mutation and restored by amber codon suppression of the full-length NR2F1 protein. Transient transfection of different NR2F1 mutant proteins in HEK293T cells show severe reduction in cell proliferation and increased cell apoptosis together with abnormal accumulation in the cytoplasm of some variants, such as the truncated Q244* and E400* forms, in line with affected protein structural stability. By evaluating the impact of single mutations on NR2F1 nuclear localization, on protein complex formation and on NR2F1-mediated control of cell proliferation and survival, we propose here a genotype to phenotype correlation of BBSOAS from a mechanistic point of view.

CONVERGENCE OF BEHAVIOURAL AND MOLECULAR PHENOTYPES IN MOUSE AND RAT MODELS FOR DOWN SYNDROME AND CONSEQUENCE FOR FURTHER THERAPIES IN HUMAN.

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Yann Herault, Marion Pellen, Arnaud Duchon, Claire Chevalier, Véronique Brault
University of Strasbourg -CNRS - INSERM, IGBMC, Translational Medicine And Neurogenetics, ILLKIRCH, France

Down syndrome (DS) is the most common genetic form of neurodevelopmental disorder with intellectual disabilities and caused by the presence of an additional copy of human chromosome 21 (Hsa21). The phenotype-genotype relationship, the identification of main driver genes and various proof-of-concepts for therapeutic improvement have benefited from the development of many mouse models and their analysis. To provide novel insights into genotype–phenotype correlations for cognition and other comorbidities found in DS, we have used several new mouse models, refine old one such as the Ts(1716)65Dn/J (Ts65Dn), and develop rat models for DS. We have performed a standardized behavioural and brain pipeline with hippocampal gene expression. We have confirmed the important role of DYRK1A as a main driver of cognitive dysfunction in DS but we have also found new loci which are involved in cognition and behaviour, highlighting the complexity of the altered neurological mechanisms in DS. Our ongoing study has unravelled several interacting loci homologous to Hsa21 gene, contributing to altering brain cognition, function and structure. Our next in-depth analysis of misregulated expressed genes showed that synaptic dysfunction was the consequence of a few altered biological cascades, with more impact in the hippocampus compared to the Entorhinal cortex in some models. Rat models highlighted the importance of investigating a complete DS models with all the regions triplicated. Finally, we provide a novel vision of the existing altered gene-gene crosstalk and molecular mechanisms in DS models that should become central to better understanding of DS and improving the development of therapies in human.

MUTATIONS IN THE MCPH GENE, RRP7A, CONVERGE ON TGFB/BMP SIGNALING AT THE PRIMARY CILIUM

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Jindriska Leischner Fialova[1], Josefine Stensbøl[1], Emma Dyke[2], Daniel Baird[3], Lars Larsen[3], Nael Nadif Kasri[2], Lotte Pedersen[1], Søren Christensen[1]
[1]University of Copenhagen, Department Of Biology, Copenhagen, Denmark, [2]RadboudUMC, Human Genetics, Nijmegen, Netherlands, [3]University of Copenhagen, Department Of Cellular And Molecular Medicine, Copenhagen, Denmark

Emerging evidence suggests that neurodevelopmental disorders are closely linked to dysfunction of primary cilia that project as solitary antenna-like organelles on the surface of most vertebrate cell types, including radial glial progenitor cells (RGCs). However, little is still known on the mechanisms by which primary cilia control brain development, and how defects in their function cause congenital brain disorders. We previously identified a homozygous missense mutation (p.W155C) in *Ribosomal RNA Processing 7 Homolog A*, *RRP7A*, segregating with MCPH in a consanguineous family with 10 affected individuals [Farooq et al. (2020) Nat. Comm. 11, 5816]. RRP7A is highly expressed in RGCs in the developing human neocortex and functions in the borderline between nucleoli and primary cilia to control neurogenesis and cell cycle entry, which in part is associated with defects in the timely resorption of primary cilia. The aim of our current work is to decipher the molecular mechanisms by which defects in RRP7A impede ciliary resorption and affect neurodevelopmental signaling in turn leading to MCPH. To this end, we show that RRP7A mutations in patient fibroblasts and (stem) cell models lead to defects in coordination of TGFB/BMP signaling at the primary cilium, and that this signaling phenotype links to defects in *in vitro* neurogenesis. These results provide novel insight into the function of primary cilia in brain development and MCPH, and experiments are underway to delineate in more detail how RRP7A at the cilium orchestrate neural and neuronal development in cerebral organoids and zebrafish models.

Novel Mitochondria-targeted Drugs for Cancer Therapy.
The search for mitochondria-targeted drugs has dramatically risen over the last decade. Mitochondria are essential organelles serving not only as a powerhouse of the cell but also as a key player in cell proliferation and cell death. Their central role in the energetic metabolism, calcium homeostasis and apoptosis makes them an intriguing field of interest for cancer pharmacology. In cancer cells, many mitochondrial signaling and metabolic pathways are altered. These changes contribute to cancer development and progression. Due to changes in mitochondrial metabolism and changes in membrane potential, cancer cells are more susceptible to mitochondria-targeted therapy. The loss of functional mitochondria leads to the arrest of cancer progression and/or a cancer cell death. Identification of mitochondrial changes specific for tumor growth and progression, rational development of new mitochondria-targeted drugs and research on delivery agents led to the advance of this promising area. This review will highlight the current findings in mitochondrial biology, which are important for cancer initiation, progression and resistance, and discuss approaches of cancer pharmacology with a special focus on the anti-cancer drugs referred to as 'mitocans'.

Septin-microtubule association via a motif unique to isoform 1 of septin 9 tunes stress fibers.
Septins, a family of GTP-binding proteins that assemble into higher order structures, interface with the membrane, actin filaments and microtubules, and are thus important regulators of cytoarchitecture. Septin 9 (SEPT9), which is frequently overexpressed in tumors and mutated in hereditary neuralgic amyotrophy (HNA), mediates the binding of septins to microtubules, but the molecular determinants of this interaction remained uncertain. We demonstrate that a short microtubule-associated protein (MAP)-like motif unique to SEPT9 isoform 1 (SEPT9_i1) drives septin octamer-microtubule interaction in cells and in vitro reconstitutions. Septin-microtubule association requires polymerizable septin octamers harboring SEPT9_i1. Although outside of the MAP-like motif, HNA mutations abrogate this association, identifying a putative regulatory domain. Removal of this domain from SEPT9_i1 sequesters septins on microtubules, promotes microtubule

stability and alters actomyosin fiber distribution and tension. Thus, we identify key molecular determinants and potential regulatory roles of septin-microtubule interaction, paving the way to deciphering the mechanisms underlying septin-associated pathologies. This article has an associated First Person interview with the first author of the paper.

Locked and Loaded: Ruthenium(II)-Capped Cucurbit[]uril-Based Rotaxanes with Antimetastatic Properties.
We report here the first coupling of Ru(II) units with cucurbit[6/7]uril-based pseudorotaxane ligands meant for biological application. The resulting ruthenium-capped rotaxanes were fully characterized, and a structure of one supramolecular system was determined by X-ray diffraction. Because the biological properties of Ru-based metallodrugs are tightly linked to the ligand-exchange processes, the effect of salt concentration on the hydrolysis of chlorides from the Ru(II) center was monitored by using H NMR spectroscopy. The biological activity of Ru(II)-based rotaxanes was evaluated for three selected mammalian breast cell lines, HBL-100, MCF-7, and MDA-MB-231. The antimetastatic activity of the assembled cationic Ru(II)-rotaxane systems, evaluated in migration assays against MCF-7 and MDA-MB-231 cell lines, is notably enhanced compared to that of RAPTA-C, a reference that was used. The indicated synergistic effect of combining Ru(II) with a pseudorotaxane unit opens a new direction in searching for anticancer supramolecular metallodrugs.

IDENTIFICATION OF DEFECTS OF HUMAN CORTICAL NEURON DEVELOPMENT USING SINGLE CELL TRANSCRIPTOMICS

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Michael Lattke[1], Vincenzo De Paola[1,2]
[1]Imperial College London, Brain Sciences, London, United Kingdom, [2]Duke-NUS Medical School, Neuroscience And Behavioural Disorders, Singapore, Singapore

Down syndrome is a common neurodevelopmental condition and the most common genetic cause of intellectual disability. Although the underlying cause, a trisomy of chromosome 21, is known for more than 60 years, it is not well understood how the increased gene dosage of the more than 400 genes on chromosome 21 leads to the observed neurodevelopmental defects, and causal therapies are lacking. Mouse models suggest molecular mechanisms impairing neural progenitor proliferation and neuronal differentiation in the cerebral cortex, but it is unclear to what extent these alterations are recapitulated in the human brain, and whether additional defects occur during neuronal development in the much more complex human cortex. To address these questions, we use single cell transcriptomics to identify molecular and cellular alterations in human cortical neuron development in Down syndrome in different experimental settings, including primary fetal brain tissue and a novel in vivo graft model. Here, we present preliminary data from our graft model, suggesting that progenitor proliferation and excitatory neuron generation are also impaired in human neuron development. This is supported by a re-analysis of a published scRNA-Seq dataset of cortical organoids, which also suggests potential regulators that may mediate these phenotypes. Overall, our work will help to clarify the mechanisms underlying neurodevelopmental alterations in Down syndrome and may indicate new strategies to ameliorate cognitive impairments in this common neurodevelopmental condition.

Pyridoxine-dependent epilepsy (PDE-ALDH7A1) and glutaric aciduria type 1 (GA1) are two rare neurometabolic disorders of lysine metabolism, caused by pathogenic variants in *ALDH7A1* and *GCDH,* respectively. Deficiency of the encoded enzymes results in accumulation of neurotoxic metabolites causing debilitating neurological sequelae in patients. Currently, no suitable human PDE-ALHD7A1 and GA1 models are available. Therefore, we here aim to develop human cellular PDE-ALDH7A1 and GA1 models to investigate the disease mechanism and identify therapeutic targets. In this study, patient-derived fibroblasts were reprogrammed into induced pluripotent stem cells (iPSCs). In addition, isogenic knock-out lines derived from control iPSCs have been generated using the CRISPR/Cas9 system. Because *ALDH7A1* and *GCDH* expression is enriched in astrocytes, we differentiated iPSC lines towards neurons and astrocytes. We show that iPSC-derived astrocytes generated using a two-step differentiation protocol, are both morphologically and functionally mature within 5 weeks of differentiation. In addition, when co-cultured together with cortical excitatory neurons, the iPSC-derived astrocytes support neuronal maturation and synapse formation confirmed by immunostainings with MAP2 and Synapsin1/2 antibodies respectively. Co-cultures of patient-derived neurons and astrocytes on micro-electrode arrays are then used for electrophysiological and molecular measurements to identify the disease-specific neural network activity. Moreover, cell extracts and medium of both the fibroblasts and neuronal and astrocyte co-cultures are collected for metabolomic analysis. By in-depth molecular, electrophysiological and metabolomic characterization of fibroblasts and neuronal and astrocyte co-cultures, we aim to understand the neurotoxicity mechanism underlying these two neurometabolic disorders.

CEREBELLUM-POSTNATAL DEVELOPMENT AND BEHAVIOR ONTOGENESIS IN A MOUSE MODEL OF THE INTELLECTUAL DISABILITY-ASSOCIATED COFFIN-LOWRY SYNDROME

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Laurine Gonzalez[1], Catherine Sébrié[2], Véronique Rousseau[1], Bernadette Wiszniowski[1], Serge Laroche[1], Cyrille Vaillend[1], Valérie Enderlin[1], Roseline Poirier[1]

Coffin-Lowry syndrome (CLS) is a rare neurodevelopmental disorder characterized by severe intellectual disability associated with physical and neurological abnormalities. CLS is due to mutations in the *rps6ka3* gene that encodes the RSK2 kinase, which acts at the end of the MAPK signaling pathway, known for its key role in cognitive processes. Once activated by ERK, RSK2 has numerous cytosolic and nuclear targets, such as CREB, Histone 3, PDL1, suggesting a key role in different cellular processes (proliferation, differentiation, and neuronal maturation). We therefore characterized postnatal brain development of the *Rsk2*-KO mouse model of CLS. Our *in vivo* MRI analyses revealed reduced volumes of the whole brain, hippocampus and cerebellum in *Rsk2*-KO mice from postnatal day (PND) 14. Interestingly, total brain volume spontaneously recovers WT level in adulthood, highlighting a delay in postnatal development. Behavioral tests revealed that *Rsk2*-KO mice display slight motor or spontaneous behavior deficits during the postnatal period, suggesting altered cerebellum integrity. We then studied cellular processes in the cerebellum and found that at PND7 the absence of RSK2 does not affect the proliferation and migration of granular cells from the external to the internal granular layer, but impacts the development of Purkinje-cell dendritic tree. Biochemical analyses further revealed a dysregulation of the MAPK signaling pathway that appears at PND14, which could be responsible for the developmental alterations observed in the cerebellum. Supported by Fondation Jerome Lejeune, Fondation Xtraordinaire, PhD (LG) supported by FRM, Graduate School Life Science and Health and Paris-Saclay University.

AIMS. Cannabinoid receptors 1 (CB1R) have attracted much attention as potential therapeutic targets for intellectual disability disorders; in fact, treatment with the CB1R antagonist rimonabant normalizes neurobehavioural alterations in Fragile X and Down syndromes murine models. Importantly, increased CB1R activation at brain mitochondria membranes (mtCB1R) can affect mitochondrial activity and memory processes via inhibition of intra-mitochondrial protein kinase A (PKA), suggesting CB1R inhibitors as promising drug candidates for intellectual disability disorders characterized by brain mitochondrial alterations. Defective brain mitochondria and the resulting increased levels of free radicals are emerging crucial factors in the pathogenesis of Rett syndrome (RTT), a rare disorder and a major cause of intellectual disability in females. In the present study, we explored whether a systemic treatment with rimonabant can rescue brain mitochondrial dysfunction in a RTT mouse model. **METHODS**. Fully symptomatic MeCP2-308 heterozygous female mice (HET) and wild-type littermates received a systemic treatment with rimonabant or vehicle (4-day-long intraperitoneal injections at the dose of 0.3 mg/kg/day) at the end of which brains were cryopreserved for bioenergetic analyses. **RESULTS**. Treatment with rimonabant normalized the reduced mitochondrial ATP production and ATP levels in the brain of HET mice. Rimonabant also rescued the overexpression of the cerebral mtCB1R and the intra-mitochondrial hypoactivation of PKA in the hippocampus of HET mice. **CONCLUSIONS**. Present results outline a potential mechanism underlying mitochondrial alterations in RTT mouse brain which could represent a novel target for the treatment of this severe disease. Treatment with the Bacterial Toxin CNF1 Selectively Rescues Cognitive and Brain Mitochondrial Deficits in a Female Mouse Model of Rett Syndrome Carrying a MeCP2-Null Mutation.
Rett syndrome (RTT) is a rare neurological disorder caused by mutations in the X-linked gene and a major cause of intellectual disability in females. No cure exists for RTT. We previously reported that the behavioural phenotype and brain mitochondria dysfunction are widely rescued by a single intracerebroventricular injection of the bacterial toxin CNF1 in a RTT mouse model carrying a truncating mutation of the gene (MeCP2-308 mice). Given the heterogeneity of mutations in RTT patients, we tested the CNF1 therapeutic efficacy in a mouse model carrying a null mutation (MeCP2-Bird mice). CNF1 selectively rescued cognitive defects, without improving other RTT-related behavioural alterations, and restored brain mitochondrial respiratory chain complex activity in MeCP2-Bird mice. To shed light on the molecular mechanisms underlying the differential CNF1 effects on the behavioural phenotype, we compared treatment effects on relevant signalling cascades in the brain of the two RTT models. CNF1 provided a significant boost of the mTOR activation in MeCP2-308 hippocampus, which was not observed in the MeCP2-Bird model, possibly explaining the differential effects of CNF1. These results demonstrate that CNF1 efficacy depends on the mutation beared by MeCP2-mutated mice, stressing the need of testing potential therapeutic approaches across RTT models.

The Anti-Diabetic Drug Metformin Rescues Aberrant Mitochondrial Activity and Restrains Oxidative Stress in a Female

Mouse Model of Rett Syndrome.
Metformin is the first-line therapy for diabetes, even in children, and a promising attractive candidate for drug repurposing. Mitochondria are emerging as crucial targets of metformin action both in the periphery and in the brain. The present study evaluated whether treatment with metformin may rescue brain mitochondrial alterations and contrast the increased oxidative stress in a validated mouse model of Rett syndrome (RTT), a rare neurologic disorder of monogenic origin characterized by severe behavioral and physiological symptoms. No cure for RTT is available. In fully symptomatic RTT mice (12 months old MeCP2-308 heterozygous female mice), systemic treatment with metformin (100 mg/kg ip for 10 days) normalized the reduced mitochondrial ATP production and ATP levels in the whole-brain, reduced brain oxidative damage, and rescued the increased production of reactive oxidizing species in blood. A 10-day long treatment with metformin also boosted pathways related to mitochondrial biogenesis and antioxidant defense in the brain of metformin-treated RTT mice. This treatment regimen did not improve general health status and motor dysfunction in RTT mice at an advanced stage of the disease. Present results provide evidence that systemic treatment with metformin may represent a novel, repurposable therapeutic strategy for RTT.

The Fragile X Syndrome (FXS) is the most common form of inherited intellectual disability and is caused by the absence of the mRNA-binding protein FMRP (Fragile X Mental Retardation Protein). FXS patients and animal models present numerous neurodevelopmental and plasticity defects. Neuronal migration is crucial to the establishment of functional neural circuits but remains mostly unexplored in FXS. We analyzed the migration defects induced by FMRP absence in the context of the postnatal Rostral Migratory Stream (RMS). In the RMS, neurons perform cyclic saltatory migration from the ventricular/subventricular zone to the olfactory bulb along with stereotypical movement of their centrosome. Through *in vivo* intraventricular electroporation of plasmids expressing fluorescent proteins followed by confocal live imaging, we show that migrating neurons in *Fmr1-null* mice display slowed-down migration along with altered trajectory and defective centrosomal dynamic. This phenotype is recapitulated by RNA interference and hence cell autonomous. Mutated neurons also display altered morphology, suggesting cytoskeletal defects. The microtubule (MT) network is essential during neuronal migration. By immunostaining, we analyzed the subcellular compartmentalization of dynamic tyrosinated MTs and observed strong defects in MT tyrosination in mutant neurons. MAP1B (Microtubule Associated Protein 1B) is a known FMRP mRNA target involved in the control of MT tyrosination. We will thus test whether increased MAP1B in mutant neurons is causal in defective MT dynamics leading to abnormal migration. Our results hence unveil a new neurodevelopmental role of FMRP, as a key element of neuronal migration, likely to be essential for the understanding of FXS pathophysiology.

Cortical circuits are built at perinatal times and gradually refined in an activity- dependent manner during the postnatal period of critical plasticity. Although lesions of the CNS occurring during this period recover better than those occurring later in life, they are often associated with long-term cognitive deficits, which suggests that neuronal circuits rewiring, in particular within the cortex, may either be incomplete or inappropriate. Here we used chronic hypoxia, a mouse model of very premature birth, to study the long-term impact of premature brain injuries on glutamatergic neuron's maturation and cortical circuit's formation. Our results reveal gradual and profound alterations of glutamatergic neurons dendritic arborizations following chronic hypoxia, that differentially affect their apical and basal dendritic compartments. Using retrograde tracing, we show that these dendritic alterations are paralleled by a global cortical hyperconnectivity as well as a redistribution of long-distance cortical connections. Finally, testing of sociability reveals an impairment for social novelty in young adult hypoxic mice, which amplifies in adulthood. Altogether, our results highlight how premature brain injuries, such as those resulting from very premature births, impact cortical neuron maturation and connectivity, as well as associated behaviors.

CORTICOGENESIS IS IMPAIRED IN A MOUSE MODEL OF DDX3X SYNDROME

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Marta Garcia-Forn[1,2,3,4], Michael Flores[1,2,3,4], Praise Ola[1,2,3,4], Silvia De Rubeis[1,2,3,4]
[1]Icahn School of Medicine at Mount Sinai, Seaver Autism Center For Research And Treatment, New York, United States of America, [2]Icahn School of Medicine at Mount Sinai, Psychiatry, New York, United States of America, [3]Icahn School of Medicine at Mount Sinai, The Mindich Child Health And Development Institute, New York, United States of America, [4]Icahn School of Medicine at Mount Sinai, Friedman Brain Institute, New York, United States of America

Background: DDX3X syndrome is caused by mutations in the *DDX3X* gene and accounts for 1-3% of unexplained intellectual disability (ID) in females, presenting also behavioral problems and motor impairments. Even though the genetic cause of the syndrome is known, the cellular and molecular mechanisms driving it remain elusive. DDX3X is an X-linked gene that regulates mRNA translation and has emerging functions in corticogenesis and synaptogenesis. We previously generated the first mouse model (*Ddx3x*$^{+/-}$) with construct and face validity for *DDX3X* loss-of-function mutations, which showed developmental and behavioral alterations accompanied by defective cortical lamination. **Aims:** The aim of this study is to elucidate the cellular and molecular functions of DDX3X syndrome during corticogenesis. **Methods:** We used our Ddx3x haploinsufficient mouse model (*Ddx3x*$^{+/-}$) to study the impact of *Ddx3x* haploinsufficiency on cortical development, by examining cortical progenitors and post-mitotic neurons using cell-specific markers at different time points of embryogenesis. We also performed *in vivo* birth dating of specific populations of glutamatergic neurons. **Results:** *Ddx3x*$^{+/-}$ mice present alterations in cortical neurogenesis and cell fate specification compared to their *Ddx3x*$^{+/+}$ littermates. *Ddx3x*$^{+/-}$ mice have changes in the abundance and/or laminar position of specific populations of cortical projection neurons. These changes are area-specific. *Ddx3x*$^{+/-}$ mice also show alterations of cortical progenitors. **Conclusion:** Our data shed new light on the cellular mechanisms driving the neurodevelopmental phenotypes of DDX3X syndrome.

Linking Autism Risk Genes to Disruption of Cortical Development.
Autism spectrum disorder (ASD) is a prevalent neurodevelopmental disorder characterized by impairments in social communication and social interaction, and the presence of repetitive behaviors and/or restricted interests. In the past few years, large-scale whole-exome sequencing and genome-wide association studies have made enormous progress in our understanding of the genetic risk architecture of ASD. While showing a complex and heterogeneous landscape, these studies have led to the identification of genetic loci associated with ASD risk. The intersection of genetic and transcriptomic analyses have also begun to shed light on functional convergences between risk genes, with the mid-fetal development of the cerebral cortex emerging as a critical nexus for ASD. In this review, we provide a concise summary of the latest genetic discoveries on ASD. We then discuss the studies in postmortem tissues, stem cell models, and rodent models that implicate recently identified ASD risk genes in cortical development.

Lack of Annexin A6 Exacerbates Liver Dysfunction and Reduces Lifespan of Niemann-Pick Type C Protein-Deficient Mice.
Niemann-Pick type C (NPC) disease is a lysosomal storage disorder characterized by cholesterol accumulation caused by loss-of-function mutations in the Npc1 gene. NPC disease primarily affects the brain, causing neuronal damage and affecting

motor coordination. In addition, considerable liver malfunction in NPC disease is common. Recently, we found that the depletion of annexin A6 (ANXA6), which is most abundant in the liver and involved in cholesterol transport, ameliorated cholesterol accumulation in Npc1 mutant cells. To evaluate the potential contribution of ANXA6 in the progression of NPC disease, double-knockout mice (Npc1/Anxa6) were generated and examined for lifespan, neurologic and hepatic functions, as well as liver histology and ultrastructure. Interestingly, lack of ANXA6 in NPC1-deficient animals did not prevent the cerebellar degeneration phenotype, but further deteriorated their compromised hepatic functions and reduced their lifespan. Moreover, livers of Npc1/Anxa6 mice contained a significantly elevated number of foam cells congesting the sinusoidal space, a feature commonly associated with inflammation. We hypothesize that ANXA6 deficiency in Npc1 mice not only does not reverse neurologic and motor dysfunction, but further worsens overall liver function, exacerbating hepatic failure in NPC disease.

Neuron type-specific increase in lamin B1 contributes to nuclear dysfunction in Huntington's disease.
Lamins are crucial proteins for nuclear functionality. Here, we provide new evidence showing that increased lamin B1 levels contribute to the pathophysiology of Huntington's disease (HD), a CAG repeat-associated neurodegenerative disorder. Through fluorescence-activated nuclear suspension imaging, we show that nucleus from striatal medium-sized spiny and CA1 hippocampal neurons display increased lamin B1 levels, in correlation with altered nuclear morphology and nucleocytoplasmic transport disruption. Moreover, ChIP-sequencing analysis shows an alteration of lamin-associated chromatin domains in hippocampal nuclei, accompanied by changes in chromatin accessibility and transcriptional dysregulation. Supporting lamin B1 alterations as a causal role in mutant huntingtin-mediated neurodegeneration, pharmacological normalization of lamin B1 levels in the hippocampus of the R6/1 mouse model of HD by betulinic acid administration restored nuclear homeostasis and prevented motor and cognitive dysfunction. Collectively, our work points increased lamin B1 levels as a new pathogenic mechanism in HD and provides a novel target for its intervention.

RTP801/REDD1 Is Involved in Neuroinflammation and Modulates Cognitive Dysfunction in Huntington's Disease.
RTP801/REDD1 is a stress-regulated protein whose levels are increased in several neurodegenerative diseases such as Parkinson's, Alzheimer's, and Huntington's diseases (HD). RTP801 downregulation ameliorates behavioral abnormalities in several mouse models of these disorders. In HD, RTP801 mediates mutant huntingtin (mhtt) toxicity in in vitro models and its levels are increased in human iPSCs, human postmortem putamen samples, and in striatal synaptosomes from mouse models of the disease. Here, we investigated the role of RTP801 in the hippocampal pathophysiology of HD. We found that RTP801 levels are increased in the hippocampus of HD patients in correlation with gliosis markers. Although RTP801 expression is not altered in the hippocampus of the R6/1 mouse model of HD, neuronal RTP801 silencing in the dorsal hippocampus with shRNA containing AAV particles ameliorates cognitive alterations. This recovery is associated with a partial rescue of synaptic markers and with a reduction in inflammatory events, especially microgliosis. Altogether, our results indicate that RTP801 could be a marker of hippocampal neuroinflammation in HD patients and a promising therapeutic target of the disease.

Increased translation as a novel pathogenic mechanism in Huntington's disease.
Huntington's disease is a neurodegenerative disorder caused by a CAG repeat expansion in exon 1 of the huntingtin gene. Striatal projection neurons are mainly affected, leading to motor symptoms, but molecular mechanisms involved in their vulnerability are not fully characterized. Here, we show that eIF4E binding protein (4E-BP), a protein that inhibits translation, is inactivated in Huntington's disease striatum by increased phosphorylation. Accordingly, we detected aberrant de novo protein synthesis. Proteomic characterization indicates that translation specifically affects sets of proteins as we observed upregulation of ribosomal and oxidative phosphorylation proteins and downregulation of proteins related to neuronal structure and function. Interestingly, treatment with the translation inhibitor 4EGI-1 prevented R6/1 mice motor deficits, although corticostriatal long-term depression was not markedly changed in behaving animals. At the molecular level, injection of 4EGI-1 normalized protein synthesis and ribosomal content in R6/1 mouse striatum. In conclusion, our results indicate that dysregulation of protein synthesis is involved in mutant huntingtin-induced striatal neuron dysfunction.

Pharmacogenetic modulation of STEP improves motor and cognitive function in a mouse model of Huntington's disease.
Huntington's disease (HD) is a hereditary neurodegenerative disorder caused by an expansion of a CAG repeat in the huntingtin (htt) gene, which results in an aberrant form of the protein (mhtt). This leads to motor and cognitive deficits associated with corticostriatal and hippocampal alterations. The levels of STriatal-Enriched protein tyrosine Phosphatase (STEP), a neural-specific tyrosine phosphatase that opposes the development of synaptic strengthening, are decreased in the striatum of HD patients and also in R6/1 mice, thereby contributing to the resistance to excitotoxicity described in this HD mouse model. Here, we aimed to analyze whether STEP inactivation plays a role in the pathophysiology of HD by investigating its effect on motor and cognitive impairment in the R6/1 mouse model of HD. We found that genetic deletion of STEP delayed the onset of motor dysfunction and prevented the appearance of cognitive deficits in R6/1 mice. This phenotype was accompanied by an increase in pERK1/2 levels, a delay in the decrease of striatal DARPP-32 levels and a reduction in the size of mhtt aggregates, both in the striatum and CA1 hippocampal region. We also found that acute pharmacological inhibition of STEP with TC-2153 improved cognitive function in R6/1 mice. In conclusion, our results show that deletion of STEP has a beneficial effect on motor coordination and cognition in a mouse model of HD suggesting that STEP inhibition could be a good therapeutic strategy in HD patients.

ALTERED BEHAVIOUR, METABOLISM AND NEURAL ACTIVITY IN A MOUSE MODEL OF INTELLECTUAL DISABILITY WITH A MUTATION IN PDZD8 GENE

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Andreea Pantiru
University of Leeds, Faculty Of Biological Sciences, Leeds, United Kingdom

Intellectual disability (ID) is the most common childhood neurodevelopmental disorder that affects learning ability, impairs cognitive functioning, and is defined by an intelligence quotient below 70. Although ID is caused by both environmental and genetic causes, severe forms are often associated with defects in single genes. We have identified four children from two unrelated families diagnosed with intellectual disability, developmental delay, macrocephaly and other autistic features caused by a specific mutation in PDZ domain containing protein 8 (PDZD8) gene. PDZD8 is an ER-mitochondria tethering protein which regulates calcium dynamics in mammalian neurons and has not previously been associated with any human disease. As PDZD8 mutation is a novel mutation linked to ID, our aim was to further characterise PDZD8 disruption in a mouse model in terms of behaviour analysis, molecular characterization and *in vivo* two-photon calcium imaging of neuronal dynamics. Mice homozygous for a premature termination codon in PDZD8 displayed abnormal brain structure, cognitive impairment, and altered neuronal activity *in vivo.* These data demonstrate the involvement of a homozygous loss of function mutation in PDZD8 in a neurodevelopmental cognitive disorder.

27535874: O'Neill P, Lindsay SL, Pantiru A, Guimond SE, Fagoe N, Verhaagen J, Turnbull JE, Riddell JS, Barnett SC Sulfatase-mediated manipulation of the astrocyte-Schwann cell interface.
Schwann cell (SC) transplantation following spinal cord injury (SCI) may have therapeutic potential. Functional recovery is limited however, due to poor SC interactions with host astrocytes and the induction of astrogliosis. Olfactory ensheathing cells (OECs) are closely related to SCs, but intermix more readily with astrocytes in culture and induce less astrogliosis. We previously demonstrated that OECs express higher levels of sulfatases, enzymes that remove 6-O-sulfate groups from heparan sulphate proteoglycans, than SCs and that RNAi knockdown of sulfatase prevented OEC-astrocyte mixing in vitro. As human OECs are difficult to culture in large numbers we have genetically engineered SCs using lentiviral vectors to express sulfatase 1 and 2 (SC-S1S2) and assessed their ability to interact with astrocytes. We demonstrate that SC-S1S2s have increased integrin-dependent motility in the presence of astrocytes via modulation of NRG and FGF receptor-linked PI3K/AKT intracellular signaling and do not form boundaries with astrocytes in culture. SC-astrocyte mixing is dependent on local NRG concentration and we propose that sulfatase enzymes influence the bioavailability of NRG ligand and thus influence SC behavior. We further demonstrate that injection of sulfatase expressing SCs into spinal cord white matter results in less glial reactivity than control SC injections comparable to that of OEC injections. Our data indicate that sulfatase-mediated modification of the extracellular matrix can influence glial interactions with astrocytes, and that SCs engineered to express sulfatase may be more OEC-like in character. This approach may be beneficial for cell transplant-mediated spinal cord repair. GLIA 2016 GLIA 2017;65:19-33.

COMPREHENSIVE DELINEATION AND PRECISION MEDICINE OF GRIN-RELATED NEURODEVELOPMENTAL DISORDERS, A PRIMARY DISTURBANCE OF THE NMDA RECEPTOR

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Xavier Altafaj[1], Ana Santos-Gómez[1], Sílvia Locubiche Serra[1,2,3], Federico Miguez-Cabello[1], David Soto[1], Mireia Olivella[4]
[1]Universitat de Barcelona, Medical School, August Pi I Sunyer Biomedical Research Institute (idibaps), Barcelona, Spain, [2]ZeClinics, Laboratory, Badalona, Spain, [3]ZeClinics, Institut De Recerca Germans Trias I Pujol (igtp), Badalona, Spain, [4]Universitat de Vic - Universitat Central de Catalunya, Bioinformatics And Medical Statistics Group, Biosciences Department, Vic, Spain

Glutamate, the main excitatory amino acid neurotransmitter plays a crucial role in neuronal physiology. Glutamatergic neurotansmission disturbance can result from primary *de novo* mutations of *GRIN* genes, encoding for the *N*-methyl-D-Aspartate receptor (NMDAR) subunits. These rare autosomic dominant conditions cause severe neurodevelopmental encephalopathies namely GRIN-related disorders (GRD, also called Grinpathies). GRD display a clinical spectrum including intellectual disability, hypotonia, ASD traits, motor impairment, epilepsy, and gastro-intestinal distress in a gene- and residue-dependent manner. Accordingly, as for other channelopathies, the functional annotation of *GRIN de novo* variants is critical i) to understand GRD pathophysiology, ii) to evaluate potential therapeutic strategies and iii) to define personalised therapeutic approaches. Accordingly, we have created a multi-angled GRIN cluster initiative, merging computational, experimental, translational, and clinical neuroscience approaches. Bioinformatic analysis allowed to build-up a comprehensive and specific *GRIN* variants database compiling genetic, structural, functional and clinical annotations. This database allowed to define a superimposition structural algorithm drastically increasing *GRIN* variants annotations with a high predictive likelihood ultimately accelerating *GRIN* variants functional annotations. Further, an experimental pipeline has been developed for the annotation of GRIN-orphan variants and their functional stratification. Finally, we evaluated and experimentally demonstrated the potential therapeutic benefit of nutraceutical interventions for the rescue of LoF *GRIN* variants, both in preclinical models and in proof-of-concept GRD cases. These findings opened the avenue for the first reported GRD clinical trial (ongoing) as well as for future treatments of genetic conditions perturbing the glutamatergic synapse.

DE NOVO MISSENSE MUTATION IN CERS6 IDENTIFIED IN A PATIENT WITH CORTICAL HETEROTOPIA

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Kaviya Chinnappa[1], Delfina Romero[1], Ana Uzquiano[1], Karine Poirier[2], Carmen Cifuentes-Diaz[3], Robert Olaso[4], Jean-François Deleuze[4], Nadia Bahi-Buisson[5], Fiona Francis[1,6,7]
[1]Institut du Fer à Moulin, Cortical Development And Pathology, Paris, France, [2]Imagine Institute, Inserm Umr1163, Paris, France, [3]Institut du Fer à Moulin, Inserm U 1270, Paris, France, [4]Université Paris-Saclay, CEA, Centre National de Recherche en Génomique Humaine (CNRGH), Institut De Biologie François Jacob, Evry, France, [5]Université de Paris, Institute Imagine, Paris, France, [6]Sorbonne Université, Sciences, Paris, France, [7]Inserm, U1270, Paris, France

A *de novo* missense mutation in CERS6 has been identified by human exome sequencing in a patient with subcortical heterotopia. This is a rare disorder associated with epilepsy and intellectual disability, which may be caused by disturbances in cortical progenitors and /or migrating neurons. Ceramide synthases are important for the biogenesis of ceramides in the endoplasmic reticulum, which will then be transported to the Golgi apparatus for the formation of complex sphingolipids to be transported to the membranes. The major aim of this project is to understand the role of ceramide synthases in normal cortical development, for which we use knockdown and overexpression approaches. Importantly, we will question the impact of the CERS6 patient-specific mutation in the processes mentioned above leading to the formation of heterotopia. Our preliminary analyses suggest delayed migration of neurons upon CerS6 knockdown in mouse cortex. Future experiments will continue loss of function experiments and phenotypic analyses. Furthermore, our future experiments will be aimed at understanding the subcellular mechanisms impacted by normal and mutant CerS6. These studies highlight the understudied role played by lipid biogenesis factors in cortical development.

ANTI-NKCC1 GENE THERAPY RESCUES COGNITIVE DEFICITS IN A MOUSE MODEL OF DOWN SYNDROME

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Fatima Ghandour, Silvia Rosati, Andrea Contestabile, Laura Cancedda
FONDAZIONE ISTITUTO ITALIANO DI TECNOLOGIA, Brain Development And Disease, GENOVA, Italy

A common feature of diverse brain disorders is the alteration of GABA-mediated inhibition because of aberrant, intracellular chloride homeostasis induced by changes in the expression and/or function of chloride transporters. Notably, pharmacological inhibition of the chloride importer NKCC1 is able to rescue brain-related core deficits in animal models of these pathologies and in some human clinical studies. In this study, we aimed to test the potential therapeutic applications of NKCC1 gene knock down in the Ts65Dn mouse model of Down syndrome (DS) by intraparenchymal injection of two different doses of adeno-associated virus (AAV) expressing artificial microRNA (amiR) targeted to NKCC1. We performed bilateral hippocampal stereotaxic injections into 2-3 month-old Ts65Dn mice with either control or NKCC1 amiR. AAV-mediated expression of NKCC1 amiR effectively diminished NKCC1 expression in vivo in a dose-dependent manner, without inducing appreciable inflammation. Ts65Dn mice showed significant deficits in learning and memory tests including a marked impairment in long-term discriminative and spatial memory, short-term working memory, and associative memory. NKCC1 amiR effectively rescued the cognitive deficits in the behavioral tasks in a dose-dependent manner. We are currently differentiating an isogenic pair of IPSCs (WT and DS) lines into neural progenitor stem cells (NPCs) into neuronal and glial cells to assess whether our NKCC1 amiR approach may be successful when applied also to human cells. Our results provide compelling evidence that NKCC1 is implicated in cognitive dysfunctions in DS adults, thereby firmly supporting the potential breakthrough of NKCC1 knockdown gene therapy in DS.

The Bosch-Boonstra-Schaaf optic atrophy-intellectual syndrome (BBSOAS), is a rare neurodevelopmental disorder due to mutations in the NR2F1 gene, which code for the strong transcriptional regulator Nr2f1, also known as COUP-TFI. The BBSOAS is characterized by several symptoms, including optic nerve atrophy, seizures, intellectual disability and autistic traits, that are often linked to mitochondrial dysfunction. Moreover, alterations in mitochondrial energy supply have been recently reported in BBSOAS patients. In this study, we combined genome-wide and in silico analyses to mouse genetics, neuroanatomical and imaging approaches to test the hypothesis that Nr2f1controls mitochondrial function. First, we found that key mitochondrial proteins are potential genomic targets under direct Nr2f1 transcriptional control in neurons. Next, we focused on the adult mouse hippocampal dentate gyrus (DG), a site of persistent neurogenesis, to genetically manipulate Nr2f1 expression in newborn neurons. These experiments showed that both Nr2f1 loss- and gain-of-function result in altered mitochondrial architecture in newborn neurons, suggesting a role for Nr2f1 on mitochondrial dynamics. In line, we identified the mitochondrial membrane protein Mfn2, a key factor for mitochondrial fusion, as a direct target gene under the Nr2f1 transcriptional activity. We found that Mfn2 is downregulated in the DG of mice heterozygous for Nr2f1, a validated BBSOAS mouse model, and we confirmed its downregulation in adult-born DG neurons conditionally depleted for Nr2f1. Our study provides the first evidence of a key role for Nr2f1 in controlling mitochondria architecture in DG neurons and open new perspectives on the mechanisms underlying the human disease BBSOAS.

NEUROANATOMICAL STUDIES IDENTIFY VPS13B AS AN IMPORTANT REGULATOR OF BRAIN ARCHITECTURE AND HIPPOCAMPAL FORMATION

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Charlotte Montillot, Sylvie Nguyen, Stephan Collins, Binnaz Yalcin
Inserm UMR1231, Genetics Of Developmental Disorders Laboratory, University Of Bourgogne Franche-comté, DIJON, France

Vacuolar Protein Sorting 13 homolog B (VPS13B) is a highly conserved protein through evolution, but its function is not well understood yet. Human mutations in *VPS13B* cause Cohen Syndrome, a rare recessive developmental disease characterized by intellectual disability, acquired microcephaly and hypotonia. Mouse *Vps13b* is highly expressed across several brain structures including the hippocampus and the cortex. Using a knockout mouse model approach, we set out to identify the role of VPS13B in the brain. We first showed that homozygous mutant mice of *Vps13b* are sub-viable, half dying progressively during the first week of life. The survivor homozygous mutant mice exhibit growth delay and microcephaly (-27% for weight and -20% for microcephaly in adult male mice). Using a systematic neuroanatomical study at multiple ages (embryonic E18.5 and postnatal 5, 7, 18 and 33 weeks), we then found severe neuroanatomical changes appearing within the first few weeks after birth in homozygous mutant mice when compared to matched controls. The hippocampus is the most affected brain region with a reduction of 34% of the size of the dentate gyrus. Finally, we performed a battery of behavioral tests and showed hyperactivity, hypotonia and altered memory but enhanced sociability and resilience to anxiety and depression in *Vps13b* homozygous mutant mice. It is noteworthy that heterozygous mutant mice did not show any apparent phenotype. Together, these findings indicate a highly specific role of VPS13B in the regulation of brain structure and an association with previously unreported features of Cohen Syndrome.

DECIPHERING THE GENETICS OF BRAIN MALFORMATION DISORDERS REVEALS THE IMPORTANCE OF WD-REPEAT 47 (WDR47) AND WD-REPEAT 91 (WDR91) GENES IN MICE

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Sylvie Nguyen, Charlotte Montillot, Stephan Collins, Binnaz Yalcin
Inserm UMR1231, Genetics Of Developmental Disorders Laboratory, University Of Bourgogne Franche-comté, DIJON, France

WD-repeat (WDR) proteins are one of largest eukaryotic family, however little is known about their role in neurodevelopment. In a previous report, we manually curated 246 WDR proteins and found that WDR genes are 3-times more likely to be linked to brain malformation disorders. Here we set out to explain how mutations in two WDR genes, WDR47 and WDR91, lead to brain structural anomalies. Using the CRISPR/cas9 system, we generated two mouse models with mutations at position p.Val660Ala for WDR47 and p.Tyr80^{STOP} for WDR91, to model variants found in human patients and assess their pathogenesis. Because both mouse models were not viable at the homozygous state, we conducted the experiments in heterozygous mutants. More specifically, we carried out systematic and ultra-standardized histological studies of brain anatomy at various timepoints, assessing 39 different brain parameters. We compared neuroanatomical defects between WDR47 and WDR91 and found the most severe brain malformations in WDR91 p.Tyr80^{STOP}. Indeed, this mutation resulted in reduced size of four main brain regions known to be implicated in cognition, motor activity and coordination, namely the hippocampus, neocortex, thalamus and cerebellum. The cerebellar area was the most affected region with a size reduction of 28%. The area of the neuroepithelial ventricular zone in the neocortex, where the cells decide to proliferate or differentiate, was the only parameter among the 39 evaluated whose size was significantly increased by 39%. These findings indicate that WDR91 has a more important role in the regulation of brain architecture from earlier developmental stages than WDR47.

Aims: Creatine Transporter Deficiency (CTD) is an X-linked neurodevelopmental disorder caused by mutations in the Creatine Transporter (CrT) gene presenting with cerebral creatine (Cr) depletion, intellectual disability, epilepsy and autistic-like behaviour. CTD has a major impact on patient quality of life and no cure is available. Here, we evaluated gene therapy as a possible solution to reverse CTD pathology.
Methods: We used Adeno-Associated Viral vectors to deliver a functional copy of CrT gene (AAV/CrT) to newborn CrT KO mice through intracerebroventricular injection. After six weeks we assessed the distribution of the vector and measured Cr levels in the brain, and we longitudinally evaluated the effectiveness of this strategy in reversing the CTD phenotype by combining behavioral and imaging analyses.
Results: Preliminary data showed that AAV/CrT administration resulted in the expression of transgenic CrT and increased Cr levels in the cerebral cortex and hippocampus. However, toxicity and inflammation were observed with high titres of the vector. Behavioural investigation on mice treated with non-toxic doses demonstrated that the treatment improved cognitive performance. We are currently optimising the vector design to obtain a widespread, physiological expression of CrT reducing the toxicity caused by creatine overload.
Conclusions: Our results indicate that AAV-mediated delivery of exogenous CrT increases cerebral Cr levels and may improve cognitive performances in a CTD mouse model, providing an encouraging first step towards the proof-of-concept for the feasibility of CrT replacement therapy.

Down syndrome (DS) is a genetic disorder that causes intellectual disability in children and adults. People with DS also present higher susceptibility to seizures and often hyperactivity. Altered GABAergic signaling through chloride-permeable $GABA_A$ receptors plays a major role in several brain disorders including DS and epilepsy. In particular, higher intracellular chloride concentration due to impairment of the expression ratio of the Cl transporters NKCC1/KCC2 is present in adult animals of the Ts65Dn mouse model of DS and in epilepsy. Accordingly, treatment with the FDA-approved, NKCC1 inhibitor bumetanide during adulthood rescues inhibitory GABAergic transmission and cognitive deficits in DS mice, although the beneficial effect of the treatment is rapidly lost upon drug withdrawal. Moreover, bumetanide treatment in adult Ts65Dn mice fails to rescue their higher susceptibility to seizure and hyperactivity. Given the crucial role of $GABA_A$ergic transmission for healthy brain development, an early pharmacological NKCC1 inhibition acting when neuronal networks are still plastic may in fact ameliorate symptoms that treatments in adult ages were not able to reverse. To this aim, we first characterized the NKCC1/KCC2 ratio and the GABAergic signaling in the hippocampus of developing Ts65Dn and WT mice. Our results showed that alterations of GABAergic signaling and NKCC1/KCC2 expression ratio are present already in early development. This opens the possibility of an early treatment with bumetanide that may have long-lasting positive effects later in life.

Introduction Down syndrome (DS) is a developmental disorder caused by trisomy of human chromosome 21 (Hsa21) that constitutes the most common genetic form of intellectual disability. Although it arises from an increased dosage of Hsa21 genes (Antonarakis, 2017), the specific mechanisms underlying cognitive dysfunction remain unclear. Multiple studies have shown defective cell proliferation and neurogenesis (Stagni et al, 2018; Reiche et al, 2019) in DS. Indeed, increased numbers of glial cells, especially astrocytes, have been reported in the DS brain (Zdaniuk et al, 2011: Chen et al., 2014). These reports support the possibility that a gliogenic shift occurs in DS and contributes to intellectual disability (Lee et al., 2016). However, there is still controversy about this hypothesis. **Aims** Here, we seek to study glial alterations in DS and their contribution to cognitive impairment– ultimately aiming to identify causative genes through studying mouse models of DS. **Methods** Previously using Dp(10)2Yey and Dp1Tyb mouse models of DS, which present duplications of Hsa21-orthologous genes on mouse chromosomes 10 and 16 respectively, we observed cognitive impairments in the T-maze Alternation task. We have now performed a protein-based investigation of different neuroinflammatory related markers in the hippocampus of 3 month-old mice by immunoblotting. Currently, we are undertaking immunofluorescence assays in cleared brains to confirm alterations in glial cell numbers. **Results** Our data so far suggest changes in the maturation state of astrocytes in Dp(10)2Yey mice and a gliocentric shift in Dp1Tyb mice. **Conclusion** Alterations in glial-related markers are potentially associated with cognitive impairment in DS.

CILIOPATHY IN MENINGEAL FIBROBLAST ACCOMPANYING THE DELAYED MATURATION OF PIAL BASEMENT MEMBRANE DURING CORTICAL DEVELOPMENT OF FMR1-/Y MICE

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Jung-Yoon Heo, Tae-Shin Park, Byung Geun Ha, Sung-Jin Jeong
KBRI, Research Group Of Developmental Disorders And Rare Diseases, Daegu, Korea, Democratic People's Republic of

Three layer of tissue membrane known as meninges contributes to protect the brain as well as form the normal brain, at early embryonic stages. The meningeal cells produce basement membrane (BM) proteins and extracellular matrix components to form the glial limitans, and they control the migration of neurons during early brain development. Cerebrospinal fluid (CSF) is mainly secreted via cilia into ventricles, and 30% of CSF is produced in the leptomeninges. While the meninges are important roles in the mechanisms of cerebral pathology, their function has not been explored in developmental disorders such as Fragile X Syndrome (FXS). We found the abnormal cilia formation in the meninges of *Fmr1*$^{-/y}$ (*Fmr1* KO) mouse including the reduction in the number of cilia in both the meninges of cortex and the primary meningeal fibroblasts (MFs). In addition, the abnormalities of cell integrity and differentiation of Meningeal Fibroblasts (MFs) are observed in the neocortex of *Fmr1* KO mice. These results suggest that the phenotypic ciliary deficit is related to the meningeal cell integrity causing abnormal meningeal differentiation during the cortical development of *Fmr 1* KO mice.

A NEW MOLECULAR PATHWAY FOR RIBOSOMAL S6 ACTIVATION IN THE BRAIN

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Luis García-Rabaneda, Emily Haimerl, Bernadette Basilico, Matteo Barel, Lena Schwarz, Gaia Novarino
IST Austria, Life Sciences, Klosterneuburg, Austria

During the last decade, the mTOR pathway has been unraveled as a critical biological pathway, which its dysfunction has been observed in an important number of neurodevelopmental disorders. mTOR signalling regulates, differentially, cell shape, migration and differentiation during brain development, and synaptic plasticity during adulthood, but how the principal targets of mTORC1 are specifically regulated during different stages of development in the nervous brain is unknown currently. Studying the principal readout of mTOR pathway, ribosomal S6 protein, we revealed how one of the component of the KICSTOR complex, Kaptin, has an essential role in the brain, regulating S6 phosphorylation through a S6 kinase-independent form. Through *in vitro* and *in vivo* analysis of full *Kptn* knockout, we uncovered how a new regulator of the mTOR pathway has a complementary function in the phosphorylation of S6 during the postnatal development. Molecular (using lysosomal and immunoprecipitation analysis), physiological (immunohistochemical and electrophysiological analysis) and behavioral data from *Kptn* full KOs and Emx1-Cre conditional *Kptn* KOs pointed to the subcortical nuclei, as a brain part where S6 has to be critically controlled. Surprisingly, our data shown a new molecular partner of Kaptin, which it has a fundamental function *in vivo* and *in vitro*. With this work, and through the specific function of Kaptin, we show a new mechanism of regulation of ribosomal protein S6 in the brain. This new mechanism should bring new pharmacological strategies to treat specific neurodevelopmental mTORopathies.

Noonan syndrome (NS) belongs to a disease family called RASopathies, linked to mutations in genes encoding components and regulators of the RAS/MAPK-signalling pathway. NS is accompanied by craniofacial features, congenital heart diseases and neurocognitive impairments. Germ-line mutations in various genes can lead to NS. KRASV14I is a NS-linked mutation that results in an increased KRAS activity and presents with mild to moderate cognitive and behavioural defects in patients. Previous experiments indicated behavioural and memory alterations and a shift in excitation/inhibition (E/I) balance in mice expressing KRASV14I mutation in the brain. In this project we wanted to address the molecular and cellular mechanisms behind the impaired long-term potentiation (LTP). This information is instrumental for the development of treatment for neurocognitive impairments seen in NS patients. We recorded extracellular field potentials from CA1 stratum radiatum evoked by the stimulation of Schaffer collaterals in acute cortico-hippocampal brain slices from 7-8 week-old WT and KRASV14I mice treated with specific drugs targeting RAS downstream signalling and E/I balance. Our results revealed specific contributions of downstream RAS targets to aberrant transmission and neuroplasticity.

MODELLING KOOLEN-DE VRIES SYNDROME IN CEREBRAL ORGANOIDS

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Brooke Latour[1], Iris Teunissen Van Manen[1], Katrin Linda[1], Anouk Verboven[1], Emma Dyke[2], Chantal Schoenmaker[1], Nael Nadif Kasri[1]
[1]Donders Institute for Brain, Cognition and Behavior, Radboud University Medical Center, Human Genetics, Nijmegen, Netherlands, [2]Radboudumc, Donders Institute for Brain, Cognition, and Behaviour, Human Genetics, Nijmegen, Netherlands

Koolen-de Vries syndrome (KdVS) is a rare genetic neurodevelopmental disorder with multisystemic phenotypes. Patients suffer from developmental delay, intellectual disability, facial dysmorphisms, epilepsy, and congenital malformations in multiple organ systems, including the brain. KdVS is caused by haploinsufficiency of *KANSL1*, which encodes for a protein involved in chromatin remodeling and microtubule stabilisation**.** KANSL1 is widely expressed early during development, but its role during early brain development is not well-established. Here we generated neuronal progenitor cells and human cerebral organoids to define the effect of KANSL1 mutations on human cortical development. Using transcriptomic analysis of KANSL1-deficient human induced-pluripotent stem cells (iPSCs), both from KdVS patients and genome-edited lines, we identified aberrant cell-cycle regulation. Analysis of cell-cycle pointed towards reduced mitotic activity in KdVS patient-derived iPSCs as well as neuronal progenitor cells (NPC), which was further accompanied with decreased proliferative capacity of NPCs. In human cerebral organoids we found that *KANSL1* haploinsufficiency caused a major disruption of neurodevelopmental trajectories with a decrease in cortical layer thickness, a reduced percentage of deep and upper layer neurons. This aberration in cortical layer formation was further accompanied by a reduction of outer radial glial cells. Taken together our results point towards a critcial role of KANSL1 in early aspects of brain development.

Congenital fibrosis of the extraocular muscles (CFEOM) as a vertical disorder of ocular movement is grouped among the congenital cranial dysinnervation disorders. There are different types of CFEOM phenotypes: CFEOM3A is accompanied with ptosis, mild hypotropic gaze position, bilateral external ophthalmoplegia, inability to elevate one or both eyes above the midline with restriction in lateral rectus and inferior rectus extraocular muscles. We describe a large Iranian family with twenty patients suffering from autosomal dominant CFEOM3A with high penetrance and variable expression. In this family surgery did not correct patients' strabismus or ptosis. Genome-wide sequence analysis of six patients and six healthy controls revealed C784>T (R262C) mutation in the *TUBB3* gene.

HYPERSYNCHRONISED GAMMA OSCILLATIONS IN THE MEDIAL PREFRONTAL CORTEX AND HIPPOCAMPUS IN A RAT MODEL OF FRAGILE X SYNDROME

POSTER SESSION 02 - SECTION: GENE THERAPY AND GENETIC DISORDERS

Joe Moore[1], Łucja Kostrzewa[1], Antonis Asiminas[1,2], Peter Kind[1,3], Emma Wood[1,3]
[1]University of Edinburgh, Centre For Discovery Brain Sciences, Edinburgh, United Kingdom, [2]University of Copenhagen, Centre For Translational Neuromedicine, København N, Denmark, [3]University of Edinburgh, Simons Initiative For The Developing Brain, Edinburgh, United Kingdom

Fragile X Syndrome (FXS) is one of the most common causes of intellectual disability and autism spectrum disorder, and is often associated with severe learning deficits. A rat model of the disorder, the *Fmr1*$^{-/y}$ rat, is impaired in associative memory tasks known to be dependent on connections between the medial prefrontal cortex (mPFC) and hippocampus. Both human FXS patients and rodent models show deficits in cognitive flexibility which could also be associated with these connections. The current study aimed to assess functional connectivity between the mPFC and hippocampus in *Fmr1*$^{-/y}$rats using *in vivo* electrophysiology. Local field potentials were recorded from tetrodes implanted into the mPFC prelimbic area and dorsal hippocampus of adult male *Fmr1*$^{-/y}$rats and their wild-type (WT) littermates as they freely explored a familiar and a novel environment, and as they performed a spatial memory task on a double Y maze. In the mPFC, average power of gamma oscillations (30-80 Hz) during exploration was significantly higher in *Fmr1*$^{-/y}$ rats compared to WTs. Furthermore, average mPFC-hippocampus gamma frequency coherence was significantly higher in *Fmr1*$^{-/y}$ rats, measured using phase coherence and weighted phase lag index. This hypersynchronous network activity may underlie cognitive inflexibility seen in *Fmr1*$^{-/y}$ rodents and FXS patients. The results also provide further evidence for gamma oscillation abnormalities as a useful cross-species biomarker of FXS.

INVESTIGATING THE REGION-SPECIFIC FUNCTION OF ZFHX3 IN THE MOUSE BRAIN, AND CHARACTERISING ITS MOLECULAR ACTIVITY

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Paige Street, Gareth Banks, Patrick Nolan
MRC Harwell Institute, Neurobehavioural Genetics, Harwell, United Kingdom

Aims: Zinc finger homeobox 3 (*Zfhx3*) is a brain-region enriched transcription factor that binds to AT motifs in promoter and enhancer regions. Multiple coding sequence mutations have been linked to a range of diseases, including schizophrenia. Data from the Allen Brain Atlas show *Zfhx3* expression within dopaminergic regions, such as the ventral tegmental area (VTA). Given the dopaminergic hypothesis of schizophrenia, and the genetic associations, we wish to investigate the contribution of *Zfhx3* to schizophrenia-related behavioural changes in mice. **Methods:** A DAT-*Cre* (dopamine active transporter) driven *Zfhx3* knockout mouse line was established – a conditional knockout mouse model which deletes *Zfhx3* in dopaminergic cells. These mice were subjected to a behavioural phenotype pipeline focused on schizophrenia-related endophenotypes, and sub-dissected dopaminergic brain regions are undergoing molecular analysis via immunofluorescent imaging and qPCR to investigate changes in gene expression. **Results:** DAT-*Cre*; *Zfhx3*-flox homozygous knockout female mice show attenuated anxiety behaviours in open field and light-dark box; and both male and female homozygotes show social dominance, sleep fragmentation differences, reduced interest in a novel object, and pre-pulse inhibition dysfunction. Analysis of the sub-dissected striatum – a dopaminergic pathway terminus - of homozygotes shows expression of dopamine receptors is significantly reduced. **Conclusions:** Homozygous knockout of *Zfhx3* in dopaminergic neurons shows significant behavioural changes in mice, when assessed with a phenotyping pipeline focused on schizophrenia endophenotypes. Further molecular analysis will elucidate the role of *Zfhx3* in schizophrenia-related behaviours in mice, and its wider function within the dopaminergic system.

DECREASED NDEL1 OLIGOPEPTIDASE ACTIVITY IS ASSOCIATED WITH ABERRANT NEURODEVELOPMENT AND IMPAIRED ANIMAL BEHAVIOR IN A TRANSGENIC RAT MODEL FOR SCHIZOPHRENIA

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

João Nani, Mirian Hayahi
Unifesp, Pharmacology, São Paulo, Brazil

The purpose of this study was to investigate the relation of nuclear-distribution element-like 1 (Ndel1) activity with neurodevelopment and dopamine associated schizophrenia-related phenotypes, using a rat model overexpressing the human non-mutant *Disrupted-in-schizophrenia 1* (*DISC1*) and presenting dysfunctional dopamine signaling. In the present work, we evaluated the neuronal cell distribution in striatum and cortex, by histology and X-ray microtomography, as well as we quantified the basal and amphetamine-stimulated locomotion and Ndel1 activity of transgenic rats compared with wild-type littermate controls. 3D assessment of neuronal cell body number and spatial organization of mercury-impregnated neurons showed altered neuronal positioning, characteristic of impaired cell migration, in striatum/nucleus accumbens, and prefrontal cortex of transgenic compared with wild-type rats. Locomotion and Ndel1 activity were significantly increased by low doses of amphetamine in transgenic but not in wild-type animals. Our present findings suggest that decreased Ndel1 activity may reflect both a trait (neurodevelopmental phenotype) and state (amphetamine-induced dopamine release), leading to hypothesize that abnormal brain structure due to impaired neuronal migration may be responsible for amphetamine sensitivity. In a previous report we have demonstrated significant lower Ndel1 activity in treatment resistant schizophrenia (TRS) which is line with the hypothesis that TRS patients could present neurodevelopmental deficits, as also observed here in the transgenic animal model. The employment of this transgenic rat, combined with Ndel1 activity measures, may be a potential model for evaluating novel treatments for TRS or any other brain disorder, including schizophrenia, in which decreased Ndel1 activity may be a biomarker of impaired neuronal functioning.

Decreased nuclear distribution nudE-like 1 enzyme activity in an animal model with dysfunctional disrupted-in-schizophrenia 1 signaling featuring aberrant neurodevelopment and amphetamine-supersensitivity.
Interaction of nuclear-distribution element-like 1 with disrupted-in-schizophrenia 1 protein is crucial for neurite outgrowth/neuronal migration, and this interaction competitively inhibits nuclear-distribution element-like 1 peptidase activity. Nuclear-distribution element-like 1 activity is reduced in antipsychotic-naïve first-episode psychosis and in medicated chronic schizophrenia, with even lower activity in treatment-resistant schizophrenia.

A study in first-episode psychosis patients: does angiotensin I-converting enzyme (ACE) activity associated with genotype predict symptoms severity reductions after treatment with the atypical antipsychotic risperidone?
Our previous studies showed increased angiotensin I-converting enzyme (ACE) activity in chronic schizophrenia (SCZ) patients compared to healthy control (HC) volunteers, and the relevance of combining ACE genotype and activity for predicting SCZ was suggested.

Evaluation of NDEL1 oligopeptidase activity in blood and brain in an animal model of schizophrenia: effects of psychostimulants and antipsychotics.
Nuclear distribution element-like 1 (NDEL1) enzyme activity is important for neuritogenesis, neuronal migration, and neurodevelopment. We reported previously lower NDEL1 enzyme activity in blood of treated first episode psychosis and chronic schizophrenia (SCZ) compared to healthy control subjects, with even lower activity in treatment resistant chronic SCZ patients, implicating NDEL1 activity in SCZ. Herein, higher NDEL1 activity was observed in the blood and several brain regions of a validated animal model for SCZ at baseline. In addition, long-term treatment with typical or atypical

antipsychotics, under conditions in which SCZ-like phenotypes were reported to be reversed in this animal model for SCZ, showed a significant NDEL1 activity reduction in blood and brain regions which is in line with clinical data. Importantly, these results support measuring NDEL1 enzyme activity in the peripheral blood to predict changes in NDEL1 activity in the CNS. Also, acute administration of psychostimulants, at levels reported to induce SCZ-like phenotype in normal rat strains, increased NDEL1 enzyme activity in blood. Therefore, alterations in NDEL1 activity after treatment with antipsychotics or psychostimulants may suggest a possible modulation of NDEL1 activity secondary to neurotransmission homeostasis and provide new insights into the role of NDEL1 in SCZ pathophysiology.

ACE activity in blood and brain axis in an animal model for schizophrenia: Effects of dopaminergic manipulation with antipsychotics and psychostimulants.
Angiotensin I-converting enzyme (ACE) was initially correlated with schizophrenia (SCZ) in studies showing a correlation of ACE increased enzyme activity with memory impairments. Possible role for ACE in SCZ was also suggested by ACE activity interaction with dopaminergic mechanisms to modulate abnormalities of sensorimotor gating. In addition, we have demonstrated higher ACE activity in blood of SCZ subjects, its implication in cognitive performance in SCZ and its power as a predictor for SCZ diagnosis. ACE activity was determined in the serum and in selected brain regions of an animal model presenting SCZ-like behaviour, before and after the treatment with typical and atypical antipsychotics, and also in the serum of animals receiving the psychostimulants amphetamine/lisdexamphetamine. Dopaminergic manipulations with antipsychotics and psychostimulants influenced the ACE activity, but with no correlation with the animal blood pressure. The validity of measuring ACE activity in animal blood to predict activity in the CNS, as well as the lack of correlation between the activity and blood pressure, before and after the treatment with antipsychotics, were confirmed here. Correlations of the present findings with data from clinical studies also strengthen the value of this animal model for studying several aspects of SCZ.

Regulation of monoamine levels by typical and atypical antipsychotics in Caenorhabditis elegans mutant for nuclear distribution element genes.
Mammalian nuclear distribution genes encode proteins with essential roles in neuronal migration and brain formation during embryogenesis. The implication of human nuclear distribution genes, namely nudC and NDE1 (Nuclear Distribution Element 1)/NDEL1 (Nuclear Distribution Element-Like 1), in psychiatric disorders including schizophrenia and bipolar disorder, has been recently described. The partial loss of NDEL1 expression results in neuronal migration defects, while ndel1 null knockout (KO) leads to early embryonic lethality in mice. On the other hand, loss-of-function of the orthologs of nuclear distribution element genes (nud) in Caenorhabditis elegans renders viable worms and influences behavioral endophenotypes associated with dopaminergic and serotoninergic pathways. In the present work, we evaluated the role of nud genes in monoamine levels at baseline and after the treatment with typical or atypical antipsychotics. Dopamine, serotonin and octopamine levels were significantly lower in homozygous loss-of-function mutant worms KO for nud genes compared with wild-type (WT) C. elegans at baseline. While treatment with antipsychotics determined significant differences in monoamine levels in WT, the nud KO mutant worms appear to respond differently to the treatment. According to the best of our knowledge, we are the first to report the influence of nud genes in the monoamine levels changes in response to antipsychotic drugs, ultimately placing the nuclear distribution genes family at the cornerstone of pathways involved in the modulation of monoamines in response to different classes of antipsychotic drugs.

A system biology approach based on metabolic biomarkers and protein-protein interactions for identifying pathways underlying schizophrenia and bipolar disorder.
Mental disorders (MDs), including schizophrenia (SCZ) and bipolar disorder (BD), have attracted special attention from scientists due to their high prevalence and significantly debilitating clinical features. The diagnosis of MDs is still essentially based on clinical interviews, and intensive efforts to introduce biochemical based diagnostic methods have faced several difficulties for implementation in clinics, due to the complexity and still limited knowledge in MDs. In this context, aiming for improving the knowledge in etiology and pathophysiology, many authors have reported several alterations in metabolites in MDs and other brain diseases. After potentially fishing all metabolite biomarkers reported up to now for SCZ and BD, we investigated here the proteins related to these metabolites in order to construct a protein-protein interaction (PPI) network associated with these diseases. We determined the statistically significant clusters in this PPI network and, based on these clusters, we identified 28 significant pathways for SCZ and BDs that essentially compose three groups representing three major systems, namely stress response, energy and neuron systems. By characterizing new pathways with potential to innovate the diagnosis and treatment of psychiatric diseases, the present data may also contribute to the proposal of new

intervention for the treatment of still unmet aspects in MDs.

Effects of Psychostimulants and Antipsychotics on Serum Lipids in an Animal Model for Schizophrenia.
Schizophrenia (SCZ) treatment is essentially limited to the use of typical or atypical antipsychotic drugs, which suppress the main symptoms of this mental disorder. Metabolic syndrome is often reported in patients with SCZ under long-term drug treatment, but little is known about the alteration of lipid metabolism induced by antipsychotic use. In this study, we evaluated the blood serum lipids of a validated animal model for SCZ (Spontaneously Hypertensive Rat, SHR), and a normal control rat strain (Normotensive Wistar Rat, NWR), after long-term treatment (30 days) with typical haloperidol (HAL) or atypical clozapine (CLZ) antipsychotics. Moreover, psychostimulants, amphetamine (AMPH) or lisdexamfetamine (LSDX), were administered to NWR animals aiming to mimic the human first episode of psychosis, and the effects on serum lipids were also evaluated. Discrepancies in lipids between SHR and NWR animals, which included increased total lipids and decreased phospholipids in SHR compared with NWR, were similar to the differences previously reported for SCZ patients relative to healthy controls. Administration of psychostimulants in NWR decreased omega-3, which was also decreased in the first episode of psychosis of SCZ. Moreover, choline glycerophospholipids allowed us to distinguish the effects of CLZ in SHR. Thus, changes in the lipid metabolism in SHR seem to be reversed by the long-term treatment with the atypical antipsychotic CLZ, which was under the same condition described to reverse the SCZ-like endophenotypes of this validated animal model for SCZ. These data open new insights for understanding the potential influence of the treatment with typical or atypical antipsychotics on circulating lipids. This may represent an outcome effect from metabolic pathways that regulate lipids synthesis and breakdown, which may be reflecting a cell lipids dysfunction in SCZ.

Impairments in Peripheral Blood T Effector and T Regulatory Lymphocytes in Bipolar Disorder Are Associated with Staging of Illness and Anti-cytomegalovirus IgG Levels.
There is now evidence that, based on cytokine profiles, bipolar disorder (BD) is accompanied by simultaneous activation of the immune-inflammatory response system (IRS) and the compensatory immune-regulatory system (CIRS), and that both components may be associated with the staging of illness. Nevertheless, no BD studies have evaluated the IRS/CIRS ratio using CD (cluster of differentiation) molecules expressed by peripheral blood activated T effector (Teff) and T regulatory (Treg) subpopulations. This study examined Teff/Treg subsets both before and after ex vivo anti-CD3/CD28 stimulation using flow cytometric immunophenotyping in 25 symptomatic remitted BD patients and 21 healthy controls and assessed human cytomegalovirus (HCMV)-specific IgG antibodies. BD is associated with a significantly lowered frequency of unstimulated CD3 + CD8 + CD71+ and CD4 + CD25 + FOXP3 and increased CD4 + CD25 + FOXP3 + CD152+ frequencies and with lowered stimulated frequencies of CD3 + CD8 + CD71+, CD4 + CD25 + FOXP3 + CD152+, and CD4 + CD25 + FOXP3 + GARP cells and, consequently, by an increased stimulated Teff/Treg ratio. Moreover, the number of manic, but not hypomanic or depressive episodes, is significantly and negatively associated with the stimulated proportions of CD3 + CD4 + CD154+, and CD69+ and CD71+ expression on CD4+ and CD8+ cells, while duration of illness (≥ 10 years) is accompanied by a depleted frequency of stimulated CD152+ Treg, and CD154+ and CD71+ CD4+ T cells. BD and anti-human cytomegalovirus (HCMV) IgG levels significantly interact to decrease the expression of CD4 + CD25 + FOXP+GARP T phenotypes. In conclusion, in BD patients, immune injuries, staging, and HCMV seropositivity interact and cause CIRS dysfunctions and exaggerated IRS responses, which play a key role in parainflammation and neuroaffective toxicity. HCMV seropositivity contributes to an immune-risk phenotype in BD.

Ndel1 oligopeptidase activity as a potential biomarker of early stages of schizophrenia.
Our previous studies showed reduced Ndel1 enzyme activity in patients with chronic schizophrenia (SCZ), and only a subtle NDEL1 mRNA increases in antipsychotic-naïve first-episode psychosis (FEP) individuals compared to matched healthy controls (HC). Aiming to refine the evaluation of Ndel1 enzyme activity in early stages of psychosis, we compared 3 groups composed by (1) subjects at ultra-high-risk (UHR) for psychosis, (2) a cohort comprising antipsychotic-naïve FEP individuals (assessed in three moments, at baseline (FEP-0), and after 2 months (FEP-2 M) and one year (FEP-1Y) of treatment with risperidone), and (3) a HC group. There was no significant difference in Ndel1 enzyme activity between UHR and HC, but this activity was significantly lower in FEP compared to HC. Conversely, Ndel1 activity in HC groups was higher than in FEP even before (FEP-0) or after the treatment with risperidone (FEP-2 M and FEP-1Y), and with progressive decrease of Ndel1 activity and significant improvement of symptoms observed after this treatment. In addition, a positive correlation was observed for Ndel1 activity with clinical symptoms as assessed by PANSS, while a negative correlation was seen for GAF scores. Our

results suggest that reductions in Ndel1 activity in FEP may be possibly related to responses to the illness, rather than to the pharmacological effects of antipsychotics, which might be acting essentially in the symptoms suppression. This hypothesis might be further evaluated in prospective long-term follow-up studies with a larger sample cohort.

Background: In recent years thought-patterns and their underlying neuronal mechanisms have been investigated mainly in healthy populations, e.g., in the context of problem-solving thoughts (Mckeen et al., 2020). In our preliminary study, we characterized thought-patterns in patients with schizophrenia (SZ) with predominantly negative symptoms and compared them to healthy controls and related thought patterns to measures of neural connectivity during resting-state fMRI. **Method:** We measured functional connectivity for 9.8 minutes using resting-state fMRI in 72 SZ patients and 61 controls matched for age and sex. Immediately afterwards, participants answered the Multi-Dimensional Experience Sampling (MDES; Gorgolewski et al., 2014) to describe their thoughts during the scan. We extracted thought-components using Principal Component Analysis (PCA) based on this questionnaire data. The association between these thought-patterns and brain-functional connectivity measures will be assessed using whole-brain functional gradient analyses. **Results:** PCA of the MDES data revealed a seven-component solution explaining 63.86% of the total variance (KMO=0.71). The first component comprised highly intrusive negative thoughts (image 1) and the SZ group displayed significantly higher values compared to controls [$t(129.35) = 3.19$, $p = .002$]. Another component was characterized by regular-vivid-positive-thoughts and showed significantly higher values among the HC. No significant group differences were found for the other components. Analyses of association between thought components and rsMRI measures are work-in-progress. **Conclusion:** Our findings showed that the MDES is an efficient tool for assessing thought-patterns with the ability to significantly distinguish between HC and SZ groups. We will assess the connection between thought-patterns and brain functional

connectivity.

D-NEURON, LIGAND NEURON OF TRACE AMINE-ASSOCIATED RECEPTOR 1 (TAAR1): KEY OF NOVEL NON-D2 RECEPTOR-BINDING ANTIPSYCHOTICS

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Keiko Ikemoto
Iwaki City Medical Center, Department Of Psychiatry, Iwaki, Japan

The latest psychopharmacological study showed effectiveness of a novel non-D2-receptor-binding drug, SEP-363856, for the treatment of schizophrenia. The compound is trace amine-associated receptor 1 (TAAR1) full agonist and also 5-hydroxytryptamin 1A (5-HT 1A) receptor partial agonist. I found the TAAR1 ligand neuron, D-neuron, in the striatum and nucleus accumbens (Acc), a neuroleptic acting site, of human brains, though failed to find in the homologous area of monkey brains. To study human D-neuron functions, total of 154 post-mortem brains, and a modified immunohistochemical method using high qualified antibodies against monoamine-related substances, was applied. As the number of immunoreactive neurons reduced accoding to the length of post-mortem interval to fixation (PMI), quantification of immunoreactive neurons has been done by using post-mortem brains with PMI shorter than 8 hours. The number of D-neurons in the caudate nucleus, putamen, and Acc was reduced in post-mortem brains with schizophrenia. The reduction was significant ($p<0.05$) in Acc. I proposed “D-cell hypothesis of schizophrenia”, that NSC dysfunction-based D-neuron reduction is cellular and molecular basis of mesolimbic dopamine hyperactivity, progressive pathophysiology of mental disorders, and prospectiveness of TAAR1 agonist as a novel antipsychotic agent. SOCIAL ANHEDONIA AS A DISRUPTED-IN-SCHIZOPHRENIA 1-DEPENDENT PHENOTYPE

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Mohammad Seidisarouei[1], Sandra Schäble[2], Marijn Wingerden[3], Svenja V Trossbach[4], Carsten Korth[4], Tobias Kalenscher[2]
[1]Hienrich Heine University, Comparative Psychology, Düsseldorf, Germany, [2]Heinrich Heine University, Comparative Psychology, Düsseldorf, Germany, [3]Tilburg University, Tilburg School Of Humanities And Digital Sciences, Tiburg, Netherlands, [4]Heinrich Heine University, Department Of Neuropathology, Düsseldorf, Germany

Deficits in social interaction or social cognition are key phenotypes in a variety of chronic mental diseases, yet, their modeling and molecular dissection are only in their infancy. The Disrupted-in-Schizophrenia 1 (DISC1) signaling pathway is considered to play a role in different psychiatric disorders such as schizophrenia, depression, and biopolar disorders. DISC1 is involved in regulating the dopaminergic neurotransmission in, among others, the mesolimbic reward system. A transgenic rat line tgDISC1 has been introduced as a model system to study behavioral phenotypes associated with abnormal DISC1 signaling pathways. Here, we evaluated the impact of impaired DISC1 signaling on social (social interaction) and non-social (sucrose) reward preferences in the tgDISC1 animal model. In a plus-maze setting, rats chose between the opportunity for social interaction with an unfamiliar juvenile conspecific (social reward) or drinking sweet solutions with variable sucrose concentrations (non-social reward). tgDISC1 rats differed from wild-type rats in their social, but not in their non-social reward preferences. Specifically, DISC1 rats showed a lower interest in interaction with the juvenile conspecific, but did not differ from wild-type rats in their preference for higher sucrose concentrations. These results suggest that disruptions of the DISC1 signaling pathway that is associated with altered dopamine transmission in the brain result in selective deficits in social motivation reminiscent of phenotypes seen in neuropsychiatric illness.

Background: 22q11.2 deletion syndrome (22q11DS) is a genetic syndrome with high penetrance for developmental neuropsychiatric disorders such as autism spectrum disorders and schizophrenia. Human imaging studies have shown alterations in functional connectivity across brain regions in individuals with 22q11DS. However, the neural underpinnings and developmental course of brain connectopathy in 22q11DS remain undetermined. **Aim:** This study was aimed at tracking the developmental trajectory of connectopathy in 22q11DS in both a mouse model and human patients. **Methods:** We longitudinally mapped resting-state fMRI (rsfMRI) connectivity and socio-cognitive behavior in juvenile and adult LgDel mice, a well characterized mouse model of 22q11DS. Guided by mouse findings, we mapped functional connectivity in prepubertal and adult 22q11DS patients. To determine the neural underpinnings of the observed rsfMRI dysconnectivity, we next investigated whether pharmacological inhibition of the GSK3β pathway produce a developmental rescue of connectivity alterations, as previous research showed that this procedure normalizes fronto-hippocampal synchrony in an analogous mouse model. **Results:** We found that 22q11DS is associated with prominent prepubertal fMRI hyperconnectivity that reverts to focal hypoconnectivity in adult mice. We also found a similar developmental trajectory across development in 22q11DS patients. Importantly, using pharmacological studies in the mouse, we linked juvenile hyperconnectivity (but not adult hypoconnectivity) to aberrant GSK3β signaling. Interestingly, the same treatment completely rescued cognitive functions in adult mice but no other socio-behavioral alteration assayed at both developmental timepoints. **Conclusions:** Our data shed light on the course and etiopathological determinants of brain dysconnectivity in 22q11DS.

Unique spatiotemporal fMRI dynamics in the awake mouse brain.
Human imaging studies have shown that spontaneous brain activity exhibits stereotypic spatiotemporal reorganization in awake, conscious conditions with respect to minimally conscious states. However, whether and how this phenomenon can be generalized to lower mammalian species remains unclear. Leveraging a robust protocol for resting-state fMRI (rsfMRI) mapping in non-anesthetized, head-fixed mice, we investigated functional network topography and dynamic structure of spontaneous brain activity in wakeful animals. We found that rsfMRI networks in the awake state, while anatomically comparable to those observed under anesthesia, are topologically configured to maximize interregional communication, departing from the underlying community structure of the mouse axonal connectome. We further report that rsfMRI activity in wakeful animals exhibits unique spatiotemporal dynamics characterized by a state-dependent, dominant occurrence of coactivation patterns encompassing a prominent participation of arousal-related forebrain nuclei and functional anti-coordination between visual-auditory and polymodal cortical areas. We finally show that rsfMRI dynamics in awake mice exhibits a stereotypical temporal structure, in which state-dominant coactivation patterns are configured as network attractors. These findings suggest that spontaneous brain activity in awake mice is critically shaped by state-specific involvement of basal forebrain arousal systems and document that its dynamic structure recapitulates distinctive, evolutionarily relevant principles that are predictive of conscious states in higher mammalian species.

α-synuclein overexpression in the retina leads to vision impairment and degeneration of dopaminergic amacrine cells.
The presence of α-synuclein aggregates in the retina of Parkinson's disease patients has been associated with vision

impairment. In this study we sought to determine the effects of α-synuclein overexpression on the survival and function of dopaminergic amacrine cells (DACs) in the retina. Adult mice were intravitreally injected with an adeno-associated viral (AAV) vector to overexpress human wild-type α-synuclein in the inner retina. Before and after systemic injections of levodopa (L-DOPA), retinal responses and visual acuity-driven behavior were measured by electroretinography (ERG) and a water maze task, respectively. Amacrine cells and ganglion cells were counted at different time points after the injection. α-synuclein overexpression led to an early loss of DACs associated with a decrease of light-adapted ERG responses and visual acuity that could be rescued by systemic injections of L-DOPA. The data show that α-synuclein overexpression affects dopamine neurons in the retina. The approach provides a novel accessible method to model the underlying mechanisms implicated in the pathogenesis of synucleinopathies and for testing novel treatments.

Altered heparan sulfate metabolism during development triggers dopamine-dependent autistic-behaviours in models of lysosomal storage disorders.
Lysosomal storage disorders characterized by altered metabolism of heparan sulfate, including Mucopolysaccharidosis (MPS) III and MPS-II, exhibit lysosomal dysfunctions leading to neurodegeneration and dementia in children. In lysosomal storage disorders, dementia is preceded by severe and therapy-resistant autistic-like symptoms of unknown cause. Using mouse and cellular models of MPS-IIIA, we discovered that autistic-like behaviours are due to increased proliferation of mesencephalic dopamine neurons originating during embryogenesis, which is not due to lysosomal dysfunction, but to altered HS function. Hyperdopaminergia and autistic-like behaviours are corrected by the dopamine D1-like receptor antagonist SCH-23390, providing a potential alternative strategy to the D2-like antagonist haloperidol that has only minimal therapeutic effects in MPS-IIIA. These findings identify embryonic dopaminergic neurodevelopmental defects due to altered function of HS leading to autistic-like behaviours in MPS-II and MPS-IIIA and support evidence showing that altered HS-related gene function is causative of autism.

AAV-mediated transcription factor EB (TFEB) gene delivery ameliorates muscle pathology and function in the murine model of Pompe Disease.
Pompe disease (PD) is a metabolic myopathy due to acid alpha-glucosidase deficiency and characterized by extensive glycogen storage and impaired autophagy. We previously showed that modulation of autophagy and lysosomal exocytosis by overexpression of the transcription factor EB (TFEB) gene was effective in improving muscle pathology in PD mice injected intramuscularly with an AAV-TFEB vector. Here we have evaluated the effects of TFEB systemic delivery on muscle pathology and on functional performance, a primary measure of efficacy in a disorder like PD. We treated 1-month-old PD mice with an AAV2.9-MCK-TFEB vector. An animal cohort was analyzed at 3 months for muscle and heart pathology. A second cohort was followed at different timepoints for functional analysis. In muscles from TFEB-treated mice we observed reduced PAS staining and improved ultrastructure, with reduced number and increased translucency of lysosomes, while total glycogen content remained unchanged. We also observed statistically significant improvements in rotarod performance in treated animals compared to AAV2.9-MCK-eGFP-treated mice at 5 and 8 months. Cardiac echography showed significant reduction in left-ventricular diameters. These results show that TFEB overexpression and modulation of autophagy result in improvements of muscle pathology and of functional performance in the PD murine model, with delayed disease progression.

Aim: Schizophrenia (SZ) is a devastating psychiatric illness affecting 1% of the world population. In addition to genetic predisposition, environmental factors contribute to the risk for developing SZ. Such genome environment interactions frequently activate epigenetic and epitranscriptomic mechansims. There are emerging evidence that genetic and environmental risk factors merge at the level of microRNA expression, which are discussed as biomarker and therapeutic target in various disorders including neuropsychiatric diseases. Methods: In this study we analyzed the blood microRNAome of 331 healthy individuals and 244 SZ patients via small RNA sequencing. Results: By combining these data with a corresponding analysis of post-mortem human brain tissue, we identify one candidate microRNA that is down-regulated in patients. Moreover, its expression is significantly correlated to disease phenotypes. Manipulation of this microRNAs in mouse prefrontal cortex causes schizophrenia-like phenotypes. Functional analysis revealed the cellular processes affected by this microRNA and allowed us to develop an arsenal of RNA-based therapeutic approaches that are able to ameliorate molecular disease phenotypes in mouse and human-based cellular systems as well as the behavioral phenotypes. In conclusion, we identify a novel microRNA as target for stratified RNA-therapeutics in schizophrenia.

Postnatal expression of the lysine methyltransferase SETD1B is essential for learning and the regulation of neuron-enriched genes.
In mammals, histone 3 lysine 4 methylation (H3K4me) is mediated by six different lysine methyltransferases. Among these enzymes, SETD1B (SET domain containing 1b) has been linked to syndromic intellectual disability in human subjects, but its role in the mammalian postnatal brain has not been studied yet. Here, we employ mice deficient for Setd1b in excitatory neurons of the postnatal forebrain, and combine neuron-specific ChIP-seq and RNA-seq approaches to elucidate its role in neuronal gene expression. We observe that Setd1b controls the expression of a set of genes with a broad H3K4me3 peak at their promoters, enriched for neuron-specific genes linked to learning and memory function. Comparative analyses in mice with conditional deletion of Kmt2a and Kmt2b histone methyltransferases show that SETD1B plays a more pronounced and potent role in regulating such genes. Moreover, postnatal loss of Setd1b leads to severe learning impairment, suggesting that SETD1B-dependent regulation of H3K4me levels in postnatal neurons is critical for cognitive function.

Interferon-driven brain phenotype in a mouse model of RNaseT2 deficient leukoencephalopathy.
Infantile-onset RNaseT2 deficient leukoencephalopathy is characterised by cystic brain lesions, multifocal white matter alterations, cerebral atrophy, and severe psychomotor impairment. The phenotype is similar to congenital cytomegalovirus brain infection and overlaps with type I interferonopathies, suggesting a role for innate immunity in its pathophysiology. To date, pathophysiological studies have been hindered by the lack of mouse models recapitulating the neuroinflammatory

encephalopathy found in patients. In this study, we generated Rnaset2 mice using CRISPR/Cas9-mediated genome editing. Rnaset2 mice demonstrate upregulation of interferon-stimulated genes and concurrent IFNAR1-dependent neuroinflammation, with infiltration of CD8 effector memory T cells and inflammatory monocytes into the grey and white matter. Single nuclei RNA sequencing reveals homeostatic dysfunctions in glial cells and neurons and provide important insights into the mechanisms of hippocampal-accentuated brain atrophy and cognitive impairment. The Rnaset2 mice may allow the study of CNS damage associated with RNaseT2 deficiency and may be used for the investigation of potential therapies.

A microRNA signature that correlates with cognition and is a target against cognitive decline.
While some individuals age without pathological memory impairments, others develop age-associated cognitive diseases. Since changes in cognitive function develop slowly over time in these patients, they are often diagnosed at an advanced stage of molecular pathology, a time point when causative treatments fail. Thus, there is great need for the identification of inexpensive and minimal invasive approaches that could be used for screening with the aim to identify individuals at risk for cognitive decline that can then undergo further diagnostics and eventually stratified therapies. In this study, we use an integrative approach combining the analysis of human data and mechanistic studies in model systems to identify a circulating 3-microRNA signature that reflects key processes linked to neural homeostasis and inform about cognitive status. We furthermore provide evidence that expression changes in this signature represent multiple mechanisms deregulated in the aging and diseased brain and are a suitable target for RNA therapeutics.

H3 acetylation selectively promotes basal progenitor proliferation and neocortex expansion.
Increase in the size of human neocortex—acquired in evolution—accounts for the unique cognitive capacity of humans. This expansion reflects the evolutionarily enhanced proliferative ability of basal progenitors (BPs), including the basal radial glia and basal intermediate progenitors (bIPs) in mammalian cortex, which may have been acquired through epigenetic alterations in BPs. However, how the epigenome in BPs differs across species is not known. Here, we report that histone H3 acetylation is a key epigenetic regulation in bIP amplification and cortical expansion. Through epigenetic profiling of sorted bIPs, we show that histone H3 lysine 9 acetylation (H3K9ac) is low in murine bIPs and high in human bIPs. Elevated H3K9ac preferentially increases bIP proliferation, increasing the size and folding of the normally smooth mouse neocortex. H3K9ac drives bIP amplification by increasing expression of the evolutionarily regulated gene, , in developing cortex. Our findings demonstrate a previously unknown mechanism that controls cortical architecture.

Fusion transcripts in normal human cortex increase with age and show distinct genomic features for single cells and tissues.
Fusion transcripts can contribute to diversity of molecular networks in the human cortex. In this study, we explored the occurrence of fusion transcripts in normal human cortex along with single neurons and astrocytes. We identified 1305 non-redundant fusion events from 388 transcriptomes representing 59 human cortices and 329 single cells. Our results indicate while the majority of fusion transcripts in human cortex are intra-chromosomal (85%), events found in single neurons and astrocytes were primarily inter-chromosomal (80%). The number of fusions in single neurons was significantly higher than that in single astrocytes ($p < 0.05$), indicating fusion as a possible contributor towards transcriptome diversity in neuronal cells. The identified fusions were largely private and 4 specific recurring events were found both in cortex and in single neurons but not in astrocytes. We found a significant increase in the number of fusion transcripts in human brain with increasing age both in single cells and whole cortex ($p < 0.0005$ and < 0.005, respectively). This is likely one of the many possible contributors for the inherent plasticity of the adult brain. The fusion transcripts in fetal brain were enriched for genes for long-term depression; while those in adult brain involved genes enriched for long-term potentiation pathways. Our findings demonstrate fusion transcripts are naturally occurring phenomenon spanning across the health-disease continuum, and likely contribute to the diverse molecular network of human brain.

A combined miRNA-piRNA signature to detect Alzheimer's disease.
Alzheimer's disease (AD) is the most common neurodegenerative disorder causing huge emotional and economic burden to our societies. An effective therapy has not been implicated yet, which is in part also due to the fact that pathological changes occur years before clinical symptoms manifest. Thus, there is a great need for the development of a translatable biomarker. Recent evidence highlights microRNAs as candidate biomarkers. In this study, we use next-generation sequencing to study the small noncoding RNAome (sncRNAome) in exosomes derived from human cerebrospinal fluid (CSF). We show that the sncRNAome from CSF-derived exosomes is dominated not only by microRNAs (miRNAs) but also by PIWI-interacting RNAs (piRNAs). We define a combined signature consisting of three miRNAs and three piRNAs that are suitable to detect AD with an AUC of 0.83 in a replication cohort and furthermore predict the conversion of mild-cognitive impaired (MCI) patients to AD dementia with an AUC of 0.86 for the piRNA signature. When combining the smallRNA signature with pTau and Aβ 42/40 ratio the AUC reaches 0.98. Our study reports a novel exosomal small noncoding RNA signature to detect AD pathology and provides the first evidence that in addition to miRNAs, piRNAs should also be considered as a candidate biomarker for AD.

Innate immune memory in the brain shapes neurological disease hallmarks.
Innate immune memory is a vital mechanism of myeloid cell plasticity that occurs in response to environmental stimuli and alters subsequent immune responses. Two types of immunological imprinting can be distinguished-training and tolerance. These are epigenetically mediated and enhance or suppress subsequent inflammation, respectively. Whether immune memory occurs in tissue-resident macrophages in vivo and how it may affect pathology remains largely unknown. Here we demonstrate that peripherally applied inflammatory stimuli induce acute immune training and tolerance in the brain and lead to differential epigenetic reprogramming of brain-resident macrophages (microglia) that persists for at least six months. Strikingly, in a mouse model of Alzheimer's pathology, immune training exacerbates cerebral β-amyloidosis and immune tolerance alleviates it; similarly, peripheral immune stimulation modifies pathological features after stroke. Our results identify immune memory in the brain as an important modifier of neuropathology.

The diphenylpyrazole compound anle138b blocks Aβ channels and rescues disease phenotypes in a mouse model for amyloid pathology.
Alzheimer's disease is a devastating neurodegenerative disease eventually leading to dementia. An effective treatment does not yet exist. Here we show that oral application of the compound anle138b restores hippocampal synaptic and transcriptional plasticity as well as spatial memory in a mouse model for Alzheimer's disease, when given orally before or after the onset of pathology. At the mechanistic level, we provide evidence that anle138b blocks the activity of conducting Aβ pores without changing the membrane embedded Aβ-oligomer structure. In conclusion, our data suggest that anle138b is a novel and promising compound to treat AD-related pathology that should be investigated further.

KMT2A and KMT2B Mediate Memory Function by Affecting Distinct Genomic Regions.
Kmt2a and Kmt2b are H3K4 methyltransferases of the Set1/Trithorax class. We have recently shown the importance of Kmt2b for learning and memory. Here, we report that Kmt2a is also important in memory formation. We compare the decrease in H3K4 methylation and de-regulation of gene expression in hippocampal neurons of mice with knockdown of either Kmt2a or Kmt2b. Kmt2a and Kmt2b control largely distinct genomic regions and different molecular pathways linked to neuronal plasticity. Finally, we show that the decrease in H3K4 methylation resulting from Kmt2a knockdown partially recapitulates the pattern previously reported in CK-p25 mice, a model for neurodegeneration and memory impairment. Our findings point to the distinct functions of even closely related histone-modifying enzymes and provide essential insight for the development of more efficient and specific epigenetic therapies against brain diseases.

HDAC1 links early life stress to schizophrenia-like phenotypes.
Schizophrenia is a devastating disease that arises on the background of genetic predisposition and environmental risk factors, such as early life stress (ELS). In this study, we show that ELS-induced schizophrenia-like phenotypes in mice correlate with a widespread increase of histone-deacetylase 1 () expression that is linked to altered DNA methylation. overexpression in neurons of the medial prefrontal cortex, but not in the dorsal or ventral hippocampus, mimics schizophrenia-like phenotypes induced by ELS. Systemic administration of an HDAC inhibitor rescues the detrimental effects of ELS when applied after the manifestation of disease phenotypes. In addition to the hippocampus and prefrontal cortex, mice subjected to ELS exhibit increased expression in blood. Moreover, levels are increased in blood samples from patients with schizophrenia who had encountered ELS, compared with patients without ELS experience. Our data suggest that HDAC1 inhibition should be considered as a therapeutic approach to treat schizophrenia.

DYSREGULATION OF PARVALBUMIN- AND CALRETININ-EXPRESSING NEURONS IN THE LATERAL SEPTUM OF THE DF(16)A+/- MOUSE MODEL OF SCHIZOPHRENIA

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Paula Sierra Diaz[1], Antonia Ruiz[1], Olivia Lofaro[2], Felix Leroy[1]
[1]Instituto de Neurociencias CSIC-UMH, Alicante, SANT JOAN D'ALACANT, Spain, [2]Deparment of neuroscience, New York, New York, United States of America

Schizophrenia is a major disabling psychiatric disease, with major consequences on patients' social life. The lateral septum (LS), a brain region connecting the cortex to the hypothalamus and critical for the regulation of affect and social interactions, is implicated in schizophrenia. We supposed that specific populations of LS neurons regulating social interactions are dysregulated during schizophrenia and leveraged the *Df(16)A*$^{+/-}$ mouse model of schizophrenia to test our hypothesis. This model contains the human 22q11 microdeletion, which in humans, confers a 30% probability to develop schizophrenia. These mice exhibit impairments in social interaction and, specifically, in social recognition reminiscent of the human patients' symptoms. We investigated the populations of LS neurons expressing the parvalbumin (PV^{+}) or calretinin (CALB2^{+}) proteins in mutant mice and their wild-type (WT) littermates. WT mice displayed a striking difference between males and females with twice more PV^{+} and CALB2^{+} neurons in males. In mutant male mice, the densities of PV^{+} and CALB2^{+} expressing neurons are specifically decreased in the ventral-lateral region of posterior LS, a region known to project to downstream hypothalamic areas involved in social interactions. Unlike male mice, mutant female mice showed little differences compared to WT. This strong gender bias in mice parallel human studies showing that the course of schizophrenia is more severe in male than female. As LS is necessary for social recognition, we are currently using chemogenetic, optogenetic and calcium imaging to probe the function of these LS neurons to evaluate whether and how their dysregulation leads to the social deficits.

A circuit from hippocampal CA2 to lateral septum disinhibits social aggression.
Although the hippocampus is known to be important for declarative memory, it is less clear how hippocampal output regulates motivated behaviours, such as social aggression. Here we report that pyramidal neurons in the CA2 region of the hippocampus, which are important for social memory, promote social aggression in mice. This action depends on output from CA2 to the lateral septum, which is selectively enhanced immediately before an attack. Activation of the lateral septum by CA2 recruits a circuit that disinhibits a subnucleus of the ventromedial hypothalamus that is known to trigger attack. The social hormone arginine vasopressin enhances social aggression by acting on arginine vasopressin 1b receptors on CA2 presynaptic terminals in the lateral septum to facilitate excitatory synaptic transmission. In this manner, release of arginine vasopressin in the lateral septum, driven by an animal's internal state, may serve as a modulatory control that determines whether CA2 activity leads to declarative memory of a social encounter and/or promotes motivated social aggression.

Aim: Schizophrenia (SCZ) is a severe psychiatric disorder. Both environmental and complex genetic factors contribute to the pathology. This is common to other diseases affecting the nervous system, such as autism spectrum disorders (ASD). Our group has previously demonstrated a role of the cytoplasmatic polyadenylation element (CPE) binding protein 4 (CPEB4) in the aetiology of ASD. CPEBs regulate the translation of specific mRNAs in response to extracellular stimuli. Regarding ASD, we have previously shown that patients show a CPEB4 splicing alteration, generating an imbalance in its isoforms that correlates with concerted mis-expression of multiple ASD risk genes whose transcripts harbour CPE sequences. The parallelism between SCZ and ASD as neurodevelopmental disorders with complex genetics led us to characterize CPEBs in SCZ. Method: First, we searched for bioinformatics evidence of a potential enrichment of CPE-containing and CPEB-binding transcripts within Schizophrenia-associated genes. Then, we performed a screening of the status of CPEBs in SCZ exploiting RNA-seq data from the PsychENCODE repository, to explore possible changes regarding their RNA level and/or splicing. Results: The bioinformatics analysis revealed that SCZ-associated genes are enriched in CPE sequences and CPEB targets. Moreover, CPEB4 splicing shows an altered distribution in SCZ when compared with controls, with an imbalance in its isoforms, as previously reported in the case of ASD. Conclusions: Our results suggest that CPEBs could potentially play a role in the aetiology of Schizophrenia, therefore underlying a novel common feature between SCZ and ASD.

P2X7 Receptor Upregulation in Huntington's Disease Brains.
Huntington's disease (HD) is a fatal degenerative disorder affecting the nervous system. It is characterized by motor, cognitive, and psychiatric dysfunctions, with a late onset and an autosomal dominant pattern of inheritance. HD-causing mutation consists in an expansion of repeated CAG triplets in the huntingtin gene (), encoding for an expanded polyglutamine (polyQ) stretch in the huntingtin protein (htt). The mutation causes neuronal dysfunction and loss through multiple mechanisms, affecting both the nucleus and cytoplasm. P2X7 receptor (P2X7R) emerged as a major player in neuroinflammation, since ATP - its endogenous ligand - is massively released under this condition. Indeed, P2X7R stimulation in the central nervous system (CNS) is known to enhance the release of pro-inflammatory cytokines from microglia and of neurotransmitters from neuronal presynaptic terminals, as well as to promote apoptosis. Previous experiments performed with neurons expressing the mutant huntingtin and exploiting HD mouse models demonstrated a role of P2X7R in HD. On the basis of those results, here, we explore for the first time the status of P2X7R in HD patients' brain. We report that in HD postmortem striatum, as earlier observed in HD mice, the protein levels of the full-length form of P2X7R, also named P2X7R-A, are upregulated. In addition, the exclusively human naturally occurring variant lacking the C-terminus region, P2X7R-B, is upregulated as well. As we show here, this augmented protein levels can be explained by elevated mRNA levels. Furthermore, in HD patients' striatum, P2X7R shows not only an augmented total transcript level but also an alteration of its splicing. Remarkably, P2X7R introns 10 and 11 are more retained in HD patients when compared with controls. Taken together, our data confirm that P2X7R is altered in brains of HD subjects and strengthen the notion that P2X7R may represent a potential therapeutic target for HD.

High concordance between hippocampal transcriptome of the mouse intra-amygdala kainic acid model and human temporal lobe epilepsy.
Pharmacoresistance and the lack of disease-modifying actions of current antiseizure drugs persist as major challenges in the

treatment of epilepsy. Experimental models of chemoconvulsant-induced status epilepticus remain the models of choice to discover potential antiepileptogenic drugs, but doubts remain as to the extent to which they model human pathophysiology. The aim of the present study was to compare the molecular landscape of the intra-amygdala kainic acid model of status epilepticus in mice with findings in resected brain tissue from patients with drug-resistant temporal lobe epilepsy (TLE).
Epilepsia, 2020; 61
32594159: Parras A, de Diego-Garcia L, Alves M, Beamer E, Conte G, Jimenez-Mateos EM, Morgan J, Ollà I, Hernandez-Santana Y, Delanty N, Farrell MA, O'Brien DF, Ocampo A, Henshall DC, Méndez R, Lucas JJ, Engel T
Polyadenylation of mRNA as a novel regulatory mechanism of gene expression in temporal lobe epilepsy.
Temporal lobe epilepsy is the most common and refractory form of epilepsy in adults. Gene expression within affected structures such as the hippocampus displays extensive dysregulation and is implicated as a central pathomechanism. Post-transcriptional mechanisms are increasingly recognized as determinants of the gene expression landscape, but key mechanisms remain unexplored. Here we show, for first time, that cytoplasmic mRNA polyadenylation, one of the post-transcriptional mechanisms regulating gene expression, undergoes widespread reorganization in temporal lobe epilepsy. In the hippocampus of mice subjected to status epilepticus and epilepsy, we report >25% of the transcriptome displays changes in their poly(A) tail length, with deadenylation disproportionately affecting genes previously associated with epilepsy. Suggesting cytoplasmic polyadenylation element binding proteins (CPEBs) being one of the main contributors to mRNA polyadenylation changes, transcripts targeted by CPEBs were particularly enriched among the gene pool undergoing poly(A) tail alterations during epilepsy. Transcripts bound by CPEB4 were over-represented among transcripts with poly(A) tail alterations and epilepsy-related genes and CPEB4 expression was found to be increased in mouse models of seizures and resected hippocampi from patients with drug-refractory temporal lobe epilepsy. Finally, supporting an adaptive function for CPEB4, deletion of Cpeb4 exacerbated seizure severity and neurodegeneration during status epilepticus and the development of epilepsy in mice. Together, these findings reveal an additional layer of gene expression regulation during epilepsy and point to novel targets for seizure control and disease-modification in epilepsy.

Identification of an ERK Inhibitor as a Therapeutic Drug Against Tau Aggregation in a New Cell-Based Assay.
Formation of Tau aggregates is a common pathological feature of tauopathies and their accumulation directly correlates with cytotoxicity and neuronal degeneration. Great efforts have been made to understand Tau aggregation and to find therapeutics halting or reversing the process, however, progress has been slowed due to the lack of a suitable method for monitoring Tau aggregation. We developed a cell-based assay allowing to detect and quantify Tau aggregation in living cells. The system is based on the FRET biosensor CST able to monitor the molecular dynamic of Tau aggregation in different cellular conditions. We probed candidate compounds that could block Tau hyperphosphorylation. In particular, to foster the drug discovery process, we tested kinase inhibitors approved for the treatment of other diseases. We identified the ERK inhibitor PD-901 as a promising therapeutic molecule since it reduces and prevents Tau aggregation. This evidence establishes the CST cell-based aggregation assay as a reliable tool for drug discovery and suggests that PD-901 might be a promising compound to be tested for further preclinical studies on AD.

Differences in structure and function between human and murine tau.
The main difference between the primary structures of human and mouse tau can be found at the N-terminal end of the protein. Residues 17 to 28 in human tau are not present in the mouse form of the molecule. Here we tested the capacity of these human tau residues to bind to specific proteins. Several proteins were observed to bind to these residues. Among those that showed the greatest binding were three related to energetic processes: enolase, glyceraldehyde 3 phosphate dehydrogenase and creatine kinase B. The latter did not bind to tau from brain extracts taken from patients with Alzheimer's disease (AD). This lack of binding could be due to the modification of CKB by oxidation in AD.
Biochim Biophys Acta Mol Basis Dis, 2019; 1865

Role of tau N-terminal motif in the secretion of human tau by End Binding proteins.
For unknown reasons, humans appear to be particular susceptible to developing tau pathology leading to neurodegeneration. Transgenic mice are still undoubtedly the most popular and extensively used animal models for studying Alzheimer's disease and other tauopathies. While these murine models generally overexpress human tau in the mouse brain or specific brain regions, there are differences between endogenous mouse tau and human tau protein. Among them, a main difference between human and mouse tau is the presence of a short motif spanning residues 18 to 28 in the human tau protein that is missing in murine tau, and which could be at least partially responsible for that different susceptibility across species. Here we report novel data using affinity chromatography analysis indicating that the sequence containing human tau residues 18 to

28 acts a binding motif for End Binding proteins and that this interaction could facilitate tau secretion to the extracellular space.

Introduction: Maternal immune activation (mIA) is a risk factor for schizophrenia. It is hypothesised that mIA-induced inflammatory cytokines influence fetal neurodevelopment and predispose offspring to neuropathology. Adult offspring of pregnant rat dams treated with the viral mimetic poly(I:C) exhibit cognitive deficits comparable to those in schizophrenia, thought to be underpinned by dysfunctional fast-spiking parvalbumin (PV)-interneurons. **Aims:** Determine the relationship between inflammation-responsive glial cells and PV-interneuron development, using cell densitometry analysis and gene expression of structural proteins produced primarily by glia, notably myelin and perineuronal net (PNN) components. **Methods:** Pregnant Wistar rats received 10mg/kg bodyweight (i.p.) poly(I:C) or saline on gestational day 15, with plasma cytokines measured at 3h to confirm mIA. Adolescent and adult offspring were assessed using novel object recognition and/or attentional set-shifting tasks. Prefrontal cell densitometry (immunohistochemistry) and mRNA expression (qPCR) analysis were performed using a satellite group of age-matched animals. Results were analysed using general linear mixed modelling. **Results:** Poly(I:C) significantly increased maternal plasma IL-6 and TNF-α concentration and increased lD/ED shift in adult offspring, with no observed deficits in adolescence. PV-interneuron density was unchanged, but accompanied by decreased astrocyte and ramified microglia, alongside increased oligodendrocyte, activated microglia and PNN densities. These cellular changes were associated with altered expression of myelin (*Mag*, *Mbp*), PNN/Perinodal (*Acan, Bcan, Ncan*, *Vcan*, *Nfasc)* and adhesion/extracellular matrix (*Gpc4, Nrxn2, Ank3*) genes. Interestingly, molecular changes presented in adolescence, preceding adult behavioural deficits. **Conclusion:** mIA induced developmental alterations in glial function and PNN formation. Aberrant PNN development could promote PV-interneuron dysfunction and cognitive deficits.

Maternal immune activation in rodent models: A systematic review of neurodevelopmental changes in gene expression and epigenetic modulation in the offspring brain.
Maternal immune activation (mIA) during pregnancy is hypothesised to disrupt offspring neurodevelopment and predispose offspring to neurodevelopmental disorders such as schizophrenia. Rodent models of mIA have explored possible mechanisms underlying this paradigm and provide a vital tool for preclinical research. However, a comprehensive analysis of the molecular changes that occur in mIA-models is lacking, hindering identification of robust clinical targets. This systematic review assesses mIA-driven transcriptomic and epigenomic alterations in specific offspring brain regions. Across 118 studies, we focus on 88 candidate genes and show replicated changes in expression in critical functional areas, including elevated inflammatory markers, and reduced myelin and GABAergic signalling proteins. Further, disturbed epigenetic markers at nine of these genes support mIA-driven epigenetic modulation of transcription. Overall, our results demonstrate that current outcome measures have direct relevance for the hypothesised pathology of schizophrenia and emphasise the importance of mIA-models in contributing to the understanding of biological pathways impacted by mIA and the discovery of new drug targets.

THE SHALLOW COGNITIVE MAP HYPOTHESIS: A HIPPOCAMPAL FRAMEWORK FOR THOUGHT DISORDER IN SCHIZOPHRENIA

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Ayesha Musa[1], Safia Khan[1], Minahil Mujahid[2], Mohamady El-Gaby[3]

Memories are not formed in isolation. They are associated and organized into relational knowledge structures that allow coherent thought. Failure to express such coherent thought is a key hallmark of Schizophrenia. Here we explore the hypothesis that thought disorder arises from disorganized Hippocampal cognitive maps. In doing so, we combine insights from two key lines of investigation, one concerning the neural signatures of cognitive mapping, and another that seeks to understand lower-level cellular mechanisms of cognition within a dynamical systems framework. Specifically, we propose that multiple distinct pathological pathways converge on the shallowing of Hippocampal attractors, giving rise to disorganized Hippocampal cognitive maps and driving conceptual disorganization. We discuss the available evidence at the computational, behavioural, network and cellular levels. We also outline testable predictions from this framework including how it could unify major chemical and psychological theories of schizophrenia and how it can provide a rationale for understanding the aetiology and treatment of the disease.

Schizophrenia pathogenesis involves synaptic function and neurotransmitter systems critical for brain circuit functionality. Diverse biological pathways with polygenic architecture are potentially affected. We aimed to identify a set of genes implicated both in genetic risk and in differential expression in a brain circuit of three brain regions. We studied how gene-set-specific schizophrenia risk translated into brain circuit function. RNA-sequencing data from dorsolateral prefrontal cortex, caudate nucleus, and hippocampus from 238 individuals (neurotypical controls [NC]:154, patients with schizophrenia[SCZ]:84) comprised 22,356 genes clustered into 69 co-expression components. We associated components with schizophrenia diagnosis and genetic risk via linear models and performed gene enrichment analyses. Parsed genetic risk was indexed by scores based on risk polymorphisms within PGC3 schizophrenia loci (GRS). We associated the GRS with fDOPA uptake in the striatum in NC (N=91) and SCZ (N=47; fixed-effect model metanalysis of linear coefficients). We replicated PET results in an independent NC cohort (N=150). Finally, we associated the GRS with reward anticipation-related fMRI activation in 86 NC. One component with striatal dopaminergic specificity overrepresented PGC3 schizophrenia loci (p[corrected]<.05), was associated with diagnosis (t[210]=3.3;p=.001), and GRS (t[93]=2.7;p=.005). The positive association of the GRS with increased striatal fDOPA uptake in NC and SCZ (coefficient[95% CI]: 0.23[0.06, 0.39]) was replicated (t[149]=3.95;16 voxels;p_{FWE}<.05). The GRS was positively correlated to striatal activation during reward anticipation (p_{TFCE}<.05;Z=3.09;68 voxels). Both in post-mortem and in PET/fMRI data, increased GRS in a striatal co-expression gene set linked with dopaminergic transmission is associated with increased estimated striatal dopamine function and related functional phenotypes.

Evidence of an interaction between and polymorphisms on levels of Negative Symptoms of Schizophrenia and their response to antipsychotics.
Genome-Wide Association Studies (GWASs) have identified several genes associated with Schizophrenia (SCZ) and exponentially increased knowledge on the genetic basis of the disease. In addition, products of GWAS genes interact with neuronal factors coded by genes lacking association, such that this interaction may confer risk for specific phenotypes of this brain disorder. In this regard, fragile X mental retardation syndrome-related 1 (FXR1) gene has been GWAS associated with SCZ. FXR1 protein is regulated by glycogen synthase kinase-3β (GSK3β), which has been implicated in pathophysiology of SCZ and response to antipsychotics (APs). rs496250 and rs12630592, two eQTLs (Expression Quantitative Trait Loci) of FXR1 and GSK3β, respectively, interact on emotion stability and amygdala/prefrontal cortex activity during emotion processing. These two phenotypes are associated with Negative Symptoms (NSs) of SCZ suggesting that the interaction

between these SNPs may also affect NS severity and responsiveness to medication.

Background and aims: Schizophrenia spectrum disorders are among the most debilitating mental disorders and evidence on its pathophysiological underpinnings is scant. The brain-derived neurotrophic factor (BDNF) appears to be involved in the pathophysiology of these complex psychiatric disorders. The present study investigates the longitudinal variation of serum BDNF levels in a 24-month observational cohort study of Sardinian psychotic patients (LABSP). This study assessed the variation in BDNF serum levels and its relationship with psychopathological and cognitive changes. Further, we also examined if genetic variations within the BDNF gene could moderate these relationships. **Methods:** Every six months 105 LABSP patients were assessed for their BDNF levels, as well as for a series of psychopathological, cognitive, and drug-related measures. Four tag single nucleotide polymorphisms (SNPs) within the BDNF gene were selected and analyzed using Polymerase Chain Reaction (PCR). Longitudinal data were analyzed using mixed-effects linear regression models (MLRM). **Results:** Analysis showed a declining trajectory of BDNF levels in psychotic patients with increased severity of depressive and negative symptoms. BDNF levels were also decreased in patients scoring lower in cognitive measures such as symbol coding and semantic fluency. Val66Met polymorphism within BDNF gene significantly moderated the relationship between the severity of negative symptoms and BDNF levels. **Conclusions:** Our findings are consistent with previous literature suggesting that peripheral BDNF levels are associated with some cognitive domains and mood disruption in major psychosis. These findings in real-life patients suggest a plausible role of peripheral BDNF levels as a marker of illness burden in major psychoses.

Suicidal Thoughts, Attempts and Motives Among University Students in 12 Muslim-Majority Countries.

There is a scarcity of research on suicidal phenomena in the Muslim world. Therefore, this study aimed at investigating the self-reported prevalence of suicidal thoughts, attempts and motives in 12 Muslim countries. A total of 8417 (54.4% women) university students were surveyed by means of a self-report questionnaire. Overall, 22% of the participants reported suicidal ideation and 8.6% reported attempting suicide. The odds of suicidal thoughts were elevated in Azerbaijan, Indonesia and Saudi Arabia, while reduced ORs were recorded in Egypt, Jordan, Lebanon and Malaysia. While odds of suicide attempts were high in Azerbaijan, Palestine and Saudi Arabia reduced odds ratios (OR) were detected in Indonesia, Iran, Jordan, Lebanon, Malaysia and Tunisia. Taking drugs and using a sharp instrument were the two most frequently used methods to attempt suicide. Only 32.7% of attempts required medical attention. Escape motives were endorsed more than social motives by participants who attempted suicide. Suicidal behaviors were more frequent in women than in men. Compered to men, fewer attempts by women required medical attention. Moreover, our results show that making suicide illegal does not reduce the frequency of suicidal behavior. Results from this comparative study show that suicidal thoughts and attempts are frequent events in young adults in countries where religious scripture explicitly prohibit suicide and the frequencies of nonfatal suicidal behavior show large variation in nations adhering to the same religion.

DOPAMINE D4 RECEPTOR MODULATION OF ELECTRICALLY STIMULATED DOPAMINE RELEASE IN RAT BRAIN SLICES: IMPLICATION FOR THE TREATMENT OF SCHIZOPHRENIA.

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Mokolapo Tenibiaje[1], Andrew Young[2]
[1]University of Leicester, Department Of Neuroscience, Psychology And Behaviour, Leicester City, United Kingdom, [2]University of Leicester, School Of Psychology, Leicester City, United Kingdom

Schizophrenia is a debilitating mental illness that affects around 0.5% of the population. Although several antipsychotic drugs are used, around 70% of patients do not respond well, and many experience severe side effects from the drugs, emphasizing the need to understand better the changes occurring in schizophrenia, and to develop better medications to treat it. Behavioural studies have suggested that dopamine D4-receptor agonists may exhibit an antipsychotic-like profile (Sood et al, 2011; J. Psychopharmacology 25, 792-800). This experiment aims to study the action of the D4-receptor agonist A412997 on dopamine release in nucleus accumbens in the context of changes in schizophrenia and potential novel treatment. Brain slices (400 µM) containing nucleus accumbens were taken from male and female juvenile Wistar rats and fast-scan cyclic voltammetry (FSCV) was used to measure electrically-stimulated dopamine release from nucleus accumbens in real-time. Repeated stimulations were given at 3 min intervals: after four baseline (no drug) stimulations, drugs were applied for the next four stimulations (12 min) to assess effects on stimulated release. . Results revealed that the D4-receptor agonist, A412997 causes a concentration-dependent attenuation of electrically stimulated dopamine release, which was abolished by the D4 specific antagonist, L-741,742. Clozapine, which has D4 antagonist properties, amongst many other pharmacological actions, reduced but did not completely abolish the attenuation caused by A412997. This demonstrates a local modulation of dopamine release by D4- receptors, providing a better understanding of the actions of this drug in behavioural models of schizophrenia perhaps suggesting a potential novel treatment for schizophrenia.

Modulation of stimulated dopamine release in rat nucleus accumbens shell by GABA in vitro: Effect of sub-chronic phencyclidine pretreatment.
Dopamine signaling in nucleus accumbens (NAc) is modulated by γ-aminobutyric acid (GABA), acting through GABA-A and GABA-B receptors: dysregulation of GABAergic control of dopamine function may be important in behavioral deficits in schizophrenia. We investigated the effect of GABA-A (muscimol) and GABA-B (baclofen) receptor agonists on electrically stimulated dopamine release. Furthermore, we explored whether drug-induced changes were disrupted by pretreatment with phencyclidine, which provides a well-validated model of schizophrenia. Using brain slices from female rats, fast-scan cyclic voltammetry was used to measure electrically stimulated dopamine release in NAc shell. Both muscimol and baclofen caused concentration-dependent attenuation of evoked dopamine release: neither effect was changed by dihydro-β-erythroidine, a nicotinic acetylcholine receptor antagonist, or the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)-type glutamate receptor antagonist, 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX), precluding indirect mechanisms using these transmitter systems in the GABAergic actions. In slices taken from rats pretreated with phencyclidine, the attenuation of evoked dopamine release by baclofen was abolished, but the attenuation by muscimol was unaffected. Since phencyclidine pretreatment was followed by drug-free washout period of at least a week, the drug was not present during recording. Therefore, disruption of GABA-B modulation of dopamine is due to long-term functional changes resulting from the treatment, rather than transient changes due to the drug's presence at test. This enduring dysregulation of GABA-B modulation of accumbal dopamine release provides a plausible mechanism through which GABA dysfunction influences accumbal dopamine leading to behavioral changes seen in schizophrenia and may provide a route for novel therapeutic strategies to treat the condition.

Distracting stimuli evoke ventral tegmental area responses in rats during ongoing saccharin consumption.
Disruptions in attention, salience and increased distractibility are implicated in multiple psychiatric conditions. The ventral

tegmental area (VTA) is a potential site for converging information about external stimuli and internal states to be integrated and guide adaptive behaviours. Given the dual role of dopamine signals in both driving ongoing behaviours (e.g., feeding) and monitoring salient environmental stimuli, understanding the interaction between these functions is crucial. Here, we investigate VTA neuronal activity during distraction from ongoing feeding. We developed a task to assess distraction exploiting self-paced licking in rats. Rats trained to lick for saccharin were given a distraction test, in which three consecutive licks within 1 s triggered a random distractor (e.g. light and tone stimulus). On each trial they were quantified as distracted or not based on the length of their pauses in licking behaviour. We expressed GCaMP6s in VTA neurons and used fibre photometry to record calcium fluctuations during this task as a proxy for neuronal activity. Distractor stimuli caused rats to interrupt their consumption of saccharin, a behavioural effect which quickly habituated with repeat testing. VTA neural activity showed consistent increases to distractor presentations and, furthermore, these responses were greater on distracted trials compared to non-distracted trials. Interestingly, neural responses show a slower habituation than behaviour with consistent VTA responses seen to distractors even after they are no longer distracting. These data highlight the complex role of the VTA in maintaining ongoing appetitive and consummatory behaviours while also monitoring the environment for salient stimuli.

Repeated phencyclidine disrupts nicotinic acetylcholine regulation of dopamine release in nucleus accumbens: Implications for models of schizophrenia.

Dopaminergic dysregulation in nucleus accumbens has been implicated in the origin of schizophrenia. Accumbal cholinergic interneurons exert powerful modulatory control of local dopamine function, through nicotinic receptors located on dopamine terminals. Fast-scan cyclic voltammetry in rat brain slices in vitro was used to measure dopamine release evoked by high-frequency electrical stimulation, mimicking phasic dopamine activity. We investigated whether cholinergic regulation of stimulated dopamine release was disrupted by pretreatment with phencyclidine, a non-competitive NMDA receptor antagonist, which provides a well validated animal model of schizophrenia. Dihydro-β-erythroidine, an antagonist at β2-subuit containing nicotinic receptors, caused a concentration-dependent enhancement of stimulated dopamine release, indicating cholinergic inhibitory control over dopamine release. The agonist, nicotine, also caused concentration-dependent increases in release, consistent with rapid desensitisation of the receptors previously described. In slices taken from animals pretreated with phencyclidine, the augmentation of electrically-stimulated dopamine release elicited by both drugs was attenuated, particularly when each drug was applied at high concentration. In addition, the concentration-dependence of each drug effect was lost. Taken together these findings indicate that pretreatment with phencyclidine causes changes in acetylcholine systems modulating dopamine release in accumbens. Since phencyclidine treatment was terminated at least a week before the slices were taken, the effects are due to long-term changes in function resulting from the treatment, rather than from transient changes due to the presence of the drug at test. Such enduring dysregulation of cholinergic control of phasic dopamine release could account for deficits in behaviours mediated by accumbal dopamine seen in schizophrenia, and may provide a route for novel therapeutic strategies to treat the disease.

Aims: Schizophrenia is a serious mental disorder caused by a chemical imbalance between neuronal circuits. However, due to the high complexity of these neuronal networks, the aetiology of schizophrenia remains poorly explored. While many other studies have identified the global impact of schizophrenia on the cerebral cortex, the aim of our study is to uncover specific neuronal subtypes with schizophrenia-associated transcriptional changes. Methods: We carried out single-nucleus RNA sequencing (snRNA-seq) on post-mortem brain tissue of more than 220 000 neurons from the dorsolateral prefrontal cortex of patients with schizophrenia and matched controls. Furthermore, we performed immunohistochemistry to bridge cortical anatomy with snRNA-seq findings. Finally, to validate the detected subtype-specific impairment, we performed in situ hybridization and spatial transcriptomics. Results: Using snRNA-seq, we show a decrease in abundance of all GABAergic neurons, and an increase in principal neurons with the highest perturbations in upper layers. Histological analysis confirmed density reduction in supragranular layers of GABAergic neurons particularly in layer 2. Spatial transcriptomics confirmed previously detected hotspot changes in layer 2-3 subtypes which exhibit functional downregulation of genes related to energy metabolism and upregulation of genes related to neurotransmission. Conclusions: Our results show an impairment of specific neuronal subtypes occupying upper cortical layers. Moreover, we also show that schizophrenia-associated changes affect multiple neuronal subtypes which indicates a general network impairment.

Decoding the Role of DVL1 in Intracranial Meningioma.
In the search for molecular candidates for targeted meningioma therapies, increasing attention has been paid to the role of signaling pathways in the development and progression of intracranial meningiomas. Although it is well known that the Wnt signaling pathway is involved in meningioma progression, the role of its central mediator, DVL1, is still unclear. In order to investigate the influence of gene alterations on the progression of human intracranial meningioma, we focused on its central PDZ domain, which is responsible for DVL interaction with the Fzd receptor and the phosphorylation of DVL mediated through the casein kinases CK1 and CK2. A genetic analysis of genomic instability revealed the existence of microsatellite instability in 9.09% and the loss of heterozygosity in 6.06% of the samples. The sequencing of the PDZ gene region showed repetitive deletions of two bases located in intron 7 and exon 8, and a duplication in intron 8 in most samples, with different outcomes on the biological function of the DVL1 protein. Immunohistochemistry revealed that the nuclear expression of DVL1 was significantly correlated with a higher expression of active β-catenin (= 0.029) and a higher meningioma grade (= 0.030), which leads to the conclusion that it could be used as biomarker for meningioma progression and the activation of the Wnt signaling pathway.

Are We Benign? What Can Wnt Signaling Pathway and Epithelial to Mesenchymal Transition Tell Us about Intracranial Meningioma Progression.
Epithelial to mesenchymal transition (EMT), which is characterized by the reduced expression of E-cadherin and increased expression of N-cadherin, plays an important role in the tumor invasion and metastasis. Classical Wnt signaling pathway has a tight link with EMT and it has been shown that nuclear translocation of β-catenin can induce EMT. This research has showed that genes that are involved in cadherin switch, and , play a role in meningioma progression. Increased N-cadherin expression in relation to E-cadherin was recorded. In meningioma, transcription factors SNAIL, SLUG, and TWIST1 demonstrated strong expression in relation to E- and N-cadherin. The expression of SNAIL and SLUG was significantly associated with higher grades (= 0.001), indicating their role in meningioma progression. Higher grades also recorded an

increased expression of total β-catenin followed by an increased expression of its active form (= 0.000). This research brings the results of genetic and protein analyzes of important molecules that are involved in Wnt and EMT signaling pathways and reveals their role in intracranial meningioma. The results of this study offer guidelines and new markers of progression for future research and reveal new molecular targets of therapeutic interventions.

EARLY-LIFE CHANGES IN PREFRONTAL CORTICAL SPONTANEOUS ACTIVITY, GABAERGIC TRANSMISSION AND RECENCY MEMORY IN THE MAM MOUSE MODEL OF SCHIZOPHRENIA.

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Konstantinos Diskos[1,2], Angeliki Velli[1,2], Kyriaki Sidiropoulou[1,2]
[1]University of Crete, Department Of Biology, Heraklion Crete, Greece, [2]Foundation for Research and Technology Heraklion, Greece, Institute Of Molecular Biology And Biotechnology, Heraklion Crete, Greece

Schizophrenia is a severe and multifactorial neuropsychiatric disorder, for which current medication mainly focuses on treating the positive symptoms of the disease, leaving cognitive deficits unaltered. An important research direction for schizophrenia is that of early diagnosis. Aim: In our study we aim to identify early-life neurophysiological changes in the methylazoxymethanol acetate (MAM) mouse model of schizophrenia compared to control mice (saline-treated). Methods: Neonatal (postnatal days (P)8-11), juvenile (P15-21) and adolescent (P40-45), female and male MAM or control prefrontal cortical (PFC) brain slices were acquired for extracellular local field recordings to measure Up states and neuronal oscillations. Adolescent MAM and control mice performed the temporal order object recognition (TOR) task, and were additionally investigated for $GABA_A$ receptor ($GABA_AR$) reversal potential in PFC through voltage-clamp recordings. Results: Delta, theta, alpha and beta frequency neuronal oscillations are significantly reduced in neonatal, but not in juvenile or adolescent MAM PFC, while juvenile MAM mice exhibit a significantly increased frequency of up states, compared to controls. In control adolescent mice, ketamine application in PFC brain slices increases the beta and gamma frequencies, but not in MAM adolescent mice. Furthermore, adolescent MAM mice display a significantly reduced discrimination index in TOR task, and a more positive $GABA_AR$ reversal potential relative to control mice. Conclusion: Early-life alterations of neuronal oscillations and up states generation could affect PFC development and network activity (depolarizing $GABA_AR$ reversal potential), leading to cognitive deficits (TOR deficits) observed in adolescent MAM mice.

DYSREGULATED MRNA TRANSLATION AND SCHIZOPHRENIA-RELEVANT BEHAVIOURS IN MICE

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Brandon Rodrigue[1], Edna Matta-Camacho[2], Argel Aguilar Valles[2]
[1]Carleton University, Neuroscience, Ottawa, Canada, [2]Carleton University, Neuroscience, OTTAWA, Canada

Schizophrenia (SCZ) is one of the leading causes of disability worldwide. SCZ arises by alterations in neurodevelopment, involving multiple etiological factors that influence the function of several neurotransmitter systems. For example, dysfunction of the dopaminergic (DAergic) system has been consistently implicated in the pathology of SCZ. Although the role of DA has been well established in SCZ, the developmental factors that lead to dysfunctional DAergic neurotransmission are still a matter of active research. mRNA translation is a key regulator of neural development and is regulated through the mammalian target of rapamycin complex 1 (mTORC1) pathway, among others. Upon its activation, mTORC1 phosphorylates the eukaryotic initiation factor 4E (eIF4E) binding proteins (4E-BPs), allowing eIF4E to recruit the remainder of the translation initiation factors. Considering the importance of the mTORC1-4E-BP pathway in development, we examined the role of 4E-BP2 in the mesolimbic dopaminergic system using a 4E-BP2 mutant mouse model. In male and female mice, we found that absence or haploinsufficiency of 4E-BP2 impaired pre-pulse inhibition of acoustic startle and exaggerated amphetamine-induced locomotion, compared to wildtype littermates (but no difference in locomotion induced by the NMDA receptor antagonist MK-801). These results demonstrate that 4E-BP2 plays an essential role in the development of the dopamine system and potentially in the pathophysiology of SCZ.

Maternal Immune Activation and the Development of Dopaminergic Neurotransmission of the Offspring: Relevance for Schizophrenia and Other Psychoses.
Prenatal infections have been linked to the development of schizophrenia (SCZ) and other neurodevelopmental disorders in the offspring, and work in animal models indicates that this is to occur through the maternal inflammatory response triggered by infection. Several studies in animal models demonstrated that acute inflammatory episodes are sufficient to trigger brain alterations in the adult offspring, especially in the mesolimbic dopamine (DA) system, involved in the pathophysiology of SCZ and other disorders involving psychosis. In the current review, we synthesize the literature on the clinical studies implicating prenatal infectious events in the development of SCZ. Then, we summarize evidence from animal models of maternal immune activation (MIA) and the behavioral and molecular alterations relevant for the function of the DAergic system. Furthermore, we discuss the evidence supporting the involvement of maternal cytokines, such as interleukin 6 (IL-6) and leptin (a hormone with effects on inflammation) in mediating the effects of MIA on the fetal brain, leading to the long-lasting effects on the offspring. In particular, IL-6 has been involved in mediating the effects of MIA animal models in the offspring through actions on the placenta, induction of IL-17a, or triggering the decrease in non-heme iron (hypoferremia). Maternal infection is very likely interacting with additional genetic and environmental risk factors in the development of SCZ; systematically investigating how these interactions produce specific phenotypes is the next step in understanding the etiology of complex psychiatric disorders.

SELECTIVE GSK3α AND β INHIBITION DURING EARLY POSTNATAL DEVELOPMENT MODIFIES WORKING MEMORY-RELATED BEHAVIOR IN A SEX-BIASED MANNER IN A MOUSE MODEL OF 22Q11.2 DELETION SYNDROME

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Johannes Passecker[1,2,3], Chloe Aloimonos[3], Chia-Yuan Chang[2], Aleksandra Dagunts[3], Maxym Myroshnychenko[3], David Kupferschmidt[3], Joseph Gogos[2], Joshua Gordon[3,4]

Working memory, a cognitive process involving short-term encoding and maintenance of information relies on prefrontal cortex (PFC) functionality, is reliably modeled in preclinical animal models and is profoundly impaired in schizophrenia. The 22q11.2 Deletion Syndrome (DS) is a clinically relevant genetic cause of schizophrenia and non-selective Glycogen Synthase Kinase (GSK)3 (α and β isoform) inhibitors have been found to rescue cognitive deficits in preclinical models, but their non-selective profiles hamper their preclinical utility. Recently developed selective inhibitors allow targeted inhibition of each isoform. Here, we tested their potential to rescue PFC-dependent spatial working memory deficits in the *Df(16)A*$^{+/-}$ mouse model of the 22q11.2DS. The selective GSK3β inhibitor BRD3731 administered during postnatal development rescued acquisition deficits in spatial working memory in male but not female *Df(16)A*$^{+/-}$ mice. Developmental medial PFC and ventral hippocampus bulk-seq transcriptomics data support the findings. GSK3β inhibition also rescued deficits in theta-frequency coherence between ventral hippocampus and medial PFC, a neurophysiological correlate of spatial working memory performance, in *Df(16)A*$^{+/-}$ mice. Ongoing analysis of medial PFC single-unit recordings aims to further verify behavioral and neurophysiological findings. Conversely, selective postnatal GSK3α inhibition by BRD0705 failed to rescue task acquisition deficits but did reverse deficits in task performance under conditions of increased working memory demand in both male and female *Df(16)A*$^{+/-}$ mice. Overall, the experiments indicate differential roles of GSK3α and β isoforms in the development of the prefrontal-hippocampal circuitry supporting spatial working memory, its disease-relevant dysfunction in mice and highlights the import of sex-specific analysis in pre-clinical research.

Background. Schizophrenia (SCZ) is a chronic brain disorder that is characterized by alterations in perception, thoughts, mood, behavior. Molecular mechanisms of SCZ are unknown today. However, a cytokine imbalance has been described in SCZ pathogenesis. **The aim** of this study was to investigate the role of over-time cytokine profile changes in predicting the pharmacotherapyeffectiveness of SCZ. **Methods**. Blood serum samples were collected from 61 SCZ patients during antipsychotic therapy (haloperidol/olanzapine) twice: before (T1) and after 28 days (T2) of treatment. Patients were divided according to the therapy effectiveness, depending on the reduction in Positive and Negative Syndrome Scale (PANSS) (>20% - effective, <20% - ineffective). Profile of 48 cytokines was assessed by Immunology Multiplex Assay (HCYTOMAG-48,Merk-Millipore,USA). **Results**. Decreased plasma proinflammatory cytokine concentrations of Il-5, Il-6, Il-7, Il-15, TNF-alpha-2, CXCL1/GRO were revealed in SCZ patients with effective response to therapy in T2 compared to T1 ($p<0.05$). Also, increased plasma proinflammatory cytokine concentrations of IL-4, CCL-22/MDC, PDGF-AB-BB were observed in SCZ patients with poor response to therapy T2 compared to T1 ($p<0.05$). Receiver-operating characteristic (ROC) analysis has been conducted for all studied cytokines in SCZ patients with effective response to therapy compared to ineffective. Cut-off value was estimated as 7.99 ng/ml for TGF-alpha (AUC=0.67;p=0.0315) and 17816 ng/ml for sCD40-L (AUC=0.65;p=0.039634). **Conclusions**. Our data showed a more pronounced decrease of proinflammatory cytokine secretion during antipsychotic therapy in SCZ patients with an effective response to therapy. Concentration of TGF-alpha and sCD40-L may be proposed as as potential biomarkers for predicting the antipsychotic therapy effectiveness.

Impaired Sphingolipid Hydrolase Activities in Dementia with Lewy Bodies and Multiple System Atrophy.
The synucleinopathies are a group of neurodegenerative diseases characterized by the oligomerization of alpha-synuclein protein in neurons or glial cells. Recent studies provide data that ceramide metabolism impairment may play a role in the pathogenesis of synucleinopathies due to its influence on alpha-synuclein accumulation. The aim of the current study was to assess changes in activities of enzymes involved in ceramide metabolism in patients with different synucleinopathies (Parkinson's disease (PD), dementia with Lewy bodies (DLB), and multiple system atrophy (MSA)). The study enrolled 163 PD, 44 DLB, and 30 MSA patients as well as 159 controls. Glucocerebrosidase, alpha-galactosidase, acid sphingomyelinase enzyme activities, and concentrations of the corresponding substrates (hexosylsphingosine, globotriaosylsphingosine, lysosphingomyelin) were measured by liquid chromatography tandem-mass spectrometry in blood. Expression levels of GBA, GLA, and SMPD1 genes encoding glucoceresobridase, alpha-galactosidase, and acid sphingomyelinase enzymes, correspondently, were analyzed by real-time PCR with TaqMan assay in CD45 + blood cells. Increased hexosylsphingosine concentration was observed in DLB and MSA patients in comparison to PD and controls ($p < 0.001$) and it was associated with earlier age at onset (AAO) of DLB ($p = 0.0008$). SMPD1 expression was decreased in MSA compared to controls ($p = 0.015$). Acid sphingomyelinase activity was decreased in DLB, MSA patients compared to PD patients ($p < 0.0001$, $p < 0.0001$, respectively), and in MSA compared to controls ($p < 0.0001$). Lower acid sphingomyelinase activity was

associated with earlier AAO of PD (p = 0.012). Our data support the role of lysosomal dysfunction in the pathogenesis of synucleinopathies, namely, the pronounced alterations of lysosomal activities involved in ceramide metabolism in patients with MSA and DLB.

Comparative Transcriptome Analysis in Monocyte-Derived Macrophages of Asymptomatic Mutation Carriers and Patients with GBA-Associated Parkinson's Disease.
Mutations of the gene, encoding for lysosomal enzyme glucocerebrosidase (GCase), are the greatest genetic risk factor for Parkinson's disease (PD) with frequency between 5% and 20% across the world. N370S and L444P are the two most common mutations in the gene. PD carriers of severe mutation L444P in the gene is characterized by the earlier age at onset compared to N370S. Not every carrier of mutations develop PD during one's lifetime. In the current study we aimed to find common gene expression signatures in PD associated with mutation in the gene (GBA-PD) using RNA-seq. We compared transcriptome of monocyte-derived macrophages of 5 patients with GBA-PD (4 L444P/N, 1 N370S/N) and 4 asymptomatic mutation carriers (GBA-carriers) (3 L444P/N, 1 N370S/N) and 4 controls. We also conducted comparative transcriptome analysis for L444P/N only GBA-PD patients and GBA-carriers. Revealed deregulated genes in GBA-PD independently of mutations (L444P or N370S) were involved in immune response, neuronal function. We found upregulated pathway associated with zinc metabolism in L444P/N GBA-PD patients. The potential important role of in the pathogenesis of GBA-PD was suggested.

Background. Schizophrenia (SCZ) is a mental disorder with a prevalence of 0.7-1% of the general population and is characterized by impairment of dopamine transmission in neurons. Last data demonstrated that lysosomal storage disorders (LSDs) accompanied by a decrease of lysosomal activity may manifest with a wide spectrum of clinical presentations including psychosis, schizophrenia, mood disorders, early-onset dementia. **The aim** was to estimate whether alteration of lysosomal activities contributes to SCZ pathogenesis. **Methods.** 34 SCZ patients and 181 patients with Parkinson's disease (PD) as patients with disease also associated with dopamine metabolism dysfunction and 176 controls were enrolled for the current study. Enzyme activities (glucoceresobridase (GCase), alpha-galactosidase (GLA), acid sphingomyelinase (ASMase)), and concentration of their corresponded substrates (hexosylsphingosine (HexSph), globotriaosylsphingosine (LysoGb3), lysosphingomyelin (LysoSM)) in blood were measured by liquid chromatography tandem-mass spectrometry. **Results.** Decreased ASMase activity was found in SCZ patients compared to PD patients ($p<0.0001$) and controls ($p<0.0001$) with increase of LysoSM concentration in SCZ patients compared to PD patients ($p<0.0001$) and controls ($p=0.00081$). Elevated GLA activity in SCZ patients compared to PD patients ($p=0.0039$) and controls ($p=0.0004$) with increase of LysoGb3 concentration in SCZ patients compared to PD patients ($p<0.0001$) and controls ($p<0.0001$) was found. HexSph concentration was increased in SCZ patients compared to PD patients and controls ($p<0.0001$) with no differences in GCase activity between all studied groups ($p>0.05$). **Conclusion.** Our data suggested possible link between SCZ and LSDs, characterized by alteration of lysosomal enzyme activities with more pronounce decreased of ASMase and increase of LysoSM.

Genetics variants and expression of the SCARB2 gene in the pathogenesis of Parkinson's disease in Russia.
Lysosomal integral membrane protein-2 (LIMP-2), encoded by the SCARB2 gene, is the specific lysosomal receptor for glucocerebrosidase enzyme. Association between rs6812193 and rs68250047 of SCARB2 with PD has been shown in genetic studies, including large genome-wide association studies. The aim of the current study was to determine whether rs6812193 and rs8475 are associated with PD in Russia. rs6812193 and rs8475 were genotyped in a total of 604 PD patients (65 PD patients with positive (fPD) and 539 PD patients with negative family history (sPD)) and 413 controls and also in 17 patients with PD associated with GBA mutations (PD-GBA) and 18 asymptomatic GBA mutation carriers (GBA-Carriers). SCARB2 expression was measured by real-time PCR in CD45+ blood cells in part of individuals in the studied groups. No linkage disequilibrium was shown between rs6812193 and rs8475 in Russian population. Increased PD risk for TT variant of rs8475 (OR = 2.02; p < 0.001) was found in sPD patients but not in fPD. rs6812193 and rs8475 were not associated with age at onset (AAO) of PD. SCARB2 expression level was decreased in GBA-PD patients and GBA-Carriers compared to PD patients (p = 0.02, p = 0.003, respectively) and GBA-Carriers compared to controls (p = 0.013) with no significant difference in PD patients and controls. SCARB2 expression was not modified with rs6812193 and rs8475. In conclusion, rs8475 was associated with PD status. rs6812193 and rs8475 are not genetic modifier of AAO of PD and do not influence on SCARB2 mRNA level in CD45+ blood cells in studied groups. SCARB2 expression could be modified with GBA mutations and is independent of PD status.

Plasma cytokine profile in synucleinophaties with dementia.
Immune response may play a pivotal role in the pathogenesis of the common synucleinopathy as Parkinson's disease (PD) and could be mediated with the accumulation of neurotoxic alpha-synuclein. There is limited evidence for immune response in another synucleinopathy as dementia with Lewy bodies (DLB). Recent data suggest that immune response may contribute to cognitive impairment. We aimed to estimate plasma cytokine profile in patients with synucleinopathies with dementia (PD dementia (PDD), DLB). Plasma cytokine levels (interferon-gamma (IFN-gamma), interleukin (IL)-4 (IL-4), IL-6, IL-10, tumor necrosis factor alpha (TNF-alpha), monocyte chemoattractant protein-1 (MCP-1)). were estimated in 16 patients with DLB, 19 patients with PDD, 28 patients with PD without dementia (PD) and 19 individuals without neurological disorders (controls) using Luminex array system. Cognitive status was assessed with the Mini-Mental State Examination (MMSE). TNF-alpha and IL-6 plasma levels were elevated in patients with synucleinopathies with dementia (DLB, PDD) compared to controls and IL-10 plasma level was increased in PDD compared to controls (p < 0.05). IFN-gamma levels were decreased in PD and PDD patients compared to controls (p < 0.001, p = 0.026, respectively) and in PD patients than in DLB patients (p = 0.032). Patients with PD, PDD, and DLB were characterized by increased plasma levels of MCP-1 compared to controls (p < 0.001). At the same time, no differences in TNF-alpha, IL-10, IL-6 plasma levels in PD patients compared to controls were found. Our

study demonstrated more pronounced immune response in synucleinopathies associated with dementia compared to PD without demetia.

OXIDATIVE STRESS MARKERS AS POTENTIAL PREDICTORS OF THE TRANSITION TO PSYCHOSIS IN INDIVIDUALS AT ULTRA-HIGH RISK.

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Victoria Rambaud[1], Ariel Frajerman[1], Margot Fournier[2], Daniella Dwir[2], Ines Khadimallah[2], Oussama Kebir[1,3], Aude Marzo[1], Marie-Odile Krebs[1,3], Kim Q Do[2], Boris Chaumette[1,3,4]
[1]Université de Paris, INSERM U1266, Institute Of Psychiatry And Neuroscience Paris, Paris, France, [2]Center for Psychiatric Neuroscience, Lausanne University Hospital (CHUV), Department Of Psychiatry, Lausanne, Switzerland, [3]Hôpital Sainte Anne, Ghu-paris Psychiatrie Et Neurosciences, PARIS, France, [4]McGill University, Department Of Psychiatry, Montréal, France

Background: Ultra-high-risk state (UHR) concept was initially applied to promote the early detection of young help-seeking patients with higher risk of psychotic transition. However, most UHR individuals do not evolve to psychosis, stressing the need for biomarkers allowing the prediction of the transition. Therefore, phase-specific approaches and mechanism-based-biomarkers are necessary to develop early prevention strategies. The interaction between redox dysregulation and neuroinflammation was shown to play a major role in the pathophysiology of psychotic disorders. **Aim:** The aim of this project is to investigate the role of blood markers for redox dysregulation in the risk of transition to psychosis in UHR. **Methods:** Blood samples were collected from 48 UHR at their first visit and 6 to 12 months later for those who did not transition to psychosis (UHR-NC), or at the time of the transition (UHR-C). Markers for redox dysregulation, including the glutathione antioxidant system, superoxide dismutase, thioredoxin, TBARS, macrophage migration inhibitory factor, peroxiredoxin 4, MMP9 and sRAGE, were assessed in erythrocytes, serum and plasma. **Results:** Statistical analyses revealed a combination of peripheral redox markers as indicators of the transition to psychosis. These markers were able to discriminate between UHR-C and UHR-NC subjects at baseline. Importantly, some of the redox markers were associated with the severity of symptoms at the final timepoint. **Conclusion:** These findings support the use of mechanism-based peripheral biomarkers of oxidative stress as predictors of the transition to psychosis. Overall, these findings hold promises for early detection and stratification of UHR, targeting redox pathways.

COMPLEMENT RESPONSES AND SYNAPTIC CHANGES AFTER TRANSIENT MICROGLIA DEFICIENCY IN THE ADOLESCENT PREFRONTAL CORTEX

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Sina-Maria Schalbetter[1], Anina Von Arx[1], Natalia Cruz-Ochoa[2], Han-Yu Lin[1], René Amport[1], Csaba Földy[2], Melanie Greter[3], Tina Notter[1], Urs Meyer[1]
[1]University of Zurich-Vetsuisse, Pharmacology And Toxicology, Zurich, Switzerland, [2]University of Zurich, Laboratory Of Neural Connectivity, Zurich, Switzerland, [3]University of Zurich, Institute Of Experimental Immunology, Zurich, Switzerland

Microglia are the resident immune cells of the brain parenchyma and account for 5-12% and 0.5-15% of the total cell population in the adult mouse and human brain, respectively. Besides their classical immunological functions, microglia also contribute to the remodeling of synaptic connections through phagocytic mechanisms. Commonly referred to as “synaptic pruning”, this process involves microglia-mediated engulfment of pre- and postsynaptic material that is tagged with components of the complement system. In the present study we used a mouse model of selective and transient depletion of microglia in the adolescent prefrontal cortex (PFC) to examine its effects on synaptic densities and functions, as well as on the complement system in the adult PFC. Using a selective and transient microglia loss-of-function approach, our study identified dynamic changes in complement component expression (i.e. an upregulation of C3 and C4) and microglial uptake of synaptic particles in the adolescent PFC. Our data further show that prefrontal microglia deficiency in adolescence has lasting effects on synaptic structures and functions in adulthood. Given the implication of C3 and C4 in neurodevelopmental disorders, such as schizophrenia, our model system offers unique opportunities for preclinical research and to examine the neurobiological consequences of non-genetic upregulation of C3 and C4b arising from transient microglia deficiency during specific stages of brain maturation.

A COMPARISON OF PSYCHOTROPIC DRUG PREFERENCES AND SIDE EFFECTS IN OLD AND YOUNG PATıENTS WITH SCHIZOPHRENIA

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Zehra Uçar-Hasanlı, Betül Yıldırım, Zeynep Tatlı, Erguvan Tuğba Özel-Kızıl
Ankara University Faculty of Medicine, Psychiatry, Ankara, Turkey

AIM: In parallel with the aging population, the treatment of elderly schizophrenic patients has become important. Antipsychotic therapy, which is the mainstay in the treatment of schizophrenia, is different due to both the course of the disease and pharmacokinetic/pharmacodynamic changes in elderly. The current study investigates the preferred psychotropic drug treatments and their tolerability in elderly patients (EP) with a diagnosis of schizophrenia or schizoaffective disorder compared to younger patients (YP). **METHOD:** The study included 154 EP and 195 YP with schizophrenia/schizoaffective disorder admitted to a university hospital in the last decade. The medical records of the patients were reviewed. The types and doses of antipsychotic drugs used by each patient, their use of other psychotropic drugs, ongoing complaints, drug-related side effects and compliance with treatment were also examined. **RESULTS:** Second generation antipsychotic use was higher in YP($p=0.046$). Antipsychotic equivalent doses were also higher in the YP group($p<0.001$). The use of clozapine and mood stabilizers were higher in YP($p<0.001$). There was a higher rate of dose reduction of antipsychotic drugs in EP($p<0.001$). When the groups were compared in terms of the reasons of antipsychotic dose reduction, it was more frequent in EP due to side effects, while the dose reduction due to remission was more common in YP($p=0.040$). **CONCLUSIONS:** Lower doses of antipsychotics in EP suggests milder symptoms or lower tolerability. The higher clozapine and mood stabilizer use in YP can be explained by avoiding side effects like extrapyramidal, cardiovascular and metabolic side effects that are more frequent in EP.

A STUDY OF THE TRANSCRIPTOMIC SIGNATURES IN MALE AND FEMALE RATS EXPOSED TO MATERNAL IMMUNE ACTIVATION AND THC DURING ADOLESCENCE

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Mario Moreno-Fernández, Roberto Capellán, Marcos Ucha, Alberto Marcos, Emilio Ambrosio, Alejandro Higuera-Matas
UNED, Psychobiology, Madrid, Spain

AIMS: To use a double-hit animal model of neurodevelopmental disorders relevant to schizophrenia and study the transcriptomic signatures of maternal immune activation (MIA) and THC administration during adolescence in peripheral blood mononuclear cells (PBMCs) with the goal of finding vulnerability markers for the disease. METHODS: Pregnant Sprague-Dawley rats were treated with lipopolysaccharides or saline at gestational days 15 and 16. During adolescence, male and female offspring were injected with incremental doses of THC or vehicle. When the animals were adults PBMCs were obtained from the blood, and RNA sequencing was performed to search for transcriptomic signatures of either each hit alone or in combination. RESULTS: In the females, MIA differentially affected 15 genes while in the males it affected 389. THC exposure affected 148 genes in the females and 604 in the males. Interestingly, THC affected the expression of 254 genes in females exposed to MIA and 109 in MIA males. A gene ontology analysis suggested that, in the males, there was an increased representation of genes related to the inflammatory response due to the MIA+THC combination. In the females, the normal response to THC of gene categories related to interferon I or interleukine was absent among MIA rats and there was an increased presence of the innate immune response ontology due to the synergy of both hits. CONCLUSIONS: The combination of a vulnerability factor (MIA) and a triggering event (exposure to THC) results in specific effects in the transcriptome that could guide the search for early biomarkers.

Ex vivo H-MRS brain metabolic profiling in a two-hit model of neurodevelopmental disorders: Prenatal immune activation and peripubertal stress.
Prenatal infections are environmental risk factors for neurodevelopmental disorders. In addition, traumatic experiences during adolescence in individuals exposed to infections during gestation could increase the risk of schizophrenia. It is of the most crucial importance to discover potential markers of the disease in its early stages or before its onset, so that therapeutic strategies may be implemented. In the present study, we combined a proposed two-hit model of schizophrenia-related symptoms with proton magnetic resonance spectroscopy (H-MRS) to discover potential biomarkers. To this end, we i.p. injected 100 µg/kg/ml of lipopolysaccharide (LPS) or saline on gestational days 15 and 16 to pregnant rats. Their male offspring were then subjected to five episodes of stress or handling on alternate days during postnatal days (PND) 28-38. Once the animals reached adulthood (PND70), we evaluated prepulse inhibition (PPI). At PND90, we performed an ex vivo H-MRS study in the cortex and striatum. While we did not detect alterations in PPI at the age tested, we found neurochemical disturbances induced by LPS, stress or (more interestingly) their interaction. LPS decreased glucose levels in the cortex and striatum and altered glutamate, glutamine and N-acetylaspartate levels. Glutamate and glutamine levels in the left (but not right) striatum were differentially affected by prenatal LPS exposure in a manner that depended on stress experiences. These results suggest that alterations in the glutamate cycle in the striatum could be used as early markers of developmental disorders.

The effects of combined intravenous cocaine and ethanol self-administration on the behavioral and amino acid profile of young adult rats.
Under paradigms of combined intravenous cocaine and ethanol self-administration, the effects on behavior have been poorly explored. Numerous studies have found sex differences in amino acids profile and behavioral responses to each drug, yet few have focused on the interactions between cocaine and ethanol. The main objective of this work was to explore the acquisition and maintenance of intravenous self-administration behavior with a combination of cocaine and ethanol in male

and female young adult rats. Likewise, the amino acids profile in blood plasma was quantified 48 hours after the last self-administration session. Male and female 52 days old Wistar rats were randomly assigned to one of 3 groups: i) saline control, ii) cocaine (1 mg/kg bodyweight/injection) and iii) cocaine and ethanol (1 mg + 133 mg/kg bodyweight/ injection). After 24 self-administration sessions carried out on a fixed-ratio-1 schedule, with a limit of 15 doses per session, 14 plasma amino acids were quantified by mean Capillary Electrophoresis technique. The curve of cocaine and ethanol combined self-administration was similar to that associated with cocaine administration alone, with females acquiring self-administration criterion before males. The self-administration of cocaine and ethanol altered the plasma concentration and relative ratios of the amino acid L-Tyrosine. In our intravenous self-administration model, females appeared more vulnerable to acquire abusive consumption of the cocaine and ethanol combination, which altered plasma L-Tyrosine levels.

CHRONIC IN VIVO ELECTROPHYSIOLOGICAL RECORDINGS OF DOPAMINE NEURONS IN A MOUSE MODEL OF THE 22Q11.2 MICRODELETION SYNDROME

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Solmaz Bikas, Jochen Roeper, Anastasia Diamantopoulou
Goethe University, Institute Of Neurophysiology, Frankfurt am Main, Germany

Dopamine (DA) dysregulation, particularly elevated striatal DA neurotransmission, as revealed by more recent imaging studies, has been at the focus of schizophrenia (SCZ) psychopathology, but its mechanistic contributions to disease manifestations are still unresolved. To examine DA dysregulation relevant to human disease, we made use of the *Df(16)A*$^{+/-}$ mouse model of the 22q11.2 Deletion Syndrome, which represents the highest genetic risk factor for SCZ. Previous work on the *Df(16)A*$^{+/-}$ mice revealed several schizophrenia-like deficits, however, the function of the DA system has not yet been studied. For this, we chronically recorded DA neuronal firing activity *and* extracellular striatal DA dynamics in awake freely moving *Df(16)A*$^{+/-}$ mice and wild-type littermates. We established chronic *in vivo* single-unit extracellular recordings of pharmacologically identified DA neurons in the medial substantia nigra (mSN) during open field exploration. For these DA mSN neurons, projecting to either dorsal or ventral striatum, we detected persistent electrophysiological hyperactivity in *Df(16)A*$^{+/-}$ mice compared to controls. This was characterized by increased mean firing frequencies (1.5–fold; $p = 0.0002$, n = 7, N =53 for WT and N=97 for *Df(16)A*$^{+/}$) and elevated bursting activity (1.7-fold; $p < 0.0001$). Using dLight1 fluorometry, we detected a (1.3-fold; $p < 0,01$, n = 7) higher rate of DA transients in *Df(16)A*$^{+/-}$ mice in DMS, as would have been predicted by an *in vivo* DA hyperexcitability phenotype, if tightly coupled to striatal DA dynamics. In summary, we made first steps towards an electrical and neurochemical characterization of DA dysfunction in a 22q11 deletion mouse model.

Hippocampal overexpression of NOS1AP promotes endophenotypes related to mental disorders.
Nitric oxide synthase 1 adaptor protein (NOS1AP; previously named CAPON) is linked to the glutamatergic postsynaptic density through interaction with neuronal nitric oxide synthase (nNOS). NOS1AP and its interaction with nNOS have been associated with several mental disorders. Despite the high levels of NOS1AP expression in the hippocampus and the relevance of this brain region in glutamatergic signalling as well as mental disorders, a potential role of hippocampal NOS1AP in the pathophysiology of these disorders has not been investigated yet.

FOXP2 is a transcriptional factor involved in the development of speech and language. It has been considered a candidate gene in schizophrenia. Indeed, deficits in FOXP2 function can lead to failure of structures relevant to normal language processing; also, FOXP2 has been associated with psychotic symptoms, such as auditory hallucinations. One of the relevant regions of the brain in schizophrenia is the thalamus, a region of gray matter composed of multiple nuclei where sensory, motor, emotional, and cognitive neural pathways relay and connect with the cerebral cortex. We have previously shown the association of FOXP2 gene variants with reductions of gray matter density and gene expression in various brain regions of patients with schizophrenia. In the present study, we investigated the expression of FOXP2 and related markers in the thalamus of postmortem brains from patients with schizophrenia and in a rat “dual hit” animal model of schizophrenia. In addition, we studied the distributions of cells containing FOXP2 protein in the macaque and rat thalamic nuclei. FOXP2 gene expression is reduced in the thalamus of postmortem brains of patients with schizophrenia. Furthermore, FOXP2 protein is differentially expressed in the macaque and rat thalamic nuclei and in the rat model of schizophrenia. These observations point to a possible role of this transcriptional factor in the regulation of thalamic nuclei and in the pathogenesis and/or pathophysiology of the disease. This work is supported by a grant from Universidad Autónoma de Madrid - Comunidad Autónoma de Madrid (SI3-PJI-2021-00417).

Background and rationale: Schizotypy can be understood as a developmental mediator between early endophenotypes and later risk for developing overt psychosis. Hippocampal dysregulation might be a key factor for the developmental trajectory of psychotic disorders and is related to poor clinical outcomes. While preliminary studies indicate alterations in gut microbiota in patients with schizophrenia, it remains unknown whether they are evident in healthy people with high level of schizotypy. **Objectives:** By exploring aberrant gut microbiota-hippocampus interactions in non-clinical individuals with high positive schizotypy we aim to investigate differences in 1) hippocampus function and neurochemistry, 2) gut microbiota composition between populations with low and high positive schizotypy and 3) whether hippocampal measures can predict different microbial profiles. **Methods:** 1) Hippocampal perfusion and activation will be measured with arterial spin labelling, fMRI, and magnetic resonance spectroscopy. 2) Quantitative Microbiome Profiling will be based on 16S ribosomal RNA sequencing. Differences in species abundance will be calculated using Bray-Curtis distances and group differences will be assessed with permutational analysis of variance. 3) Clusters of enterotypes will be determined based on Dirichlet Multinomial Modelling. **Expected results:** Most prominent hippocampus differences between high and low schizotypy will be hypothesized in GABA and glutamate concentrations, with lower GABA and higher glutamate concentrations in people with high positive schizotypy. We hypothesize enterotypes to be predicted by hippocampal measures, with GABA and glutamate providing the most explanatory power. This project may deliver novel prognostic and predictive biomarkers supporting the improvement of psychosis prediction and the development of novel interventions.

There is growing evidence for changes in lipid metabolism associated with psychiatric diseases, including schizophrenia, and the brain itself has the second-highest concentration of lipids in the human body. The goal of our study was to investigate changes in lipidome composition of various brain regions associated with schizophrenia on the whole-brain scale. We assessed the lipidome composition of 75 anatomically distinct regions of four healthy and four schizophrenic individuals. Lipid fraction was extracted and measured using liquid chromatography coupled with mass spectrometry. After recalibration peaks were filtered based on their retention time, mean intensity, number of missed values, and their intensity in blank samples. Selected peaks were manually annotated, yielding 379 lipid species, covering 21 lipid classes. Comparison of lipid abundance in the brain of healthy and schizophrenic individuals showed different degrees of changes for various lipid categories with the greatest changes in the myelin-associated and brain function-associated lipids. Regions with the most pronounced changes in lipid abundance were identified: thalamus, associative and secondary cortex (increased levels); white matter, and basal ganglia (decreased levels). The results of our work indicate statistically significant differences in the behavior of different types of lipids in various regions of the brain, which might be associated with cytoarchitectural and myeloarchitectural differences. Moreover, the association to the functional architecture of the brain makes lipids a potential target for the diagnosis of mental disorders. The reported study was funded by RFBR, project number №20-34-90146.

The Hitchhiker's Guide to Untargeted Lipidomics Analysis: Practical Guidelines.
Lipidomics is a newly emerged discipline involving the identification and quantification of thousands of lipids. As a part of the omics field, lipidomics has shown rapid growth both in the number of studies and in the size of lipidome datasets, thus, requiring specific and efficient data analysis approaches. This paper aims to provide guidelines for analyzing and interpreting lipidome data obtained using untargeted methods that rely on liquid chromatography coupled with mass spectrometry (LC-MS) to detect and measure the intensities of lipid compounds. We present a state-of-the-art untargeted LC-MS workflow for lipidomics, from study design to annotation of lipid features, focusing on practical, rather than theoretical, approaches for data analysis, and we outline possible applications of untargeted lipidomics for biological studies. We provide a detailed R notebook designed specifically for untargeted lipidome LC-MS data analysis, which is based on software.

Peptidomics dataset: Blood plasma and serum samples of healthy donors fractionated on a set of chromatography sorbents.
Blood as connective tissue potentially contains evidence of all processes occurring within the organism, at least in trace amounts (Petricoin et al., 2006) [1]. Because of their small size, peptides penetrate cell membranes and epithelial barriers more freely than proteins. Among the peptides found in blood, there are both fragments of proteins secreted by various tissues and performing their function in plasma and receptor ligands: hormones, cytokines and mediators of cellular response (Anderson et al., 2002) [2]. In addition, in minor amounts, there are peptide disease markers (for example, oncomarkers) and even foreign peptides related to pathogenic organisms and infection agents. To propose an approach for detailed peptidome characterization, we carried out an LC-MS/MS analysis of blood serum and plasma samples taken from 20 healthy donors on a TripleTOF 5600+ mass-spectrometer. We prepared samples based on our previously developed method of peptide desorption from the surface of abundant blood plasma proteins followed by standard chromatographic steps (Ziganshin et al., 2011) [3]. The mass-spectrometry peptidomics data presented in this article have been deposited to the ProteomeXchange Consortium (Deutsch et al., 2017) [4] via the PRIDE partner repository with the dataset identifier PXD008141 and 10.6019/PXD008141.

Exposure to the Epstein-Barr Viral Antigen Latent Membrane Protein 1 Induces Myelin-Reactive Antibodies .
Multiple sclerosis (MS) is an autoimmune chronic inflammatory disease of the central nervous system (CNS). Cross-reactivity of neuronal proteins with exogenous antigens is considered one of the possible mechanisms of MS triggering. Previously, we showed that monoclonal myelin basic protein (MBP)-specific antibodies from MS patients cross-react with Epstein-Barr virus (EBV) latent membrane protein 1 (LMP1). In this study, we report that exposure of mice to LMP1 results in induction of myelin-reactive autoantibodies . We posit that chronic exposure or multiple acute exposures to viral antigen may redirect B cells from production of antiviral antibodies to antibodies, specific to myelin antigen. However, even in inbred animals, which are almost identical in terms of their genomes, such an effect is only observed in 20-50% of animals, indicating that this change occurs by chance, rather than systematically. Cross-immunoprecipitation analysis showed that only part of anti-MBP antibodies from LMP1-immunized mice might simultaneously bind LMP1. In contrast, the majority of anti-LMP1 antibodies from MBP-immunized mice bind MBP. sequencing of anti-LMP1 and anti-MBP antibodies by mass spectrometry demonstrated enhanced clonal diversity in LMP1-immunized mice in comparison with MBP-immunized mice. We suggest that induction of MBP-reactive antibodies in LMP1-immunized mice may be caused by either Follicular dendritic cells (FDCs) or by T cells that are primed by myelin antigens directly in CNS. Our findings help to elucidate the still enigmatic link between EBV infection and MS development, suggesting that myelin-reactive antibodies raised as a response toward EBV protein LMP1 are not truly cross-reactive but are primarily caused by epitope spreading.

[The importance of C-terminal aspartic acid residue (D141) to the antirestriction activity of the ArdB (R64) protein].
Antirestriction proteins of the ArdB/KlcA family are specific inhibitors of restriction (endonuclease) activity of type-I restriction/modification enzymes. The effect of conserved amino acid residues on the antirestriction activity of the ArdB protein encoded by the transmissible R64 (IncI1) plasmid has been investigated. An analysis of the amino acid sequences of ArdB homologues demonstrated the presence of four groups of conserved residues ((1) R16, E32, and W51; (2) Y46 and G48; (3) S81, D83 and E132, and (4) N77, L(I)140, and D141) on the surface of the protein globule. Amino acid residues of the fourth group showed a unique localization pattern with the terminal residue protruding beyond the globule surface. The replacement of two conserved amino acids (D141 and N77) located in the close vicinity of each other on the globule surface showed that the C-terminal D141 is essential for the antirestriction activity of ArdB. The deletion of this residue, as well as replacement by a hydrophobic threonine residue (D141T), completely abolished the antirestriction activity of ArdB. The synonymous replacement of D141 by a glutamic acid residue (D141E) caused an approximately 30-fold decrease of the antirestriction activity of ArdB, and the point mutation N77A caused an approximately 20-fold decrease in activity. The residues D141 and N77 located on the surface of the protein globule are presumably essential for the formation of a contact between ArdB and a currently unknown factor that modulates the activity of type-I restriction/modification enzymes.

The association between schizophrenia and nicotine addiction is already evident during adolescence. Here, to investigate the mechanisms that underlie the early establishment of this comorbidity, we used phencyclidine-evoked locomotor sensitization, a proxy model of psychotic behavior, and nicotine minipump infusions. Considering the involvement of dopamine D_2 receptors in both schizophrenia and addiction mechanisms, we further tested the role of these receptors by treating mice with raclopride. Adolescent mice exposed to nicotine (24mg/Kg/day) or not, received single daily raclopride (0.5mg/kg, s.c.) or saline followed by phencyclidine injections (10mg/Kg, s.c.). Drugs administration was followed by open field testing for 6 days (acquisition period, ACQ1-6). Phencyclidine and nicotine challenges (sensitization tests, ST) were carried out after a 5-day withdrawal. Ambulation both escalated in response to repeated phencyclidine exposure during ACQ and was increased after phencyclidine challenge, evidencing development and expression of locomotor sensitization. Raclopride prevented phencyclidine-evoked development of sensitization. However, raclopride pretreatment during ACQ only partially inhibited its expression in phencyclidine-challenged mice. Nicotine failed to interfere with phencyclidine stimulatory effects during ACQ but potentiated raclopride inhibitory outcomes during the first ACQ days. During ST, nicotine history prevented the expression of phencyclidine-evoked sensitization. Nicotine challenge had no relevant impact on locomotion, which is consistent with a lack of nicotine/phencyclidine cross-sensitization. In conclusion, nicotine does not worsen, and may even ameliorate phencyclidine-sensitized psychotic-like behavior in adolescent mice. The potentiation of raclopride-mediated inhibition further suggests that nicotine might improve the therapeutic efficacy of medication on psychotic symptoms through mechanisms that converge on D_2 receptors.

TOXIC EFFECTS AND OVERDOSE OF CARBAMAZEPINE AFTER PSYCHIATRIC CONDITIONS: POSTMORTEM ANALYSIS IN HUMAN BONE

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Javier Navarro-Zaragoza[1], Lucia Fernandez-Lopez[1], Pilar Almela[1], Manuela Pellegrini[2], Rosanna Mancini[2], Maria Falcon[3]
[1]University of Murcia, Department Of Pharmacology, Murcia, Spain, [2]National Centre on Drug Addiction and Doping, Istituto Superiore Di Sanità, Roma, Italy, [3]University of Murcia, Health And Social Sciences, Murcia, Spain

Carbamazepine is the main option to be used as a preventive medication to treat bipolar disorder when there is no response to lithium. One of the reasons why carbamazepine is not the first choice to treat bipolar disorder is the high rate of toxicity that this drug produces. According to the US Poison Control Center, nearly 2000 cases each year, only in the US. So, it is necessary a validated tool to determine carbamazepine levels in post-mortem studies to discard a suicide or to know if the death has been a consequence of an ADR Sometimes. blood and urine are not available so other specimens are submitted, i.e., stomach contents, bile, vitreous humour, liver and other tissues, muscle, or bone marrow. In these cases, it can be hard to test and interpret data as these matrices are not frequently analysed, and therefore there is a lack of literature and published results to compare with. The aim of this work was to analyse different post-mortem samples obtained from human ribs randomly arrived at our laboratory to find a correlation to concentration levels in blood using gas chromatography–mass spectrometry. The method was applied to bone samples from a forensic case where carbamazepine was found in blood and the level detected in bone was 46 ng/mg.

TARGETED MODULATION OF MD-PFC THALAMOCORTICAL LOOPS – A NOVEL THERAPEUTIC STRATEGY TOWARDS THE TREATMENT OF SCHIZOPHRENIA

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Arghya Mukherjee[1], Michael Halassa[2]
[1]Massachusetts Institute of Technology, Brain And Cognitive Sciences, Building 46-5089, Cambridge, United States of America, [2]Massachusetts Institute of Techno, Brain And Cognitive Sciences, CAMBRIDGE, United States of America

Schizophrenia ranks within the top 15 leading causes of disability worldwide. Despite severe side effects and limited effectivity, antipsychotics from the 1950's continue to be the primary treatment option for the disorder. To develop much needed targeted therapies at par with modern medicine we need to isolate dysfunctions of discrete brain circuits that underlie different symptoms of schizophrenia. While prefrontal cortex dysfunction is well established in Schizophrenia, recent studies have shown that its interactions with the MD thalamus, is also perturbed. I have discovered genetically identifiable MD neurons that required for prefrontal control over flexible behavior. Specifically, one MD projection that targets disinhibitory (VIP+) PFC interneurons is required to amplify task relevant neural activity and maintain task performance; while another MD projection that targets inhibitory parvalbumin (PV+) neurons within the PFC suppresses task irrelevant activity for task switching. Thus, rational targeting of MD-PFC sub circuits with neurostimulation may result in targeted therapeutics for schizophrenia and is the central aim of this project. Here using virus-based circuit tracing, vivo electrophysiology and optogenetic manipulations I uncover specific anatomical and functional perturbations in MD-PFC sub circuits in a mouse model of Schizophrenia. Furthermore, this mouse model exhibits a specific deficit in prefrontal driven task switching which can be ameliorated with precise optogenetic manipulation of a MD-PFC sub-circuit. In conclusions, given the role of the MD as a bottleneck for information flow into the PFC, my work provides exciting evidence for the MD as a particularly attractive target for intervention in schizophrenia.

There is evidence that in schizophrenia, imbalances in inflammatory and oxidative processes occur during pregnancy and in the early postnatal period, generating interest in the potential therapeutic efficacy of anti-inflammatory and antioxidant compounds. Mangiferin (MG) is a polyphenolic compound abundant in mango tree with robust antioxidant and anti-inflammatory properties, could be a candidate for treating schizophrenia. Hence, this study set-out to evaluate the effect of MG in a model of schizophrenia based on maternal immune activation by Poly I:C administration to pregnant rats. Young adult or adolescent male offspring received a MG extract daily, and the effects of MG in adolescence were compared to those of risperidone, assessing behavior, brain magnetic resonance images (MRI), and oxidative/inflammatory and antioxidant mediators in the adult offspring. MG treatment in adulthood reversed the deficit in prepulse inhibition (PPI) but it failed to attenuate the sensitivity to amphetamine and the deficit in novel object recognition (NOR) induced. By contrast, adolescent MG treatment prevented the sensorimotor gating deficit in the PPI test, producing an effect similar to that of risperidone. This MG treatment also produced a reduction in grooming behaviour and an anxiolytic-like effect, but it had no effect in the NOR test. MRI studies revealed that adolescent MG administration partially dampened the cortical shrinkage, and cerebellum and ventricle enlargement. In addition, MG administration in adolescence reduced iNOS mediated inflammatory activation and it promoted compensatory antioxidant activity in the prefrontal cortex and hippocampus, as witnessed through Keap1 reduction and NRF2, NQO1 and HO1 enhancement.

MOSAIC CAS9 FUSIONS TO INVESTIGATE REGULATORY PHENOTYPES OF SCHIZOPHRENIA RISK GENES IN THE RODENT BRAIN

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Andrea Romanowski, Bekir Altas, Alexandros Poulopoulos
University of Maryland School of Medicine, Department Of Pharmacology, Baltimore, United States of America

Large-scale patient sequencing suggests that neuropsychiatric genetics often involve polygenic variants in regulatory regions of risk genes. These affect the timing and dosage of expression rather than the protein structure of gene products. In order to study the consequences of polygenic schizophrenia risk gene dysregulation in the rodent brain, we developed an in utero electroporation approach using Cas9 fusions to investigate novel phenotypes produced by changing expression dosage and timing of multiple risk genes. We targeted cell adhesion molecules of the immunoglobulin superfamily implicated in the risk for schizophrenia. We demonstrate that dosing multiple genes affects local development of the cerebral cortex. The broader aim is to establish a generalizable approach to investigate dysregulation of dosage and timing across risk genes in the developing brain to reveal impacts on cortical wiring across neurodevelopmental and neuropsychiatric conditions.

Background Pharmacogenomics studies the association between gene variations and drug responses. Here we present a novel pharmacogenetic panel (iDNA PGx CNS), providing clinically useful information to Psychiatrists and Neurologists for the treatment of diseases of the Central Nervous System (CNS). Materials For the construction of the pharmacogenetic panel, 24 SNPs on 13 genes were analyzed to optimize the selection of the treatment and support medical decisions for diseases of the CNS, by providing individualized pharmacogenetic information about the response, the efficacy of the treatment, and the ADEs of 31 drugs. A bioinformatics platform that contains an in-house database and a user interface, was built and used for the analysis of 1387 patient-derived samples from a southeastern European population. The samples were genotyped, using the TaqMan Drug Metabolism and Custom Genotyping Assays at the QuantStudio™ 12 K Flex Real-Time PCR System (Applied Biosystems by Life Technologies). Results Results reveal that the frequencies of each SNP in the genotyped samples are consistent with European population frequencies. The metabolic efficiency (poor, intermediate, extensive, ultra-rapid) of members of the CYP family and the frequency of clinical useful pharmacogenetic, associations in the population (drug relevance), are also presented. These results are indicating the strong potential of the PGX CNS panel as a companion diagnostic assay. Conclusion Overall, the results illustrate that the PGx-CNS panel is a valuable tool providing statistically accurate clinically relevant information, supporting therapeutic medical decisions, and highlighting its broad clinical implementation.

STAGE DEPENDENT OSCILLATORY PATTERN ANALYSIS IN WISKET SCHIZOPHRENIA RAT MODEL

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Leatitia Adlan[1], Mátyás Csordás-Nagy[2], Balázs Bodosi[1], György Kalmár[2], László G. Nyúl[3], Attila Nagy[1], Gabriella Kekesi[1], Alexandra Büki[1], Gyongyi Horvath[1]
[1]University of Szeged, Department Of Physiology, Szeged, Hungary, [2]University of Szeged, Department Of Technical Informatics Institute Of Informatics, Szeged, Hungary, [3]University of Szeged, Department Of Image Processing And Computer Graphics Institute Of Informatics, Szeged, Hungary

Schizophrenia is defined as a severe neuropsychiatric condition with positive, negative symptoms and cognitive impairments. Patients with schizophrenia steadily report sleep disturbances which are contributed to cognitive or affective symptoms. The current study aimed to evaluate the oscillatory pattern of Wisket animals during awake, REM, and NREM sleep stages. Male, adult control, and Wisket rats were involved in the study. After chronic implantation of cortical electrodes, continuous electroencephalographic (EEG) registration was performed in freely moving condition. Automated stage discrimination was carried out using software developed in-house. The Wisket rats showed a clear light-dark cycle similar to controls, and their sleep-wake rhythm displayed only a tendency to spend more time in NREM and less in REM stage. In contrast, the analysis of the oscillatory pattern resulted in significant group differences in the relative power of different frequency bands by stages compared to controls,
accordingly:

Bands (Hz)	Awake		NREM		REM	
	↓	↑	↓	↑	↓	↑
Delta: 0.5–4			3 – 4	1.2 – 2	1.9 – 2.5	
Theta: 4–8	6.4 – 7.6		4.12– 5.6		6.5 – 7.5	
Alpha: 8–12		8.4 – 9.7				8.25 – 10
Beta: 12–30		12.1 – 19.3		12.9 – 17.5		12.1 – 15.7
Gamma: 30–48	44.2– 48					

In conclusion, the investigation of the oscillatory pattern by frequency bands revealed complex alterations in Wisket animals, which might be involved in the cognitive dysfunctions obtained in this schizophrenia animal model.

CANNABINOIDS MODULATE SOCIABILITY DEFICITS IN PSYCHOSIS THROUGH A CDK5-DEPENDENT MECHANISM

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Marta Barrera-Conde[1], Emma Veza-Estévez[1], Maria Gomis-Gonzalez[1], Jordi Garcia-Quintana[1], Víctor Pérez[2], Rafael De La Torre[1], Daniel Bergé[3], Patricia Robledo[1]
[1]IMIM Hospital del Mar Research Institute, Pharmacology And Integrative Neurosciences, Barcelona, Spain, [2]Ciber of Mental Health (CIBERSAM), ISCIII, Cb/07/09/0033 Group, Madrid, Spain, [3]University Pompeu Fabra, Melis: Department Of Medicine And Life Sciences, Barcelona, Spain

Aims: Negative and cognitive symptoms, including social deficits, are associated with greater functional disability in first-episode psychosis (FEP) patients. We investigated the implication of cyclin-dependent kinase 5 (CDK5) and postsynaptic density protein 95 (PSD95) in these traits in a population of FEP with and without a history of cannabis use (FEP/c and FEP/nc, respectively). Methods: In a cross-sectional study, patients underwent clinical and neuropsychological evaluations before the extraction of olfactory neuroepithelium (ON) cells. Samples were then processed to quantify the expression of PSD95 and CDK5 via western blot. In a parallel dual-hit mouse model of psychosis (phencyclidine (PCP) and WIN 55,212-2 (WIN) administration during adolescence), we evaluated enduring social and cognitive alterations, and changes in PSD95 and CDK5 in the hippocampus and the prefrontal cortex. Results: Higher levels of CDK5 and lower levels of PSD95 in ON cells from FEP/nc correlated with fewer premorbid social skills. Contrastingly, FEP/c patients exhibited better social functioning than FEP/nc and the expression of CDK5 and PSD95 was normalized to control levels. We corroborated these findings in a mouse model of psychosis, where mice exposed to PCP alone showed more sociability deficits, higher CDK5 and lower PSD95 expression than mice exposed concomitantly to PCP and WIN. The blockade of CDK5 activity restored sociability impairments in PCP-treated mice. Conclusions: We provide translational evidence showing that CDK5 overexpression is linked to social deficits in psychosis, and that a history of cannabis use in FEP is associated with better social functioning and normal levels of CDK5 and PSD95.

THE HIPPOCAMPAL CA2 SUBREGION IN THE NMDA RECEPTOR HYPOFUNCTION PATHOLOGY OF PSYCHIATRIC DISORDERS

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Alessa A. Franz[1], Stefan Jaeger[1], Marzieh Funk[1], Dennis Kätzel[2], Bastian Hengerer[1]
[1]Boehringer Ingelheim Pharma GmbH & Co.KG, Cns Diseases Research, Biberach an der Riß, Germany, [2]Ulm University, Institute Of Applied Physiology, Ulm, Germany

The *Cornu Ammonis* (CA) 2 subregion of the hippocampus has been linked to social memory, a higher brain function strongly impaired in patients with psychiatric disorders. Moreover, alterations in the balance of excitation and inhibition (E/I) of networks - key for the proper function of neuronal networks - have been described in CA2 of patients. These findings lead to the suggestion of a causal link between E/I balance in CA2, alterations upon disease and symptomatology. Nevertheless, there is a lack in the deeper understanding of molecular alterations in disease. We hypothesize that the E/I balance in CA2 is disrupted in mice displaying a subset of psychiatric symptoms. A common and well-known model showing cognitive deficits is the N-methyl-D-aspartate glutamate receptor (NMDAR) hypofunction model, induced by the treatment with a NMDAR antagonist. In order to probe our hypothesis, we performed immunohistochemistry on subchronic phencyclidine (scPCP) treated adult mice followed by high-throughput confocal imaging combined with automated multiparameter analysis. Exploring the expression levels of key proteins in CA2 and the intrahippocampal E/I balance in scPCP model broadened the understanding of molecular abnormalities following chronic NMDAR hypofunction. Furthermore, this study points out the importance of better understanding molecular alterations of models for drug discovery and translational research.

DEEP BRAIN STIMULATION OF THE VENTRAL TEGMENTAL AREA TO CONTROL POSITIVE SYMPTOMS OF SCHIZOPHRENIA: A CASE REPORT.

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Juan Antonio Barcia[1], Bryan Strange[2], Miguel Yus[3], Roberto Capellán[1], Cristina Nombela Otero[1]
[1]Hospital Clínico San Carlos, Neurosurgery, Madrid, Spain, [2]Universidad Politécnica de Madrid, Laboratory For Clinical Neuroscience, Pozuelo de Alarcón, Spain, [3]Hospital Clínico San Carlos, Radiology, Madrid, Spain

Background: Current treatments for schizophrenia modulate global neurotransmission through medication but are neither specific nor anatomically directed. Tailored stimulation of target nuclei could increase treatment efficacy while reducing side effects. **Aims:** To assess safety and clinical impact of deep brain stimulation (DBS) of the ventral tegmental area (VTA) on a patient with Treatment-Resistant Schizophrenia (TRS). **Methods:** In a registered clinical trial, one 41-year-old male with a 22-year history of schizophrenia underwent a bilateral DBS surgery targeting the VTA. The first stimulation trial period included eleven blind-random stimulation patterns to assess safety and potential adverse events. The best four parameters were selected for a second blind trial in outpatient settings during one month each, with a wash-out period of a week between every stimulation phase. The final stimulation pattern set at chronic bases was controlled by PET and DAT-Scans, and monthly clinical & neuropsychological double-blinded assessments. **Results:** After six months of ultimate stimulation pattern, the patient was clinically stable, maintained a reduction of PANSS-positive score in 58%, PANSS-negative score in 30%, and PANSS-GP score in 52%. During this period of DBS, the patient did not need further sessions of Electroconvulsive Therapy. The neuropsychological assessment showed a decreased performance in visual processing and impairments in memory retrieval. Some improvement in social cognition was also detected. In the following months, the patient had mood fluctuations, adding clozapine. **Conclusion:** DBS stimulation in VTA may work as an alternative for patients with TRS. Further studies are needed to see whether this brings even more benefits.

POPULATION-LEVEL LINKS BETWEEN SCHIZOPHRENIA AND THE GUT MICROBIOME

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Sophie Paschke[1,2], Nikhil Sharma[2]
[1]ENS, Ibens, Paris, France, [2]UCL, Department Of Clinical And Movement Neurosciences, London, United Kingdom

The human gut microbiome has received increased interest for its mediating role in neuropsychiatric disorders as an effect of the gut-brain-axis. Multiple studies proposed a link with schizophrenia. Therapeutic measures via the easily accessible, scalable, and cost-effective modulation of the gut microbiome could aid in the less-than-optimal treatment options currently available for schizophrenia. However, great inter-individual variability, small sample sizes and a confounding effect of antipsychotic medication on microbiota limitate studies on the relationship between the two and reproducibility across them. Links between the gut microbiome and schizophrenia were therefore assessed at a population level using epidemiological methods. Standard microbiome analyses were conducted on samples from two multidimensional large-scale datasets grouped according to their location and corresponding prevalence of schizophrenia. Additionally, a machine learning model was employed to determine whether samples could be accurately attributed to high or low prevalence groups based on their characteristics. Diversity differed significantly between samples from high and low prevalence locations. Several taxa were significantly enriched as well as differentially abundant between groups. The machine learning model determined the prevalence level with high accuracy. Multiple taxa implicated in the analyses were linked with bile acid metabolism, which might provide an interesting avenue for future research. However, effect sizes were relatively small and direct correlation was hard to establish, emphasising the need for greater data availability and consistent data collection methods. Still, these results present an additional strengthening of the proposed link between gut microbiome and schizophrenia, pointing to a potential avenue for therapeutic measures.

THE EFFECT OF LIRAGLUTIDE ON STRATEGY-SHIFTING IN A SUBCHRONIC KETAMINE MODEL OF COGNITIVE DYSFUNCTION

POSTER SESSION 02 - SECTION: SCHIZOPHRENIA

Jonathan Flintoff[1], Suzy Alexander[1], James Kesby[1,2], Thomas Burne[1,3]
[1]University of Queensland, Queensland Brain Institute, Brisbane, Australia, [2]QIMR Berghofer, Child & Youth Mental Health, Brisbane, Australia, [3]Centre for Mental Health, Queensland Centre For Mental Health Research, Brisbane, Australia

Cognitive impairment is an enduring feature of schizophrenia that remains untreated by current medications. To address this, preclinical tools used to measure cognitive impairment must be improved to screen novel drug candidates. In the current study, a novel dynamic strategy-shifting task (SST) was designed with automated shifts between a cue-light task, fixed location task, continuous detection task, and an auditory continuous detection task. The SST was used to examine the effects of the glucagon-like peptide-1 receptor agonist liraglutide on strategy-shifting. Liraglutide exerts neuroprotective actions within the brain and is a promising therapeutic candidate for improving cognitive flexibility impaired in individuals with schizophrenia. Sixteen Sprague-Dawley rats were trained to lever-press on the SST. After completing training, they were administered 30 mg/kg ketamine to disrupt strategy-shifting, or saline via intraperitoneal injection over 10 days. After a drug washout of 14 days and open-field testing, rats were administered either 0.4 mg/kg liraglutide or saline, 1 hour before testing on the SST (N=4 per group). This study shows that acute liraglutide administration does not improve strategy-shifting performance at any stage of the novel SST. Furthermore, subchronic ketamine did not consistently impair strategy-shifting performance as shown in similar tasks. Interestingly, rats given liraglutide and ketamine showed a perseverative strategy and were unable to shift away from the response required in the cue-light task when tested on the fixed location task. Importantly, animals showed rapid training times and limited omissions on the SST suggesting this task may be a promising preclinical tool to screen therapeutic candidates.

BRAIN AGE PREDICTION OF HEALTHY ADULTS BASED ON STRUCTURAL AND FUNCTIONAL CONNECTIVITY USING CONVOLUTIONAL NEURAL NETWORKS

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Ardalan Aarabi[1], Maedeh Khalilian[2], Olivier Godefroy[2]
[1]University of Picardie-Jules Verne, Faculty Of Medicine, Amiens, France, [2]Laboratory of Functional Neuroscience and Pathologies (LNFP, EA4559), University Research Center (curs), Amiens, France

Aims Brain age prediction can help characterize conditions that may affect the normal aging trajectory. In this work, we used functional and structural connectivity measures for brain age prediction using convolutional neural networks. **Methods** We used resting-state functional MR and diffusion-weighted imaging data from 619 healthy participants (18-89 yrs) included in the CamCAN cohort to construct functional and structural matrices based on functional correlation and structural strength (number of streamlines resulted from fiber tracking) between 1133 parcels. We further estimated three nodal graph metrics including degree (K), clustering coefficient (C), and local efficiency (E) from each connectivity matrix. A convolutional neural network (CNN) was then trained and evaluated using the 5-fold cross-validation strategy for the brain age prediction using connection strengths (S) and each of the nodal graph features. We further used principal component analysis (PCA) to reduce the dimensionality of features. **Results** Among the structural connectivity features, our method achieved the lowest mean absolute error (MAE) of 7.4 yrs using structural connection strengths (S) with 50 principal components (PCs) with a strong correlation ($\rho = 0.9$) in comparison with other features. The age prediction with the combined structural features (K, C, and E) also yielded an MAE of 7.6 yrs with 40 PCs. The CNN based on functional strengths (S) achieved age prediction errors higher than 9 yrs. **Conclusions** Our findings suggest higher predictive values for brain age prediction using structural connectivity features in comparison with the topological properties of resting-state functional networks.

INTRODUCING STRUCTURAL DISCONNECTION MASKS IN WHOLE-BRAIN MODELS: A MECHANISTIC EXPLANATION OF STROKE PATIENTS' EFFECTIVE CONNECTIVITY

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Sebastian Idesis[1], Chiara Favaretto[2], Nicholas Metcalf[3], Joseph Griffis[3], Gordon Shulman[3], Maurizio Corbetta[2], Gustavo Deco[4]
[1]Universitat Pompeu Fabra, Center Of Brain And Cognition, Barcelona, Spain, [2]University of Padova, Padova Neuroscience Center, Padova, Italy, [3]Washington University School of Medicine, Department Of Neurology, St. Louis, United States of America, [4]Universitat Pompeu Fabra, Department Of Technology And Information, Barcelona, Spain

The understanding of the stroke lesions' consequences is limited, relying mostly on behavioral reports and descriptive information from neuroimaging techniques. Here we present a generative model that introduces a mechanistic explanation for these phenomena. The whole-brain model combines the structural and functional information, next to structural disconnection maps, by optimizing it with an Effective Connectivity. As a result, the prediction of behavioral responses got enhanced compared to previous models while the classification of the stroke behavior severity showed a higher accuracy compared to the most common techniques. These results, together with the proposed topological metrics, provided by the asymmetricity of the model, allow a more personalized treatment in order to achieve a better recovery of the patients. Furthermore, it opens the possibility to apply external manipulations such as neurostimulation in order to treat such a word-wide disease as stroke lesions.

The brain exhibits a rich repertoire of oscillatory patterns organized in space, time and frequency, detected from human brains with electro- and magnetoencephalography (EEG/MEG). However, the principles driving coherent oscillations and their link with neural activity remain unclear. Here, we propose that the transient emergence of brain rhythms is a signature of weakly stable synchronization between spatially distributed brain areas, occurring at network-specific collective frequencies due to non-negligible conduction times. We test this mechanism using a reduced network model representing interactions between neural mass potentials (resonating at 40Hz) in the Connectome. Despite the deliberate reduction, we find a critical regime where metastable oscillatory modes emerge spontaneously in the delta (0.5-4Hz), theta (4-8Hz), alpha (8-13Hz) and beta (13-30Hz) frequency bands from weak synchronization of different subsystems, approximating the MEG power spectra from heathy individuals. Grounded on the physics of delay-coupled oscillators, this work demonstrates the role of the Connectome spacetime structure in modulating brain activity in the frequency domain.

THE CAUSAL STRUCTURE OF BAND-LIMITED CORTICAL DYNAMICS

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Paul Hege[1,2,3,4], Markus Siegel[1,2,3]
[1]University of Tuebingen, Dept. Neural Dynamics And Meg, Hertie Institute For Clinical Brain Research, Tübingen, Germany, [2]University of Tuebingen, Centre For Integrative Neuroscience, Tübingen, Germany, [3]University of Tuebingen, Meg Center, Tübingen, Germany, [4]University of Tuebingen, Mathematical Institute, Tübingen, Germany

The instantaneous correlation of cortical activity reflects functional interactions between brain regions, but the directed, causal structure of these interactions remains unclear. To address this, we investigated the dynamics of human cortical activity using source-reconstructed magnetoencephalography (MEG) and by considering the time-antisymmetric cross-correlation of neural activity across different frequency bands and the full cortical space. We employed a tensor decomposition to identify components of this cross-correlation that are interpretable as causal patterns of lagged correlation across cortical regions and frequency bands. We identified several fundamental, causal patterns that were consistent across subjects, that were selectively modulated by cognitive tasks, and that were expressed across distinct frequency bands and wide-spread cortical networks. Our results provide new insights into the causal structure of large-scale human brain dynamics and open a new window to study these dynamics in the healthy and diseased brain.

MACHINE LEARNING-BASED SUPPORT NETWORK EXTRACTION FOR NEURAL STATE CHARACTERIZATION

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Michael Depass, Ignasi Cos, Montse Comas, Oriol Pujol Vila
Universitat de Barcelona, Mathematics, Barcelona, Spain

Discriminative support network extraction is a relatively new technique which involves two principal steps. First, machine learning classifiers are employed to distinguish the classes, or neural states, of interest. Second, the most important features are extracted and visualized. This support network of important features serves as a signature of the classification and can be used, considering the feature set upon which the classifiers were trained, to characterize the neural states being analyzed.Though discriminative support networks have been used for neural state characterization in the past, a thorough analysis of the methods used for their extraction as well as their statistical relevance, remains to be performed. Absent such analyses, support networks remain difficult to interpret and require additional analyses to be performed post-extraction to establish their scientific relevance. Thus, we developed a discriminative support network extraction pipeline involving three classifiers and three feature importance algorithms in combination with statistical analyses to elucidate the statistical relevance of the extracted networks. Furthermore, we evaluated the techniques based on their computational complexity, classification accuracy, and replicability over repeated extractions. Multinomial logistic regression (MLR), k-nearest neighbors (KNN), 1D convolutional neural networks (CNN) were used to classify five neuro-motor states associated with a reach-to-grasp task. Subsequently, recursive feature elimination (RFE), beta regression coefficients, and perturbation-based feature importance algorithms were used to derive the support networks. CNN-based methods resulted in the highest classification accuracy though the derived support network exhibits lower replicability and statistical significance compared to the other techniques. MLR+RFE, however, resulted in the highest replicability and statistical relevance.

RELIABLE DETECTION OF CLAUSTRUM CONNECTIONS INTO THE FOREBRAIN BY TRACTOGRAPHY OF TWO LARGE HUMAN SAMPLES

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Jil Wendt, Dennis Hedderich, Antonia Neubauer, Christian Sorg, Aurore Menegaux
Klinikum rechts der Isar der Technischen Universität München, Department Of Diagnostic And Interventional Neuroradiology, Munich, Germany

Aim: The claustrum, a thin layer of neurons located between the external and extreme capsule and below the insular cortex, is widely connected in the mammalian forebrain. However, despite numerous ex- and in-vivo studies in non-human mammals, investigations into the claustrum's connections in humans are few with small sample sizes. To address this problem, we performed diffusion imaging-based tractography of claustrum connections in two large human adult samples. **Methods:** We used diffusion imaging in a cohort of 81 healthy young adults and 60 subjects from the human connectome project (HCP) to assess in-vivo claustrum connectivity. The bilateral claustra were individually delineated using deep learning-based automated segmentation. Tracts between the claustrum and 13 cortical and 10 subcortical regions were reconstructed in each subject using probabilistic tractography. Probabilistic group average maps and connection density were generated to assess the claustrum's connectivity profile. **Results:** Robust streamline probability maps were found to most cortical areas as well as to a selection of subcortical areas, notably the pallidum and thalamus. We replicated these findings in the HCP cohort (see Figure 1 for some examples). Further evidence of connectivity to the contralateral hemisphere was also found. **Conclusion:** This study is the first to investigate the white matter connections of the claustrum to cortical and subcortical regions in large human samples. Our results demonstrate the reliable reconstruction of claustrum connectivity in humans and provide a base for further examinations of claustrum connectivity in health and in the context of different pathologies. INFERRING BRAIN-WIDE CIRCUIT MODULES LINKING STRUCTURAL AND FUNCTIONAL CONNECTIVITY IN ZEBRAFISH LARVAE

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Matteo Bruzzone[1], Karan Manjunatha[2], Giorgio Nicoletti[2], Samir Suweis[1,2], Marco Dal Maschio[1,3]
[1]University of Padova, Padua Neuroscience Center -pnc, Padua, Italy, [2]University of Padua, Department Of Physics And Astronomy, Padua, Italy, [3]University of Padua, Department Of Biomedical Sciences, Padua, Italy

How neuronal circuits support the processing of the sensory information and the coordination of an appropriate motor outcome is still an open challenge. In zebrafish larvae, optical methods allow for the reconstruction of the activity from several thousand neurons across the entire brain at once, while tracking the behavioral outcome, in response to a sensory stimulation. This kind of datasets provides an ideal workbench for the application of theoretical approaches aiming at generating plausible circuit models where to test hypotheses on the circuit mechanisms, to assess the network properties and its functional organization. This approach is also taking advantage from everyday-more-detailed reconstructions of the neuronal wiring diagrams and connectomes whose layouts offer a sort of structural blueprint underlying the circuit activity. However, it's not yet clear if and to what extent the patterns extracted from the connectome reconstruction can explain the observed functional information, and viceversa. Here, we address these aspects. We started with the generation of a structural connectome from the publicly available dataset of single cell reconstructions to characterize the network properties of the fish brain. An algorithm for graph analysis was implemented to reveal distinct circuit modules based on the relative connection strength between cells. We are currently comparing the structure of the identified modules and the activity recorded from neurons, both registered into the same anatomical space. This method could represent a valid approach for the analysis of the brain functioning and its underlying organization.

Measuring recognition memory in zebrafish larvae: issues and limitations.
Recognition memory is the capacity to recognize previously encountered objects, events or places. This ability is crucial for many fitness-related activities, and it appears very early in the development of several species. In the laboratory, recognition memory is most often investigated using the novel object recognition test (NORt), which exploits the tendency of most vertebrates to explore novel objects over familiar ones. Despite that the use of larval zebrafish is rapidly increasing in research on brain, cognition and neuropathologies, it is unknown whether larvae possess recognition memory and whether the NORt can be used to assess it. Here, we tested a NOR procedure in zebrafish larvae of 7-, 14- and 21-days post-fertilization (dpf) to investigate when recognition memory first appears during ontogeny. Overall, we found that larvae explored a novel stimulus longer than a familiar one. This response was fully significant only for 14-dpf larvae. A control experiment evidenced that larvae become neophobic at 21-dpf, which may explain the poor performance at this age. The preference for the novel stimulus was also affected by the type of stimulus, being significant with tri-dimensional objects varying in shape and bi-dimensional geometrical figures but not with objects differing in colour. Further analyses suggest that lack of effect for objects with different colours was due to spontaneous preference for one colour. This study highlights the presence of recognition memory in zebrafish larvae but also revealed non-cognitive factors that may hinder the application of NORt paradigms in the early developmental stages of zebrafish.

Whole brain functional recordings at cellular resolution in zebrafish larvae with 3D scanning multiphoton microscopy.
Optical recordings of neuronal activity at cellular resolution represent an invaluable tool to investigate brain mechanisms. Zebrafish larvae is one of the few model organisms where, using fluorescence-based reporters of the cell activity, it is possible to optically reconstruct the neuronal dynamics across the whole brain. Typically, leveraging the reduced light scattering, methods like lightsheet, structured illumination, and light-field microscopy use spatially extended excitation profiles to detect in parallel activity signals from multiple cells. Here, we present an alternative design for whole brain imaging based on sequential 3D point-scanning excitation. Our approach relies on a multiphoton microscope integrating an electrically

tunable lens. We first apply our approach, adopting the GCaMP6s activity reporter, to detect functional responses from retinal ganglion cells (RGC) arborization fields at different depths within the zebrafish larva midbrain. Then, in larvae expressing a nuclear localized GCaMP6s, we recorded whole brain activity with cellular resolution. Adopting a semi-automatic cell segmentation, this allowed reconstructing the activity from up to 52,000 individual neurons across the brain. In conclusion, this design can easily retrofit existing imaging systems and represents a compact, versatile and reliable tool to investigate neuronal activity across the larva brain at high resolution.
Sci Rep, 2021; 11
34755638: Gatto E, Bruzzone M, Lucon-Xiccato T
Innate visual discrimination abilities of zebrafish larvae.
The ability to discriminate between objects visually plays a key role in animals' interactions with their environment because it enables them to recognise companions, prey, and predators. In the zebrafish, Danio rerio, hatching occurs early on during development (48-72 h post fertilisation), and the larvae must forage and evade predators despite their immature sensory and cognitive systems. Using a preference paradigm, we investigated whether larval zebrafish are nonetheless capable of discriminating between visual stimuli. We found that larvae discriminated not only between figures with different colours or different shapes, but also between two identical figures with different orientations and between sets of figures with different numerosities. By manipulating larvae's exposure to objects before the test, we demonstrated that their discrimination abilities are innate and do not depend upon experience. This study highlighted that zebrafish possess relatively sophisticated visual discrimination abilities even at the larval stage. These abilities likely improve larval survival via the recognition of biologically relevant stimuli.

PARCELLATION AND CONNECTIVITY OF THE HUMAN SUPERIOR COLLICULUS.

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Matteo Diano[1], Carlos Andres Mendez[1], Marco Lanzilotto[1], Olga Dal Monte[1,2], Enrico Premi[3], Alessia Celeghin[1], Matteo Panormita[1], Marco Tamietto[1,4]
[1]University of Turin, Department Of Psychology, Turin, Italy, [2]Yale University, Department Of Psychology, New Haven, United States of America, [3]"Spedali Civili" Hospital, Stroke Unit, Vascular Neurology, Brescia, Italy, [4]Tilburg University, Department Of Medical And Clinical Psychology, Tilburg, Netherlands

The Superior Colliculus (SC) serves basic functions of everyday human life thanks to the unique architecture of its connections with almost the entire brain, which is well documented in other mammals. Here, we performed several analyses using data from the Human Connectome Project to parcellate and profile the connectivity of SC in the human brain. To this end, we first manually recorded the SC ROIs in MNI space and calculated probabilistic tractography in 200 subjects. Then, we clustered the SC ROI of each subject into 3 components and created a probabilistic map for each cluster among the participants. Finally, machine learning and searchlight approaches were applied to determine the specificity of the probabilistic map and the accuracy of connectivity among 3 clusters. The first cluster (Superficial Division - SUP) is located in the anterior and superior part of SC. Its connectivity is closely related to the visual cortices, such as the primary visual cortex (V1), LGN, Amygdala, and the MT + complex. The second cluster (Intermediate-Deep Division - INTDP) is located more ventrally in the posterior-dorsal part of the SC and its connectivity profile suggests preferential connectivity with auditory, somatosensory, and parietal cortices. The third cluster (Deep Division - DEEP) is located in the most ventral part of the SC and its main connectivity is with the pons, cerebellum, corticospinal tracts and contralateral SC. In addition, each cluster shows a specific functional activity that links SUP and INTDP to each other and in opposition to the DEEP compartment.

THE POTENTIAL OF VOLTAGE IMAGING FOR ACCURATE INFERENCE OF NEURON CONNECTIONS IN VIVO

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Tomas Fiers, Matias Ison, Mark Humphries
University of Nottingham, School Of Psychology, Nottingham, United Kingdom

In the ideal systems neuroscience experiment, we would be able see the connections between neurons in living animals. We could then track how this wiring changes after an experimental intervention — or even over the animal's lifetime. Wire tracing from thin tissue slices is the gold standard for connectivity mapping, but cannot be done in vivo. Hence, we turn to *network inference* (**NI**) methods, based on in-vivo recordings of neural activity. These methods are typically spike-based, working from calcium imaging or extracellular electrode recordings. This makes network inference challenging, as spiking is sparse, and spike-based NI algorithms typically perform poorly. We propose to use *voltage imaging* (**VI**) recordings for network inference. Because such recordings can be sub-threshold, we can exploit a direct causal link between connectivity and activity: a successful spike will elicit a precisely-timed post-synaptic potential (PSP) in the downstream neuron's membrane voltage. We simulate VI data using a spiking model neuron, stimulated by Poisson inputs. We find that we can detect connections using spike-triggered averaging (STA) of PSPs alone. This simple method detects both excitatory and inhibitory connections with unusually high sensitivity and specificity, under realistic VI conditions (10-minute recording, 20 dB spike-SNR) — *iff* the input has a high spike rate. Based on these encouraging results, we plan to extend our experiment to full spiking neural networks. Our results suggest necessary voltage imaging conditions for network inference, and highlight the potential of this technique for accurate and large-scale *in-vivo* connectivity

mapping.

BAYESIAN INFERENCE OF SPIKE-TIMING-DEPENDENT PLASTICITY LEARNING RULES FROM DATA

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Ingeborg Hem[1], Benjamin Dunn[2], Claudia Battistin[2]
[1]Norwegian University of Science and Technology, Department Of Mathematical Sciences, Trondheim, Norway, [2]NTNU, Department Of Mathematical Sciences, Trondheim, Norway

The brain can be thought of as a network of neurons that interact through a complex system of connections. These connections are dynamic and develop over time according to unknown or partially unknown rules. Recent advances in recording technology have made large neural recordings common, but to date, there is no established method for inferring learning rules from them. We look at this from a statistical point of view and assume the system of connections can be modeled with a parameterized spike-timing-dependent plasticity learning rule. The goal is to infer the parameters from neural recordings, and we choose a Bayesian approach, with which we are able to get the uncertainty of the learning rule parameters as well as incorporate prior beliefs on their values. We use a Metropolis-Hastings sampling algorithm with particle filtering to obtain a posterior distribution of the parameters of the learning rule, which we can use to say something about the neural connections. We have tested the algorithm with both simulated and real data, and the results are promising.

Increasingly evidence is emerging to support the organization of neural activity in travelling waves (TWs), which have been reported in the hippocampus, visual, auditory, motor, and somatosensory systems. Previous work suggested that β oscillations (18 – 30 Hz) over motor areas propagate as planar waves during movement planning and execution, but no studies reported on motor inhibition. We recorded neural activity from Utah arrays in the dorsal premotor cortex (PMd) of three rhesus monkeys and from the middle frontal gyrus of one epilepsy patient. All subjects performed a countermanding reaching task, where randomly presented Stop signals instructed to suppress the planned movement after the Go signal. We used a novel approach by fitting the linear equation of a planar wave to the instantaneous phases of the LFPs. Wave parameters (i.e., direction, speed) were then computed from the estimated coefficients of the fitted models. We detected TWs in a narrow frequency range of the β band (~ 20 Hz) during movement planning and, more interestingly, during movement inhibition. Wave parameters were comparable across subjects, species, and behavioural conditions, but during inhibition, the TWs exhibited greater intensity. With graph theory methods, the functional interactions between the phase of the TWs and the average local spiking activity (SA) were quantified. We found a relationship between the topological arrangement of local SA changes across behavioural outcomes and the wave parameters. Thus, motor decisions depend on the variations of the TWs parameters and intensity and on a topological reorganization of the premotor network.

DYNAMIC MULTIPLEX NETWORK ANALYSIS OF HUMAN INTRACRANIAL RECORDINGS DURING POSTICTAL APHASIA

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Nicola Pedreschi
University of Oxford, Mathematical Institute, Oxford, Italy

We analyse long intracranial EEG recordings of a few patients suffering from pharmaco-resistant epilepsy and postictal aphasia, whose language capabilities are tested after a seizure until their full recovery. We study the functional connectivity between different cortical sites in the time-frequency domain, to capture how the flexible dynamics of inter-regional interactions is affected by the seizure onset and recovery. Specifically, for each recording we compute the wavelet coherence, in 5 frequency bands peaked around 1 Hz, 5 Hz, 10 Hz, 20 Hz, 40 Hz, of each pair of electrodes at each time stamp, thus representing each recording as a time-varying, multilayer network (dynamic multiplex). Within each layer of the dynamic multiplex, we characterizee the flow between consecutive network frames, identifying and comparing different types of network dynamics depending on the task stage. We studied in particular: the rate of overall reconfiguration of links from one frame to the next (dynamic Functional Connectivity speed); and the flexibility/crystallisation of network modules through time, by means of a dynamic Allegiance matrix (dAm) analysis. We find different dynamics types corresponding to baseline, seizure and long post-seizure recovery phases. Importantly, we persistently recover a pathological state whose occurrence is correlated with the language-test fallacies reported by the physicians. This pathological state corresponds to momentary drops of the speed of network reconfiguration during the recovery phase. In conclusion, in our work we devise a data driven pipeline that can help both shed light on general mechanisms underlying postictal aphasia and address patient specific issues.

OBJECTIVE AND EASILY PERFORMED ASSESSMENT OF FINE MOTOR SKILLS TO SUPPORT THE DIFFERENTIAL DIAGNOSIS OF PARKINSON'S DISEASE (PD) AND OTHER MOVEMENT DISORDERS WITH TREMOR

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Christoforos Papasavvas[1], Rutger Zietsma[1], Steve Dodds[2], Luc Cluitmans[3], Angela Deutschlander[4], Richard Walker[2,5]
[1]Manus Neurodynamica Ltd, Research & Development, Edinburgh, United Kingdom, [2]Northumbria Healthcare NHS Foundation Trust, North Tyneside General Hospital, North Shields, United Kingdom, [3]VTT, Technical Research Centre Of Finland, Tampere, Finland, [4]Mayo Clinic, Department Of Neurology, Jacksonville, United States of America, [5]Newcastle University, Global Challenges Academy, Newcastle upon Tyne, United Kingdom

Aim: The differential diagnosis between PD and other tremor disorders still poses a challenge, especially at the early stages of the disease. An objective assessment of the patients' tremor and motor skills is a valuable tool in clinical practice, assisting in the diagnosis of PD and other movement disorders with tremor. We aim to assess the ability of a handheld device and its accompanying data analytics to distinguish between tremor disorders. Methods: We assessed fine motor skills in 108 patients with movement disorders (68 PD, 40 non-PD patients). Data were collected while the patients were completing drawing and writing tasks on a tablet with a proprietary multi-sensor digital pen (NeuroMotor Pen) intended to measure and analyse neuromotor function. We extracted and analysed 123 features quantifying multiple symptoms of the disease. Results: The analysis revealed a subset of five features which serve as biomarkers for differential diagnosis between PD and non-PD patients. A classifier was built based on those five features, and it was tested on a separate set of 12 PD and 15 patients with other tremor disorders, achieving 85.2% accuracy (93.3% specificity, 75.0% sensitivity). Conclusions: The device shows potential in assisting in the differential diagnosis between PD and other tremor disorders. The accuracy level of the classifier is comparable to current diagnostic imaging practices (DaTSCAN). Clinical use of the device will enable cost and workflow benefits as well as patient benefits. It will also allow identifying early stage patients for clinical trials on medications.

TOWARD A NEW DIMENSIONAL APPROACH TO ADDICTION: LINKING ADDICTION MARKERS TO THE CONNECTIVITY PROFILES OF STRIATUM SUBDIVISIONS

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Kenza Kadri[1], Billy Hosking[1], Jacqueline School[2], Miriam Klein-Flugge[2], Elsa Fouragnan[1]
[1]University of Plymouth, School Of Psychology, Plymouth, United Kingdom, [2]University of Oxford, Department Of Experimental Psychology, Oxford, United Kingdom

Aims: Examining a dimensional approach to addiction is essential for refining possible treatments and prevention strategies, particularly because there is significant heterogeneity of the disease across addiction to different substances. One promising avenue to inform this approach is to advance our understanding of large-scale variation in neurobiological circuits mediating addiction to different substances. In this new study, we aim at capitalizing on the natural variation in 1)latent behaviours related to different substances and 2)connectivity profiles of several subdivisions of the striatum in a large population extracted from the Human Connectome Project (HCP). Methods: In this study, we used factor analyses on the HCP questionnaires' answers from 564 individuals to extract latent behaviours relevant for addiction and impulsivity. We then explored variations in functional brain connectivity related to these behavioural factors. We first segmented the striatum according to anatomically and functionally defined landmarks. We also used 23 cortical and 13 subcortical regions that are anatomically or functionally known to be linked to the striatum to infer the Resting-State-Functional Connectivity (RSFC) of its subdivisions. Results: We found three addiction-related factors underlying general behavioural variation in (i) use of tobacco, (ii) alcohol and (iii) illicit drugs as well as one transdiagnostic factor defining (v) impulsivity. We postulate that distinct RSFC of the striatum are related to distinct substances abuse disorders. Conclusion: We hope that by building on the effectiveness of large-scale imaging and online data collected on a general population, we will provide a reliable link between anatomical relationships and markers of addiction.

GENE CONNECTIVITY ANALYSIS OF CO-EXPRESSION NETWORKS PROVIDES INSIGHTS INTO THE OMNIGENIC MODEL AND IDENTIFIES NOVEL GENETIC HUBS OF SCHIZOPHRENIA RISK

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Christopher Borcuk[1], Madhur Parihar[2], Leonardo Sportelli[1,2], Joel Kleinman[2,3], Joo Heon Shin[2], Thomas Hyde[2,3,4], Alessandro Bertolino[1,5], Daniel R. Weinberger[2,6,7], Giulio Pergola[1,2]

The omnigenic model posits that polygenic risk arises from cumulative effects of many peripheral genes on “core genes” that mechanistically drive disease traits. However, understanding omnigenic architecture and identifying core genes in gene co-expression networks remains challenging. In co-expression networks derived from postmortem brain RNAseq parsed for age and region (LIBD, GTEx), we found that within gene sets enriched for schizophrenia (SCZ) risk – and not within others – the most central genes accumulated SCZ-GWAS signal. This suggests a definition of core genes as those most connected with SCZ-GWAS genes. This phenomenon was more prevalent in SCZ than Alzheimer’s disease or multiple sclerosis, and strongest in the developmental stage prefrontal cortex. We re-performed this analysis in simulations from variable numbers of random seeds (representing core genes) displaying either cis-heritability (only the seed genes had high importance), trans-heritability (the seed genes only conferred importance to the genes most connected to them), or cis-trans mixture. The simulations that most closely matched real SCZ networks had a number of seeds in the thousands, and a cis-trans importance mixture of 70%-30%. Finally, we prioritized candidate SCZ core genes as those most highly connected to SCZ-GWAS genes. In consensus across LIBD and GTEX networks, this procedure revealed cerebrum wide genes (across 12 networks), and tissues specific genes in the striatum (across 5 networks) and the hippocampus (across 3 networks). Our results revealed properties of the genetic architecture of SCZ, and leveraged omnigenic model predictions to identify targets to further assess disease risk pathways.

RADIOMICS FEATURES CAN IDENTIFY LATERALITY IN MRI-NEGATIVE TEMPORAL LOBE EPILEPSY PATIENTS

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

E-Nae Cheong[1], Ji Eun Park[2], Hyejeong Kim[2], Miseon Kim[2]
[1]Asan Medical Center, University of Ulsan College of Medicine, Department Of Medical Science And Asan Medical Institute Of Convergence Science And Technology, Seoul, Korea, Republic of, [2]Asan Medical Center, University of Ulsan College of Medicine, Department Of Radiology And Research Institute Of Radiology, Seoul, Korea, Republic of

In this study, we hypothesized that radiomic features from MRI can predict the lateralization of the epileptogenic focus of the patients with MRI-negative Temporal lobe epilepsy(TLE). And we also assumed that the radiomic features of hippocampus and extrahippocampal regions, especially, would provide useful information in patients with hippocampal sclerosis (MRI-positive) and those with MRI-negative TLE. Participants for this study consisted of training set and validation set. The training set used to develop a radiomic model includes patients with MRI-positive TLE, and age- and sex-matched healthy controls (n=50). To validate the radiomic model, internal verification set consisted of patients with MRI-negative TLE. Radiology features for identifying lateralization were extracted from the hippocampus and extrahippocampal temporal region of the participant's affected and unaffected areas, respectively. Based on these features, an evaluation was conducted to predict the laterization of epileptogenic focus using supervised learning. Then, feature selection and modeling were performed. Radiomic features that can predict to identify laterization of the epileptogenic focus were extracted 48 from Hippocampus and 99 from Extrahippocampal regions. The models for predicting laterality in MRI-negative TLE showed an AUC of 0.67 and 0.90, respectively. In the results, radiomic features representing the difference between the affected and the unaffected side had a larger number of features in the extrahippocampal model than in the hippocampal model and better performance, which indicates that extrahippocampal model can more effectively predict epileptogenic focus on the affected side of patients with MRI-negative TLE. In conclusion, radiomic analysis could potentially help to identify MRI-negative TLE.

PREDICTING INTELLIGENCE FROM FMRI DATA OF THE HUMAN BRAIN

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Gabriele Lohmann[1], Eric Lacosse[2], Thomas Ethofer[1], Vinod Kumar[2], Klaus Scheffler[2], Juergen Jost[3]
[1]University Hospital, Biomedical Magnetic Resonance, Tuebingen, Germany, [2]Max-Planck-Institute for Biological Cybernetics, Magnetic Resonance Center, Tuebingen, Germany, [3]Max-Planck-Institute for Mathematics in the Sciences, Geometry And Complex Systems, Leipzig, Germany

In recent years, the prediction of individual behaviour from the fMRI-based functional connectome has become a major focus of research. The motivation behind this research is to find generalizable neuromarkers of cognitive functions. However, insufficient prediction accuracies and long scan time requirements are still unsolved issues. Here we propose a new machine learning algorithm for predicting intelligence scores of healthy human subjects from resting state (rsfMRI) or task-based fMRI (tfMRI). In a cohort of 390 unrelated test subjects of the Human Connectome Project, we found correlations between the observed and the predicted general intelligence of more than 50~percent in tfMRI, and of around 59~percent when results from two tasks are combined. Surprisingly, we found that the tfMRI data were significantly more predictive of intelligence than rsfMRI even though they were acquired at much shorter scan times (approximately 10~minutes versus 1~hour). Existing methods that we investigated in a benchmark comparison underperformed on tfMRI data and produced prediction accuracies well below our results. Our proposed algorithm differs from existing methods in that it achieves dimensionality reduction via ensemble learning and partial least squares regression rather than via brain parcellations or ICA decompositions. In addition, it introduces Ricci-Forman curvature as a novel type of edge weight. Reference: G. Lohmann, E. Lacosse, T. Ethofer, V.J. Kumar, K. Scheffler, J. Jost, Predicting intelligence from fMRI data of the human brain in a few minutes of scan time, biorxiv (2021), doi: https://doi.org/10.1101/2021.03.18.435935

MULTI-CHANNEL AUTOMATED SPIKE SORTING ACHIEVES NEAR-HUMAN PERFORMANCE

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Tali Remenick[1,2], Lidor Spivak[1,3], Amir Levi[1,3], Shirly Someck[1,3], Hadas Sloin[1,3], Roni Gattegno[1,3], Eran Stark[1,4]

Identifying spike timing of individual neurons recorded simultaneously is essential for investigating neuronal circuits that underlie cognitive functions. Recent developments allow simultaneous recording of multi-channel extracellular spikes from hundreds of neurons. However, even state-of-the-art spike sorters require a substantial degree of manual curation, making the process time consuming and lacking in uniformity. Here, we developed a fully automated alternative to manual curation. As input to the automated curator (AC), we over-cluster spikes using standard software. From this point onwards we refer to manual curation as a sequence of two binary classification problems. To solve the first problem, we developed a “noise classifier” that uses adaptive boosting to remove non-neuronal clusters. To solve the second problem, we developed a “merge classifier” that uses a deep convolutional neural network to determine whether any given pair of non-noise clusters should be merged, resulting in a set of well-isolated units. To train the classifiers, we used multi-channel spike data recorded by high-density silicon probes from freely moving mice, curated manually by expert neurophysiologists. To evaluate AC performance, test data were manually curated by five human experts and by the novel AC. We quantified pairwise similarity between sorting solutions using the adjusted Rand index. We found that the AC reached a high similarity to human results, within inter-expert variance. Thus, the novel automated curator can replace human curation of spikes without compromising performance. Recently, neural decoding has been used in conjunction with deep neural networks, leading to important advances in our understanding of higher-level visual cerebral representations, allowing the reconstruction of visual stimuli from fMRI patterns (van Gerven MAJ et al., 2019; Dado et al., 2020). We are interested in establishing a linear relationship between a deep-derived 'Voice latent space' and neural activity measured by fMRI. The goodness of fit in different cerebral regions will be probed via brain-based voice reconstruction. The main idea is to learn a deep auto-encoder to reconstruct spectrograms of human voice, then to learn a linear mapping from the encoding space of the autoencoder to the fMRI space, a strategy assumed to be more relevant for learning such a mapping between fMRI maps and sounds. Then, an fMRI acquisition of test stimuli is mapped to the autoencoder space and subsequently decoded as a spectrogram, enabling stimulus reconstruction. We developed and proposed a simple framework to perform brain voice decoding from fMRI patterns using DNNs. We applied our voice decoding method using different functionally-defined ROIs. We found that the decoded spectrograms only contained human voice when the ROI consisted of the fMRI-defined Temporal Voicer Areas. Ongoing analyses aim to further refine reconstruction quality and systematically test it as a function of anatomical cerebral location. The reconstruction obtained by the linear regression will allow us to better understand the functional representation of voice stimuli in the brain and potential analogies to the DNN-generated latent representations.

A STOCHASTIC SIMULATION EXPERIMENT FOR A BETTER UNDERSTANDING OF UNCERTAINTY IN SELF-ORGANIZING MAPS

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

José Mira
Universidad Politécnica de Madrid, Statistics-ingeniería De Organización, A. De Empresas Y Estadística, Madrid, Spain

Self Organizing Maps (SOM) were developed by Kohonen, as a simplified abstract version of the Wilshaw-von der Malsburg modelling of the retina-cortex connection development. Statistically speaking, SOM is a clustering technique assigning observations from an original p-dimensional space, to a typically two-dimensional map, in such way that the distances between the corresponding points in the map reflect those in the original space. The original Kohonen algorithm is deterministic, but work also exists under a stochastic approach. In this paper, a computational experiment is performed to learn about the propagation of uncertainties along the SOM algorithm. We assume there exists, in the original dimensión of the data (p), a data generating process or probability distribution, which is transformed, through the (SOM) algorithm, into a stochastic process. This process is indexed by the iterations of the algorithm, so we formulate the estimation of a stochastic model in terms of the (estimation of) its (the process) limit distribution. Thus, two sources of uncertainty follow: the aforementioned SOM final weight variability and the one associated to the estimation of the parameters of the weight stochastic model. In our computational experiment, a large (Monte Carlo simulated) sample is generated from a mixture of tri-variate Gaussian distributions. We then divide the sample into subsamples of and apply the Kohonen algorithm to each subsample on a 2-D map, thus obtaining a sample of the final SOM weights, and subsequently estimating their statistical properties. Additionally, uncertainty in the distribution parameters is estimated by means of bootstrap resampling.

STATISTICAL LIMITATIONS IN THE RECONSTRUCTION OF LOW-DIMENSIONAL NEURAL TRAJECTORIES FROM HIGH-DIMENSIONAL ACTIVITY RECORDINGS

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Mariia Legenkaia[1,2], Remi Monasson[3], Laurent Bourdieu[4]
[1]Ecole Normale Superieure, Departement De Biologie, PARIS, France, [2]Ecole Normale Supérieure, Paris, Departement De Physique, Paris, France, [3]Ecole Normale Superieure, Physics, PARIS, France, [4]École Normale Supérieure, Département De Biologie, Paris, France

Multi-electrode or calcium-imaging techniques now make possible to record the activity of hundreds or thousands of neurons in a brain area. A common assumption is that this high-dimensional activity is embedded on a low-dimensional manifold, and describes a trajectory informative about the ongoing e.g. sensory or motor computations. Principal component analysis, among other manifold-reconstruction methods, is routinely used to infer the relevant neural subspace and visualize the corresponding trajectories. An important issue is the reliability of this trajectory reconstruction process. The limited recording time, the size of the recorded population, the presence of dynamical neural noise, as well as intrinsic limitations of the recording methods, such as errors or biases in spike identification from voltage or fluorescence signals may considerably affect the reconstructed trajectories, and our understanding of the underlying computational processes. In our work, we present a systematic characterization of these effects on low-dimensional trajectory inference. We derive analytical expressions for the reconstruction error using the tools of the statistical physics of disordered systems, and derive phase diagrams locating regions in which the error is under control, or in which reconstruction is not possible. Our results are confirmed by extensive numerical simulations. We then show, on various existing recordings in the visual cortex, the hippocampus, and in the prefrontal cortex, how our results can be used to characterize the expected error on trajectory obtained from real datasets.

SCALABLE NEURAL NETWORK-BASED PREDICTION OF NEURODEGENERATIVE DISEASES USING CLINICAL AND GENOMIC DATA FROM THE UK BIOBANK

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Yazeed Zoabi, Noam Shomron
Tel Aviv University, Medicine, Tel Aviv, Israel

Predictive modeling with clinical patient data is anticipated to drive personalized medicine and improve healthcare quality. Constructing predictive statistical models typically requires extraction of curated predictor variables from normalized clinical data, a labor-intensive process that discards most of the information in each patient's record. Representation of health data using Fast Healthcare Interoperability Resources (FHIR) - an international standard for exchanging digital health data increasingly used in health information technology - should represent clinical data in a consistent, hierarchical, and extensible container format, regardless of the health system, which simplifies data interchange between sites. We propose a representation of participants from the UK Biobank entire raw clinical records based on the FHIR format, including molecular and genomic data, to demonstrate that deep learning methods using this representation are capable of accurately predicting multiple neurodegenerative diseases (e.g. Alzheimer's, Parkinson's) using integrative data from multiple data sources. We believe that this approach would allow to create accurate and scalable predictions for a variety of clinical scenarios, where molecular data can be supplemented to clinical patient data to improve prediction quality of neurodegenerative conditions and other ageing-related conditions.

Predicting bloodstream infection outcome using machine learning.
Bloodstream infections (BSI) are a main cause of infectious disease morbidity and mortality worldwide. Early prediction of BSI patients at high risk of poor outcomes is important for earlier decision making and effective patient stratification. We developed electronic medical record-based machine learning models that predict patient outcomes of BSI. The area under the receiver-operating characteristics curve was 0.82 for a full featured inclusive model, and 0.81 for a compact model using only 25 features. Our models were trained using electronic medical records that include demographics, blood tests, and the medical and diagnosis history of 7889 hospitalized patients diagnosed with BSI. Among the implications of this work is implementation of the models as a basis for selective rapid microbiological identification, toward earlier administration of appropriate antibiotic therapy. Additionally, our models may help reduce the development of BSI and its associated adverse health outcomes and complications.
Sci Rep, 2021; 11

Machine learning-based prediction of COVID-19 diagnosis based on symptoms.
Effective screening of SARS-CoV-2 enables quick and efficient diagnosis of COVID-19 and can mitigate the burden on healthcare systems. Prediction models that combine several features to estimate the risk of infection have been developed. These aim to assist medical staff worldwide in triaging patients, especially in the context of limited healthcare resources. We established a machine-learning approach that trained on records from 51,831 tested individuals (of whom 4769 were confirmed to have COVID-19). The test set contained data from the subsequent week (47,401 tested individuals of whom 3624 were confirmed to have COVID-19). Our model predicted COVID-19 test results with high accuracy using only eight binary features: sex, age ≥60 years, known contact with an infected individual, and the appearance of five initial clinical symptoms. Overall, based on the nationwide data publicly reported by the Israeli Ministry of Health, we developed a model that detects COVID-19 cases by simple features accessed by asking basic questions. Our framework can be used, among other considerations, to prioritize testing for COVID-19 when testing resources are limited.

Marginal Contribution Feature Importance - an Axiomatic Approach for Explaining Data.
In recent years, methods were proposed for assigning feature importance scores to measure the contribution of individual

features. While in some cases the goal is to understand a specific model, in many cases the goal is to understand the contribution of certain properties (features) to a real-world phenomenon. Thus, a distinction has been made between feature importance scores that explain a and scores that explain the . When explaining the data, machine learning models are used as proxies in settings where conducting many real-world experiments is expensive or prohibited. While existing feature importance scores show great success in explaining models, we demonstrate their limitations when explaining the data, especially in the presence of correlations between features. Therefore, we develop a set of axioms to capture properties expected from a feature importance score when explaining data and prove that there exists only one score that satisfies all of them, the (MCI). We analyze the theoretical properties of this score function and demonstrate its merits empirically.

Processing and Analysis of RNA-seq Data from Public Resources.
Advances in next generation sequencing (NGS) technologies resulted in a broad array of large-scale gene expression studies and an unprecedented volume of whole messenger RNA (mRNA) sequencing data, or the transcriptome (also known as RNA sequencing, or RNA-seq). These include the Genotype Tissue Expression project (GTEx) and The Cancer Genome Atlas (TCGA), among others. Here we cover some of the commonly used datasets, provide an overview on how to begin the analysis pipeline, and how to explore and interpret the data provided by these publicly available resources.

Differential network analysis of multiple human tissue interactomes highlights tissue-selective processes and genetic disorder genes.
Differential network analysis, designed to highlight network changes between conditions, is an important paradigm in network biology. However, differential network analysis methods have been typically designed to compare between two conditions and were rarely applied to multiple protein interaction networks (interactomes). Importantly, large-scale benchmarks for their evaluation have been lacking.

ASSESSING THE INFLUENCE OF LOCAL NEURAL ACTIVITY ON GLOBAL CONNECTIVITY FLUCTUATIONS: APPLICATION TO HUMAN INTRACRANIAL EEG DURING A COGNITIVE TASK

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Manel Vila-Vidal[1,2], Mariam Khawaja[3], Mar Carreño[4], Pedro Roldán[3], Jordi Rumiá[3], Antonio Donaire[4], Gustavo Deco[5], Adrià Tauste Campo[2]

Aims. Cognitive-relevant information is processed by different brain areas that cooperate to eventually produce a response. The relationship between local activity and global brain states during such processes, however, remains for the most part unexplored. **Methods**. To address this question, we designed a simple face-recognition task performed in drug-resistant epileptic patients with intracranial EEG. Based on our observations, we developed a novel analytical framework (named “local-global” framework) to statistically correlate the brain activity in every recorded gray-matter region with the widespread connectivity functions as proxy to assess the level of influence of local neural activations into the brain’s global state during cognition. **Results**. The application of our analysis to the data from two subjects was able to detect the local gamma activity in task-relevant brain areas including the primary visual and motor cortices. Despite substantial differences in the recorded regions of each subject, the connectivity functions (functional connectivity derived from Pearson correlation and phase-locking value) consistently showed a significant global decrease around alpha and beta bands occurring a few hundred milliseconds after the stimulus onset. In this context, the local-global framework revealed that the reported desynchronization was better explained by the local activity of brain areas involved in face information processing, providing evidence that the global measures might be a novel signature of functional brain activity reorganization taking place when a stimulus is processed in a task context. **Conclusion**. Overall, the findings of this study suggest that task-driven connectivity fluctuations might be interpreted of relevant local neural activity.

Ictal spitting in non-dominant temporal lobe epilepsy: an anatomo-electrophysiological correlation.
We report a patient presenting drug-resistant, non-dominant temporal lobe epilepsy with ictal spitting and prosopometamorphopsia, both extremely rare semiologies. Second-phase pre-surgical monitoring was performed using SEEG due to lesion-negative imaging and the rare semiology. The seizure onset zone was delimited to the right anterior hippocampus and the temporobasal cortex, with the propagation zone within the entorhinal cortex. Interestingly, direct electrical stimulation to the entorhinal cortex, which was reproduced in a number of trials, evoked spitting without leading to seizures or post-discharges. After the resection of the epileptogenic zone, the patient remained seizure-free without AEDs for a follow-up period of five years (Engel Class 1a). The neuropathology revealed a focal cortical dysplasia type FCD-Ia. Spectral analysis of intracranial ictal EEG (iEEG) data suggested a possible role of the basal temporal and entorhinal cortex as a necessary node in ictal spitting. A Set of 200 Musical Stimuli Varying in Balance, Contour, Symmetry, and Complexity: Behavioral and Computational Assessments.
We present a novel set of 200 Western tonal musical stimuli (MUST) to be used in research on perception and appreciation of music. It consists of four subsets of 50 stimuli varying in balance, contour, symmetry, or complexity. All are 4 s long and designed to be musically appealing and experimentally controlled. We assessed them behaviorally and computationally. The behavioral assessment (Study 1) aimed to determine whether musically untrained participants could identify variations in each attribute. Forty-three participants rated the stimuli in each subset on the corresponding attribute. We found that inter-rater reliability was high and that the ratings mirrored the design features well. Participants' ratings also served to create an abridged set of 24 stimuli per subset. The computational assessment (Study 2) required the development of a specific battery of computational measures describing the structural properties of each stimulus. We distilled nonredundant composite measures for each attribute and examined whether they predicted participants' ratings. Our results show that the composite measures indeed predicted participants' ratings. Moreover, the composite complexity measure predicted complexity ratings as well as existing models of musical complexity. We conclude that the four subsets are suitable for use in studies that require presenting participants with short musical motifs varying in balance, contour, symmetry, or complexity, and that the stimuli and the computational measures are valuable resources for research in music psychology, empirical aesthetics, music information retrieval, and musicology. The MUST set and MATLAB toolbox codifying the computational measures are freely available at osf.io/bfxz7.

Low entropy map of brain oscillatory activity identifies spatially localized events: A new method for automated epilepsy focus prediction.
The spatial mapping of localized events in brain activity critically depends on the correct identification of the pattern signatures associated with those events. For instance, in the context of epilepsy research, a number of different electrophysiological patterns have been associated with epileptogenic activity. Motivated by the need to define automated seizure focus detectors, we propose a novel data-driven algorithm for the spatial identification of localized events that is based on the following rationale: the distribution of emerging oscillations during confined events across all recording sites is highly non-uniform and can be mapped using a spatial entropy function. By applying this principle to EEG recording obtained from 67 distinct seizure epochs, our method successfully identified the seizure focus on a group of ten drug-resistant temporal lobe epilepsy patients (average sensitivity: 0.94, average specificity: 0.90) together with its characteristic electrophysiological pattern signature. Cross-validation of the method outputs with postresective information revealed the consistency of our findings in long follow-up seizure-free patients. Overall, our methodology provides a reliable computational procedure that might be used as in both experimental and clinical domains to identify the neural populations undergoing an emerging functional or pathological transition.

FROM NEURAL CORRELATIONS TO POPULATION CODES AND BACK- UNDERSTANDING A DUALITY IN THE TOPOLOGICAL ANALYSIS OF NEURAL DATA

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Melvin Vaupel[1], Erik Hermansen[2], Benjamin Dunn[3]
[1]NTNU, Department Of Mathematical Sciences, TRONDHEIM, Norway, [2]NTNU, Department Of Mathematical Sciences, Trondheim, Norway, [3]Department of Mathematical Sciences, Ntnu, Trondheim, Norway

There are two distinct but complementary ways to approach the analysis of recorded neural spikes. The first one is to analyse the correlation structure between neurons, while the second is concerned with understanding the population vector or *state space* representation. As an example, consider electrophysiological recordings from head direction neurons with single-peaked receptive fields. The circular shape of possible head directions can in principle be recovered both in the correlation structure of the neurons and in the space of observed population vectors. While in this simple example, the two approaches provide equivalent descriptions, they differ in general, for example if one of the head direction neurons has multiple fields. A natural question is then how to relate and reconcile the two views. We try to give an answer by using topological data analysis - the science of shapes in datasets. This is motivated by many recent studies that showcase the relevance of shapes for understanding the brain. Using the principle of Dowker duality we provide a theoretical framework for their comparison and discuss implications for the analysis and interpretation of neural data.

THE ROLE OF EXCITATORY-INHIBITORY HOMEOSTASIS IN THE RECOVERY OF FUNCTIONAL CONNECTIVITY AFTER FOCAL LESION – A COMPUTATIONAL ACCOUNT

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Francisco Páscoa Dos Santos[1,2,3], Paul Verschure[3,4]
[1]Eodyne Systems SL, Eodyne Systems Sl, Barcelona, Spain, [2]Universitat Pompeu Fabra (UPF), Department Of Information And Communication Technologies (dtic), Barcelona, Spain, [3]Institute for Bioengineering of Catalonia (IBEC), Laboratory Of Synthetic, Perceptive, Emotive And Cognitive Systems (specs), Barcelona, Spain, [4]Catalan Institution for Research and Advanced Studies (ICREA), Catalan Institution For Research And Advanced Studies (icrea), Barcelona, Spain

Stroke-related disruptions in functional connectivity (FC) often spread beyond lesioned areas. Thus, it is unclear how the recovery of FC can be orchestrated on a global scale. Given that post-stroke recovery is accompanied by long-term increases in excitability, we propose excitatory-inhibitory homeostasis as a mechanism of recovery and aim to model its role in restoring FC properties, relating it to observed changes in excitability. In this study, we modelled stroke in connectome-based networks of Wilson-Cowan masses with homeostatic scaling of local inhibition. Activity was recorded pre-lesion (T0), post-lesion (T1) and post-lesion after stabilization of inhibitory weights (T2). Effects were quantified through changes in FC and local inhibitory weights were used as a proxy for excitability. Results showed decreased interhemispheric connectivity at T1, strongly correlated with lesion severity, and further recovered towards baseline levels at T2, independently of lesion strength. The similarity of FC with baseline was improved from T1 to T2 and, similarly to interhemispheric connectivity, it correlated with lesion severity at T1, but not at T2, revealing independence between recovery and lesion severity. We further observed long-term increases in local excitability, correlated with structural connectivity to lesioned areas, with severe lesions requiring larger and more widespread changes. Thus, our model not only replicated acute effects of stroke in FC but also showed an ability to recover it towards pre-stroke levels through the regulation of local excitability. Therefore, we present excitatory-inhibitory homeostasis as a key driver of stroke recovery, tying long-term changes in local excitability to the restoration of FC.

Aims Stroke lesions can cause structural disconnection leading to network disruption and cognitive deficits. Our study aims at modeling the association between lesion-derived structural network disconnections and motor-action speed deficits. **Methods** We applied the lesion-network mapping to MR images from 93 stroke patients (right-handed, 40-80 yrs) with lesions in the left corticospinal tract to predict motor and action speed deficits assessed by the standardized GRECogVASC battery of clinical tests at six-month post-injury. For each lesion, a probability disconnection map was first generated after removing white matter (WM) pathways passing through the lesion from the tractography (diffusion-weighted imaging) profile of 403 healthy participants (40-80 yrs) in the Human Connectome Project. *A voxel-wise multiple regression analysis (p<0.01 FDR corrected) was then* carried out with lesion binary masks-disconnection maps (dependent variables) and motor-action speed scores (independent variables). **Results** The statistical maps of lesions showed a voxel cluster in the left corticospinal tract (-26,-7,16), significantly associated with motor deficits. No association was found between the lesion location and action speed deficits using the voxelwise lesion-symptom mapping (VLSM). The lesion-network mapping, however, showed that WM disconnections in the left corticospinal and internal capsule were significantly correlated with motor deficits. The action speed deficit was significantly correlated with disconnected WM pathways along the right corticospinal tract and internal capsule between supplementary motor areas, inferior frontal gyrus, thalamus, caudate, and putamen. **Conclusions** Compared to VLSM, our findings revealed that the lesion-network mapping could better identify regions impacted by network disruption causing motor-action speed deficits.

THE FUNCTIONAL NETWORK STRUCTURE OF LEXICAL DECISION-MAKING

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Gemini Katwa[1], Stacey Bedwell[2]
[1]Birmingham City University, Psychology, Birmingham, United Kingdom, [2]King's College London, Ioppn, London, United Kingdom

Abstract The Functional Network Structure of Lexical Decision-Making Decision-making is arguably an important human cognitive function and an area of research prioritisation. Mapping anatomical cortical regions, including structural and functional networks in decision-making is yet to be achieved in detail. Exposing these neuronal circuits will improve understanding of the underlying structure and functional properties involved in lexical decision-making processes. **Aims:** Further analysing an existing lexical decision-making dataset (Dufau et al., 2015) to establish specific network structural properties in healthy adults, to increase understanding of the complexities of human decision-making. **Methods:** Brain graph theory was applied to explore structural properties. Binary and weighted matrices were constructed, whereby nodes = electrodes and edges exist where ERP amplitude is r >0.7 at 280ms post-stimulus, and nodes = electrode and weighted edges = correlation co-efficient of ERP amplitude at 280ms post-stimulus, respectively. **Results:** Findings revealed a gradient in average degree from anterior to posterior frontal regions in both the binary (10→14.5→18) and weighted (15.34→18.52→20.45) networks. Results also showed greater average degree in frontal regions in both binary and weighted networks (weighted=18.36 [average = 16.95], binary = 14.7 [average = 11.44]) and a shorter than average path length in frontal regions in the binary network (1.09 [average 1.72]). **Conclusions:** Findings indicate greater connectivity and efficiency of prefrontal compared to other cortical networks in lexical decision-making. Additionally, these findings align with anatomical evidence of connectivity gradient from anterior-posterior in the prefrontal cortex, forming an important basis on which to build future developments in the understanding of decision-making networks.

Aims: Psychotic disorders are characterized by heterogeneity in etiopathology, clinical presentation and individual trajectory, complicating diagnosis and treatment. Despite the increasing amount of studies investigating significant alterations, the mechanisms underlying the emergence and progression of these disorders remains unclear. It is therefore fundamental to improve our ability to differentiate between clinical subgroups and to move towards a more personalised approach. Here, we aim to highlight critical neural correlates in early stages of psychosis, and to identify relevant biomarkers correlating with clinical staging. **Methods:** In this study, we included resting-state fMRI and DTI data from a cohort of 129 healthy controls and 94 patients with early psychosis stratified into four distinct groups based on the severity of their condition and their ability to recover after the first episode. We used a whole-brain model that combines functional dynamics and anatomical structure to fit the empirical data and to extract global and local properties of the brain network. **Results:** This model allowed us to highlight significant differences between subgroups and to identify critical networks involved in damaging mechanisms relevant for emergence of the disease as well as in potential compensatory mechanisms involved in the recovery process. In particular, the disruption of local dynamical properties in areas previously identified as hubs of connectivity emerged as a critical biomarker of progression of disease. **Conclusions:** These preliminary results allow us to progress in understanding of the mechanisms underlying the emergence and the disruption progression of psychosis, and could open the way for possible future therapeutic applications.

INFORMATION PROCESSING IN SUBCLINICAL PSYCHOSIS: INCREASED PRECISION OF SENSORY EVIDENCE IN PERCEPTUAL INFERENCE ASSOCIATED WITH HALLUCINATION- AND DELUSION-LIKE EXPERIENCES.

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Francesco Scaramozzino, Nicholas Furl, Ryan Mckay
Royal Holloway, University of London, Psychology, EX, United Kingdom

AIMS We aim to identify neurocomputational patterns possibly involved in hallucinations- and delusion-like experiences. In predictive coding, the precision (inverse of variance) of neural signals quantifies the noise in the information source. Psychosis is hypothesised to emerge from overestimating the precision of prior beliefs or sensory evidence. Evidence from the Beads Task (BT) (cognitive inference) shows delusion-like experiences predict impulsive sampling and increased sensory precision. It is unclear whether these patterns feature also in perceptual inference. We investigated this question evaluating how psychotic-like experiences affect performance in the Random Dot Motion task (RDM). METHODS We fitted RDM data (N=191) to hierarchical drift-diffusion models that allowed drift-rate (proxy of precision of sensory evidence) and decision-threshold (proxy of impulsive sampling) parameters to vary: 1) between groups with higher vs. lower scores of subclinical psychotic symptoms; 2) as response variables of a regression model having subclinical psychotic symptoms as predictors. We also attempted to replicate impulsivity associated with delusion-like symptomatology in BT. RESULTS In RDM, both delusion- and hallucination-like experiences were associated with higher precision of sensory evidence (higher drift-rates). Hallucination-like experiences were also associated with lower decision-thresholds. In BT, we did not find impulsive sampling associated with psychotic-like experiences. CONCLUSIONS Our findings suggest increased precision of sensory evidence in perceptual inference may represent a candidate neurocomputational mechanism contributing to subclinical psychotic traits. Significantly, they indicate a link between perceptual mechanisms and abnormal beliefs, hinting that alterations of perceptual processing could precede and contribute to changes in the belief system.

Mental disorders are among the leading causes of morbidity globally, and some of the costliest disorders to affect humanity. Identifying the underlying pathophysiology is an imperative step to unlocking better treatment and prevention strategies, and can lead to major health benefits. Mental disorders are complex, combining biological and psychosocial mechanisms, and hence a multidisciplinary approach is necessary to generate new knowledge about the pathology of severe mental disorders. Based on integrated statistical genetics, brain imaging, and electrophysiological measurements on patient-derived brain organoids, we present a framework for building computational models for mental phenotypes that are relevant in Schizophrenia and Bipolar Disorder.

[1]Centro Interdisciplinario de Neurociencia de Valparaíso (CINV), Facultad De Ciencias, Universidad De Valparaíso, Valparaíso, Chile, [2]The Latin American Brain Health Institute (BrainLat), Universidad Adolfo Ibáñez, Santiago, Chile, [3]Carl von Ossietzky University Oldenburg, Department Of Psychology, Oldenburg, Germany, [4]Brain and Mind Centre, University Of Sydney, Sidney, Australia, [5]Centro de Investigación y Modelamiento de Fenómenos Aleatorios (CIMFAV-Ingemat), Facultad De Ingeniería, Universidad De Valparaíso, Valparaíso, Chile, [6]Centre National de la Recherche Scientifique (CNRS), Institut Des Neurosciences Paris-saclay (neuropsi), Saclay, France, [7]Universidad de Valparaíso, Instituto De Neurociencia, Valparaíso, Chile

Integration and segregation are recognized as two fundamental principles of brain organization. The brain manage the transitions between different functional states, more segregated or integrated, through neuromodulatory systems. Recently computational and experimental works suggest a pro-integration (segregation) role of noradrenergic (cholinergic) neuromodulation. Here, we studied the effects of the cholinergic system on brain functional connectivity using both empirical fMRI data and computational modeling. The model, informed with neuroimaging data, was used to find causal mechanisms about the effects of cholinergic system on brain dynamics. We first analyzed the effects of nicotine on functional connectivity and network topology in resting-state conditions and during an attentional task. Then, we built a whole-brain neural mass model embedded into a human connectome for simulating the effects of nicotine. The drug was modeled decreasing both the global coupling and local feedback inhibition parameters of the model. We found that nicotine incremented functional segregation in both empirical and simulated data, and the effects are context-dependent: observed during task, but not in resting-state. In-task performance correlates with functional segregation, finding a link between functional network topology and behavior. Also, we observed that the particular regional density of the nicotinic acetylcholine α4β2 receptor is meaningful to explain the effects of nicotine at the whole-brain level. Our results suggest that cholinergic neuromodulation promotes functional segregation in a context-dependent fashion, propose biophysical mechanisms to simulate cholinergic neuromodulation, and explain how functional segregation could be desirable in visual-attentional tasks.

Structural Features of the Human Connectome That Facilitate the Switching of Brain Dynamics via Noradrenergic Neuromodulation.
The structural connectivity of human brain allows the coexistence of segregated and integrated states of activity. Neuromodulatory systems facilitate the transition between these functional states and recent computational studies have shown how an interplay between the noradrenergic and cholinergic systems define these transitions. However, there is still much to be known about the interaction between the structural connectivity and the effect of neuromodulation, and to what extent the connectome facilitates dynamic transitions. In this work, we use a whole brain model, based on the Jasen and Rit equations plus a human structural connectivity matrix, to find out which structural features of the human connectome network define the optimal neuromodulatory effects. We simulated the effect of the noradrenergic system as changes in filter gain, and studied its effects related to the global-, local-, and meso-scale features of the connectome. At the global-scale, we found that the ability of the network of transiting through a variety of dynamical states is disrupted by randomization of the connection weights. By simulating neuromodulation of partial subsets of nodes, we found that transitions between integrated and segregated states are more easily achieved when targeting nodes with greater connection strengths-local feature-or belonging to the rich club-meso-scale feature. Overall, our findings clarify how the network spatial features, at different levels, interact with neuromodulation to facilitate the switching between segregated and integrated brain states and to sustain a richer brain dynamics.

33600402: Coronel-Oliveros C, Cofré R, Orio P

Cholinergic neuromodulation of inhibitory interneurons facilitates functional integration in whole-brain models.
Segregation and integration are two fundamental principles of brain structural and functional organization. Neuroimaging studies have shown that the brain transits between different functionally segregated and integrated states, and neuromodulatory systems have been proposed as key to facilitate these transitions. Although whole-brain computational models have reproduced this neuromodulatory effect, the role of local inhibitory circuits and their cholinergic modulation has not been studied. In this article, we consider a Jansen & Rit whole-brain model in a network interconnected using a human connectome, and study the influence of the cholinergic and noradrenergic neuromodulatory systems on the segregation/integration balance. In our model, we introduce a local inhibitory feedback as a plausible biophysical mechanism that enables the integration of whole-brain activity, and that interacts with the other neuromodulatory influences to facilitate the transition between different functional segregation/integration regimes in the brain.

Prenatal exposure to ketamine in rats: Implications on animal models of schizophrenia.
Schizophrenia is a complex neuropsychiatric disorder characterized by hallucinations, delusions, anhedonia, flat affect and cognitive impairments. The aim of this study was to propose a prenatal treatment with ketamine, a psychedelic drug that acts as a non-competitive inhibitor of glutamate NMDA receptors, as a neurodevelopmental animal model of schizophrenia. The drug was applied (i.m. 60 mg.kg h) in pregnant Sprague-Dawley rats on gestational Day 14. Offspring behavior was studied on pubertal (4 weeks old) and adult (10 weeks old) stages. Also, hippocampal CA1-CA3 morphology was assessed in adult animals through a Nissl stain. Results showed a disinhibition and hyperactive behavior in pubertal animals exposed to ketamine, followed in adulthood with cognitive impairments, social withdrawal, anxiety, depression, and aggressive-like behaviors. In the hippocampus, a reduction of the CA3 layer thickness was observed, without changes in cell density. These results strongly suggest a robust link between prenatal pharmacologic manipulation of NMDA receptors and schizophrenia.

Slow cortical oscillations play a crucial role in processing the speech envelope, which is perceived atypically by children with developmental dyslexia. Here, we use EEG and natural speech listening paradigms to identify neural speech processing patterns that characterise and classify dyslexic children. Using a powerful linear method to derive supervised EEG spatial filters (CSP), we were able to accurately classify dyslexic and typically-developing children during a story listening task. Delta-band oscillations were particularly discriminative. Furthermore, accurate classifications for this story listening dataset could be derived from oscillatory spatial patterns from another EEG dataset, in which typically-developing and dyslexic children attended to rhythmic speech - the repetition of the syllable (“ba”) presented isochronously at 2Hz. The data demonstrate the feasibility of cross-dataset transfer learning of CSP features and the role of spatially-filtered delta-band oscillations in classifying dyslexia across very different speech tasks. This cross-dataset transfer may be due to the role of delta-band modulations in speech rhythm processing – a mechanism that is known to be atypical in dyslexia.

Aims: Essential tremor (ET) is considered the most common movement disorder (National Tremor Foundation, 2022), affecting up to one percent of adults over 40 years of age. Magnetic Resonance guided focused ultrasound (MRgFUS) thalamotomy is a proven treatment for ET (Miller et al, 2022), however its success is highly dependent on the accuracy of lesioning the target thalamic nucleus – the ventral intermediate nucleus (VIM). This study aimed to improve our understanding of target location via a data driven computational approach to visualise the treatment. **Methods:** The Schaltenbrand and Wahren (1977) stereotactic atlas was used to construct a model via the open-source software 3D Slicer (Fedorov, 2012). First, 20 of these atlas images were stacked in Matlab (R2021a, Mathworks Inc.), to obtain a resolution of 0.1mm per pixel. This data was imported into 3D Slicer to allow segmentation of the thalamus (including key nuclei such as VIM), and adjacent structures such as the internal capsule. The resulting structures were smoothed to produce the final three-dimensional model. **Results:** The resulting model was used to plot patient treatments and assess accuracy of targeting. Furthermore, the target locations from several international MRgFUS centres were mapped to compare the evolution of targeting in MRgFUS across centres and over time. **Conclusions:** This model provides a visualisation of targeting within the thalamus. The model will be developed into a thermal finite element model to fully understand clinical efficacy with regards to lesion location and sonication, to improve the clinical effect for people with essential tremor.

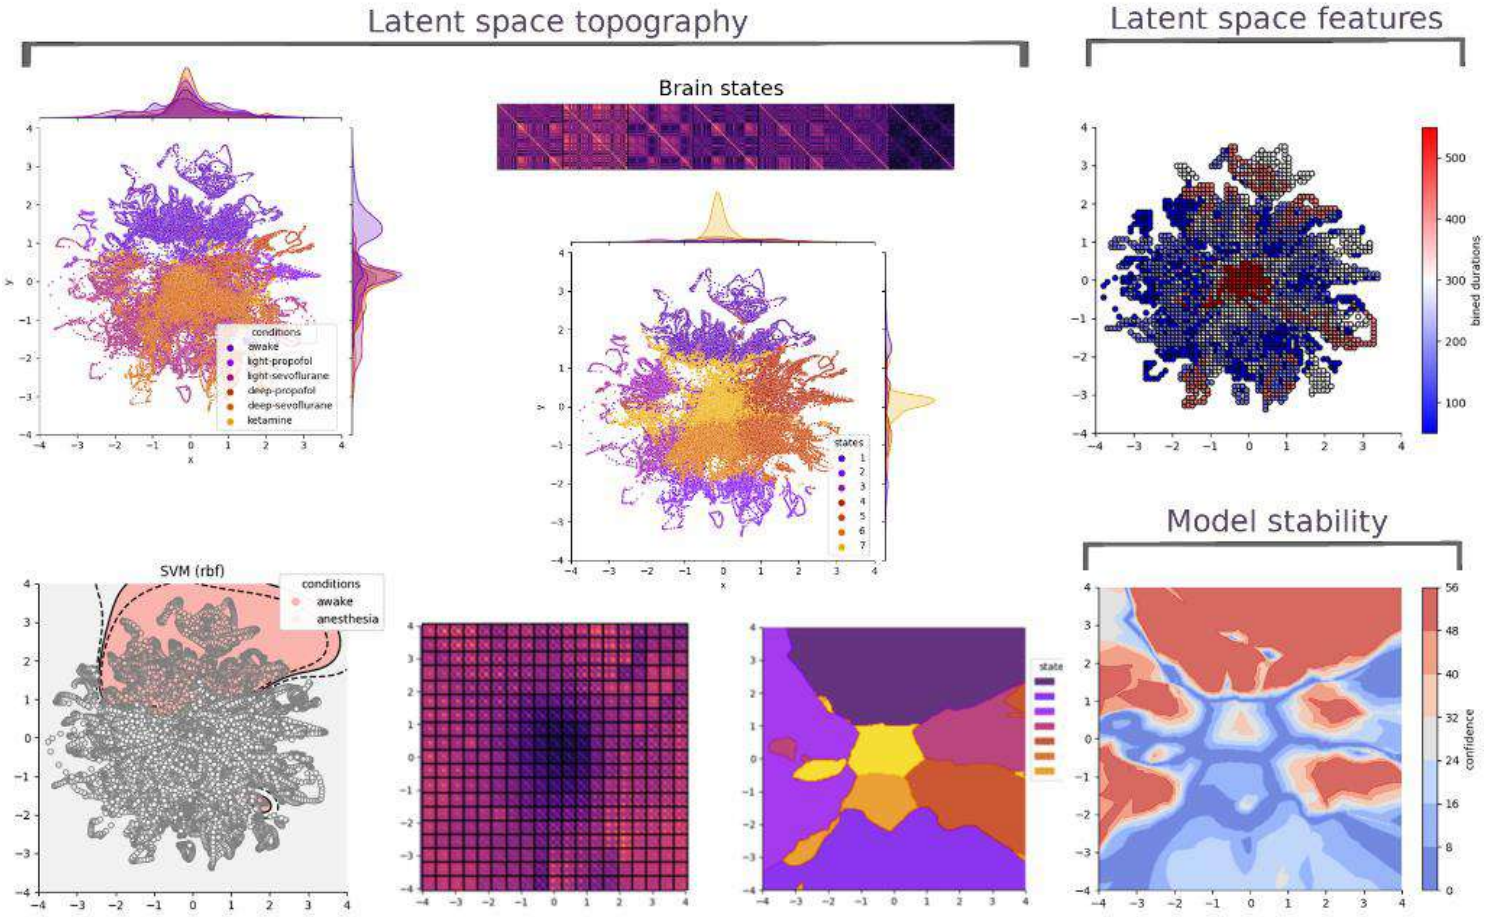
A GENERATIVE MODEL OF BRAIN STATES DYNAMIC IN NON-HUMAN PRIMATES BASED ON VARIATIONAL AUTO-ENCODER

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Chloé Gomez[1], Antoine Grigis[1,2], Lynn Uhrig[1,3], Béchir Jarraya[1,3,4]
[1]Commissariat à l'Énergie Atomique et aux Énergies Alternatives, Université Paris-Saclay, Neurospin Center, Gif-sur-Yvette, France, [2]Commissariat à l'Énergie Atomique et aux Énergies Alternatives, Neurospin Center, Gif-sur-Yvette, France, [3]Institut National de la Santé et de la Recherche Médicale U992, Cognitive Neuroimaging Unit, Gif-sur-Yvette, France, [4]University of Versailles, Université Paris-Saclay, Neurosurgery Department, Foch Hospital, Suresnes, France



Aims The states of consciousness are characterized by different configurations of resting-state fMRI (rs-fMRI) patterns. By applying k-means clustering to dynamic functional connectivity matrices (dFCs), we could identify repertoires of brain states that are specific to wakefulness and anesthesia-induced loss of consciousness. Recent studies show that a low-dimensional manifold keep information on the main properties of the different dynamic configurations. We hypothesize that by using deep learning models, we might characterize the structure of the brain states repertoire. **Methods** We previously acquired rs-fMRI in non-human primates during wakefulness or under anesthesia. We trained a dense-Variational Auto-Encoder to encode the dFCs to probability distributions in a 2D-space. Then we used the generative decoder to produce new realistic samples and extrapolate configurations. **Results** The latent space obtained contains ordered topography of brain states. The brain state

that is more correlated to the underlying brain structure occupies the central place surrounded by the other brain states. The generative approach of the model makes possible to reconstruct new brain states in a coherent and stable way despite the limited dataset size. **Conclusions** This is consistent with our previous work in which we demonstrated that the repertoire of brain states associated with wakefulness is rich, flexible and uncorrelated with brain anatomy; while the opposite occurs for the one associated with consciousness loss. By capturing essential information, our model helps visualizing and interpreting the dynamic brain states repertoire. In the future, we will model the transition probabilities, and trajectories across states of consciousness.

SEIZURE PREDICTION IN MEA SIGNALS WITH DEEP LEARNING

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Ángel Canal[1,2], Guillermo Hernández[2], Sara Rodríguez[1,2], Fernando De La Prieta[1,2], Juan Corchado[1,2]
[1]Institute for Biomedical Research of Salamanca, Bioinformatics And Intelligent Systems, Salamanca, Spain, [2]Universidad de Salamanca, Bisite Research Group, Salamanca, Spain

Epilepsy affects a large part of the world's population causing not only a lot of problems from a pathilogy point of view but also from the economic and social point of view of the patients. One of the treatment paradigms when the pharmacological approach is not effective is deep brain stimulation.
Currently, brain stimulation devices use predefined stimulation protocols that do not take into account the underlying situation of the brain at any given moment. Therefore, in this work we propose the development of an artificial intelligence algorithm to predict epileptic seizures from Microelectrode Array signals and thus be able to control the stimulation in a responsive way. Using a neural network based on Long Short-term memory neurons, an architecture has been established that is able to predict ictal events 2 minutes in advance, which is enough time to initiate seizure-avoiding stimulation. As an experimental basis, hippocampal slices recorded with a multi-electrode array have been used.
This algorithm opens the door to implementations in clinical devices and to a change in the current design of deep brain stimulation systems.

Inferior Colliculus Transcriptome After Status Epilepticus in the Genetically Audiogenic Seizure-Prone Hamster GASH/Sal.
The Genetic Audiogenic Seizure Hamster from Salamanca (GASH/Sal), an animal model of reflex epilepsy, exhibits generalized tonic-clonic seizures in response to loud sound with the epileptogenic focus localized in the inferior colliculus (IC). Ictal events in seizure-prone strains cause gene deregulation in the epileptogenic focus, which can provide insights into the epileptogenic mechanisms. Thus, the present study aimed to determine the expression profile of key genes in the IC of the GASH/Sal after the status epilepticus. For such purpose, we used RNA-Seq to perform a comparative study between the IC transcriptome of GASH/Sal and that of control hamsters both subjected to loud sound stimulation. After filtering for normalization and gene selection, a total of 36 genes were declared differentially expressed from the RNA-seq analysis in the IC. A set of differentially expressed genes were validated by RT-qPCR showing significant differentially expression between GASH/Sal hamsters and Syrian control hamsters. The confirmed differentially expressed genes were classified on ontological categories associated with epileptogenic events similar to those produced by generalized tonic seizures in humans. Subsequently, based on the result of metabolomics, we found the interleukin-4 and 13-signaling, and nucleoside transport as presumably altered routes in the GASH/Sal model. This research suggests that seizures in GASH/Sal hamsters are generated by multiple molecular substrates, which activate biological processes, molecular processes, cellular components and metabolic pathways associated with epileptogenic events similar to those produced by tonic seizures in humans. Therefore, our study supports the use of the GASH/Sal as a valuable animal model for epilepsy research, toward establishing correlations with human epilepsy and searching new biomarkers of epileptogenesis.

Smart Buildings IoT Networks Accuracy Evolution Prediction to Improve Their Reliability Using a Lotka-Volterra Ecosystem Model.
Internet of Things (IoT) is the paradigm that has largely contributed to the development of smart buildings in our society. This technology makes it possible to monitor all aspects of the smart building and to improve its operation. One of the main challenges encountered by IoT networks is that the the data they collect may be unreliable since IoT devices can lose accuracy for several reasons (sensor wear, sensor aging, poorly constructed buildings, etc.). The aim of our work is to study the evolution of IoT networks over time in smart buildings. The hypothesis we have tested is that, by amplifying the Lotka-Volterra equations as a community of living organisms (an ecosystem model), the reliability of the system and its components can be predicted. This model comprises a set of differential equations that describe the relationship between an IoT network

and multiple IoT devices. Based on the Lotka-Volterra model, in this article, we propose a model in which the predators are the non-precision IoT devices and the prey are the precision IoT devices. Furthermore, a third species is introduced, the maintenance staff, which will impact the interaction between both species, helping the prey to survive within the ecosystem. This is the first Lotka-Volterra model that is applied in the field of IoT. Our work establishes a proof of concept in the field and opens a wide spectrum of applications for biology models to be applied in IoT.

SELF-SUPERVISED LEARNING AS A GATEWAY TO REVEAL UNDERLYING DYNAMICS IN ANIMAL BEHAVIOUR

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Kevin Luxem[1], Petra Mocellin[1], Falko Fuhrmann[2], Stefan Remy[1,2]
[1]Leibniz Institute for Neurobiology, Cellular Neuroscience, Magdeburg, Germany, [2]German Center for Neurodegenerative Diseases, Neuronal Networks Group, Bonn, Germany

The brain is a dynamical system and its dynamics are reflected in the actions it performs. In order to understand brain functions, observable motion is a fundamental resource. Technological approaches towards understanding and dissecting the spatiotemporal order of animal motion are still in its infancy compared to approaches aiming at dissecting brain functions. Recent advances in representation and self-supervised learning can be leveraged to learn robust representations of animal behavior in an unprecedented manner. In this work, we explore combining autoregressive models with the notion of variational auto-encoding to learn robust spatiotemporal embeddings of animal behavior. By using a mouse model of beta amyloidosis as a use case, we show that our framework (VAME) not only identifies discrete behavioral motifs, but also captures their hierarchical representation. Thus, we present a novel and robust approach to learn the representation of animal motion, which is applicable to a wide range of experimental setups, models and conditions without requiring supervised or a-priori human interference.

ULTRA-RAPID VISUAL SEARCH IN NATURAL IMAGES USING ACTIVE DEEP LEARNING

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Jean-Nicolas Jeremie[1], Emmanuel Daucé[2], Laurent Perrinet[1]
[1]Institut de neurosciences de la Timone, Aix-marseille Université | Amu · Cnrs (umr7289), Marseille, France, [2]Ecole centrale Marseille, Aix-marseille Université | Amu · Institut De Neurosciences Des Systèmes (umr_s 1106 Ins), Marseille, France

Visual search, or the simultaneous localization and detection of a visual target of interest, is a vital task. Applied to the case of natural scenes, searching for example an animal (either a prey, a predator or a partner) constitutes a challenging problem due to large variability over numerous visual dimensions. Yet, biological visual systems are able to perform such detection efficiently in briefly flashed scenes in a very short amount of time. Deep convolutional neuronal networks (DCNNs) were shown to be well fitted to the image classification task. Previous models also managed to solve the visual search task by roughly dividing the image into sub-areas. This is at the cost, however, of computer-intensive parallel processing on relatively low-resolution image. Taking inspiration from natural vision systems, we develop here a model builds over the anatomical visual processing pathways observed in mammals, namely the "What" and the "Where" pathways. It operates in two steps, first by selecting regions of interest, before knowing their actual visual content, through an ultra-fast/low resolution analysis of the full visual field, and the second providing a detailed categorization over the detailed "foveal" selected region attained with a saccade. Modeling this dual-pathways architecture brings an efficient model of visual search as active vision and may allows to fill the gap with the shortcomings of DCNNs with respect to physiological performances. In the future, we expect to apply this model to better understand visual pathologies involving one of the two pathways while contributing to the computer vision field.

Aims Pain is a subjective experience typically measured through patient's self-report. Researchers have tried to achieve an objective measurement of pain and its relative biomarkers by developing machine learning (ML) algorithms. However, most of these studies do not consider that pain has also emotional components. Consequently, today there is no reliable model of pain prediction considering all its multifaceted aspects. We aim at investigating how emotional, cognitive, and physiological components are impacting pain perception. **Methods** To achieve this goal, ML techniques have been applied to data collected from 40 healthy and chronic pain patients, who underwent experimentally induced pain while their physiological and complete psychological profiles have been collected. Through explainable AI models we investigated which are the most important features to distinguish pain and to what type of measurement (physical or psychological) they belong. **Results** Our models were able to classify pain vs no pain with more than 90% of accuracy. We found that the most important features to detect pain in the physiological recordings belong to the EEG power spectral density and the derivative features of the SC. Most importantly, the pain level was identifiable through physiological recordings adjusted by a subjective bias, meaning that the reported pain level was dependent on a subjective perception of pain. **Conclusions** For the first time, ML is applied to give neuroscientific insights on biomarkers of the subjective pain perception. Our model has the potential of opening the way to personalized therapies based on a comprehensive evaluation of each individual's pain experience.

MODEL BASED META REINFORCEMENT LEARNING FOR ALCHEMY

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Homa Priya Tarigopula[1], Anders Malthe-Sørenssen[2], Mikkel Lepperød[3]
[1]University of Oslo, Department Of Biosciences, Oslo, Norway, [2]University of Oslo, Department Of Physics, Oslo, Norway, [3]Simula, Research Laboratory, Oslo, Norway

Meta-learning emphasises the 'learning to learn' paradigm where the similar characteristics between the tasks generate a common basis bearing relevance that extends beyond the trained tasks and acts as an inductive bias that helps the learning agent to quickly generalize to unseen tasks from the same distribution. For example during navigation, understanding the underlying structure of the environment can aid inferences when going back to an explored state from an unexplored point of view. Recent work by Whittington et al 2020 has shown that the underlying graph defining the structure once learnt is reusable across different environments consisting of different sensory observations, thus forming an invariant feature basis. This can be extenteded to the relational inference scenarios encountered by reinforcement learning (RL) agents. A recently introduced benchmark 'Alchemy' aims at challenging meta-RL by providing both a convenient interface and an optimal solution for assessing agent efficiency. The meta-RL agent navigating the alchemy environment is challenged with understanding the latent causal structure to excel at this task with maximum reward. We aim to train model-based meta-RL agents to solve alchemy, by introducing useful inductive bias for capturing the underlying structure of explored environments. We hypothesize that training such an agent, in addition to improving the meta-RL knowledge base, may help shed light on the interactions between Prefrontal cortex and Entorhinal cortex. Here, we present preliminary results from initial studies that show promising performance on the task compared to the two deep RL agents (VMPO, IMPALA) previously deployed to solve Alchemy.

EXPLORATION OF THE RESPECTIVE ROLES OF CORTEX AND BASAL GANGLIA IN CATATONIA WITH A COMPUTATIONAL MODEL.

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Lise Aubin[1,2], Marie Raffin[1,2], Ghilès Mostafaoui[3], David Cohen[2,4], Benoît Girard[4]
[1]Sorbonne Université, Isir, Paris, France, [2]Hôpital Pitié-Salpêtrière, Services De Psychiatrie De L'enfant Et De L'adolescent, Paris, France, [3]CY Cergy Paris University, Etis, Cergy-Pontoise Cedex, France, [4]CNRS - Sorbonne University, Institut Des Systèmes Intelligents Et De Robotique (isir), Paris, France

Catatonia is a psychomotor syndrome associating both motor and affective symptoms. One of the most characteristic symptoms of catatonia –posturing– corresponds to patients assuming unusual and uncomfortable body postures. No animal model of catatonia is available, impairing deeper experimental exploration of its physiological mechanisms. As such, the physiopathology of the syndrome is not fully understood. Its first-line treatment is high doses of benzodiazepines and related drugs, which suggests the implication of an excitation-inhibition imbalance. The dominant conception of catatonia focuses on frontal cortex disorders that would be relayed by the basal ganglia, resulting in the observed motor disorders. However, a large naturalistic cohort study shows significant organic morbidity with implication of basal ganglia dysfunction. As most of the basal ganglia neural populations are inhibitory, we hypothesize that the basal ganglia may indeed have a more direct role in catatonia. To investigate this hypothesis, we present here a biologically constrained computational model of the cortico-baso-thalamo-cortical loops, with which we explore the effects of attenuating the weight of inhibitions. For this first attempt at modeling catatonia with computational tools, we focus on the study of neural dynamics, and explore how irregular activity collapses to oscillatory regimes when inhibition is attenuated in the cortex, the basal ganglia, or both, and we use disconnection approaches to identify which circuit causes the oscillations.

THE FRACTAL CORTEX: A MULTI-SCALE SURFACE-PRESERVING ANALYSIS SUGGESTS ALL CORTICES ARE APPROXIMATIONS OF A SINGLE UNIVERSAL SHAPE

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Bruno Mota, Yujiang Wang
UFRJ, Instituto De Física, Rio de Janeiro, RJ, Brazil

The mammalian cerebral cortex is probably one of the most complex structures ever studied by science. At first glance, any attempt to express its diversity, or significant features thereof, from universal principles, would seem doomed to failure. Indeed, there are many ways of comparing the morphological features of cerebral cortices. In what follows, working from first principles, we will express cortical morphology using a more natural set of variables across length scales, rather than across spatial position. We will introduce an algorithm for 'melting' cortical shape that erases structural features smaller than a set scale while maintaning surface self-avoidance and topological structure, and show that this process occurs in a universal self-similar manner. Using this new framework, we will finally show that the morphology of all cerebral cortices analyzed so far, across both mammalian species and individuals, are approximations of a single, universal fractal shape; and that the main distinction between different cortical shapes is the range of scales at which this approximation remains valid. This universal description of the cortical shape is at the same time mechanistically insightful and in full agreement with empirical data across species and individuals. Prospectively, we hope this new framework for expressing and analyzing cortical morphology, besides revealing a hitherto hidden regularity of nature, can become a powerful tool to characterize and compare cortices of different species and individuals, across development and aging, and across health and disease.

DEEP LEARNING BASED PERSONALIZED OUTCOME PREDICTION AFTER ACUTE ISCHEMIC STROKE

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Dooyoung Kim[1,2], Jina Hong[1,3], A Yeon Kang[3], Hansol Lee[1], Kangho Choi[1], Jahae Kim[2,3]
[1]Chonnam National University Hospital, Neurology, Gwangju, Korea, Republic of, [2]Chonnam National University, Ai Convergence, Gwangju, Korea, Republic of, [3]Chonnam National University Medical School and Hospital, Nuclear Medicine, Gwangju, Korea, Republic of

Purpose The long-term risk of major vascular events after acute ischemic stroke (AIS) cannot be reliably assessed by traditional survival analysis at an individual level. We aimed to develop a personalized outcome prediction model using deep learning after AIS. **Methods** A total of 6,247 patients with AIS were enrolled in this study. The primary outcome was the occurrence of major adverse cerebro/cardiovascular events (MACE) over 12 months. We compared deep learning models (DeepSurv and DeepHit) with traditional survival models (Cox proportional hazards [CoxPH] and random survival forest [RSF]) using the time-dependent concordance (C^{td}) index and the mean absolute day error (MADE). **Results** The performances of the deep learning models (DeepSurv and DeepHit) were improved after adding the brain image features to clinical data (C^{td} index = 0.8303 and 0.8137, respectively). The performances were similar with the survival models of CoxPH (C^{td} index = 0.8059) and RSF (C^{td} index = 0.8352) for predicting MACE. The deep learning model of DeepHit had the lowest day error for predicting MACE. The MADE of the DeepSurv, DeepHit, CoxPH, and RSF models to predict MACE were 235.99 (95% CI, 200.25-273.73), 113.57 (95% CI, 88.87-141.45), 215.24 (95% CI, 178.34-253.02), and 303.24 (95% CI, 275.48-328.35), respectively, in the analyses with clinical and image factors. **Conclusion** This study showed that deep learning models developed using clinical data and brain images outperformed traditional survival models predicting MACE after AIS. Deep learning can improve the prediction of major vascular events and provide personalized outcome prediction in patients with AIS.

COMMUNICATION AND CAUSATION IN THE HUMAN BRAIN

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Kayson Fakhar, Claus Hilgetag, Fatemeh Hadaeghi
University Klinikum Eppendorf (UKE), Institute Of Computational Neuroscience, Hamburg, Germany

The human brain is a complex network where nodes communicate with one another via direct and indirect pathways. Graph-theoretical metrics are employed to understand how information is transmitted in such networks. Among these metrics, communicability describes the communication efficiency of two nodes given all direct and indirect paths existing between them. However, it is unclear if the brain harnesses its infrastructure optimally, such that the most efficient routes are the most influential ones. To address this point, we first represented each node of the human connectome as a dynamical system to model information propagation. We then used a game-theoretical framework called Multi-perturbation Shapley value Analysis (MSA) that systematically perturbs every possible combination of nodes to quantify their causal influences on each other. We found that communicability and MSA contributions provide qualitatively similar measures, indicating that nodes largely influence each other via direct connections and to a lesser extent also via indirect paths. However, contrasting results from the two approaches revealed that nodes deviate from the efficient communication channels by overusing the less efficient routes and underutilizing the more efficient ones (warm and cold entries in the figure below, respectively). Our results show that knowledge of the structural connectome of the brain by itself is insufficient for understanding its causal functional interactions.

ESTIMATING THE EXPOSOME SCORE FOR STRESS-RELATED MENTAL DISORDERS USING PREDICTIVE MODELLING

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Vera Karlbauer, Tanja Brückl, Elisabeth Binder
Max Planck Institute of Psychiatry, Department Of Translational Research In Psychiatry, Munich, Germany

Aims: Environmental risk factors for mental disorders are often studied in isolation and with no consideration of high correlations between exposures. The exposome approach addresses this problem by incorporating a multitude of environmental exposures over the entire life span and using advanced statistical techniques to appropriately model environmental risk. We aimed to demonstrate the validity of this approach for a transdiagnostic phenotype by constructing an exposome score for stress-related mental disorders using predictive modelling. **Methods:** The sample consisted of 269 cases with lifetime diagnoses of depression, anxiety disorders, or PTSD and 104 healthy controls. Measures of childhood abuse and neglect, lifetime trauma and loss events, and current and parental sociodemographic information were used as predictors. A simple sum score of dichotomized predictors was compared to a Gaussian Naïve Bayes model, simple logistic regression, and LASSO and Ridge penalized logistic regression models. Models were trained and tested via repeated 10x10 cross-validation. The area under the ROC curve was chosen as the primary outcome measure. **Results:** The LASSO-regularized model outperformed all other predictive models including the simple sum score (AUC_{LASSO}=.68, $AUC_{other\ models}$=.65-.67). The exposome score resulting from the coefficients of the LASSO model successfully discriminated cases from controls (OR=2.69, Nagelkerke's R^2=.28, p<.001) and significantly predicted several continuous measures of anxiety and depression (R^2=.09-.30, p<.05). **Conclusions:** These results indicate that the exposome approach is a valid model for studying environmental risk, yields better results than the use of simple unweighted sum scores, and can be applied to transdiagnostic phenotypes.

CLASSIFICATION OF COGNITIVE PERFORMANCE FROM HOME-BASED EEG REPEATED MEASUREMENTS IN OLDER ADULTS

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Laura Rueda-Delgado[1], Florentine Barbey[2], Alison Buick[3], John Dyer[4], Francesca Farina[2], Md Islam[1], Bernadette Mcguinness[5], Hugh Nolan[1], Peter Passmore[5], Robert Whelan[2], Brian Murphy[1]
[1]Cumulus Neuroscience, Ltd., Science & Analytics, Dublin, Ireland, [2]Trinity College Dublin, School Of Psychology, Dublin, Ireland, [3]Cumulus Neuroscience Ltd, Clinical Trial Operations, Belfast, United Kingdom, [4]Cumulus Neuroscience, Research And Development, Belfast, United Kingdom, [5]Queen's University Belfast, School Of Medicine, BL, United Kingdom

Aims: The earliest cognitive effects of neurodegeneration are challenging to detect on an individual basis. Common laboratory-based face-to-face assessments are usually snapshots of performance, hindering the detection of early cognitive changes. This can be addressed with remote digital assessment of cognition which enable repeated measurements in more naturalistic settings. This is the case of home-based electro-encephalography (EEG) combined with gamified laboratory tasks. Here we identified neurotypical participants who have low performance in the MoCA assessment (Montreal Cognitive Assessment) using home-based EEG recordings. **Methods:** Neurotypical older adults (N=91) were asked to perform a session 5 times a week during a 6-week or 12-week period while neurophysiology was recorded with a dry-EEG headset designed for unsupervised use in the home. Participants performed a gamified 2-stimulus visual oddball paradigm and a resting state (RS) paradigm. EEG features during the task and RS paradigm were extracted. Reaction time to the infrequent stimuli was extracted as a benchmark metric. Participants were labelled as high/low performers based on the median split of the MoCA score (27). Machine learning methods were applied to subsets of the data using repeated 10-fold nested cross validation to classify high/low performers. **Results:** Data with all features and only EEG features classified participants with an accuracy of 65-75% using random forests. This was above the accuracy obtained with behavioural data only (59%). **Discussion:** Features extracted from home-based EEG recordings during the visual oddball task and resting state can be used to identify participants with high (or low) cognitive performance.

PREDICTION OF CHRONIC PAIN ONSET FROM UK BIOBANK DATA

POSTER SESSION 02 - SECTION: MACHINE LEARNING FOR NEUROSCIENCE & PSYCHIATRY

Andrew Segerdahl, Suyi Zhang, Anushka Soni, Ben Seymour, Irene Tracey
University of Oxford, Clinical Neurosciences; Wellcome Centre For Integrative Neuroimaging, Oxford, United Kingdom

Aims: The purpose of this work is to apply machine learning methods to the UK Biobank dataset to identify potential mechanisms that predict the development of chronic pain. **Methods:** Participant data (n=8776) was included if s/he: i) reported no pain-related medical condition; ii) did not experience pain at the time of the FMRI vist (visit 2); and iii) completed the online follow-up pain questionnaire after visit 2 was completed. Those participants that answered “yes” to the question “troubled by pain or discomfort present for more than 3 months” were defined those that developed chronic pain (CP+). Data categories included: 1) clinical questionnaires; 2) brain imaging-derived phenotypes; and 3) preprocessed multimodal brain MRI data. Data compression was completed using the FSL tool BigFLICA. Random forest classification was then applied, and the most relevant classifier features were identified (Python; sklearn v0.24.2). Hyperparameters were tuned using 4-fold cross-validation (Optuna v2.9.1). **Results:** A total of 3163 (36%) of the participants developed CP+ (mean age: 63.3 s.d.=7.14; M/F ratio: 0.465) versus n=5613 (64%) that did not (mean age: 63.2 s.d.=7.31; M/F ratio:0.503). The best performing classifier that correctly identified CP+ participants achieved a balanced accuracy of 57.4% and an AUC of 60.1%. This classifier contains 298 features across all data categories. **Conclusions:** Preliminary analyses show that a combination of questionnaire (e.g., health satisfaction, insomnia, neuroticism, frequency of unenthusiasm, miserableness) and brain activation maps (task-evoked FMRI) are most important for predicting which UKB participants are likely to develop chronic pain at follow-up.

GEOMETRY OF POPULATION ACTIVITY IN SPIKING NETWORKS WITH LOW-RANK STRUCTURE

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Ljubica Cimesa[1], Lazar Ciric[1], Srdjan Ostojic[2]
[1]École Normale Supériure, Départment D'Études Cognitives, Paris, France, [2]École Normale Supérieure, Département D'Études Cognitives, Paris, France

An influential paradigm posits that computations in the brain can be understood at the collective level by studying the geometry of dynamics in the state space of joint activity of all neurons [Vyas et al 2020]. Within that framework, low-rank recurrent neural networks (RNNs) have emerged as a rich class of computational models for linking connectivity, the geometry of dynamics and computations [Mastrogiuseppe and Ostojic 2018]. RNNs are however highly abstract models, in which activity is represented in terms of continuous firing rates and basic biological constraints are lacking. Here we examine how results obtained using low-rank RNNs extend to more biologically plausible models where neurons interact through discrete action potentials. We consider randomly connected networks of excitatory and inhibitory integrate-and-fire neurons [Brunel 2000], to which we add a low-rank connectivity structure. We then compare the resulting geometry of spiking activity to the predictions of rate-based low-rank RNNs. We find that the predictions for the geometry of dynamics hold in spiking networks irrespective of the underlying regime of activity. The dynamics induced by the low-rank structure can moreover be highly nonlinear and develop multiple attractors or oscillations, and we show how they can be employed to perform nonlinear computations such as perceptual decision-making. Altogether our results demonstrate that the mechanistic insights obtained in abstract RNN models remain valid when taking into account additional biological constraints.

SHAPING ACTIVITY MANIFOLDS IN LOW-RANK RECURRENT NEURAL NETWORKS

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Arianna Di Bernardo[1], Francesca Mastrogiuseppe[2], Adrian Valente[1], Srdjan Ostojic[1]
[1]École Normale Supérieure, Group For Neural Theory, Paris, France, [2]University College London, Gatsby Computational Neuroscience Unit, London, United Kingdom

Mounting evidence across cortical circuits suggests that continuous variables are encoded in the brain in terms of continuous manifolds in neural activity space. For example head direction or position are represented by ring-shaped or torus-shaped manifolds [Chaudhuri et al. 2019, Gardner et al. 2022], and it has been hypothesized that such structures are signatures of continuous attractors generated by recurrent connectivity. A variety of computational models have been developed to explain how connectivity determines the properties of the resulting manifold, but a unifying picture has yet to emerge. For instance, ring attractors can be generated from different connectivity structures, giving rise to different properties at the individual neuron as well as the population level. In this work, we aim to identify general principles for how connectivity structures shape particular continuous attractors such as rings or tori. We approach this problem through the scope of low-rank recurrent neural networks, which are a recently introduced class of models providing a mathematical link between recurrent connectivity and neural latent dynamics [Mastrogiuseppe & Ostojic 2018]. We show how hidden symmetries in the low-rank structure of the connectivity matrix directly determine the geometrical properties of the continuous attractor. Using these principles, we derive a general blueprint to build continuous attractors of various dimensionalities, and with various levels of neural heterogeneity, unifying different previously proposed computational models.

DYNAMICAL ENTROPY IN POPULATION ACTIVITY OF ZEBRAFISH LARVAE

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Joshua Paik[1], Enrique Hansen[2], German Sumbre[2], Carina Curto[1]
[1]Penn State University, Mathematics, STATE COLLEGE, United States of America, [2]Ecole Normale Superieure, L'institut De Biologie, Paris, France

The optic tectum in zebrafish larvae displays rich assembly dynamics that can be observed via calcium imaging. The population activity is shaped by an abundance of inhibition, and displays attractor-like phenomena. To investigate the effects of stimulation on assembly dynamics, we defined a mass distribution on neurons that assigns to each neuron its fraction of the total population activity. The Shannon entropy of this distribution measures whether activity is concentrated on a few neurons or spread out evenly across the entire population. Using light sheet microscopy, spontaneous activity of ~2000 neurons was recorded for a period of two hours. In the experimental fish, there was a five-minute period of light dot stimulation presented one hour into the recording. We found that in the stimulated fish, the entropy of the mass distribution dropped significantly between the pre- and post-conditioning periods. This was true both for individual assemblies (see Figure) and the entire population. However, this entropy drop was not seen in control fish. Next, we investigated whether a simple inhibition-dominated network model could explain the entropy behavior. We constructed a random threshold-linear network of 1000 excitatory neurons in an inhibition dominated regime. In the conditioning phase, 30% of neurons were stimulated, which sharply decreased the population entropy. Surprisingly, these effects on the dynamics remained even after stimulation was removed: population entropy in the postconditioning period was significantly lower than in preconditioning. These findings suggest that the observed changes in entropy following stimulation may be a generic feature of inhibition-dominated network
dynamics.

IDENTIFYING THE ROLE OF TEMPORAL DYNAMICS IN THE AUDITORY SYSTEM.

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Othman Lahrach[1], Sophie Bagur[2], Brice Bathellier[3], Srdjan Ostojic[4]
[1]École Normale Supérieure, Départment D'Études Cognitives, Paris, France, [2]Institut Pasteur, Institut De L'audition, Paris, France, [3]Institut Pasteur, INSERM, Institut De L'audition, Paris, France, [4]École Normale Supérieure, Département D'Études Cognitives, Paris, France

Neural processing across sensory areas is often conceptualized as a series of static, feed-forward steps analogous to successive layers in a deep network. In contrast, the role of temporal dynamics generated by recurrent connectivity is only starting to be explored. In this study, we sought to uncover the role of temporal dynamics in sensory representations of static and dynamical sound features across the mouse auditory pathway. We examined large-scale calcium-imaging and electrophysiological recordings performed across the Inferior Colliculus, the Auditory Thalamus and the Auditory Cortex in response to a set of 140 auditory stimuli. The stimuli consisted of pure tones of various frequencies and amplitudes, as well as temporal modulations and superpositions thereof. We hypothesized that at a population level, frequency and amplitude are represented as continuous variables that give rise to continuous surfaces –manifolds– in the neural activity space. We first exploited dimensionality reduction methods on responses to static, pure sounds to identify the static frequency-amplitude manifolds in the different areas. We then compared the response to temporally modulated stimuli with the predictions of the static manifolds, and reasoned that the difference between the two corresponds to temporal processing. Altogether, our approach allows us to extract the representation of dynamical sound properties as it unfolds along the auditory pathway.

EXTRACTING COMPUTATIONAL MECHANISMS FROM NEURAL ACTIVITY USING LOW-RANK RECURRENT NEURAL NETWORKS

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Adrian Valente[1], Jonathan Pillow[2], Srdjan Ostojic[1]
[1]École Normale Supérieure, Group For Neural Theory, Paris, France, [2]Princeton University, Princeton Neuroscience Institute, Princeton, United States of America

An influential proposal within systems neuroscience posits that neural computations can be understood in terms of low-dimensional dynamics [Vyas et al 2020]. A key issue within that framework is that any given computational task may be compatible with a variety of dynamical mechanisms. To identify the mechanisms at play in the brain, it is therefore crucial to constrain models using recorded neural activity. Here we introduce a new approach for extracting low-dimensional dynamics from data, based on inferring low-rank recurrent neural networks (lrRNNs), a highly expressive and interpretable class of models [Mastrogiuseppe 2018, Dubreuil-Valente 2022]. We first apply our technique to synthetic data generated from full-rank RNNs trained on a variety of neuroscience tasks. We show that lrRNNs fitted to neural activity allow us to identify the collective computational mechanisms, and generate novel predictions for inactivations in the original RNNs. We then apply our methodology to data recorded from the primate prefrontal cortex in a context-dependent decision making task. Our approach allows us to assign computational roles to the different latent variables and provides us with a mechanistic model of the recorded dynamics, on which *in silico* experiments like inactivations can be performed.

In the primary visual cortex (V1) of higher mammals, spontaneous activity is modular and reflects the underlying structure - co-active regions are highly correlated to orientation maps[1]. This activity travels in sparse waves, in line with the propagation speed of unmyelinated lateral connections [2]. These two intertwined phenomena have so far only been studied separately, both experimentally [1,4] and computationally [5,2]. Furthermore, there is a lack of theoretical and mechanistic understanding of how these two phenomena interact with evoked activity. In this study we offer a unifying computational theory of structured spontaneous activity and traveling waves, by presenting a single large-scale spiking model of cat V1 that exhibits both phenomena. Our model exhibits spontaneous activity, travelling in sparse waves matching the conduction speed of V1 layer 2/3 horizontal connections, and is simultaneously correlated with the underlying orientation map. From the outset [3], our model demonstrates a wide variety of previously reported visually evoked properties, which shows the compatibility of the identified mechanisms of spontaneous travelling waves and structured activity with the mechanisms required by the evoked regime. 1. FLEXIBLE SENSORY REPRESENTATION LEARNING IN NON-STATIONARY ENVIRONMENTS

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

[1]University of Bern, Physiology, Bern, Switzerland, [2]Newcastle University, Adaptive Decisions Lab, Biosciences Institute, Newcastle upon Tyne, United Kingdom, [3]University of Zurich, Brain Research Institute, Zurich, Switzerland

Neural representations of sensory stimuli are modulated by internal states and beliefs about the world. Such top-down modulations—informed by context and task contingencies—are crucial to the perception and behaviour of animals but remain poorly understood. Inspired by the theoretical framework of temporal difference (TD) learning, we propose a task-dependent attentional feedback model of layer 2/3 pyramidal neurons in the primary somatosensory cortex (S1). It has long been proposed that top-down excitation of apical dendrites mediates attention. Our computational model learns to attend to stimuli that predict future rewards or punishments by raising their apical excitation proportionally to the magnitude of the TD error they produce. The TD error is fed back to apical dendrites through top-down signals involving a disinhibitory circuit of VIP+ and somatostatin (SST) expressing interneurons. If the learned attention allocation is no longer appropriate for the ongoing task, apical inhibition can revoke it. The lateral orbitofrontal cortex (lOFC) is responsive to changes in task contingency and has been found to target SST neurons, which are known to inhibit apical dendrites. By incorporating recorded lOFC activity into our model, we show that attention can be flexibly reallocated to in case a task change. Finally, the evolution of sensory representations predicted by the model is confirmed by S1 population imaging in mice. In summary, this work contributes to solving the credit assignment problem and understanding sensory representation learning in non-stationary environments by explaining how top-down apical attention prolongs and strengthens the neural representation of task-relevant information.

DOPAMINE-DEPENDENT PLASTICITY AND ATTRACTOR DYNAMICS COOPERATE IN BASAL GANGLIA-CORTICAL LOOP FOR MOTOR LEARNING

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Arthur Leblois[1], Thomas Boraud[1], David Hansel[2]
[1]Université de Bordeaux, Imn, Umr Cnrs 5293, Bordeaux, France, [2]CNRS, Cerebral Dynamics Plasticity And Learning Lab, Paris, France

Aims: The basal ganglia (BG) are subcortical nuclei known for their implication in motor control, sensorimotor integration and procedural learning. The BG shape activity patterns in their thalamocortical target structures to optimize actions. In particular, plasticity in BG output implements corrections in behavior to maximize reward and correct errors during learning. While BG models typically rely on action repertoires represented in discrete populations, shaping the right motor pattern during reward-driven learning is more difficult than simply choosing from separately encoded actions. **Methods**: Building on anatomical, physiological and behavioral evidence, we propose a model for the generation, learning and adaptation of reaching movement in the BG-cortical loop. In the motor cortex, a distributed representation of actions (population vector) drives continuous motor patterns. **Results**: We show that the BG shape sensorimotor transformation, driving cortical motor output patterns as a function of sensory cortical activity, corticostriatal synaptic weights and overall gains of the feedback loops. The attractor dynamics of the network confers the system with resistance to noisy input, persistent activity and complex spatiotemporal activity profiles in response to transient inputs. In a reinforcement learning paradigm reflecting classical conditioning tasks implemented labs, dopamine-dependent corticostriatal plasticity enables robust learning in the sensorimotor transformation. Following striatal dopamine depletion, the network loses its ability to shape cortical activity through attractor dynamics. Strong depletion may ultimately lead to the emergence of pathological beta oscillations. **Conclusion**: Our study suggests the BG-cortical network shapes motor output based on its rich closed-loop dynamics and corticostriatal dopamine-dependent plasticity.

Understanding how stable neural circuits implement flexible, context-dependent behavior is crucial to understanding cognition. How different brain areas interact through fixed communication channels to select relevant stimuli and ignore irrelevant ones remains to be fully elucidated. Here, we focus on the population dynamics previously recorded from the primary auditory cortex (A1) and prefrontal cortex (PFC), while rats exhibited flexible, context-dependent behavior. Specifically, rats performed stimuli discrimination (go/no-go) according to either the location or the pitch of the auditory stimuli, depending on the context that was not explicitly cued. Using linear decoders, we found that A1 represented relevant and irrelevant stimuli during both contexts. On the other hand, PFC exclusively represented the stimuli relevant for the ongoing context. This raised the question of how these areas interacted to effectively select the relevant stimulus in PFC, specifically assuming a fixed readout from A1. To address this question, we trained recurrent neural networks (RNN) with back-propagation on a similar task. We found that both the relevant and irrelevant stimuli were represented, similar to A1. We reverse-engineered the mechanism employed by these networks, predicting that different populations that selectively integrate the relevant stimuli can be identified by different context-specific activity during the pre-stimulus period. Motivated by these predictions, we found two distinct populations in A1, each discriminating more strongly the relevant stimuli in its preferred context. Finally, we built a multi-area RNN in which decision and context were communicated feedforward and feedback, respectively, through fixed channels, inspired by the communication subspace hypothesis.

Establishing accurate as well as interpretable models of neural networks activity is an open challenge in systems neuroscience. Here we infer an energy-based generative network model of the anterior rhombencephalic turning region (ARTR) of zebrafish larvae using calcium-imaging recordings of the spontaneous activity of hundreds of neurons. While our data-driven model is trained to solely reproduce the short-term statistics of the neural activity, its dynamics exhibits persistence on much longer time scales. The model's persistence time decreases with water temperature in agreement with neuronal and behavioral observations. Mathematical analysis of the model unveils a low-dimensional landscape-based representation of the population activity where the long-term dynamics reflects slow Arrhenius-like activated processes between metastable activity states. We show how this effective landscape is modified in the presence of light stimuli, which allows us to reinterpret previous experiments characterizing the visually-driven operation of the ARTR.

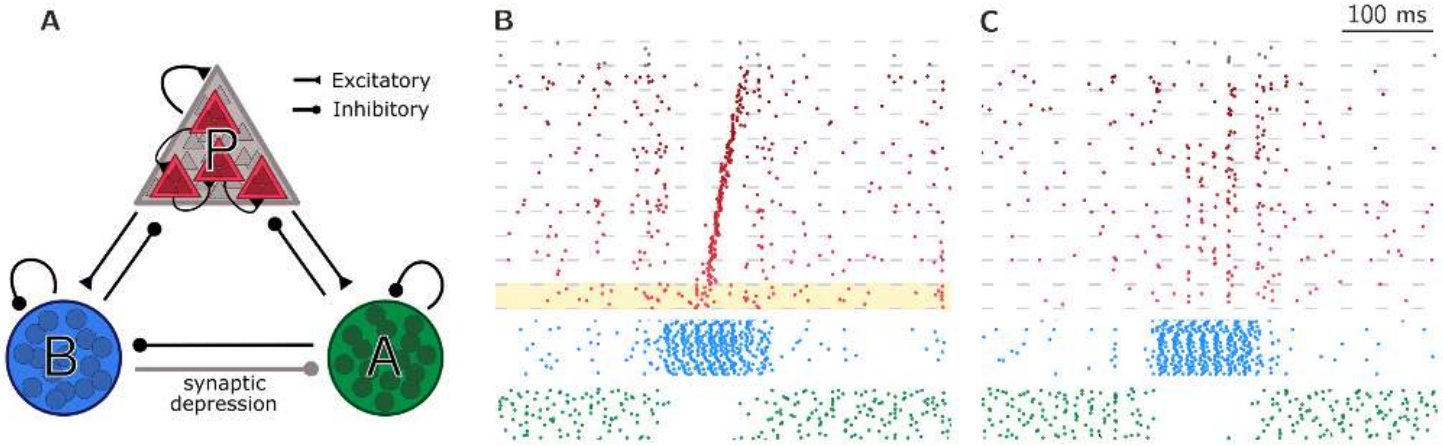
MEMORY REPLAY IN A DISINHIBITION-BASED MODEL OF HIPPOCAMPAL SHARP-WAVES

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Gaspar Cano[1], Nikolaus Maier[2], Dietmar Schmitz[2], Richard Kempter[1]
[1]Humboldt-Universität zu Berlin, Institute Of Biology, Berlin, Germany, [2]Charité – Universitätsmedizin Berlin, Neuroscience Research Center, Berlin, Germany

The hippocampus encodes new episodic memories during active wakefulness (Buzsáki, *Neuroscience*, 1989), which are gradually consolidated into the neocortex through sharp wave-ripple (SWR) associated replays. Chenkov et al. (*PLOS Comput. Biol.*, 2017) showed that balanced recurrent spiking networks are capable of replaying memory sequences, but sharp-wave dynamics were not considered. Evangelista et al. (*J Neurosci*, 2020) introduced a disinhibition-based homogeneous network with two different classes of interneurons, explaining sharp-wave dynamics, but replay was not investigated. Our work combines these results and shows how disinhibition-based networks can produce spontaneous sharp-waves while replaying encoded sequences. We model neuronal activity in a slice of CA3 rodent hippocampus with a three-population spiking network governed by disinhibition. To investigate replay, we embed sequentially connected assemblies in the pyramidal cell population (Fig-A). We find that a stored sequence can be replayed during spontaneous SWRs if we bias the network, e.g., by a small enduring depolarization of the initial assembly (Fig-B); replay can also be elicited by transient stimulation of a specific assembly (as in Chenkov et al., 2017). Without bias, there is no replay, and the network exhibits global bursts of activity (Fig-C). These bursts emerge from the SWR-state's tendency to generate oscillations in the low-gamma frequency
range.



Overall, we specify conditions under which replay succeeds or fails in such models, improving the understanding of the mechanisms governing sharp-waves and memory replay.

Recent developments of new and powerful brain activity recording techniques, combined with the increasing anatomical knowledge provided by atlases and the growing understanding of neuromodulation principles, are allowing the study of the brain at a whole new level, paving the way to the creation of data-driven extremely detailed effective network models. In this

work, aiming at reproducing the complex spatio-temporal dynamics of slow waves observed in experimental recordings of the cortical hemisphere of a mouse under ketamine anesthesia (A), a two-step inference procedure is proposed (B). First, *inner loop*, parameters of a mean-field model are optimized by likelihood maximization, exploiting anatomical knowledge to define connectivity priors; then, *outer loop*, the space of “external" parameters is explored in search of an optimal match between the simulation outcome and the data, to enrich the spontaneous activity generated by the model with the desired variety of dynamical features observed in the data. The validation of the model relies on the development of a versatile ensemble of analysis tools, applicable to both experimental and simulated data and capable of identifying and quantifying the spatio-temporal propagation of waves across the cortex; the tools enable the comparison of wave dynamics, evaluating the differences in the distribution of local observables (speed, direction, frequency, C), and, in the channel space, through the multivariate gaussian approach. Thanks to the interplay between data analysis and inference, the so-tuned model is capable of reproducing most of the non-stationary and non-linear dynamics displayed by biological networks (D).

MOTION INTENTION PREDICTION

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Marie Schmidt[1], Tobias Glasmachers[2], Ioannis Iossifidis[1]
[1]University of Applied Sciences Ruhr West, Computer Science, Mülheim an der Ruhr, Germany, [2]Ruhr University, Institute For Neural Computation, Bochum, Germany

Motion intention prediction is the key to robot-assisted rehabilitation systems. These can rely on various biological signals. One commonly used signal is the muscle activity measured by an electromyogram that occurs between 50-100 milliseconds before the actual movement, allowing a real-world application to assist in time. We show that upper limb motion can be estimated from the corresponding muscle activity. To this end, eight-arm muscles are mapped to the joint angle, velocity, and acceleration of the shoulder, elbow, and wrist. For this purpose, we specifically develop an artificial neural network that estimates complex motions involving multiple upper limb joints. The network model is evaluated concerning its ability to generalize across subjects as well as for new motions. This is achieved through training on multiple subjects and additional transfer learning methods so that the prediction for new subjects is significantly improved. In particular, this is beneficial for a robust real-world application. Furthermore, we investigate the importance of the different parameters such as angle, velocity, and acceleration for simple and complex motions. Predictions for simple motions along with the main components of complex motions achieve excellent accuracy while joints that do not play a dominant role during the motion have comparatively lower accuracy.

20 Hz Steady-State Response in Somatosensory Cortex During Induction of Tactile Perceptual Learning Through LTP-Like Sensory Stimulation.
The induction of synaptic plasticity requires the presence of temporally patterned neural activity. Numerous cellular studies in animals and brain slices have demonstrated that long-term potentiation (LTP) enhances synaptic transmission, which can be evoked by high-frequency intermittent stimulation. In humans, plasticity processes underlying perceptual learning can be reliably induced by repetitive, LTP-like sensory stimulation. These protocols lead to improvement of perceptual abilities parallel to widespread remodeling of cortical processing. However, whether maintained rhythmic cortical activation induced by the LTP-like stimulation is also present during human perceptual learning experiments, remains elusive. To address this question, we here applied a 20 Hz intermittent stimulation protocol for 40 min to the index-, middle- and ring-fingers of the right hand, while continuously recording EEG over the hand representation in primary somatosensory cortex in young adult participants. We find that each train of stimulation initiates a transient series of sensory-evoked potentials which accumulate after about 500 ms into a 20 Hz steady-state response persisting over the entire period of the 2-s-train. During the inter-train interval, no consistent evoked activity can be detected. This response behavior is maintained over the whole 40 min of stimulation without any indication of habituation. However, the early stimulation evoked potentials (SEPs) and the event-related desynchronization (ERD) during the steady-state response change over the 40 min of stimulation. In a second experiment, we demonstrate in a separate cohort of participants that the here-applied pneumatic type of stimulation results in improvement of tactile acuity as typically observed for electrically applied 20 Hz intermittent stimulation. Our data demonstrate that repetitive stimulation using a 20 Hz protocol drives rhythmic activation in the hand representation of somatosensory cortex, which is sustained during the entire stimulation period. At the same time, cortical excitability increases as indicated by altered ERD and SEP amplitudes. Our results, together with previous data underlining the dependence of repetitive sensory stimulation effects on NMDA-receptor activation, support the view that repetitive sensory stimulation elicits LTP-like processes in the cortex, thereby facilitating perceptual learning processes.

Bumblebee visual allometry results in locally improved resolution and globally improved sensitivity.
The quality of visual information that is available to an animal is limited by the size of its eyes. Differences in eye size can be observed even between closely related individuals, yet we understand little about how this affects vision. Insects are good

models for exploring the effects of size on visual systems because many insect species exhibit size polymorphism. Previous work has been limited by difficulties in determining the 3D structure of eyes. We have developed a novel method based on x-ray microtomography to measure the 3D structure of insect eyes and to calculate predictions of their visual capabilities. We used our method to investigate visual allometry in the bumblebee and found that size affects specific aspects of vision, including binocular overlap, optical sensitivity, and dorsofrontal visual resolution. This reveals that differential scaling between eye areas provides flexibility that improves the visual capabilities of larger bumblebees.

AN INHIBITORY NETWORK MODEL EXPLAINS THE TRANSIENT DYNAMICS OF HIPPOCAMPAL RIPPLE OSCILLATIONS

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Natalie Schieferstein[1], Tilo Schwalger[2], Benjamin Lindner[3], Richard Kempter[1]
[1]Humboldt-Universität zu Berlin, Institute For Theoretical Biology, Berlin, Germany, [2]Technische Universität Berlin, Institute For Mathematics, Berlin, Germany, [3]Humboldt-Universität zu Berlin, Physics Department, Berlin, Germany

Hippocampal ripple oscillations have been implicated in important cognitive functions such as memory consolidation (Buzsáki, 1989). The mechanisms underlying ripple generation however are still debated. Modeling studies have shown that interneuron networks can produce oscillations in the ripple-band (140-220 Hz) (Brunel & Hakim, 1999; Donoso, 2018) and even exhibit the experimentally observed intra-ripple frequency accommodation (IFA) — an asymmetric decrease in the instantaneous frequency within a ripple event (Donoso, 2018; Ponomarenko, 2004).
Here we show that IFA is an inherent feature of the inhibition-based ripple model and explain its mechanism. We consider a network of leaky integrate-and-fire units with delayed inhibitory coupling receiving white noise and a common excitatory drive. In the mean-field limit the population rate and the density of membrane potentials are described by the Fokker-Planck Equation. Focusing only on the mean-driven dynamics for strong drive we can approximate analytically the frequency and the amplitude of the network oscillation as a function of the external drive. Numerical simulations verify that the approximation works in a large parameter regime. We show that for fast changing, sharp wave-like drive the network frequency response is asymmetric due to a speed-dependent hysteresis effect in the oscillation amplitude of the mean membrane potential. We predict that IFA vanishes in the limit of slowly changing drive, which can be tested optogenetically.
Our results demonstrate how understanding transient features of ripple oscillations can guide model selection. Buzsáki, Neuroscience, 1989

FLYING CLOSE TO THE PRECIPICE - THE BREAKING POINT OF THE CONTINUOUS QUASI-ATTRACTOR

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Francesca Schönsberg[1], Remi Monasson[2], Alessandro Treves[1]
[1]SISSA, Cognitive Neuroscience, Trieste, Italy, [2]Ecole Normale Superieure, Physics, PARIS, France

Small mammals, like larger ones, navigate in complex territories. It is believed that they create *cognitive maps* of the environments they explore. Spatially selective cells in the hippocampal formation are neuronal candidates involved in this capability. In the development of mathematically defined network models, it has been hypothesized that the dynamics underlying the retrieval of place cell maps could be driven by *continuous attractors*. Such models typically assume homogeneity across units. However, the wilder the environment the more place cells seem to be activated unevenly. Recently published recordings of place cells in bats flying in a 200*mt* long track show, for example, multiple fields of variable width and peak rate. Can a 1D continuous attractor be established, to encode also such complex nonuniform activity? In this poster we argue that it can, if relaxing the requirement of a continuous manifold of fixed points, to a continuous dynamical flow. We see, indeed, that the stable states which persist with noisy maps, still lie on the manifold, inducing an effective flow along it. We call this mathematical object a *continuous quasi-attractor*. We find that there is a critical level of noise at which the quasi-attractive manifold abruptly breaks, through a phase transition. Applying our analysis to the experimental recordings measured in bats, we see that they lie close to the edges of the transition. This result leads us to hypothesize that place maps may be effectively memorized in a 1D continuous quasi-attractive manifold.

Efficiency of Local Learning Rules in Threshold-Linear Associative Networks.
We derive the Gardner storage capacity for associative networks of threshold linear units, and show that with Hebbian learning they can operate closer to such Gardner bound than binary networks, and even surpass it. This is largely achieved through a sparsification of the retrieved patterns, which we analyze for theoretical and empirical distributions of activity. As reaching the optimal capacity via nonlocal learning rules like back propagation requires slow and neurally implausible training procedures, our results indicate that one-shot self-organized Hebbian learning can be just as efficient.

CONTEXTUAL CONTROL OVER EPISODIC MEMORY THROUGH HIERARCHICAL PREDICTIVE PROCESSING

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Hugo Chateau-Laurent, Frederic Alexandre
Inria, Computer Science, Talence, France

Aims: The ability to rapidly form pattern-separated memories in the hippocampus comes with a risk of storing mutually inconsistent memory traces. Cognitive control over memory encoding and retrieval leverages context and goal information to resolve conflicts between similar episodes and to improve behavioral flexibility. Experimental evidence pointing to the prominent role of prefrontal-hippocampal interactions for achieving this have accumulated. However, the implementation details of this function are not yet known. Methods: We consider two existing biologically-inspired neural networks that have been proposed to account for hippocampal and prefrontal functions separately. The hippocampal module is a self-supervised autoencoder that learns to predict incoming sensory information. The prefrontal component is a hierarchical network in which individual layers learn to predict lower layers' prediction errors given the current context, and bias their predictions accordingly. We explore how the prefrontal cortex can be used to bias hippocampal activity by comparing different combinations of these two modules. Results: We confront the resulting models to experimental data of rodents learning two conflicting lists of stimulus pairs with selective inactivations of the prefrontal cortex and the medial temporal lobe. The ability of the resulting models to reproduce these findings is evaluated and contributes to the understanding of the functional involvement of different prefrontal-hippocampal anatomical pathways. Conclusion: Our results participate in guiding the development of prefrontal-hippocampal models. Such models will play a pivotal role in understanding high-level episodic memory functions beyond stimulus-driven recall, including goal-directed memory retrieval and imagination.

DISCOVERING LOW-DIMENSIONAL INTERPRETABLE DYNAMICS FROM HIGH-DIMENSIONAL NEURONAL ACTIVITY

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Nosratullah Mohammadi[1], Anne-Lise Giraud[1,2], Timothée Proix[1]
[1]University of Geneva, Department Of Basic Neurosciences, Geneva, Switzerland, [2]Institut Pasteur, INSERM, Institut De L'audition, Paris, France

Recent improvements in brain recording techniques have provided tools to record activity from hundreds to thousands of neurons simultaneously. Modeling and interpreting the resulting spike train data is a challenging task that is central to the quest of understanding brain functions. For this task, data-driven models such as point-process generalized linear models (PPGLMs) have been developed to fit and predict high-dimensional neuronal activity. Continuous approximations and basis projections of PPGLMs have previously been introduced to uncover the latent underlying dynamics. Yet, the question of interpreting those equations with regards to functional behavior remains difficult. On the other hand, frameworks such as structured flows on manifolds (SFM) propose a compelling description of behavior using interpretable dynamical systems, but remain detached from actual recordings. To overcome this gap between models, we analytically performed separation between two time scales of the continuous approximation of the PPGLM equations. In the first fast time-scale, high-dimensional dynamics collapse into a low-dimensional manifold, effectively constraining the set of possible behaviors. In the second slow time-scale, trajectories are traced out on the manifold to represent a particular behavior. We demonstrated the functional relevance of this decomposition in simulations of neuronal networks, and derived the resulting constraints on the network connectivity matrices. These simulations provide a testbed for the proposed framework, which will be next applied to human microelectrode array recordings during speech processing task, and opens new avenues for the analyses of neural data.

DYNAMICAL EVOLUTION OF ELECTRICALLY COUPLED NEURONS THAT PARTICIPATE IN THE COORDINATION OF SEQUENTIAL NEURAL ACTIVITY

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Pablo Sanchez-Martin, Blanca Berbel, Rafael Levi, Roberto Latorre, Pablo Varona
Universidad Autónoma de Madrid, Departamento De Ingeniería Informática, Madrid, Spain

Many central pattern generator circuits (CPGs) contain electrically coupled cells whose activity show different synchronization degrees. CPGs generate robust sequential activations that result in highly coordinated motor activity. We assessed the contribution of electrically coupled cells in shaping cycle-by-cycle intervals that define robust sequences. By using a mixed experimental and modeling approach, we characterized the level of synchronization, the dynamical evolution of membrane potential in electrically coupled cells, and the relationship between the level of synchronization and the duration and variability of time intervals that build robust sequences.

Experiments in the pyloric CPG of *Carcinus maenas* were performed with intracellular recordings of the two electrically coupled PD neurons and the LP cell. The coupled PDs showed a variable level of synchronization progressing along the bursts. The spike timing was measured unveiling an adaptive delay and transient desynchronizations. Time intervals between the LP bursts were also quantified. A conductance-based model of the CPG was employed to study the effect of altering the electrical conductance between the PD neurons to match the synchronization level observed in the experiments. We also evaluated the variability of the intervals which build the sequence cycle-by-cycle in the model.

We related the observed interval variability to the evolving synchronization between the PD neurons. Our joint experimental/modeling results indicate that the coordination of time intervals that define robust CPG sequences is shaped both by the inhibitory chemical interaction between cells and the dynamical coupling of the electrical synapses.

MODELING PARALLEL SPECIALIZED PATHWAYS OF MAMMALIAN VISUAL SYSTEM

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Shahab Bakhtiari[1], Blake Richards[2,3]
[1]McGill University, Computer Science, Montreal, Canada, [2]McGill University, The Neuro, Montereal, Canada, [3]McGill University, Mila (the Québec Institute For Artificial Intelligence), Montréal, Canada

Aims: Visual system of mammals is comprised of two parallel pathways: the “what” and the “where” pathways which are specialized for object categorization and movement, respectively. Therefore, an artificial neural network (ANN) model of mammalian visual systems should also have the same specialized parallel pathways. In this work, we studied the sufficient and necessary factors for learning the “what” and “where” representations in an ANN. **Methods:** We trained an ANN with two segregated parallel pathways with a combination of path-specific and shared loss functions. We used two methods to evaluate the type of learned representations in our model: 1) linear evaluation on downstream tasks, such as motion discrimination and object categorization, and 2) evaluatng the similarity of the ANN with the “what” and “where” pathways of mouse and monkey visual systems using Representational Similarity Analysis (RSA). **Results:** We show that training an ANN that has two parallel pathways with a self-supervised prediction loss function is sufficient for learning both “what”- and “where”-like representations. However, we show that additional, path-specific loss functions are necessary to further encourage and stabilize the learning of each type of representation within the two pathways. For example, adding the self-motion estimation loss to one of the two pathways leads to learning a better “where”-like pathway in our ANN. **Conclusions:** Our results show that an ANN with segregated parallel pathways trained with a combination of a global self-supervised prediction and path-specific loss functions can explain the development of parallel specialized pathways in mammalian visual systems.

Training with optic flow stimuli promotes recovery in cortical blindness.
Cortical blindness is a form of severe vision loss that is caused by damage to the primary visual cortex (V1) or its afferents. This condition has devastating effects on quality of life and independence. While there are few treatments currently available, accumulating evidence shows that certain visual functions can be restored with appropriate perceptual training: Stimulus sensitivity can be increased within portions of the blind visual field. However, this increased sensitivity often remains highly specific to the trained stimulus, limiting the overall improvement in visual function.

Visual perceptual learning generalizes to untrained effectors.
Visual perceptual learning (VPL) is an improvement in visual function following training. Although the practical utility of VPL was once thought to be limited by its specificity to the precise stimuli used during training, more recent work has shown that such specificity can be overcome with appropriate training protocols. In contrast, relatively little is known about the extent to which VPL exhibits motor specificity. Previous studies have yielded mixed results. In this work, we have examined the effector specificity of VPL by training observers on a motion discrimination task that maintains the same visual stimulus (drifting grating) and task structure, but that requires different effectors to indicate the response (saccade vs. button press). We find that, in these conditions, VPL transfers fully between a manual and an oculomotor response. These results are consistent with the idea that VPL entails the learning of a decision rule that can generalize across effectors.

The Role of the Subthalamic Nucleus in Inhibitory Control of Oculomotor Behavior in Parkinson's Disease.
Inhibiting inappropriate actions in a context is an important part of the human cognitive repertoire, and deficiencies in this ability are common in neurological and psychiatric disorders. An anti-saccade is a simple oculomotor task that tests this ability by requiring inhibition of saccades to peripheral targets (pro-saccade) and producing voluntary eye movements toward the mirror position (anti-saccades). Previous studies provide evidence for a possible contribution from the basal ganglia in anti-

saccade behavior, but the precise role of different components is still unclear. Parkinson's disease patients with implanted deep brain stimulators (DBS) in subthalamic nucleus (STN) provide a unique opportunity to investigate the role of the STN in anti-saccade behavior. Previous attempts to show the effect of STN DBS on anti-saccades have produced conflicting observations. For example, the effect of STN DBS on anti-saccade error rate is not yet clear. Part of this inconsistency may be related to differences in dopaminergic states in different studies. Here, we tested Parkinson's disease patients on anti- and pro-saccade tasks ON and OFF STN DBS, in ON and OFF dopaminergic medication states. First, STN DBS increases anti-saccade error rate while patients are OFF dopamine replacement therapy. Second, dopamine replacement therapy and STN DBS interact: L-dopa reduces the effect of STN DBS on anti-saccade error rate. Third, STN DBS induces different effects on pro- and anti-saccades in different patients. These observations provide evidence for an important role for the STN in the circuitry underlying context-dependent modulation of visuomotor action selection.

NONLINEAR OPTIMAL CONTROL OF NEURAL POPULATIONS

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Lena Salfenmoser, Klaus Obermayer
Technical University of Berlin, Institute Of Software Engineering And Theoretical Computer Science, Berlin, Germany

We apply methods from nonlinear optimal control theory to a biophysical neural mass model to study optimal control strategies and their effects on neural populations. External control is realized by time-dependent inputs to two mutually coupled populations of excitatory and inhibitory neurons. Optimality is defined by cost functions that trade the deviation of the controlled variable from its target value against the ”strength” of the control, which is quantified by the 1- and 2-norms of the control signal. We focus on a bistable region in state space where one low- (”down state”) and one high-activity (”up state”) stable fixed point coexist. We search for the most cost-efficient control function to switch between both states. We compare two types of control signals, which mimic either the ion flow across a neuron’s cell membrane ("current control"), or synaptic inputs from other connected neurons ("rate control"). We analyze optimal external stimulation for a deterministic system, and for a more realistic, stochastic system. Cost-efficient control strategies consist of a pulse of finite duration, which – for deterministic systems – pushes the state variables only minimally into the basin of attraction of the target state. For stochastic processes, control amplitudes are increased to reliably push the system into another state. Penalizing control strength via the averaged 1-norm (2-norm) yields finite inputs along one (vs. several) input channels. Restrictions in transition time result in faster transitions produced by larger inputs. Our study highlights the applicability of nonlinear optimal control to understand neuronal processing under constraints better.

NETWORK MECHANIMS UNDERLYING LONG-DISTANCE DEPENDENCIES

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Alexis Dubreuil[1], Vimala Maillard[1], Arthur Leblois[2]
[1]Université de Bordeaux - CNRS, Centre Broca Nouvelle Aquitaine, Bordeaux, France, [2]CNRS - Université de Bordeaux, Neuroscience, Bordeaux, France

Sequential behaviors such as language or bird songs are structured in time. This structure relies on the notion of long-distance-dependencies: transitions between words depend on the identity of words produced in the past. Here we propose network mechanisms supporting such dependencies. To do so we trained artificial neural networks to produce a minimal set of sequences exhibiting long-distance-dependencies. By reverse-engineering the trained networks we found this to rely on two superposing neural sequences, one responsible for the production of the motor sequence and another one encoding a contextual memory. We show how these two sequences are supported by neural activity and network connectivity and how they interact with each other to decide on transitions between words. We discuss similarities between the neural activity of our artificial neural networks and neural correlates of long-distance-dependencies that have recently been exposed in songbirds.

A HYBRID COMPUTATIONAL MODEL OF THE HIPPOCAMPAL FORMATION TO REPLICATE THETA-NESTED GAMMA OSCILLATIONS AND THETA PHASE RESET DURING NEUROSTIMULATION

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Nikolaos Vardalakis[1,2], Amélie Aussel[1,2], Nicolas Rougier[1,2], Fabien Wagner[1]

Theta and gamma oscillations in the hippocampal formation play a crucial role in memory processes and are disrupted in several neurological disorders. Recently, electrical neurostimulation of the human entorhinal area has been shown to enhance memory encoding, but the underlying mechanisms need to be investigated. Here, we aimed to validate the hypothesis that neurostimulation entrains theta-gamma oscillations and induces phase reset of theta oscillations, through a novel hybrid computational model that replicates both theta-gamma hippocampal oscillations and theta phase reset. Specifically, we used an existing biophysically realistic model of the hippocampal formation able to generate theta-nested gamma oscillations, and interfaced it with abstract Kuramoto oscillators that dynamically generate theta oscillations and theta phase reset. Biophysically realistic neurons were modeled using the Hodgkin-Huxley formalism and connected based on anatomical data from the literature. The set of Kuramoto oscillators had reciprocal connections with the CA1 field of the hippocampus and was meant as an abstract representation of the generation of hippocampal theta, which is thought to originate mainly from the medial septum. Our model replicates both theta-nested gamma oscillations and theta phase reset, and can be used to probe the effects of different neurostimulation protocols on theta and gamma oscillations and their couplings. In particular, we show that neurostimulation pulses delivered in-phase with the underlying theta rhythm can rescue impaired oscillations caused by changes in the model parameters that reflect pathophysiological circuit alterations. Overall, our novel computational framework opens new avenues for studying the effects of neurostimulation on hippocampal circuits

FOUR GRID CELL MODULES CAN CODE FOR A PRECISE LOCATION AT A LOW ERROR

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Isabelle Hoxha[1], Alvaro Feito Boirac[2], Gabriel Orellana[3], Lianne Klaver[4], Jonathan Coutinho[5], Fabio Solari[6]
[1]Université Paris-Saclay, Ciams, Faculté Des Sciences Du Sport, Orsay Cedex, France, [2]Bermuda Automation, Bermuda Automation, Warwick, Bermuda, [3]Protera, Protera Biosciences, Santiago, Chile, [4]Virginia Tech, School Of Neuroscience, Blacksburg, United States of America, [5]Queen's University, Centre For Neuroscience Studies, Kingston, Canada, [6]University of Genova, Department Of Informatics, Bioengineering, Robotics And Systems Engineering, Genova, Italy

Aims: Grid cells in the rat entorhinal cortex fire according to the animal's location in space. Depending on their anatomical location, grid cells belong to modules with different field sizes, which combine to encode location precisely. While previous studies have addressed the importance of modular architecture for location accuracy, we aim at computing the optimal number of modules for accurate location. **Methods:** We built two artificial neural networks, whose input layers contain N modules * 16 cells each. Our initial model rests on the observation that one cell encodes the rat's position ambiguously with possible overlap of firing patterns between cells. The first model multiplies those spatial firing patterns to obtain the position. To explore more optimal encodings of the animal's location, we added two fully connected hidden layers between noisy activation patterns and the output layer, trained to predict the rat's 2D Cartesian coordinates. **Results:** Our initial model can map 75% of the output space, with 25% of four-cell combinations coding position ambiguously. Using a model with one spatial module results in inaccurate location, either due to high error rates if the separation is large, or to high ambiguity with small field sizes. Increasing the number of layers reduces ambiguity and error. **Conclusions:** Increasing the number of modules from 1 to 4 increases the performance of our model on predicting location at a reduced error. Further research could investigate the relation between the number of modules and the animal's range of motion, and the energetic cost of modular architecture.

INHIBITION STABILIZATION AND PARADOXICAL EFFECTS IN NETWORKS WITH SHORT-TERM PLASTICITY

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Yue Kris Wu[1,2], Julijana Gjorgijeva[1,2]
[1]Max Planck Institute for Brain Research, Computation In Neural Circuits Group, Frankfurt am Main, Germany, [2]Technical University of Munich, School Of Life Sciences, Freising, Germany

Inhibition stabilization is a ubiquitous property of cortical networks, whereby inhibition ensures that network activity remains at a realistic level despite the presence of strong recurrent excitation. Networks operating in the inhibition stabilized regime are capable of performing various computations, including input amplification, response normalization, and network multistability. In excitatory and inhibitory networks with static connectivity, an identifying characteristic of inhibition stabilization is that increasing (decreasing) excitatory input to the inhibitory population leads to a decrease (increase) in its firing, known as the paradoxical effect. However, synaptic strengths are subject to short-term plasticity (STP) on a time scale of milliseconds to seconds. How inhibition stabilization relates to paradoxical effect in networks with short-term plasticity is unclear. Here, we analytically identified the conditions of being inhibition stabilized and the conditions of having paradoxical effects in networks with STP. We found that while the paradoxical effect implies inhibition stabilization, inhibition stabilization does not imply the paradoxical effect. Interestingly, in the presence of STP, networks can undergo non-monotonic transitions between inhibition stabilized regime and non-inhibition-stabilized regime when the excitatory drive to the inhibitory population increases. Furthermore, networks with STP can exhibit a novel response profile, which cannot be observed in conventional static networks, in response to excitatory input to the inhibitory population. In summary, our work establishes the link between inhibition stabilization and paradoxical effects in the presence of STP. This makes important predictions for future experimental studies that aim to identify cortical operating regimes in the brain.

Nonlinear transient amplification in recurrent neural networks with short-term plasticity.
To rapidly process information, neural circuits have to amplify specific activity patterns transiently. How the brain performs this nonlinear operation remains elusive. Hebbian assemblies are one possibility whereby strong recurrent excitatory connections boost neuronal activity. However, such Hebbian amplification is often associated with dynamical slowing of network dynamics, non-transient attractor states, and pathological run-away activity. Feedback inhibition can alleviate these effects but typically linearizes responses and reduces amplification gain. Here, we study nonlinear transient amplification (NTA), a plausible alternative mechanism that reconciles strong recurrent excitation with rapid amplification while avoiding the above issues. NTA has two distinct temporal phases. Initially, positive feedback excitation selectively amplifies inputs that exceed a critical threshold. Subsequently, short-term plasticity quenches the run-away dynamics into an inhibition-stabilized network state. By characterizing NTA in supralinear network models, we establish that the resulting onset transients are stimulus selective and well-suited for speedy information processing. Further, we find that excitatory-inhibitory co-tuning widens the parameter regime in which NTA is possible in the absence of persistent activity. In summary, NTA provides a parsimonious explanation for how excitatory-inhibitory co-tuning and short-term plasticity collaborate in recurrent networks to achieve transient amplification.

Homeostatic mechanisms regulate distinct aspects of cortical circuit dynamics.
Homeostasis is indispensable to counteract the destabilizing effects of Hebbian plasticity. Although it is commonly assumed that homeostasis modulates synaptic strength, membrane excitability, and firing rates, its role at the neural circuit and network level is unknown. Here, we identify changes in higher-order network properties of freely behaving rodents during prolonged visual deprivation. Strikingly, our data reveal that functional pairwise correlations and their structure are subject to homeostatic regulation. Using a computational model, we demonstrate that the interplay of different plasticity and homeostatic mechanisms can capture the initial drop and delayed recovery of firing rates and correlations observed experimentally. Moreover, our model indicates that synaptic scaling is crucial for the recovery of correlations and network

structure, while intrinsic plasticity is essential for the rebound of firing rates, suggesting that synaptic scaling and intrinsic plasticity can serve distinct functions in homeostatically regulating network dynamics.

Rapid and active stabilization of visual cortical firing rates across light-dark transitions.
The dynamics of neuronal firing during natural vision are poorly understood. Surprisingly, mean firing rates of neurons in primary visual cortex (V1) of freely behaving rodents are similar during prolonged periods of light and darkness, but it is unknown whether this reflects a slow adaptation to changes in natural visual input or insensitivity to rapid changes in visual drive. Here, we use chronic electrophysiology in freely behaving rats to follow individual V1 neurons across many dark-light (D-L) and light-dark (L-D) transitions. We show that, even on rapid timescales (1 s to 10 min), neuronal activity was only weakly modulated by transitions that coincided with the expected 12-/12-h L-D cycle. In contrast, a larger subset of V1 neurons consistently responded to unexpected L-D and D-L transitions, and disruption of the regular L-D cycle with 60 h of complete darkness induced a robust increase in V1 firing on reintroduction of visual input. Thus, V1 neurons fire at similar rates in the presence or absence of natural stimuli, and significant changes in activity arise only transiently in response to unexpected changes in the visual environment. Furthermore, although mean rates were similar in light and darkness, pairwise correlations were significantly stronger during natural vision, suggesting that information about natural scenes in V1 may be more strongly reflected in correlations than individual firing rates. Together, our findings show that V1 firing rates are rapidly and actively stabilized during expected changes in visual input and are remarkably stable at both short and long timescales.

RELATING LOCAL CONNECTIVITY AND GLOBAL DYNAMICS IN EXCITATORY-INHIBITORY NETWORKS

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Yuxiu Shao, Srdjan Ostojic
Ecole Normale Superieur, Group For Neural Theory, Paris, France

One of the key questions in neuroscience is how the cortical connectivity structure determines the collective dynamics of neural activity. Two complementary approaches have been developed to address this question: (i) representing connectivity in terms of local statistics of excitatory-inhibitory motifs; (ii) representing connectivity through a global low-rank structure that determines the low-dimensional dynamics. It is however currently unclear how local connectivity statistics are related to the global structure and shape the low-dimensional activity. To bridge this gap, we map local EI statistics onto global statistics of low-rank connectivity and examine the dynamics. We consider a randomly connected, block-like network composed of excitatory and inhibitory subpopulations. Connections in each block are specified by cell-type-dependent statistics and consist of independent and reciprocal parts. We first determine the dominant eigenvalues and eigenvectors of the connectivity matrix, and show that the statistics of their entries universally obey a mixture of Gaussian distribution. We then approximate random EI networks by Gaussian-mixture low-rank networks and show that mean connectivity determines the dominant low-rank structure, which the reciprocal motifs further modify by modulating the dominant eigenvalue. Comparing the dynamics in the original EI network and their low-rank approximations, we find that the mean and variance of population activity closely match. In both cases, reciprocal motifs enhance feedback and induce dynamic state transition. Altogether, our analytical mapping of the local EI statistics to low-rank description provides an intuitive picture of how local connectivity statistics determine global low-dimensional dynamics and resulting computations.

THE IMPACT OF SPARSITY ON THE DYNAMICS OF LOW-RANK RECURRENT NEURAL NETWORKS

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Elizabeth Herbert, Srdjan Ostojic
École Normale Supérieure, Group For Neural Theory, Paris, France

Neural population dynamics are often highly coordinated, allowing task-related computations to be understood as neural trajectories through low-dimensional subspaces. How the connectivity and input structure give rise to such activity can be investigated with the aid of low-rank recurrent neural networks, a recently-developed class of computational models which offer a rich theoretical framework linking the underlying connectivity structure to emergent low-dimensional dynamics. However, this framework has so far relied on the assumption of all-to-all connectivity, while cortical networks are known to be highly sparse. Here we investigate the influence of sparsity on the dynamics of recurrent networks in which the underlying connectivity structure is low rank. We first analyse how the eigenvalue spectrum of low-rank connectivity matrices is modified when the network connections are sparsified, and then examine the implications for the dynamics. We find that in the presence of sparsity, the eigenspectra consist of a central bulk distribution and isolated outliers, analogously to matrices composed of a low-rank and a random, full-rank component. This analogy allows us to characterise distinct dynamical regimes of the sparsified low-rank network as a function of key network parameters. Altogether, we find that the low-dimensional dynamics induced by low-rank structure in the connectivity are preserved even at high levels of sparsity, and therefore give rise to highly robust computations.

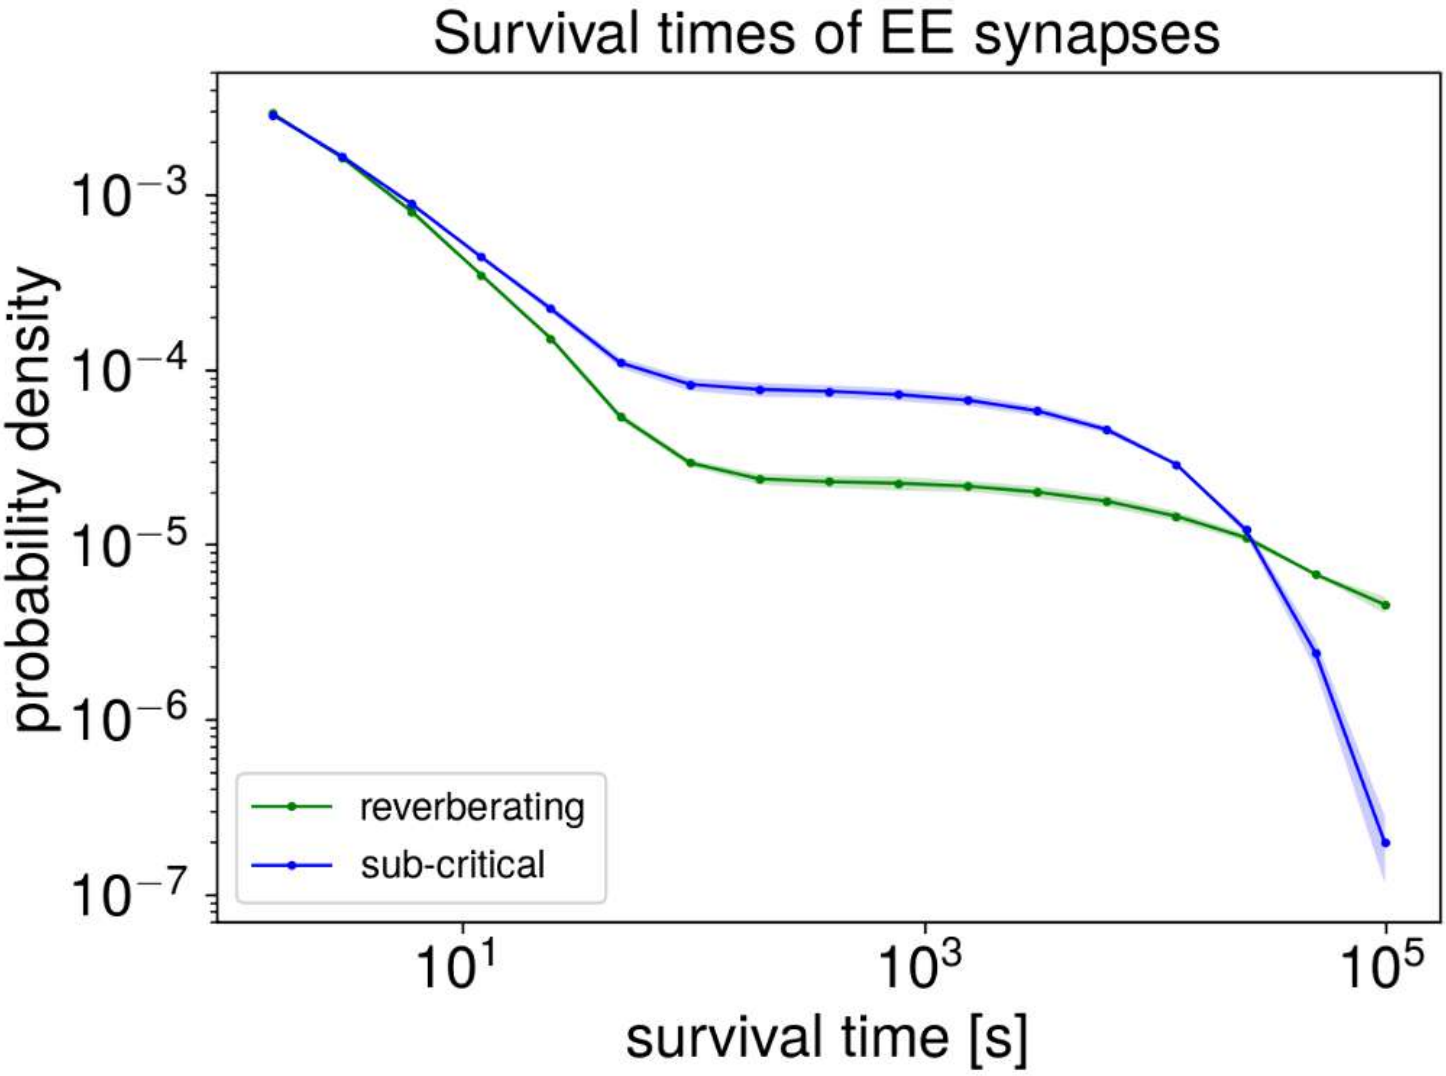
The connectome of the brain is highly dynamic, exhibiting high turnover of synaptic connections even under basal conditions. Nevertheless, our brains are able to maintain life-long memories. How are such memories formed and safeguarded in such a dynamic environment? We hypothesize that plastic recurrent neural networks can generate self-sustaining connectivity patterns if they operate in the reverberating regime close to criticality. To test this hypothesis, we simulate spiking neural networks with spike timing-dependent, homeostatic, and structural plasticity. Structural plasticity creates new excitatory-to-excitatory (EE) synapses and randomly prunes those below a certain threshold. We find that the reverberating regime promotes long survival times of EE synapses, while the sub-critical regime shows more pruning/creation events and a lack of very long synaptic life times. Furthermore, we find that random Kesten processes, a popular model of synaptic fluctuations, reproduce the short survival times of the sub-critical regime but fail to account for the long synaptic life times of the reverberating regime. Together, these findings indicate that long synaptic and memory life times may be explained by self-sustaining synaptic weight patterns shaping network activity so as to reinforce their own existence.



The reverberating regime (green, branching factor m≥0.9) promotes long survival times of excitatory-to-excitatory synapses. In contrast, the sub-critical regime (blue, branching factor m~0.3) is characterized by frequent creation/pruning events, leading to more synapses with short and medium survival times. The shaded area indicates the standard deviation from the mean calculated using three random initializations of the simulation for each regime.

META-LEARNT PLASTICITY RULES IN SPIKING NETWORKS AND THEIR IMPLICATIONS FOR NEUROSCIENCE RESEARCH

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Basile Confavreux[1], Alexia Wilson[1], Friedemann Zenke[2,3], Everton Agnes[4], Timothy Lillicrap[5], Tim Vogels[1]
[1]ISTA, Neuroscience, Klosterneuburg, Austria, [2]Friedrich Miescher Institute, Neuroscience, Basel, Switzerland, [3]Friedrich Miescher Institute for biomedical research, Neurobiology, Basel, Switzerland, [4]Biozentrum, University of Basel, Neuroscience, Basel, Switzerland, [5]Google DeepMind, Neuroscience, London, United Kingdom

Synaptic plasticity is essential for learning and memory throughout the animal kingdom. However, the link between changes at individual synapses and emerging network-level computations remains obtuse. Theoretical studies model synaptic plasticity with plasticity rules, collapsing various molecular contributions into the evolution of a scalar synaptic weight across time. Deriving a complete set of functional plasticity rules analytically in a spiking neural network (SNNs) remains largely out of reach. Here, we approach the problem numerically (Confavreux *et al.* NeurIPS 2020), and meta-learn plasticity rules in large SNNs in silico to solve memory tasks. In our attempt to meta-learn and interpret plasticity rules, we use an evolutionary strategy (CMA-ES) to recover rules that robustly solve a familiarity detection task in a biologically plausible way. We discuss the challenges in designing meta-objectives that combine performance while ensuring biologically relevant solutions. We compare two search spaces for plasticity rules (both comprising around 100 meta-parameters). One is a polynomial with interpretable terms, considering quantities classically involved in plasticity: spike timing, spike history, membrane potential *etc*. The other is a multilayer perceptron, combining the same variables as the polynomial search space in a non interpretable, more flexible way. These search spaces give rise to different solutions. To understand and compare these high-dimensional meta-learnt rules, we use the covariance matrix learned along the optimisation with CMA-ES. Preliminary analysis revealed that the learned rules used inhibitory plasticity both for stability and computation, and operated mainly via codependent terms, corroborating recent theoretical work.

STRUCTURAL PLASTICITY WITH A GAUSSIAN ACTIVITY RULE PREDICTS DEPRIVATION-INDUCED NETWORK REMODELING

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Han Lu[1], Sandra Diaz-Pier[2], Andreas Vlachos[1,3,4]
[1]University of Freiburg, Department Of Neuroanatomy, Institute Of Anatomy And Cell Biology, Faculty Of Medicine, Freiburg, Germany, [2]Jülich Aachen Research Alliance, Forschungszentrum Jülich, Simulation Lab Neuroscience, Jülich Supercomputing Centre, Institute For Advanced Simulation, Jülich, Germany, [3]University of Freiburg, Center For Basics In Neuromodulation (neuromodulbasics), Faculty Of Medicine, Freiburg, Germany, [4]University of Freiburg, Bernstein Center Freiburg, Freiburg, Germany

Aims: Homeostatic plasticity is fundamental for neuronal networks to maintain network activity within a dynamic range. In this context, structural synaptic plasticity—including changes in spine sizes, densities, and synapse numbers—is not consistently regulated in a homeostatic manner as seen for the synaptic weights. Increased network activity induces homeostatic down-scaling of excitatory neurotransmission and spine density reduction. Conversely, a decrease in network activity increases excitatory synaptic weights, while either reducing, increasing, or not changing spine densities. To reconcile the rich scenarios of activity-dependent structural plasticity, we proposed a homeostatic structural plasticity model with a Gaussian law with two firing activity setpoints. **Methods**: We studied the divergent behaviors of the Gaussian rule in a large Brunel neural network with spiking neurons in response to excitation and input deprivation to the excitatory subpopulation. **Results**: Simulations showed that this model maintains homeostatic properties upon stimulation whereas formation or loss of dendritic spines is observed depending on the extent of deprivation. When dendritic spines are lost due to silencing or denervation, homeostatic synaptic up-scaling or weak external stimulation rescues firing activity and pushes the structural dynamics into regeneration. **Conclusions**: Our study suggests that (i) a Gaussian structural plasticity rule predicts divergent activity-dependent structural remodeling following activity perturbations, (ii) homeostatic synaptic scaling and homeostatic structural plasticity are not redundant but complementary under certain conditions. i.e., after deprivation. (iii) Applying weak stimulation achieves similar effects and prevents partially denervated neurons from disconnecting from the network—with important implications for clinically applied (non-)invasive brain stimulation techniques.

The molecular neurobiology of chronic pain-induced depression.
The increasing number of individuals with comorbidities poses an urgent need to improve the management of patients with multiple co-existing diseases. Among these comorbidities, chronic pain and mood disorders, two long-lasting disabling conditions that significantly reduce the quality of life, could be cited first. The recent development of animal models accelerated the studies focusing on the underlying mechanisms of the chronic pain and depression/anxiety comorbidity. This review provides an overview of clinical and pre-clinical studies performed over the past two decades addressing the molecular aspects of the comorbid relationship of chronic pain and depression. We thus focused on the studies that investigated the molecular characteristics of the comorbid relationship between chronic pain and mood disorders, especially major depressive disorders, from the genetic and epigenetic point of view to key neuromodulators which have been shown to play an important role in this comorbidity.

Network remodeling induced by transcranial brain stimulation: A computational model of tDCS-triggered cell assembly formation.
Transcranial direct current stimulation (tDCS) is a variant of noninvasive neuromodulation, which promises treatment for brain diseases like major depressive disorder. In experiments, long-lasting aftereffects were observed, suggesting that persistent plastic changes are induced. The mechanism underlying the emergence of lasting aftereffects, however, remains elusive. Here we propose a model, which assumes that tDCS triggers a homeostatic response of the network involving growth and decay of synapses. The cortical tissue exposed to tDCS is conceived as a recurrent network of excitatory and inhibitory

neurons, with synapses subject to homeostatically regulated structural plasticity. We systematically tested various aspects of stimulation, including electrode size and montage, as well as stimulation intensity and duration. Our results suggest that transcranial stimulation perturbs the homeostatic equilibrium and leads to a pronounced growth response of the network. The stimulated population eventually eliminates excitatory synapses with the unstimulated population, and new synapses among stimulated neurons are grown to form a cell assembly. Strong focal stimulation tends to enhance the connectivity within new cell assemblies, and repetitive stimulation with well-chosen duty cycles can increase the impact of stimulation even further. One long-term goal of our work is to help in optimizing the use of tDCS in clinical applications.

"Female Preponderance" of Depression in Non-clinical Populations: A Meta-Analytic Study.
Clinical observations and research suggest a female preponderance in major depressive disorder. However, it is unclear whether a similar gender difference is found for the reporting of depressive symptoms in non-clinical populations. The present meta-analysis was conducted to address this issue. We searched for published papers targeting non-clinical populations in which the 21-item Beck Depression Inventory (BDI) was used. Eighty-four papers (91 studies) published between 1977 and 2014 were included in the final meta-analysis, which comprised 23,579 males and 29,470 females. Females in the general population reported higher level of depressive symptoms than males (= -0.187, corresponding to 1.159 points in the 21-item BDI). This pattern was not found to influence by years of publication, socioeconomic status, or version of the BDI used. Using age group as a moderator, studies with adolescents and young adults were found to show a smaller effect size than studies with older participants. Our results appear to confirm the "female preponderance" in the level of self-report depressive symptoms in the general population, and support the social gender role theory in explaining gender difference over biological susceptibility theory and evolutionary theory.

Time Course of Homeostatic Structural Plasticity in Response to Optogenetic Stimulation in Mouse Anterior Cingulate Cortex.
Plasticity is the mechanistic basis of development, aging, learning, and memory, both in healthy and pathological brains. Structural plasticity is rarely accounted for in computational network models due to a lack of insight into the underlying neuronal mechanisms and processes. Little is known about how the rewiring of networks is dynamically regulated. To inform such models, we characterized the time course of neural activity, the expression of synaptic proteins, and neural morphology employing an in vivo optogenetic mouse model. We stimulated pyramidal neurons in the anterior cingulate cortex of mice and harvested their brains at 1.5 h, 24 h, and $48\,\mathrm{h}$ after stimulation. Stimulus-induced cortical hyperactivity persisted up to 1.5 h and decayed to baseline after $24\,\mathrm{h}$ indicated by c-Fos expression. The synaptic proteins VGLUT1 and PSD-95, in contrast, were upregulated at $24\,\mathrm{h}$ and downregulated at $48\,\mathrm{h}$, respectively. Spine density and spine head volume were also increased at $24\,\mathrm{h}$ and decreased at $48\,\mathrm{h}$. This specific sequence of events reflects a continuous joint evolution of activity and connectivity that is characteristic of the model of homeostatic structural plasticity. Our computer simulations thus corroborate the observed empirical evidence from our animal experiments.

A MODEL OF THE TEMPORAL DYNAMICS OF THE SONGBIRD'S PREMOTOR NUCLEUS

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Fjola Hyseni[1], Arthur Leblois[2], Nicolas Rougier[3]
[1]IMN, Mnemosyne, Bordeaux, France, [2]CNRS - Université de Bordeaux, Neuroscience, Bordeaux, France, [3]Université de Bordeaux, Institut Des Maladies Neurodégénératives, Bordeaux, France

Aim: Temporal processing in the range of tens to hundreds of milliseconds is critical for sensory tasks such as interval and duration discrimination, whereas temporal control is crucial for the generation of a wide range of actions. In the setting of the acquisition and performance of a complex sensorimotor task, we aim to understand the underlying mechanisms encoding timing. Methods: Zebra finches' premotor nucleus HVC (proper name) is responsible for the precise control of song timing. To model the sequential pattern of neuronal activity in the HVC, we use attractor dynamics, the Ring Model. Thereafter, we use a reward covariance learning rule (Williams, 1992) to investigate the behaviour of the model in a widely used lab conditioning paradigm. Results: We show that the ring model is able to robustly reproduce the activity of HVC neurons observed in recordings. Moreover, the duration of a syllable can be modified in either direction (lengthened or shortened) and, consistent with behavioral data, the change in duration is specific to the targeted syllable. Conclusion: Although, current computational models of HVC rely on synfire chains, we propose that it may be modelled using the ring attractor (Zhang, 1996; Hansel and Sompolinsky, 1998), which is more robust and can sustain a localized activity profile for a wide range of weights. Using reinforcement learning, we acquire a duration change consistent with experimental results. Lastly, we derive a prediction from the model, showing that a local inhibition in HVC only perturbs and delays song initiation, while singing is sustained.

CONTROL OF WORKING MEMORY IN A RECURRENT NEURAL NETWORK

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Emilia Piwek, Christopher Summerfield, Mark Stokes
University of Oxford, Experimental Psychology, Oxford, United Kingdom

Aim. We aimed to model and understand how retrospective cues (retrocues) benefit performance and drive neural geometry during multi-item delayed recall tasks. A recent study in macaques studied the neural patterns that stimuli evoke before (pre-cue) and after (post-cue) retrocue onset. They found that in the pre-cue period, individual stimuli were maintained in short-term memory in orthogonal neural subspaces, whereas in the post-cue period, the prioritized items were rotated into a parallel subspace. To understand how such representational shifts can be learnt through error minimisation, we trained recurrent neural networks (RNNs) to perform an equivalent task. *Methods*. RNNs were trained with supervision to perform a cued-recall task. Networks were presented with two conjunctive colour-location stimuli, followed by a *pre-cue* memory delay*,* a retro-cue*,* and a *post-cue* memory delay. We used dimensionality reduction methods to analyse the neural geometry of the cued item representations formed in the delay periods. *Results and conclusions*. We found that the neural geometry previously observed in monkeys emerged naturally in RNNs optimized to perform the task. This is in accordance with a growing literature showing that neural networks project information into orthogonal subspaces to minimize interference, and into parallel subspaces to permit readout generalisation. Additionally, only RNNs trained with longer *post-cue* delay intervals learnt to transform the cued item information from orthogonal to parallel subspaces. This suggests that the parallel geometry might aid robust memory maintenance. Overall, our findings are consistent with the view that retro-cues benefit performance by transforming memories into a prospective, action-oriented format.

SEGREGATED NETWORKS ARE MORE PRONE TO SYNERGY AND DYNAMICAL FUNCTIONAL CONNECTIVITY

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Patricio Orio[1,2], Javier Palma-Espinosa[1], Sebastián Orellana[1]

How the brain generates complex behavior –metastable dynamics, synergistic interactions– has many standing issues to be answered. As the brain ages, decreased structural segregation correlates with less dynamic and more redundant functional connectivity (FC). Structural and dynamical features have been identified as sources of rich dynamics: modular/hierarchical structure, time delays, and others. However, a systematic assessment of the relationship between topology and landmarks of complex behavior has not been undertaken. We built a series of structural matrices of different nature: small-world, scale-free, modular, and hierarchical, spanning a range of topological measures. Then, dynamics were simulated using either a neural mass model or an oscillatory neuron model sweeping the global connectivity parameter G. Dynamics were assessed for dynamic FC (dFC) and for the emergence of high-order statistics (redundancy, synergy) in triplets and quintuplets of nodes. For dFC, the variance of the dFC matrix was taken as metastability index. High-order statistics was measured using the information theory-based O-information, that discriminates between synergy- and redundancy-predominating interactions. Metastability and synergy were more frequently observed in segregated networks and in those classified as regular by the small-world index ω. Networks of random nature (including scale-free networks) display a steeper transition to synchrony and more redundant interactions. Synergistic interactions are more frequent in triplets with few connections, while redundancy governs when measured in more connected tuples. We show for the first time that synergistic interactions emerge more frequently with metastable dynamics, contributing to understand how complex behavior relates to structural constraints.

CHARACTERIZATION OF NEURAL NETWORK DYNAMICS: INSIGHTS FROM DISSIPATION

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Jules Bouté[1], Mallory Carlu[2], Damien Depannemaecker[3], Alain Destexhe[4]
[1]NeuroPSI – Institut des Neurosciences Paris-Saclay, Icn, Saclay, France, [2]CNRS, Neuropsi, Saclay, France, [3]CNRS, Neuropsi – Institut Des Neurosciences Paris-saclay, Saclay, France, [4]Université Paris-Saclay - NeuroPsi (CNRS), Integrative & Computational Neuroscience (icn), Saclay, France

Aim: Models of neural networks are often built by using single-neuron models describing neural excitability interacting together with appropriate connectivity. Different dynamical behaviors observed in experiments may be reproduced by varying parameters. Such large networks may have highly chaotic dynamics that are very difficult to understand, even with a good knowledge of the individual modeled neurons that constitute it. We study these dynamics and focus on the fluctuations around the time average activity and how they can influence the response of the network to perturbations.
Method: We ran numerous simulations with different neural networks models. Inspired by statistical physics, we consider dissipation, an observable that gives the contraction of phase space around a given point of the dynamics.

Results: A stable network has on average a negative dissipation, meaning that fluctuations converge to a global attractor of the trajectories, but punctual positive dissipation can arise too and show how the system can fluctuate. We observed that dissipations are correlated to the response of a system to perturbations. We identified that the connectivity of each individual single neuron may strongly change their impact on the global dynamics as their dissipation differs. We specifically found that positive dissipation has an important impact on the dynamic and can help characterize different models, even when they have similar firing rates.

Conclusion: Our results show that dissipation can be used to characterize more accurately neural networks dynamics, and may help to understand the intrinsic activity leading to the global behavior observed.

FACILITATING SYNAPSES AND BROAD RECURRENT CONNECTIONS CAN INCREASE THE SELECTIVITY OF CORTICAL POPULATIONS TO SENSORY STIMULI

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Laura Bernaez Timon, Pierre Ekelmans, Tatjana Tchumatchenko
University Medical Center | Johannes-Gutenberg University Mainz, Institute Of Physiological Chemistry, Mainz, Germany

Even the simpler sensory stimuli trigger the activation of large groups of neurons in the cortex. This finding has motivated the hypothesis that the neural representation of sensory stimuli is encoded at the population level. The particular activity pattern of a cortical neuronal population in response to a sensory stimulus is determined by the characteristics of the circuit: its feed-forward and recurrent connections, the type of synaptic dynamics, or the degree of excitation-inhibition balance. However, the causal relationship between each of these circuit features and its impact on the population tuning response remains difficult to study in experimental settings. Here, we propose a theoretical framework to dissect the role of recurrent connectivity and synaptic plasticity in the establishment of the population tuning properties. This framework relies on the assumption of balanced excitation and inhibition, a phenomenon that has been observed in cortical circuits. Using mean-field models and spiking network simulations we show that the type of synapses controls the width of the population tuning — facilitating synapses increase the network selectivity by decreasing tuning width while depressing synapses have the opposite effect. We also demonstrate that the width of the recurrent connections plays a crucial role in the regulation of the population tuning width. Counter-intuitively, the broader the recurrent connections extend in space, the lower the width of the population tuning. These results lead to specific experimentally-testable predictions and map the physiology of recurrency and plasticity to the population response to sensory stimuli.

MANIFOLD PROPAGATION THROUGH RECURRENT NEURAL NETWORKS

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Bechkov[1], Verhellen[1], Elle Lepperød[2]
[1]University of Oslo, Ibv, Oslo, Norway, [2]Simula, Research, Oslo, Norway

For a long time neuroscientists have attempted to understand neural computation through simplified neural network models. Recurrent neural networks (RNNs) with rate dynamics are one of the simplest examples of such models. Due to their conceptual and mathematical simplicity, a large amount of effort has been spent on understanding their formal properties. Another area that has gained significant traction in the last few years is that of neural manifolds, which allow one to think of the activity of neural populations as tracing out a surface in high dimensional space. The geometry and topology of such a surface are informative of the nature of computation in the neural population, but it has been difficult to relate the structure of a neural network to that of the manifolds it produces. In this work we address this problem by studying projection mappings from a manifold with a particular topology to RNNs with differing weight matrix structures. We then study how the topological and geometric properties of neural manifolds change through time depending on the properties of a network. We study two main properties that determine the network dynamics, the first being the eigenvalue spectrum of the weight matrix and the second - the orientation of the projection mapping from the stimulus manifold to the network with respect to the weight basis. By simulating neural network dynamics using random RNNs we seek conditions that allow for the topology of a neural manifold to be retrieved from a network.

Aims: rTMS is a non-invasive brain stimulation technique that induces neuronal plasticity in the human cortex. Despite its clinical use, mechanisms through which rTMS affects neural networks remain elusive. To complement our experimental efforts and explore the vast parameter space of rTMS, we employed a computational approach to explore the impact of stimulation parameters on network dynamics and connectivity. **Methods:** rTMS was modeled as a train of brief and strong depolarizations of the somatic membrane potential. We explored the effects of rTMS on network dynamics and remodeling in a balanced recurrent network with and without homeostatic structural plasticity (HSP). When subject to HSP, excitatory neurons dynamically form/retract synapses with each other to homeostatically maintain their firing-rate. **Results:** Simulations of static networks showed that rTMS influenced network dynamics (i.e.,neural firing-rate) in a frequency- and intensity-dependent manner. The firing-rate versus intensity relationship was found to be non-linear. We suspect feedback-inhibition as a cause of this non-linearity. Plastic network simulations supported a similar relationship between stimulation intensity and network remodeling. In the plastic network, we further observed an increase and saturation of connectivity after “long-enough” stimulation at a given frequency. **Conclusion:** Our simulations confirmed that the exact protocol design has a profound impact on network activity and resulting remodeling. We identified an overstimulation risk in terms of both intensity and duration. Intensities above an ‘optimal’ value cause detrimental effects, and durations exceeding a certain length do not contribute to further remodeling. rTMS initiated feedback-inhibition influences the net stimulation outcome, highlighting the role of inhibitory neurons in rTMS induced plasticity.

ENTROPY, FREE ENERGY, SYMMETRY AND DYNAMICS IN THE BRAIN

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Hiba Sheheitli, Viktor Jirsa
Aix-Marseille University, Institut De Neuroscience De Systemes, Marseille, France

Neuroscience is home to concepts and theories with roots in a variety of domains including information theory, dynamical systems theory, and cognitive psychology. Not all of those can be coherently linked, some concepts are incommensurable, and domain-specific language poses an obstacle to integration. Still, conceptual integration is a form of understanding that provides intuition and consolidation, without which progress remains unguided. This work is concerned with the integration of deterministic and stochastic processes within an information theoretic framework, linking information entropy and free energy to mechanisms of emergent dynamics and self-organization in brain networks. We identify basic properties of neuronal populations leading to an equivariant matrix in a network, in which complex behaviors can naturally be represented through structured flows on manifolds establishing the internal model relevant to theories of brain function. We propose a neural mechanism for the generation of internal models from symmetry breaking in the connectivity of brain networks. The emergent perspective illustrates how free energy can be linked to internal models and how they arise from the neural substrate.

SHAPING CIRCUIT CONNECTIVITY BY INHIBITION

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Dylan Festa, Julijana Gjorgijeva
MPI for Brain Research, Gjorgjieva Group, Frankfurt an Main, Germany

It is widely accepted that activity-dependent plasticity plays a fundamental role in determining andreshaping connectivity in the brain. Numerous studies considered the effects of plasticity on smallgroups of neurons (circuit motifs), or larger populations, modeling how the interplay of plasticity rulesand correlated external inputs shapes circuit connectivity(Ocker et al.2015; Ocker and Doiron2019).For example, it has been shown that, even in the absence of structured external inputs, simple plasticityrules can give rise to organized structures, such as neural assemblies or feedforward chains(Montangieet al.2020; Tannenbaum and Burak2016). Most of these studies focus on the excitatory neural populations, and include an inhibitory componentfor the sole purpose of stabilizing the excitatory activity. However structured inhibitory interactionscan change the correlation statistics of the excitatory activity, which in turn determines the effect ofspike-timing dependent plasticity (STDP) on the circuit. In this work we use both analytic and numerical approaches to account for the role of inhibition inshaping connectivity through STDP rules. We consider small-scale circuit motifs that include inhibitorycomponents, and we show how the presence of inhibitory interactions influences the firing patternsof the excitatory population, and what are the consequences on circuit connectivity when plasticity ispresent.

MECHANISMS OF PLASTICITY FOR PUP CALL SOUNDS IN THE MATERNAL AUDITORY CORTEX

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Christoph Miehl[1,2], Soomin Song[3,4], Robert Froemke[3,4], Julijana Gjorgijeva[1,2]
[1]Max Planck Institute for Brain Research, Computation In Neural Circuits Group, Frankfurt, Germany, [2]Technical University Munich, School Of Life Sciences, Freising, Germany, [3]New York University School of Medicine, Skirball And Neuroscience Institutes For Biomolecular Medicine, New York, United States of America, [4]New York University, Center For Neural Science, New York, United States of America

Distress calls of mice pups outside their nest elicit pup retrieval in maternal female mice but not in their virgin ('naive') conspecifics. However, when co-housed with maternal mice, naive mice become 'experienced' and learn to perform pup retrieval. This process correlates with neuronal changes in the primary auditory cortex: While excitatory (E) neuron responses are sharply tuned to a certain inter- pup-call interval and inhibitory (I) neuron responses are broadly tuned in naive mice, the two neuron types are co-tuned in experienced mice. This change in behavior and tuning is mediated by oxytocin (Schiavo et al., 2020). Here, we aim to dissect the underlying mechanisms behind the behaviorally-relevant changes in tuning from naive to experienced mice by combining computational modeling and in-vitro experiments. Using optogenetic targeting of somatostatin-positive (SST) or parvalbumin-positive (PV) inhibitory neurons, we quantified short-term plasticity at SST-to-E and PV-to-E connections. Furthermore, pairing experiments reveal sufficient long-term plasticity at SST-to-E but not PV-to-E connections. Using a model, we study the interaction of three neuron populations with synapses experiencing short- and long-term plasticity. We show that 1) short-term plasticity leads to the tuning of excitatory and inhibitory neurons to inter-stimulus intervals; 2) oxytocin-gated long-term plasticity of E-to-E and SST-to-E connections lead to changes in tuning from naive to experienced mice. Furthermore, 3) short-term plasticity can control the signal amplitude without changing the tuning properties. Our results reveal that short- and long-term plasticity cooperate to generate tuning of excitatory and inhibitory neurons in microcircuits with important implications for maternal behavior.

ADDING DENDRITES TO SPIKING NEURAL NETWORKS WITH DENDRIFY

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Michalis Pagkalos[1,2], Spyridon Chavlis[1], Panayiota Poirazi[1]
[1]Foundation for Research and Technology Hellas, Institute Of Molecular Biology And Biotechnology, Heraklion, Greece, [2]University of Crete, Biology Department, Heraklion, Greece

Computational modelling has been indispensable for understanding how subcellular features of neurons can influence circuit processing. Yet, the influence of dendritic computations on network-level operations remains largely unexplored. This is partly because existing tools do not allow the development of realistic and efficient network models that account for dendrites. Current spiking neural networks, although efficient, are usually overly simplistic, overlooking essential dendritic properties. Conversely, circuit models with morphologically detailed neuron models are computationally costly, thus impractical for large-network simulations. To bridge the gap between these two, we introduce *Dendrify*, an open-source Python package compatible with *Brian2,* designed to facilitate the development of bioinspired spiking neural networks. *Dendrify*, through simple commands, automatically generates reduced compartmental neuron models with realistic dendritic and synaptic integrative properties that match experimental findings. Such models strike a good balance between flexibility, performance, and biological accuracy, allowing us to explore dendritic contributions to network-level functions while paving the way for the development of more powerful neuromorphic systems.

THE OPTIMAL STATE FOR COMPUTATION CHANGES DEPENDING ON THE AVAILABLE PROCESSING TIME

POSTER SESSION 02 - SECTION: NEURAL DYNAMICS AND NETWORK COMPUTATIONS

Sahel Azizpour[1], Joahannes Zierenberg[2], Viola Priesemann[2], Anna Levina[3]
[1]Radboud University, Donders Institute For Brain, Cognition And Behaviour, Nijmegen, Netherlands, [2]Max Planck Institute, Dynamics And Self Organization, Göttingen, Germany, [3]Tübingen University, Computer Science Department, Tübingen, Germany

Common estimates of information processing capabilities such as the dynamic range are defined in terms of expected values that do not incorporate effects from finite processing time. However, in real-world tasks, animals and humans have only a limited amount of time to process input and make a decision. Here, using a stochastic neural network with integrate-and-fire units as an example, we propose new definitions for dynamic range and perceptual resolution that explicitly include uncertainty arising from the finite processing time. We evaluate these measures both analytically and using simulations and find that the network's ability to discriminate inputs within a finite time is maximized in a subcritical regime. Interestingly, with a longer processing time, the optimal regime moves closer to criticality (Fig.1d-e). This result highlights the importance of incorporating the constraints of finite processing time when studying the information processing capacity of any system in noisy real-world situations. Aims: In the absence of direct sensory stimuli, animals locomote in a way adapted to their internal needs to explore their environment. In all vertebrates, these commands are driven by the mesencephalic locomotor region (MLR) that controls forward locomotion through the reticulospinal neurons (RSNs) that directly contact the spinal effector circuits. However, the nature of the RSNs the MLR recruits to initiate and modulate forward locomotion remains obscure due to the heterogeneity and difficulty to access these systems. Here, we leverage the optically and genetically accessible larval zebrafish to investigate the recruitment of a genetically-defined population of RSNs conserved across vertebrates, referred to as V2a RSNs, during MLR-induced forward swimming. Methods: We monitored the calcium activity of V2a neurons in the medulla while electrically stimulating the MLR to elicit forward locomotion in head-embedded larval zebrafish. Results: We identified that 20% of the medial V2a RSNs in the medulla were recruited during MLR-induced forward swims. Although a subset of these neurons maintained their activity throughout the duration of the swim, the kinematic of the calcium responses differed. Using multiple linear regression to model activity with motor regressors, we found that a cluster of V2a RSNs in the caudal medulla encoded locomotor frequency and number of oscillations, while another cluster in the rostral medulla encoded locomotor frequency and the increase in the movement amplitude. Conclusions: Our results reveal that a previously unappreciated population of V2a RSNs in the medulla act as maintain neurons encoding speed and duration during MLR induced exploratory locomotion.

TARGETED ACTIVATION OF MIDBRAIN NEURONS RESTORES LOCOMOTOR FUNCTION IN MOUSE MODELS OF PARKINSONISM

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Debora Masini[1], Ole Kiehn[2]
[1]University of Copenhagen, Integrative Neuroscience, Copenhagen, Denmark, [2]University of Copenhagen, Department Of Neuroscience, Copenhagen, Denmark

The pedunculopontine nucleus (PPN) is together with the cuneiform nucleus (CnF) a locomotor command area containing glutamatergic neurons that control locomotor initiation, speed and maintenance. These motor actions are deficient in Parkinson's disease (PD), where dopaminergic neurodegeneration alters basal ganglia activity. Of the two locomotor-initiating areas, the PPN is directly downstream of the basal ganglia and it is therefore a suitable target for ameliorating parkinsonian motor symptoms. In this study we have used in vivo cell-type specific PPN activation to recover motor function in mouse models of parkinsonism made by acute pharmacological blockage of dopamine transmission. With a combination of chemo- and opto-genetics, we show that excitation of caudal glutamatergic PPN neurons can induce locomotion and is sufficient to normalize the otherwise severe locomotor deficit observed in parkinsonian mice. Targeting the local GABAergic population only leads to partial recovery. The motor rescue driven by glutamatergic PPN activation is independent of activity in nearby locomotor promoting glutamatergic Cuneiform area. Moreover, the locomotor phenotype induced by caudal glutamatergic PPN in parkinsonian mice is proficient and shares all the characteristics of normal locomotion found in wild type mice. Our observations point to caudal glutamatergic PPN neurons as a potential target for neuromodulatory restoration of locomotor function in PD. This work was supported by the Lundbeck Foundation and the Novo Foundation.

Disrupted gene expression perturbs spontaneous Ca activity causing abnormal brain development and increased anxiety. The L-type voltage-gated Ca channel gene is a risk gene for various psychiatric conditions, including schizophrenia and bipolar disorder. However, the cellular mechanism by which contributes to psychiatric disorders has not been elucidated. Here, we report that the embryonic deletion of in neurons destined for the cerebral cortex using an strategy disturbs spontaneous Ca activity and causes abnormal brain development and anxiety. By combining computational modeling with electrophysiological membrane potential manipulation, we found that neural network activity was driven by intrinsic spontaneous Ca activity in distinct progenitor cells expressing marginally increased levels of voltage-gated Ca channels. MRI examination of the knockout mouse brains revealed volumetric differences in the neocortex, hippocampus, and periaqueductal gray. These results suggest that acts as a molecular switch and that its disruption during embryogenesis can perturb Ca handling and neural development, which may increase susceptibility to psychiatric disease.

Targeted activation of midbrain neurons restores locomotor function in mouse models of parkinsonism.
The pedunculopontine nucleus (PPN) is a locomotor command area containing glutamatergic neurons that control locomotor initiation and maintenance. These motor actions are deficient in Parkinson's disease (PD), where dopaminergic neurodegeneration alters basal ganglia activity. Being downstream of the basal ganglia, the PPN may be a suitable target for ameliorating parkinsonian motor symptoms. Here, we use in vivo cell-type specific PPN activation to restore motor function in two mouse models of parkinsonism made by acute pharmacological blockage of dopamine transmission. With a combination of chemo- and opto-genetics, we show that excitation of caudal glutamatergic PPN neurons can normalize the otherwise severe locomotor deficit in PD, whereas targeting the local GABAergic population only leads to recovery of slow locomotion. The motor rescue driven by glutamatergic PPN activation is independent of activity in nearby locomotor promoting glutamatergic Cuneiform neurons. Our observations point to caudal glutamatergic PPN neurons as a potential target for neuromodulatory restoration of locomotor function in PD.

A Guide to the Generation of a 6-Hydroxydopamine Mouse Model of Parkinson's Disease for the Study of Non-Motor Symptoms.
In Parkinson's disease (PD), a large number of symptoms affecting the peripheral and central nervous system precede, develop in parallel to, the cardinal motor symptoms of the disease. The study of these conditions, which are often refractory to and may even be exacerbated by standard dopamine replacement therapies, relies on the availability of appropriate animal models. Previous work in rodents showed that injection of the neurotoxin 6-hydroxydopamine (6-OHDA) in discrete brain regions reproduces several non-motor comorbidities commonly associated with PD, including cognitive deficits, depression, anxiety, as well as disruption of olfactory discrimination and circadian rhythm. However, the use of 6-OHDA is frequently associated with significant post-surgical mortality. Here, we describe the generation of a mouse model of PD based on bilateral injection of 6-OHDA in the dorsal striatum. We show that the survival rates of males and females subjected to this lesion differ significantly, with a much higher mortality among males, and provide a protocol of enhanced pre- and post-operative care, which nearly eliminates animal loss. We also briefly discuss the utility of this model for the study of non-motor comorbidities of PD.

Inhibition of mTORC1 Signaling Reverts Cognitive and Affective Deficits in a Mouse Model of Parkinson's Disease.
Non-motor symptoms, including cognitive deficits and affective disorders, are frequently diagnosed in Parkinson's disease (PD) patients and are only partially alleviated by dopamine replacement therapy. Here, we used a 6-hydroxydopamine (6-OHDA) mouse model of PD to examine the effects exerted on non-motor symptoms by inhibition of the mammalian target of rapamycin complex 1 (mTORC1), which is involved in the control of protein synthesis, cell growth, and metabolism. We show that rapamycin, which acts as an allosteric inhibitor of mTORC1, counteracts the impairment of novel object recognition. A similar effect is produced by PF-4708671, an inhibitor of the downstream target of mTORC1, ribosomal protein S6 kinase (S6K). Rapamycin is also able to reduce depression-like behavior in PD mice, as indicated by decreased immobility in the forced swim test. Moreover, rapamycin exerts anxiolytic effects, thereby reducing thigmotaxis in the open field and increasing exploration of the open arm in the elevated plus maze. In contrast to rapamycin, administration of PF-4708671 to PD mice does not counteract depression- and anxiety-like behaviors. Altogether, these results identify mTORC1 as a target for the development of drugs that, in combination with standard antiparkinsonian agents, may widen the efficacy of current therapies for the cognitive and affective symptoms of PD.

Induction of functional dopamine neurons from human astrocytes in vitro and mouse astrocytes in a Parkinson's disease model.
Cell replacement therapies for neurodegenerative disease have focused on transplantation of the cell types affected by the pathological process. Here we describe an alternative strategy for Parkinson's disease in which dopamine neurons are generated by direct conversion of astrocytes. Using three transcription factors, NEUROD1, ASCL1 and LMX1A, and the microRNA miR218, collectively designated NeAL218, we reprogram human astrocytes in vitro, and mouse astrocytes in vivo, into induced dopamine neurons (iDANs). Reprogramming efficiency in vitro is improved by small molecules that promote chromatin remodeling and activate the TGFβ, Shh and Wnt signaling pathways. The reprogramming efficiency of human astrocytes reaches up to 16%, resulting in iDANs with appropriate midbrain markers and excitability. In a mouse model of Parkinson's disease, NeAL218 alone reprograms adult striatal astrocytes into iDANs that are excitable and correct some aspects of motor behavior in vivo, including gait impairments. With further optimization, this approach may enable clinical therapies for Parkinson's disease by delivery of genes rather than cells.

A mouse model of non-motor symptoms in Parkinson's disease: focus on pharmacological interventions targeting affective dysfunctions.
Non-motor symptoms, including psychiatric disorders, are increasingly recognized as a major challenge in the treatment of Parkinson's disease (PD). These ailments, which often appear in the early stage of the disease, affect a large number of patients and are only partly resolved by conventional antiparkinsonian medications, such as L-DOPA. Here, we investigated non-motor symptoms of PD in a mouse model based on bilateral injection of the toxin 6-hydroxydopamine (6-OHDA) in the dorsal striatum. This model presented only subtle gait modifications, which did not affect horizontal motor activity in the open-field test. Bilateral 6-OHDA lesion also impaired olfactory discrimination, in line with the anosmia typically observed in early stage parkinsonism. The effect of 6-OHDA was then examined for mood-related dysfunctions. Lesioned mice showed

increased immobility in the forced swim test and tail suspension test, two behavioral paradigms of depression. Moreover, the lesion exerted anxiogenic effects, as shown by reduced time spent in the open arms, in the elevated plus maze test, and by increased thigmotaxis in the open-field test. L-DOPA did not modify depressive- and anxiety-like behaviors, which were instead counteracted by the dopamine D2/D3 receptor agonist, pramipexole. Reboxetine, a noradrenaline reuptake inhibitor, was also able to revert the depressive and anxiogenic effects produced by the lesion with 6-OHDA. Interestingly, pre-treatment with desipramine prior to injection of 6-OHDA, which is commonly used to preserve noradrenaline neurons, did not modify the effect of the lesion on depressive- and anxiety-like behaviors. Thus, in the present model, mood-related conditions are independent of the reduction of noradrenaline caused by 6-OHDA. Based on these findings we propose that the anti-depressive and anxiolytic action of reboxetine is mediated by promoting dopamine transmission through blockade of dopamine uptake from residual noradrenergic terminals.

Developmental molecular and functional cerebellar alterations induced by PCP4/PEP19 overexpression: implications for Down syndrome.
PCP4/PEP19 is a modulator of Ca(2+)-CaM signaling. In the brain, it is expressed in a very specific pattern in postmitotic neurons. In particular, Pcp4 is highly expressed in the Purkinje cell, the sole output neuron of the cerebellum. PCP4, located on human chromosome 21, is present in three copies in individuals with Down syndrome (DS). In a previous study using a transgenic mouse model (TgPCP4) to evaluate the consequences of 3 copies of this gene, we found that PCP4 overexpression induces precocious neuronal differentiation during mouse embryogenesis. Here, we report combined analyses of the cerebellum at postnatal stages (P14 and adult) in which we identified age-related molecular, electrophysiological, and behavioral alterations in the TgPCP4 mouse. While Pcp4 overexpression at P14 induces an earlier neuronal maturation, at adult stage it induces increase in cerebellar CaMK2alpha and in cerebellar LTD, as well as learning impairments. We therefore propose that PCP4 contributes significantly to the development of Down syndrome phenotypes through molecular and functional changes.

Midbrain circuits that set locomotor speed and gait selection.
Locomotion is a fundamental motor function common to the animal kingdom. It is implemented episodically and adapted to behavioural needs, including exploration, which requires slow locomotion, and escape behaviour, which necessitates faster speeds. The control of these functions originates in brainstem structures, although the neuronal substrate(s) that support them have not yet been elucidated. Here we show in mice that speed and gait selection are controlled by glutamatergic excitatory neurons (GlutNs) segregated in two distinct midbrain nuclei: the cuneiform nucleus (CnF) and the pedunculopontine nucleus (PPN). GlutNs in both of these regions contribute to the control of slower, alternating-gait locomotion, whereas only GlutNs in the CnF are able to elicit high-speed, synchronous-gait locomotion. Additionally, both the activation dynamics and the input and output connectivity matrices of GlutNs in the PPN and the CnF support explorative and escape locomotion, respectively. Our results identify two regions in the midbrain that act in conjunction to select context-dependent locomotor behaviours.

The histamine H3 receptor antagonist thioperamide rescues circadian rhythm and memory function in experimental parkinsonism.
Parkinson's disease (PD) is a common neurodegenerative disorder, characterized by motor impairment and a wide range of non-motor symptoms, including sleep disorders and cognitive and affective deficits. In this study, we used a mouse model of PD based on 6-hydroxydopamine (6-OHDA) to examine the effect of thioperamide, a histamine H3 receptor antagonist, on circadian activity, recognition memory and anxiety. A partial, bilateral 6-OHDA lesion of the striatum reduces motor activity during the active phase of the 24 h cycle. In addition, the lesion disrupts the endogenous circadian rhythm observed when mice are maintained in constant darkness. Administration of thioperamide to 6-OHDA-lesion mice rescues the normal rest/activity cycle. Moreover, thioperamide counteracts the deficit of novel object recognition produced by 6-OHDA. Our experiments show that this memory impairment is accompanied by disrupted gamma oscillations in the hippocampus, which are also rescued by thioperamide. In contrast, we do not observe any modification of the anxiogenic effect of 6-OHDA in response to administration of thioperamide. Our results indicate that thioperamide may act as a multifunctional drug, able to counteract disruptions of circadian rhythm and cognitive deficits associated with PD.

ANATOMICAL AND FUNCTIONAL ORGANIZATION OF RED NUCLEUS CIRCUITS

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Kevin Fidelin[1,2], Silvia Arber[1,2]
[1]Friedrich Miescher Institute for Biomedical Research, Neurobiology, Basel, Switzerland, [2]University of Basel, Biozentrum, Basel, Switzerland

Many types of descending projection neurons distributed throughout the brain drive motor output and modulate distinct movement features. Isolating individual projection-specific circuit modules has recently proven successful to stratify spatially intermingled but functionally distinct subpopulations in the brainstem, opening new avenues to address long-standing questions in the field of motor control. Linking cortical and cerebellar output to spinal cord circuits, the red nucleus represents one of most ancient and conserved structures implicated in limb control and skill regulation in vertebrates. Rubrospinal neurons in the magnocellular division of the red nucleus have been shown to play a key role in processes ranging from controlling forelimb and digit mobilization to compensating for motor impairment following cortical lesions. Yet, the precise cellular and circuit mechanisms involved are not understood and their relevance in humans remains debated. In stark contrast, evidence for parvicellular rubral circuits organization and function are extremely sparse, leaving their contribution to movement control unknown. To address this century-old problem, we first use a combination of viral tracing and 3D cellular reconstruction approaches to map the topographic organization of red nucleus neurons and their full projection profiles. Importantly, this strategy identifies a previously uncharacterized rubral module projecting to limb control-specific brainstem structures. We then take advantage of novel anatomical entry points to study the function of rubral subpopulations through neuronal recordings, optogenetic manipulations, and behavioral analysis in freely moving mice. Altogether, this work reveals the first comprehensive functional map of rubral circuits and how it relates to the control of movement.

Spinal sensory neurons project onto the hindbrain to stabilize posture and enhance locomotor speed.
In the spinal cord, cerebrospinal fluid-contacting neurons (CSF-cNs) are GABAergic interoceptive sensory neurons that detect spinal curvature via a functional coupling with the Reissner fiber. This mechanosensory system has recently been found to be involved in spine morphogenesis and postural control but the underlying mechanisms are not fully understood. In zebrafish, CSF-cNs project an ascending and ipsilateral axon reaching two to six segments away. Rostralmost CSF-cNs send their axons ipsilaterally into the hindbrain, a brain region containing motor nuclei and reticulospinal neurons (RSNs), which send descending motor commands to spinal circuits. Until now, the synaptic connectivity of CSF-cNs has only been investigated in the spinal cord, where they synapse onto motor neurons and premotor excitatory interneurons. The identity of CSF-cN targets in the hindbrain and the behavioral relevance of these sensory projections from the spinal cord to the hindbrain are unknown. Here, we provide anatomical and molecular evidence that rostralmost CSF-cNs synapse onto the axons of large RSNs including Mauthner cells and V2a neurons. Functional anatomy and optogenetically assisted mapping reveal that rostral CSF-cNs also synapse onto the soma and dendrites of cranial motor neurons innervating hypobranchial muscles. During acousto-vestibular evoked escape responses, ablation of rostralmost CSF-cNs results in a weaker escape response with a decreased C-bend amplitude, lower speed, and deficient postural control. Our study demonstrates that spinal sensory feedback enhances speed and stabilizes posture, and reveals a novel spinal gating mechanism acting on the output of descending commands sent from the hindbrain to the spinal cord.

Dynactin1 depletion leads to neuromuscular synapse instability and functional abnormalities.
Dynactin subunit 1 is the largest subunit of the dynactin complex, an activator of the molecular motor protein complex dynein. Reduced levels of DCTN1 mRNA and protein have been found in sporadic amyotrophic lateral sclerosis (ALS) patients, and mutations have been associated with disease, but the role of this protein in disease pathogenesis is still unknown.

Mechanosensory neurons control the timing of spinal microcircuit selection during locomotion.
Despite numerous physiological studies about reflexes in the spinal cord, the contribution of mechanosensory feedback to active locomotion and the nature of underlying spinal circuits remains elusive. Here we investigate how mechanosensory feedback shapes active locomotion in a genetic model organism exhibiting simple locomotion-the zebrafish larva. We show that mechanosensory feedback enhances the recruitment of motor pools during active locomotion. Furthermore, we demonstrate that inputs from mechanosensory neurons increase locomotor speed by prolonging fast swimming at the expense of slow swimming during stereotyped acoustic escape responses. This effect could be mediated by distinct mechanosensory neurons. In the spinal cord, we show that connections compatible with monosynaptic inputs from mechanosensory Rohon-Beard neurons onto ipsilateral V2a interneurons selectively recruited at high speed can contribute to the observed enhancement of speed. Altogether, our study reveals the basic principles and a circuit diagram enabling speed modulation by mechanosensory feedback in the vertebrate spinal cord.

Optimization of a Neurotoxin to Investigate the Contribution of Excitatory Interneurons to Speed Modulation In Vivo.
Precise control of speed during locomotion is essential for adaptation of behavior in different environmental contexts [1-4]. A central question in locomotion lies in understanding which neural populations set locomotor frequency during slow and fast regimes. Tackling this question in vivo requires additional non-invasive tools to silence large populations of neurons during active locomotion. Here we generated a stable transgenic line encoding a zebrafish-optimized botulinum neurotoxin light chain fused to GFP (BoTxBLC-GFP) to silence synaptic output over large populations of motor neurons or interneurons while monitoring active locomotion. By combining calcium imaging, electrophysiology, optogenetics, and behavior, we show that expression of BoTxBLC-GFP abolished synaptic release while maintaining characterized activity patterns and without triggering off-target effects. As chx10(+) V2a interneurons (V2as) are well characterized as the main population driving the frequency-dependent recruitment of motor neurons during fictive locomotion [5-14], we validated our silencing method by testing the effect of silencing chx10(+) V2as during active and fictive locomotion. Silencing of V2as selectively abolished fast locomotor frequencies during escape responses. In addition, spontaneous slow locomotion occurred less often and at frequencies lower than in controls. Overall, this silencing approach confirms that V2a excitation is critical for the production of fast stimulus-evoked swimming and also reveals a role for V2a excitation in the production of slower spontaneous locomotor behavior. Altogether, these results establish BoTxBLC-GFP as an ideal tool for in vivo silencing for probing the development and function of neural circuits from the synaptic to the behavioral level.

Three-dimensional spatiotemporal focusing of holographic patterns.
Two-photon excitation with temporally focused pulses can be combined with phase-modulation approaches, such as computer-generated holography and generalized phase contrast, to efficiently distribute light into two-dimensional, axially confined, user-defined shapes. Adding lens-phase modulations to 2D-phase holograms enables remote axial pattern displacement as well as simultaneous pattern generation in multiple distinct planes. However, the axial confinement linearly degrades with lateral shape area in previous reports where axially shifted holographic shapes were not temporally focused. Here we report an optical system using two spatial light modulators to independently control transverse- and axial-target light distribution. This approach enables simultaneous axial translation of single or multiple spatiotemporally focused patterns across the sample volume while achieving the axial confinement of temporal focusing. We use the system's capability to photoconvert tens of Kaede-expressing neurons with single-cell resolution in live zebrafish larvae.

State-Dependent Modulation of Locomotion by GABAergic Spinal Sensory Neurons.
The cerebrospinal fluid (CSF) constitutes an interface through which chemical cues can reach and modulate the activity of neurons located at the epithelial boundary within the entire nervous system. Here, we investigate the role and functional connectivity of a class of GABAergic sensory neurons contacting the CSF in the vertebrate spinal cord and referred to as CSF-cNs. The remote activation of CSF-cNs was shown to trigger delayed slow locomotion in the zebrafish larva, suggesting that these cells modulate components of locomotor central pattern generators (CPGs). Combining anatomy, electrophysiology, and optogenetics in vivo, we show that CSF-cNs form active GABAergic synapses onto V0-v glutamatergic interneurons, an essential component of locomotor CPGs. We confirmed that activating CSF-cNs at rest induced delayed slow locomotion in the fictive preparation. In contrast, the activation of CSF-cNs promptly inhibited ongoing slow locomotion. Moreover, selective activation of rostral CSF-cNs during ongoing activity disrupted rostrocaudal propagation of descending excitation along the spinal cord, indicating that CSF-cNs primarily act at the premotor level. Altogether, our results

demonstrate how a spinal GABAergic sensory neuron can tune the excitability of locomotor CPGs in a state-dependent manner by projecting onto essential components of the excitatory premotor pool.

Inhibition and motor control in the developing zebrafish spinal cord.
Vertebrate locomotion relies on oscillatory activity along the spinal cord. Inhibition is involved in controlling the alternation of activity between each side and contributes in modulating propagation and termination of locomotor activity. Spinal inhibitory neurons are thought to regulate these mechanisms but the exact contribution of specific cell types remains difficult to tackle during active locomotion. In the past two decades, use of the transparent zebrafish larva has enabled morphological, functional, and genetic characterization of specific inhibitory spinal neurons. A wide range of new optical tools has been developed to monitor and to manipulate the activity of genetically targeted spinal populations. Combining these techniques with conventional electrophysiology will provide a better understanding of the contribution of inhibitory spinal interneurons in regulating essential features of locomotor patterns.

CDK7 regulates the mitochondrial localization of a tail-anchored proapoptotic protein, Hid.
The mitochondrial outer membrane is a major site of apoptosis regulation across phyla. Human and C. elegans Bcl-2 family proteins and Drosophila Hid require the C-terminal tail-anchored (TA) sequence in order to insert into the mitochondrial membrane, but it remains unclear whether cytosolic proteins actively regulate the mitochondrial localization of these proteins. Here, we report that the cdk7 complex regulates the mitochondrial localization of Hid and its ability to induce apoptosis. We identified cdk7 through an in vivo RNAi screen of genes required for cell death. Although CDK7 is best known for its role in transcription and cell-cycle progression, a hypomorphic cdk7 mutant suppressed apoptosis without impairing these other known functions. In this cdk7 mutant background, Hid failed to localize to the mitochondria and failed to bind to recombinant inhibitors of apoptosis (IAPs). These findings indicate that apoptosis is promoted by a newly identified function of CDK7, which couples the mitochondrial localization and IAP binding of Hid.

Metabolic regulation of cellular plasticity in the pancreas.
Obese individuals exhibit an increase in pancreatic β cell mass; conversely, scarce nutrition during pregnancy has been linked to β cell insufficiency in the offspring [reviewed in 1, 2]. These phenomena are thought to be mediated mainly through effects on β cell proliferation, given that a nutrient-sensitive β cell progenitor population in the pancreas has not been identified. Here, we employed the fluorescent ubiquitination-based cell-cycle indicator system to investigate β cell replication in real time and found that high nutrient concentrations induce rapid β cell proliferation. Importantly, we found that high nutrient concentrations also stimulate β cell differentiation from progenitors in the intrapancreatic duct (IPD). Furthermore, using a new zebrafish line where β cells are constitutively ablated, we show that β cell loss and high nutrient intake synergistically activate these progenitors. At the cellular level, this activation process causes ductal cell reorganization as it stimulates their proliferation and differentiation. Notably, we link the nutrient-dependent activation of these progenitors to a downregulation of Notch signaling specifically within the IPD. Furthermore, we show that the nutrient sensor mechanistic target of rapamycin (mTOR) is required for endocrine differentiation from the IPD under physiological conditions as well as in the diabetic state. Thus, this study reveals critical insights into how cells modulate their plasticity in response to metabolic cues and identifies nutrient-sensitive progenitors in the mature pancreas.

BASAL GANGLIA-SPINAL CORD PATHWAY THAT COMMANDS LOCOMOTOR ASYMMETRIES

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Jared Cregg[1], Simrandeep Sidhu[1], Ilary Allodi[1], Roberto Leiras[1], Ole Kiehn[1,2]
[1]University of Copenhagen, Department Of Neuroscience, Copenhagen N, Denmark, [2]Karolinska Institutet, Neuroscience, Solna, Sweden

Motor impairments in Parkinson's disease are caused by loss of dopamine input to basal ganglia circuits. Although the basal ganglia are important for locomotion in particular, mechanisms underlying basal ganglia control over spinal locomotor networks remain unclear. One hallmark feature of human Parkinsonism is an exacerbated turning gait and failure to negotiate turns. *Chx10* gigantocellular (Gi) neurons are required for turning gait asymmetries (Cregg et al., 2020; Usseglio et al., 2020), suggesting that turning deficits in Parkinson's disease may arise via this spinal projection pathway. Using deep brainstem calcium recording in mice, we found that D1 and D2 striatal projection neurons (SPNs) evoke discrete changes in *Chx10* Gi activity during locomotor turns. Leveraging *Chx10* Gi neurons as an entry point, we used a reverse dissection approach to uncover the dominant basal ganglia-spinal cord pathway for locomotor asymmetries in mammals: striatal projection neurons → substantia nigra pars reticulata (SNr) → pontine nucleus oralis (PnO) → *Chx10* Gi neurons → spinal locomotor networks. PnO was identified using an intersectional viral screening strategy, where a subset of PnO neurons defined by *Vglut2* expression and commissural projection proved to act as the critical link between basal ganglia output and *Chx10* Gi neurons. Stimulation of this small cluster of neurons evoked contralateral turning, whereas photoinhibition evoked ipsilateral turning. Our results reveal the circuit logic underlying a critical motor program, from action commitment in the basal ganglia to execution by spinal locomotor networks.

Aims: Throughout vertebrate species, locomotion relies on high brain centres converging onto the mesencephalic locomotor region (MLR). How the MLR recruits downstream reticulospinal neurons (RSNs) to initiate locomotor movements remains poorly understood due to the difficulty of recording brainstem neurons during locomotion. Methods: To tackle this question, we leveraged the transparency and genetic accessibility of larval zebrafish. Results: We identified for the first time, functionally and anatomically, the MLR in larval zebrafish as a small region located medially and dorsal to the locus coeruleus, containing glutamatergic and cholinergic neurons. MLR stimulation reliably controlled the duration and locomotor frequency of forward swimming bouts. Using calcium imaging in combination with MLR stimulation, we investigated whether the MLR recruits V2a RSNs shown to be involved in starting, steering and stopping locomotion. We show that the MLR sequentially recruits a subset of V2a RSNs throughout the brainstem. While pontine and retropontine V2a RSNs are recruited at once at low MLR stimulation strength, increasing intensities of the MLR stimulation recruits gradually medullary V2a RSNs, suggesting that V2a RSNs in the medulla could set the speed of forward locomotion. Conclusion: Our study reveals that the mesencephalic locomotor region specifically recruits a subset of V2a RSNs to control forward locomotion. The description of the MLR in larval zebrafish represents a breakthrough for future investigation of the supraspinal motor centres as virtually each and all RSNs can be identified, monitored and manipulated in this transparent genetic model organism

LIGHT ON THE SPINAL PROJECTIONS AND ROLES OF MEDULLARY V2A RETICULOSPINAL NEURONS IN LOCOMOTION

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Xinyu Jia, Mathilde Lapoix, Martin Carbo-Tano, Claire Wyart
Sorbonne Université, Paris Brain Institute (icm), Paris, France

Across vertebrate species, locomotion relies on reticulospinal neurons (RSNs) in the brainstem who provide descending commands to spinal locomotor circuits. Among them, V2a RSNs are necessary to initiate locomotion. Due to the difficulty to record these cells during movement, we lack information on the projection of the V2a RSNs to spinal circuits and their role in eliciting locomotion at different speeds. Here we tackle this question by leveraging the transparency and genetic accessibility of larval zebrafish using advanced optical methods. We used a photoconvertible protein to identify RSNs among V2a brainstem neurons to backfill optically their axons in the spinal cord. To survey their projection range, photoconversion was performed at different rostrocaudal positions in the spinal cord. We found that early-born V2a RSNs recruited during powerful movements project to caudal spinal cord while late-born V2a RSNs recruited during weak exploratory locomotion project more rostrally. To test their roles, we used 2D optogenetics to selectively activate a column of V2a RSNs in the brainstem of head-restrained tail-free larval zebrafish. We observed that the patterned activation of late born V2a RSNs was effective at eliciting forward locomotion at a set tail-beat frequency. Altogether our work reveals in a simple vertebrate species the structure and function of medullary V2a RSNs in the control of locomotion.

Parkinson's disease (PD) is caused by loss of dopaminergic neurons of the nigrostriatal pathway, leading to disrupted function of basal ganglia circuits. PD is associated with a variety of locomotor impairments, including freezing and difficulties in making turns. With the recent identification of a basal ganglia-spinal cord pathway for turning gait asymmetries (Cregg et al., FENS Forum 2022)—a pathway that includes the substantia nigra pars reticulata, pontine nucleus oralis (PnO), and *Chx10* reticulospinal neurons—we hypothesized that turning deficits in PD may be alleviated by targeted activation of this pathway. To induce Parkinsonian turning gait deficiencies, we used the unilateral 6-hydroxydopamine (6-OHDA) mouse model of PD. Unilateral 6-OHDA lesioned mice exhibited loss of dopaminergic neurons of the ipsilateral substantia nigra pars compacta and their axonal terminals in the striatum. 6-OHDA lesioned mice developed pronounced turning behavior with a dominance to the ipsilateral (lesioned) side within days, which persisted into the chronic state (>2 weeks). Using excitatory DREADDS, we demonstrate that stimulation of *Chx10* reticulospinal neurons contralateral to the lesion restores contralateral turning gaits in both acutely and chronically lesioned states. In accordance, optogenetic stimulation of excitatory PnO neurons ipsilateral to the lesion—projecting to *Chx10* reticulospinal neurons on the contralateral side—also restores contralateral turning gaits with millisecond precision. Our data outline promising brainstem targets for improving locomotor function in PD. This work was supported by the Novo Nordisk Foundation and the Lundbeck Foundation.

PASSIVE LIMB TRAINING MODULATES THE RESPIRATORY RHYTHM

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Rosamaria Apicella, Giuliano Taccola
SISSA, Neuroscience, Trieste, Italy

Initial modifications of breathing at the onset of exercise are mainly provided by afferent feedback from exercising limbs and descending input from the suprapontine areas. To better characterize neural systems controlling respiration during physical activity, we designed a novel experimental in vitro platform. Thus, an isolated preparation of the central nervous system from neonatal rodents had the limbs attached to an ad-hoc robot (BIKE) driving passive pedaling at calibrated speeds. In these conditions, a stable spontaneous respiratory rhythm was extracellularly recorded for more than four hours from all cervical ventral roots. The duration of single respiratory bursts was already reduced at lower pedaling speeds (1 Hz), while only an intense exercise (3.5 Hz) modulated the pace of breathing. Brief sessions (5 min) of BIKE at 3.5 Hz augmented the respiratory rate of preparations that showed slow bursting in control (slower breathers), whereas slowed down the rhythm of faster breathers. Accordingly, when spontaneous breathing was accelerated by high potassium concentrations, BIKE reduced bursting frequency. Regardless of the baseline respiratory pace, BIKE at 3.5 Hz always decreased single burst duration with unaffected amplitude. The surgical ablation of suprapontine structures completely prevented modulation of breathing by intense training. Albeit the variability in baseline breathing rates, intense passive cyclic movement of limbs tuned the frequency of fictive respiration toward a common value, while each respiratory event became shorter. These modulatory effects of passive training rely on suprapontine areas. The observations presented contribute to defining how the respiratory system integrates sensory input from limbs.

Selective Antagonism of A1 Adenosinergic Receptors Strengthens the Neuromodulation of the Sensorimotor Network During Epidural Spinal Stimulation.
Although epidural spinal stimulation (ESS) results in promising therapeutic effects in individuals with spinal cord injury (SCI), its potential to generate functional motor recovery varies between individuals and remains largely unclear. However, both preclinical and clinical studies indicate the capacity of electrical and pharmacological interventions to synergistically increase the engagement of spinal sensorimotor networks and regain motor function after SCI. This study explored whether selective pharmacological antagonism of the adenosine A1 receptor subtype synergizes with ESS, thereby increasing motor response. We hypothesized that selective pharmacological antagonism of A1 receptors during ESS would produce facilitatory effects in spinal sensorimotor networks detected as an increased amplitude of spinally-evoked motor potentials and sustained duration of ESS induced activity. Terminal experiments were performed in adult rats using trains of stereotyped pulses at 40 Hz delivered at L5 with the local administration to the cord of 8-cyclopentyl-1,3-dipropylxanthine (DPCPX). We demonstrated that ESS combined with the blockage of A1 receptors increased the magnitude of the endogenous modulation and postponed the decay of responses that occur during ESS alone. Although DPCPX significantly increased the yield of repetitive stimulation in intact spinal cords, the effects of A1 antagonism on motor evoked responses after an acute spinal transection was not detected. These studies support the future investigation of the optimal dosage, methods of delivery, and systemic effects of the synergistic application of A1 antagonists and spinal stimulation in the intact and injured spinal cord.

THE ROLE OF HINDBRAIN SEGMENTATION AND THE MAUTHNER ARRAY DURING VISUAL ESCAPE BEHAVIOUR IN LARVAL ZEBRAFISH

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Aaron Ostrovsky, Pedro Tomás Silva, Adrien Jouary, Edite Figueiras, João Marques, Michael Orger
Champalimaud Foundation, Champalimaud Research Neuroscience Programme, Lisbon, Portugal

Segmentation in the hindbrain plays an important role in the organization of motor circuits in vertebrates and gives rise to sets of homologous neurons that share similar morphology and functionality. A key question in the field is what purpose does segmental homology serve? One explanation that has been advanced is that using homologous neurons in different combinations allows for modulation of the kinematics of a particular movement. Another possibility is that the homologues allow for sequences of behavior to play out over time. Larval zebrafish serve as an ideal model in which to test these hypotheses, and in particular the Mauthner array (M-array) are known to contribute to the generation of the fast escape swim, known as the Short Latency C-start (SLC). The M-array consists of three homologous pairs of neurons: the Mauthner cells, and two pairs of homologues, MiD2cm and MiD3cm. Using genetic ablations of the Mauthner cells, we show they are not necessary for SLCs in response to a visual threat, but that there is a reduction in the length of sequences of SLCs, suggesting that the homologue array may play a role in sustaining chains of behavior. In ongoing work we are recording the M-array using fast volumetric light-sheet imaging, while presenting larvae with a visual predator-like stimulus that evokes sequences of SLCs in order to evaluate how the M-array is activated. With this work we hope to contribute to the debate over why segmentation is fundamental to motor systems.

CHARACTERIZATION OF PHOX2B-EXPRESSING PREMOTORS IN THE HINDBRAIN RETICULAR FORMATION

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Selvee Sungeelee[1], Bowen Dempsey[2], Jean-François Brunet[1]
[1]Institut de Biologie de l'ENS, Ens.cnrs Umr8197 . Inserm U1024, Paris, France, [2]Macquarie university, Faculty Of Medicine, Health And Human Sciences, NSW, Australia

Aims The reticular formation of the pons and medulla is known to contain neurons involved in vital functions (respiratory and cardiovascular) and in orofacial movements, but remains poorly characterized in terms of genetically defined neuron types. The transcription factor *Phox2b* specifies most autonomic neurons, and orofacial motor nuclei. Moreover, genetic anterograde tracing of all hindbrain glutamatergic Phox2b+ interneurons reveals terminals in jaw opening and closing motor nuclei, pointing to orofacial Phox2b+ premotor populations. Previous work from the lab identified jaw-opener Phox2b+ premotor neurons in the intermediate reticular formation (Dempsey et al., 2021). Here we explore the function of another Phox2b+ interneuronal population (Sup5^{Phox2b}) located in the supratrigeminal nucleus, a region known to project to the trigeminal (jaw-closing) motor nucleus. **Methods** In the Sup5^{Phox2b} of *Phox2b::Cre* mice, we stereotaxically injected a virally encoded Cre-dependent opsin or calcium indicator, combined with fiber optic cannula implantation, then video-recorded and motion-tracked head-fixed animals by DeepLabCut. **Results** We found that a 100ms pulse of blue light minimally adducts the jaw from its resting position, while a 1000ms light pulse interrupts a spontaneous licking sequence. Changes in bulk calcium fluorescence in spontaneously chewing animals suggest that Sup5^{Phox2b} is recruited during this behavior. **Conclusion** Expression of the transcription factor *Phox2b* in the supratrigeminal nucleus identifies a likely jaw-closing premotor center and provides access to its further functional characterization. IMAGING NEURAL ACTIVITY DYNAMICS DURING GAIT SWITCHING IN LARVAL ZEBRAFISH.

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Elena Hindinger, Edite Figueiras, Alexandre Laborde, Adrien Jouary, Michael Orger
Champalimaud Foundation, Champalimaud Research, Lisbon, Portugal

Animals need to perform a diverse range of behaviours to navigate their environment successfully. Larval zebrafish swim using discrete episodes of propulsion called bouts that can be classified into 13 categories of movement. We aim to elucidate the mechanism of transition between different movements, particularly in the context of forward swimming, on both a behavioural and neural level. To characterise gait-switching behaviour, larval zebrafish were presented with gratings moving from tail to head at different speeds eliciting forward swimming, known as the optomotor response. Collecting various kinematic parameters, through tracking fish position and tail angle, allowed swims to be classified into different categories of movement. In response to slow gratings, larval zebrafish predominantly exhibited slow swims, whereas fast gratings elicited a rapid transition from slow to sustained trains of fast swims. To identify the neural correlates of slow and fast swims and elucidate the population dynamics underlying gait transitions, we recorded activity from genetically labelled neural populations in the brainstem of head-fixed larval zebrafish while they performed the optomotor response in a closed-loop configuration, utilising a 'SCAPE' light-sheet microscope. Head-fixed fish showed differences in bout kinematics from freely swimming fish, with longer movements that included switches in frequency within a single bout. We therefore use regression analysis, based on kinematics of individual half-beats within each bout to identify neuronal populations associated with different modes of swimming. By showing how the brain selects dynamically between two distinct motor outputs we strive to understand fundamental principles in the supra-spinal control of locomotion.

DESCENDING EXCITATORY RETICULOSPINAL DRIVE TO SPINAL NEURONS IN SALAMANDERS.

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Jordan Swiegers[1], Alberto Joven[2], Auke Ijspeert[3], Andras Simon[2], Dimitri Ryczko[1]
[1]Université de Sherbrooke, Pharmacology-physiology, Sherbrooke, Canada, [2]Karolinska Institutet, Cell And Molecular Biology, Stockholm, Sweden, [3]École polytechnique fédérale de Lausanne, Biorob, School Of Engineering, Lausanne, Switzerland

Salamanders are the only tetrapods that recover voluntary locomotion after full spinal transection. However, the neurons that play a key role in the recovery of locomotor control are still largely unknown. As in other vertebrates, excitatory reticulospinal neurons likely play an important role in the initiation of locomotion, while excitatory spinal neurons likely generate the locomotor rhythm. However, there is little information about these neurons in salamanders compared to lamprey, zebrafish or mouse models. Here, we used neural tracing, in situ hybridization (RNAScope), and immunofluorescence to anatomically study glutamatergic markers (vesicular glutamate transporter Vglut2, and Chx10) in reticulospinal and spinal neurons of the Iberian newt (Pleurodeles waltl). We also used calcium imaging in an ex vivo brainstem-spinal cord preparation to examine the role of the descending glutamatergic reticulospinal drive in the activation pattern of spinal neurons. Our results suggest that the glutamatergic locomotor neurons described in other species are present in salamanders. These neurons are good candidates to play a role in the recovery of locomotor control after spinal cord regeneration in salamanders.

SENSORY-EVOKED CALCIUM RESPONSES IN NEURONS OF THE MESENCEPHALIC LOCOMOTOR REGION IN FREELY BEHAVING MICE.

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Cornelis Immanuel Van Der Zouwen[1], Joël Boutin[1], Léonie Dejas[1], Aurélie Flaive[1], Ted Hsu[2], Vaibhav Konanur[2], Mitchell Roitman[2], Dimitri Ryczko[1]
[1]Université de Sherbrooke, Pharmacology-physiology, Sherbrooke, Canada, [2]University of Illinois at Chicago, Department Of Psychology, Chicago, United States of America

Considerable knowledge has been gained on the role of Mesencephalic Locomotor Region (MLR) in locomotor control. However, little is known about the sensory events that increase MLR activity. Locomotion potentially needs to be initiated in various environmental contexts, which could be channeled to the MLR through sensory modalities. Here, we investigated whether MLR neurons show increases in activity in response to unconditioned sensory stimulations in freely moving mice. First, to validate our ability to target the glutamatergic (Vglut2$^+$) MLR neurons generating the locomotor drive, we injected a virus encoding for a channelrhodopsin in a Cre-dependent manner in the MLR of Vglut2-Cre mice. Applying blue light to the MLR initiated locomotion. Then, we recorded the activity of MLR neurons with fiber photometry by injecting a virus encoding for a calcium sensor (GCaMP7f) in a Cre-dependent manner in the MLR of Vglut2-Cre mice. When mice were made to walk on a motorized treadmill, calcium signals increased in Vglut2$^+$ MLR neurons, confirming the locomotor nature of these neurons. An air puff applied to the mouse body, a brief unexpected sound, or a looming stimulus all evoked calcium increases in Vglut2$^+$ MLR neurons, indicating that these neurons can encode sensory information. Interestingly, calcium responses were not always associated with an escape response. In contrast, our preliminary data suggest that no calcium responses were evoked by the same sensory stimulations in GABAergic (VGAT$^+$) MLR neurons. This indicates that sensory events encoding potentially dangerous environmental conditions are channeled to a specific cell type in the MLR.

Optogenetic stimulation of glutamatergic neurons in the cuneiform nucleus controls locomotion in a mouse model of Parkinson's disease.
In Parkinson's disease (PD), the loss of midbrain dopaminergic cells results in severe locomotor deficits, such as gait freezing and akinesia. Growing evidence indicates that these deficits can be attributed to the decreased activity in the mesencephalic locomotor region (MLR), a brainstem region controlling locomotion. Clinicians are exploring the deep brain stimulation of the MLR as a treatment option to improve locomotor function. The results are variable, from modest to promising. However, within the MLR, clinicians have targeted the pedunculopontine nucleus exclusively, while leaving the cuneiform nucleus unexplored. To our knowledge, the effects of cuneiform nucleus stimulation have never been determined in parkinsonian conditions in any animal model. Here, we addressed this issue in a mouse model of PD, based on the bilateral striatal injection of 6-hydroxydopamine, which damaged the nigrostriatal pathway and decreased locomotor activity. We show that selective optogenetic stimulation of glutamatergic neurons in the cuneiform nucleus in mice expressing channelrhodopsin in a Cre-dependent manner in Vglut2-positive neurons (Vglut2-ChR2-EYFP mice) increased the number of locomotor initiations, increased the time spent in locomotion, and controlled locomotor speed. Using deep learning-based movement analysis, we found that the limb kinematics of optogenetic-evoked locomotion in pathological conditions were largely similar to those recorded in intact animals. Our work identifies the glutamatergic neurons of the cuneiform nucleus as a potentially clinically relevant target to improve locomotor activity in parkinsonian conditions. Our study should open avenues to develop the targeted stimulation of these neurons using deep brain stimulation, pharmacotherapy, or optogenetics.

Freely Behaving Mice Can Brake and Turn During Optogenetic Stimulation of the Mesencephalic Locomotor Region.
A key function of the mesencephalic locomotor region (MLR) is to control the speed of forward symmetrical locomotor movements. However, the ability of freely moving mammals to integrate environmental cues to brake and turn during MLR stimulation is poorly documented. Here, we investigated whether freely behaving mice could brake or turn, based on

environmental cues during MLR stimulation. We photostimulated the cuneiform nucleus (part of the MLR) in mice expressing channelrhodopsin in Vglut2-positive neurons in a Cre-dependent manner (Vglut2-ChR2-EYFP) using optogenetics. We detected locomotor movements using deep learning. We used patch-clamp recordings to validate the functional expression of channelrhodopsin and neuroanatomy to visualize the stimulation sites. In the linear corridor, gait diagram and limb kinematics were similar during spontaneous and optogenetic-evoked locomotion. In the open-field arena, optogenetic stimulation of the MLR evoked locomotion, and increasing laser power increased locomotor speed. Mice could brake and make sharp turns (~90°) when approaching a corner during MLR stimulation in the open-field arena. The speed during the turn was scaled with the speed before the turn, and with the turn angle. Patch-clamp recordings in Vglut2-ChR2-EYFP mice show that blue light evoked short-latency spiking in MLR neurons. Our results strengthen the idea that different brainstem neurons convey braking/turning and MLR speed commands in mammals. Our study also shows that Vglut2-positive neurons of the cuneiform nucleus are a relevant target to increase locomotor activity without impeding the ability to brake and turn when approaching obstacles, thus ensuring smooth and adaptable navigation. Our observations may have clinical relevance since cuneiform nucleus stimulation is increasingly considered to improve locomotion function in pathological states such as Parkinson's disease, spinal cord injury, or stroke.

Serotonergic Modulation of Locomotor Activity From Basal Vertebrates to Mammals.
During the last 50 years, the serotonergic (5-HT) system was reported to exert a complex modulation of locomotor activity. Here, we focus on two key factors that likely contribute to such complexity. First, locomotion is modulated directly and indirectly by 5-HT neurons. The locomotor circuitry is directly innervated by 5-HT neurons in the caudal brainstem and spinal cord. Also, indirect control of locomotor activity results from ascending projections of 5-HT cells in the rostral brainstem that innervate multiple brain centers involved in motor action planning. Second, each approach used to manipulate the 5-HT system likely engages different 5-HT-dependent mechanisms. This includes the recruitment of different 5-HT receptors, which can have excitatory or inhibitory effects on cell activity. These receptors can be located far or close to the 5-HT release sites, making their activation dependent on the level of 5-HT released. Here we review the activity of different 5-HT nuclei during locomotor activity, and the locomotor effects of 5-HT precursors, exogenous 5-HT, selective 5-HT reuptake inhibitors (SSRI), electrical or chemical stimulation of 5-HT neurons, genetic deletions, optogenetic and chemogenetic manipulations. We highlight both the coherent and controversial aspects of 5-HT modulation of locomotor activity from basal vertebrates to mammals. This mini review may hopefully inspire future studies aiming at dissecting the complex effects of 5-HT on locomotor function.

Heterogeneous expression of dopaminergic markers and Vglut2 in mouse mesodiencephalic dopaminergic nuclei A8-A13.
Co-transmission of glutamate by brain dopaminergic (DA) neurons was recently proposed as a potential factor influencing cell survival in models of Parkinson's disease. Intriguingly, brain DA nuclei are differentially affected in Parkinson's disease. Whether this is associated with different patterns of co-expression of the glutamatergic phenotype along the rostrocaudal brain axis is unknown in mammals. We hypothesized that, as in zebrafish, the glutamatergic phenotype is present preferentially in the caudal mesodiencephalic DA nuclei. Here, we used in mice a cell fate mapping strategy based on reporter protein expression (ZsGreen) consecutive to previous expression of the vesicular glutamate transporter 2 (Vglut2) gene, coupled with immunofluorescence experiments against tyrosine hydroxylase (TH) or dopamine transporter (DAT). We found three expression patterns in DA cells, organized along the rostrocaudal brain axis. The first pattern (TH-positive, DAT-positive, ZsGreen-positive) was found in A8-A10. The second pattern (TH-positive, DAT-negative, ZsGreen-positive) was found in A11. The third pattern (TH-positive, DAT-negative, ZsGreen-negative) was found in A12-A13. These patterns should help to refine the establishment of the homology of DA nuclei between vertebrate species. Our results also uncover that Vglut2 is expressed at some point during cell lifetime in DA nuclei known to degenerate in Parkinson's disease and largely absent from those that are preserved, suggesting that co-expression of the glutamatergic phenotype in DA cells influences their survival in Parkinson's disease.

DEEP LEARNING-BASED MOVEMENT ANALYSES DURING WALKING AND SWIMMING IN SALAMANDERS

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Ines Khsime[1], Cornelis Immanuel Van Der Zouwen[1], Alberto Joven[2], Andras Simon[2], Auke Ijspeert[3], Dimitri Ryczko[1]
[1]Université de Sherbrooke, Pharmacology-physiology, Sherbrooke, Canada, [2]Karolinska Institutet, Cell And Molecular Biology, Stockholm, Sweden, [3]École polytechnique fédérale de Lausanne, Biorob, School Of Engineering, Lausanne, Switzerland

Salamanders swim underwater and walk on ground. They are an ideal animal model to study how the locomotor circuitry can generate two different behaviors. They are also able to recover voluntary locomotion after full spinal transection. However, a precise description of the gradual recovery of swimming and walking movements after full spinal transection is lacking. In order to do such analysis, here we introduce the use of a deep-learning based software to analyze the locomotor movements of the salamander *Pleurodeles waltl*. We recorded swimming and walking movements from below at 300 frames per second in a motorater. We used DeepLabCut software to track twenty-five user-defined anatomical points distributed on the body axis, limbs and head without the need to place any physical markers. Tracking of the axial body parts allowed us to measure the phase coupling and the amplitude of the angular excursion between the anatomical points along the body axis as a function of time. Tracking of the limbs allowed us to measure the speed of limb movements, from which we can evaluate the footfall pattern, and therefore swing and stance duration, cycle duration and stride length. Our study shows that the use of DeepLabCut provides a powerful approach to obtain a detailed analysis of salamander locomotion. This will allow us to study the recovery of swimming and walking movements during regeneration of the locomotor circuitry.

SACCADIC PREMOTOR BURST NEURONS AND HISTOCHEMICAL CORRELATES OF THEIR FIRING PATTERNS IN RHESUS MONKEY

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Ümit Suat Mayadali[1,2], Karoline Lienbacher[1], Aasef G. Shaikh[3], Anja Horn[1]
[1]Ludwig-Maximilians-University of Munich, Institute Of Anatomy And Cell Biology, Munich, Germany, [2]Graduate School of Systemic Neurosciences, Department Biology Ii Neurobiology, Planegg-Martinsried, Germany, [3]Case Western Reserve University, Department Of Neurology, Cleveland, United States of America

Bursting behavior of brainstem premotor burst neurons (BNs) is essential for initiation of saccades and calibrating their metrics. Several ion channel families such as voltage-gated potassium (Kv) channels, low-voltage-activated calcium (Cav3) channels and hyperpolarization-activated cyclic nucleotide–gated (HCN) channels are major regulators of the bursting in neurons. Therefore, it was speculated that ion channels with rapid kinematics are essential for characteristic firing patterns of the BNs and rapid saccade velocities. However, the expression patterns of ion channels are yet to be confirmed in order to support the neuromimetic model predictions for saccade generation in brainstem, and also to support contemporary views that channelopathy can cause saccade disorders in humans. For the proof of concept, we examined excitatory BNs in rostral interstitial nucleus of medial longitudinal fasciculus (RIMLF, vertical saccades) and inhibitory BNs in nucleus paragigantocellularis dorsalis (PGD, horizontal saccades) histochemically in macaque monkeys. We found strong expression of Kv channels, HCN1&2 and Cav3.2&3.3 in both BN populations. These channels are known for their fast-kinematic properties and are essential for post-inhibitory rebound. Moreover, PGD was found to host multiple neuron groups regarding calretinin immunoreactivity. Our results provide histochemical evidence in support for proposed post-inhibitory rebound bursting model of BNs. Furthermore, our findings confirm that deduction can be made about electrophysiological firing properties by histochemical examination of functional groups of the brainstem saccadic circuitry. This development is an important building block supporting the concept of channelopathies in saccadic disorders. Future histological studies in humans will confirm this theory for saccadic disorders.

Histochemical Characterization of the Vestibular Y-Group in Monkey.
The Y-group plays an important role in the generation of upward smooth pursuit eye movements and contributes to the adaptive properties of the vertical vestibulo-ocular reflex. Malfunction of this circuitry may cause eye movement disorders, such as downbeat nystagmus. To characterize the neuron populations in the Y-group, we performed immunostainings for cellular proteins related to firing characteristics and transmitters (calretinin, GABA-related proteins and ion channels) in brainstem sections of macaque monkeys that had received tracer injections into the oculomotor nucleus. Two histochemically different populations of premotor neurons were identified: The calretinin-positive population represents the excitatory projection to contralateral upgaze motoneurons, whereas the GABAergic population represents the inhibitory projection to ipsilateral downgaze motoneurons. Both populations receive a strong supply by GABAergic nerve endings most likely originating from floccular Purkinje cells. All premotor neurons express nonphosphorylated neurofilaments and are ensheathed by strong perineuronal nets. In addition, they contain the voltage-gated potassium channels Kv1.1 and Kv3.1b which suggests biophysical similarities to high-activity premotor neurons of vestibular and oculomotor systems. The premotor neurons of Y-group form a homogenous population with histochemical characteristics compatible with fast-firing projection neurons that can also undergo plasticity and contribute to motor learning as found for the adaptation of the vestibulo-ocular reflex in response to visual-vestibular mismatch stimulation. The histochemical characterization of premotor neurons in the Y-group allows the identification of the homologue cell groups in human, including their transmitter inputs and will serve as basis for correlated anatomical-neuropathological studies of clinical cases with downbeat nystagmus.

Transmitter and ion channel profiles of neurons in the primate abducens and trochlear nuclei.
Extraocular motoneurons initiate dynamically different eye movements, including saccades, smooth pursuit and vestibulo-

ocular reflexes. These motoneurons subdivide into two main types based on the structure of the neuro-muscular interface: motoneurons of singly-innervated (SIF), and motoneurons of multiply-innervated muscle fibers (MIF). SIF motoneurons are thought to provoke strong and brief/fast muscle contractions, whereas MIF motoneurons initiate prolonged, slow contractions. While relevant for adequate functionality, transmitter and ion channel profiles associated with the morpho-physiological differences between these motoneuron types, have not been elucidated so far. This prompted us to investigate the expression of voltage-gated potassium, sodium and calcium ion channels (Kv1.1, Kv3.1b, Nav1.6, Cav3.1-3.3, KCC2), the transmitter profiles of their presynaptic terminals (vGlut1 and 2, GlyT2 and GAD) and transmitter receptors (GluR2/3, NMDAR1, GlyR1α) using immunohistochemical analyses of abducens and trochlear motoneurons and of abducens internuclear neurons (INTs) in macaque monkeys. The main findings were: (1) MIF and SIF motoneurons express unique voltage-gated ion channel profiles, respectively, likely accounting for differences in intrinsic membrane properties. (2) Presynaptic glutamatergic synapses utilize vGlut2, but not vGlut1. (3) Trochlear motoneurons receive GABAergic inputs, abducens neurons receive both GABAergic and glycinergic inputs. (4) Synaptic densities differ between MIF and SIF motoneurons, with MIF motoneurons receiving fewer terminals. (5) Glutamatergic receptor subtypes differ between MIF and SIF motoneurons. While NMDAR1 is intensely expressed in INTs, MIF motoneurons lack this receptor subtype entirely. The obtained cell-type-specific transmitter and conductance profiles illuminate the structural substrates responsible for differential contributions of neurons in the abducens and trochlear nuclei to eye movements.

Potassium channels in omnipause neurons.
Potassium (K) channels are major contributors to fast and precise action potential generation. The aim of this study was to establish the immunoreactivity profile of several potassium channels in omnipause neurons (OPNs), which play a central role in premotor saccadic circuitry. To accomplish this, we histochemically examined monkey and human brainstem sections using antibodies against the voltage gated K-channels K1.1, K3.1b and K-Cl cotransporter (KCC2). We found that OPNs of both species were positive for all three K-antibodies and that the staining patterns were similar for both species. In individual OPNs, K3.1b was detected on the somatic membrane and proximal dendrites, while K1.1 was mainly confined to soma. Further, KCC2 immunoreactivity was strong in distal dendrites, but was weak in the somatic membrane. Our findings allow the speculation that the alterations in K-channel expression in OPNs could be the underlying mechanism for several saccadic disorders through neuronal and circuit-level malfunction.

PEDUNCULOPONTINE NEURONS FOR GLOBAL MOTOR ARREST

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Haizea Goñi-Erro[1], Roberto Leiras[1], Raghavendra Selvan[1,2], Ole Kiehn[1,3]
[1]University of Copenhagen, Department Of Neuroscience, Copenhagen, Denmark, [2]University of Copenhagen, Department Of Computer Science, Copenhagen, Denmark, [3]Karolinska Institutet, Department Of Neuroscience, Solna, Sweden

The episodic nature of movement requires neural mechanisms for movement initiation and arrest. Motor arrest may happen in diverse contexts such as the termination of a goal-directed movement, or in behavioral responses that lead to global motor arrest, for example fear/defensive freezing and behavioral interruption upon detection of salient environmental cues. Within global motor arrest, previous studies have mainly focused on the circuits mediating defensive freezing. However, the neuronal circuits that bridge with the executive motor circuits to implement a global motor arrest in non-defensive contexts are poorly understood. Using a combined anatomical, physiological, and behavioral approach, we report the discovery that glutamatergic Chx10^{+} neurons in the pedunculopontine nucleus (PPN) evoke global motor arrest in mice. First, we describe a subpopulation of glutamatergic PPN neurons that expresses the transcription factor Chx10 (Chx10-PPN) and is preferentially located in the rostral-half of the nucleus. Second, we show that optogenetic activation of Chx10-PPN neurons arrests all ongoing movements including locomotion, grooming, and rearing. Third, we find that Chx10-PPN evoked motor arrest is accompanied by apnea and bradycardia. Moreover, we demonstrate that the arrest evoked from Chx10-PPN neurons differs from the defensive freezing evoked from glutamatergic neurons in the ventrolateral periaqueductal gray (vlPAG), both in its motor and autonomic components. Thus, our study defines a cluster of excitatory neurons that evokes a global motor arrest that is different from defensive freezing, and identifies a locomotor-opposing role for Chx10^{+} glutamatergic neurons in the rostral PPN.

REPRESENTATION OF BODY ORIENTATION IN VESTIBULAR-DEFECTIVE PATIENTS BEFORE AND AFTER UNILATERAL VESTIBULAR LOSS

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Liliane Borel[1], Jacques Honore[2], Mathilde Bachelard-Serra[3], Jean-Pierre Lavieille[3], Arnaud Saj[4]
[1]CNRS - Aix-Marseille Université, Laboratoire De Neurosciences Cognitives, Marseille, France, [2]University of Lille, CNRS, Laboratoire Scalab -, Villeneuve d'Ascq, France, [3]Hôpital La Conception, APHM, Department Of Otorhinolaryngology, Head And Neck Surgery, Marseille, France, [4]University of Montréal, Department Of Psychology, Montréal, Canada

Aims: The unilateral vestibular syndrome results in postural, oculomotor, perceptive, and cognitive symptoms. The present study was designed to investigate the role of vestibular signals in the representation of body orientation, which remains poorly considered in vestibular patients. **Methods:** We investigated the subjective straight ahead (SSA) direction using a horizontal rod allowing to dissociate the translation and rotation components of the body midline representation in 21 patients with unilateral vestibular loss (right = 8; left = 13) and in 12 healthy controls. Patients were tested the day before surgery and during the recovery period, 7 days and 2 months after the surgery. **Results and Conclusions:** In the chronic phases, i.e., before and two months after unilateral vestibular neurotomy, the patients showed a rightward translation bias of their SSA, without rotation bias, whatever the side of the vestibular loss. This biais could be considered as a sign of spatial neglect. In the early phase after surgery, SSA moved toward the operated side both in translation and in rotation, as typically found for biases occurring after unilateral vestibular loss. Therefore, the recovery time-course of the SSA differed depending on the side of the vestibular loss, with more extensive changes over time before and after left vestibular loss. This study strongly supports the notion that the vestibular system plays a major role in body representation processes and more broadly in spatial cognition. From a clinical point of view, SSA appeared to be a reliable indicator for the presence of a vestibular disorder.

FUNCTIONAL REGIONALIZATION OF THE VESTIBULO-CEREBELLUM IN RATS

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Idriss Tsayem Ngueguim[1], Aurelie Gourgeon[2], Clement Lena[3], Guillaume Dugue[1]
[1]École normale supérieure Université PSL CNRS INSERM, Institut De Biologie De L'École Normale Supérieure (ibens), Paris, France, [2]Ecole Normale Superieure, Institut De Biologie De L'ecole Normale Superieure, Paris, France, [3]École Normale Supérieure Université PSL CNRS Inserm, Institut De Biologie De L'École Normale Supérieure (ibens), Paris, France

The vestibulo-cerebellum (VC) encompasses cerebellar regions targeted by fibers originating from vestibular end organs and/or brainstem vestibular nuclei. At the level of the vermis, the VC corresponds to the most posterior lobules designated as nodulus and uvula (NU) which are themselves subdivided in a series of parasagittal modules. Despite the involvement of the VC in multiple pathways, from the control of gaze and posture to spatial orientation, these modules have not yet been linked with specific functions, with the exception of the processing of specific patterns of optic flow in pigeons. To unravel the functional regionalization of the NU, we chronically recorded NU units at various antero-posterior and medio-lateral locations in rats while tracking the 3D rotations and accelerations of their head using inertial measurements units, both during active (self-generated) or passively-applied movements. The sensitivity of the recorded units to head kinematics was assessed using a model-free approach linking their instantaneous firing rate with head angular velocity and/or tilt. In our preliminary analysis, rotation-sensitive vs tilt-sensitive units were preferentially found in medial vs lateral regions. NU units within a medial band appeared to anticipate head angular velocity, consistent with the encoding of either a sensory prediction or of angular acceleration. Additionally, many medially-located units exhibited larger modulations during passive vs active movement, a pervasive feature of a number of other vestibular structures. Taken together, these results are consistent with the existence of specialized medio-lateral bands in the NU, whose associated functions within specific vestibular pathways remain to be precisely established.

MAGNETIC ACTUATION OF EAR STONES ALLOWS BEHAVIORAL AND NEURONAL EXPLORATION OF VESTIBULO-MOTOR PROCESSING IN LARVAL ZEBRAFISH

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Natalia Beiza[1], Thomas Pujol[1,2], Hippolyte Moulle[1], Thomas Panier[1], Geoffrey Migault[1], Nicolas Desprat[3], Pierre Tapis[1], Georges Debrégeas[1], Volker Bormuth[1]

Whether animals walk, fly, or swim, active sensorimotor control is required to maintain balance while moving. The vestibular system of the inner ear plays a central role in this process as it continuously informs the brain of the gravitational field and the head acceleration. Monitoring the neural circuits that process vestibular information remains challenging as vestibular stimulations require a rotation or a translation of the animal's head. Here, we report on a new method to deliver in vivo fictive vestibular stimulation in zebrafish larvae through magnetic actuation of the otoliths. After injecting a ferrofluid into the inner ear, we were able to exert controlled forces on the ear stone of immobilized larvae, eliciting consistent eye and tail compensatory movements. We showed that these behavioral responses corresponded to normal body rotations of up to 20$degree$ in amplitude. Using simultaneous light-sheet based calcium imaging, we were able to record the brain-wide neuronal response to this fictive vestibular stimuli, showing evoked activity in the vestibular nucleus and downstream nuclei. We disentangled the contribution of both ears using unilateral ferrofluid injection. The recorded neuronal activity shows contralateral inhibition between the ears. As they are compatible with fluorescence microscopy, optogenetics, and electrophysiological techniques, magnetic stimulations open new perspectives for dissecting the neural circuits processing vestibular information.

FUNCTIONAL AND MOLECULAR HETEROGENEITY IN THE DEVELOPING VESTIBULO-OCULAR REFLEX CIRCUIT

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Paige Leary, David Schoppik
New York University Grossman School of Medicine, Depts. Of Otolaryngology, Neuroscience & Physiology, And The Neuroscience Institute, New York, United States of America

All vertebrates need to stabilize gaze during movement. As animals develop, gaze stabilization improves. However, it is unclear how the developing brain comes to stabilize gaze. It is well established that mature neurons in the reflex arc (sensory; central; motor neurons) responsible for gaze stabilization have heterogeneous response dynamics. I hypothesize that such heterogeneities will correlate with—and potentially control—different features of behavioral maturation, reflecting differential roles in development. We generated lines of transgenic zebrafish to express the calcium indicator GCaMP6s in two of these nuclei: the central vestibular nucleus and extraocular motor neurons of the trochlear nuclei. I measured neural activity with a multiphoton microscope while delivering whole-body tilts in pitch and roll axes in the same cells at 3, 5, and 7 days post fertilization, tiling the time before and during maturation of gaze stabilization. I observed systematic changes in neural activity, including a strengthening period of tuning. To probe response dynamics of neurons, I recorded evoked activity as a function of increasing stimulus amplitude and direction. These events were correlated, consistent with prior studies of mature neuron function. However, the slope of this relationship varied considerably, implying differential contributions to gaze stabilizing behavior. I have adopted a multipronged approach including correlative imaging and perturbative assays to directly address how the heterogeneity of response profiles differentially influences the maturation of behavior. Additionally, we are working to characterize the molecular correlates of these changes with transcriptomic approaches. This work will speak to the mechanisms responsible for development of gaze stabilization.

Efference copies: Side-eyeing across species.
Efference copies of movement-inducing neural signals have been proposed to serve a role in gaze stabilization. Prior work has demonstrated a spino-extraocular motor circuit in the tadpole that relays copies of spinal commands to extraocular motor neurons. A recent study demonstrates the presence of this circuitry in mice, suggesting a unique method of gaze stabilization in the locomoting mouse.

An Excitatory and Epileptogenic Effect of Dentate Gyrus Mossy Cells in a Mouse Model of Epilepsy.
The sparse activity of hippocampal dentate gyrus (DG) granule cells (GCs) is thought to be critical for cognition and behavior, whereas excessive DG activity may contribute to disorders such as temporal lobe epilepsy (TLE). Glutamatergic mossy cells (MCs) of the DG are potentially critical to normal and pathological functions of the DG because they can regulate GC activity through innervation of GCs or indirectly through GABAergic neurons. Here, we test the hypothesis that MC excitation of GCs is normally weak, but under pathological conditions, MC excitation of GCs is dramatically strengthened. We show that selectively inhibiting MCs during severe seizures reduced manifestations of those seizures, hippocampal injury, and chronic epilepsy. In contrast, selectively activating MCs was pro-convulsant. Mechanistic in vitro studies using optogenetics further demonstrated the unanticipated ability of MC axons to excite GCs under pathological conditions. These results demonstrate an excitatory and epileptogenic effect of MCs in the DG.

Adult-born hippocampal neurons bidirectionally modulate entorhinal inputs into the dentate gyrus.
Young adult-born granule cells (abGCs) in the dentate gyrus (DG) have a profound impact on cognition and mood. However, it remains unclear how abGCs distinctively contribute to local DG information processing. We found that the actions of abGCs in the DG depend on the origin of incoming afferents. In response to lateral entorhinal cortex (LEC) inputs, abGCs exert

monosynaptic inhibition of mature granule cells (mGCs) through group II metabotropic glutamate receptors. By contrast, in response to medial entorhinal cortex (MEC) inputs, abGCs directly excite mGCs through -methyl-d-aspartate receptors. Thus, a critical function of abGCs may be to regulate the relative synaptic strengths of LEC-driven contextual information versus MEC-driven spatial information to shape distinct neural representations in the DG.

Converging and Differential Brain Phospholipid Dysregulation in the Pathogenesis of Repetitive Mild Traumatic Brain Injury and Alzheimer's Disease.
Repetitive mild traumatic brain injury (rmTBI) is a major epigenetic risk factor for Alzheimer's disease (AD). The precise nature of how rmTBI leads to or precipitates AD pathology is currently unknown. Numerous neurological conditions have shown an important role for dysfunctional phospholipid metabolism as a driving factor for the pathogenesis of neurodegenerative diseases. However, the precise role in rmTBI and AD remains elusive. We hypothesized that a detailed phospholipid characterization would reveal profiles of response to injury in TBI that overlap with age-dependent changes in AD and thus provide insights into the TBI-AD relationship. We employed a lipidomic approach examining brain phospholipid profiles from mouse models of rmTBI and AD. Cortex and hippocampal tissue were collected at 24 h, 3, 6, 9, and 12 months post-rmTBI, and at ages representing 'pre', 'peri' and 'post' onset of amyloid pathology (i.e., 3, 9, 15 months-old). Total levels of phosphatidylcholine (PC), phosphatidylethanolamine (PE), LysoPE, and phosphatidylinositol (PI), including their monounsaturated, polyunsaturated and saturated fatty acid (FA) containing species were significantly increased at acute and/or chronic time points post-injury in both brain regions. However, levels of most phospholipid species in PS1/APP mice were nominal in the hippocampus, while in the cortex, levels were significantly decreased at ages post-onset of amyloid pathology. Sphingomyelin and LysoPC levels showed coincidental trends in our rmTBI and AD models within the hippocampus, an increase at acute and/or chronic time points examined. The ratio of arachidonic acid (omega-6 FA) to docosahexaenoic acid (omega-3 FA)-containing PE species was increased at early time points in the hippocampus of injured versus sham mice, and in PS1/APP mice there was a coincidental increase compared to wild type littermates at all time points. This study demonstrates some overlapping and diverse phospholipid profiles in rmTBI and AD models. Future studies are required to corroborate our findings in human post-mortem tissue. Investigation of secondary mechanisms triggered by aberrant downstream alterations in bioactive metabolites of these phospholipids, and their modulation at the appropriate time-windows of opportunity could help facilitate development of novel therapeutic strategies to ameliorate the neurodegenerative consequences of rmTBI or the potential triggering of AD pathogenesis by rmTBI.

Disruption in Brain Phospholipid Content in a Humanized Tau Transgenic Model Following Repetitive Mild Traumatic Brain Injury.
Repetitive mild traumatic brain injury (mTBI) is a risk factor for the development of neurodegenerative diseases such as chronic traumatic encephalopathy typified by immunoreactive tau aggregates in the depths of the sulci. However, the underlying neurobiological mechanisms involved have not been largely explored. Phospholipids are important molecules which form membrane lipid bilayers; they are ubiquitous to every cell in the brain, and carry out a host of different functions. Imbalance in phospholipid metabolism, signaling and transport has been documented in some neurological conditions. However, not much is currently known about their roles in repetitive mTBI and how this may confer risk for the development of age-related neurodegenerative diseases. To address this question, we designed a longitudinal study (24 h, 3, 6, 9, and 12 months post-injury) to comprehensively investigate mTBI dependent brain phospholipid profiles compared to sham counterparts. We use our established mouse model of repetitive mTBI that has been extensively characterized up to 1-year post-injury in humanized tau (hTau) mice, which expresses all six human tau isoforms, on a null murine background. Our data indicates a significant increase in sphingomyelin, phosphatidylethanolamine (PE), phosphatidylcholine (PC), and derivative lysoPE and lysoPC at acute and/or sub-acute time points post-injury within the cortex and hippocampus. There was also a parallel increase at early time points in monounsaturated, polyunsaturated and saturated fatty acids. Omega-6 (arachidonic acid) to omega-3 (docosahexaenoic acid) fatty acid ratio for PE and PC species was increased also at 24 h and 3 months post-injury in both hippocampus and cortex. The long-term consequences of these early changes in phospholipids on neuronal and non-neuronal cell function is unclear, and warrants further study. Understanding phospholipid metabolism, signaling and transport following TBI could be valuable; they may offer novel targets for therapeutic intervention not only in TBI but other neurodegenerative diseases.

Subchronic Pathobiological Response Following Chronic Repetitive Mild Traumatic Brain Injury in an Aged Preclinical Model of Amyloid Pathogenesis.

Repetitive mild traumatic brain injury (r-mTBI) is a risk factor for Alzheimer disease (AD). The precise nature of how r-mTBI leads to, or precipitates, AD pathogenesis remains unclear. In this study, we explore subchronic effects of chronic r-mTBI (12-impacts) administered over 1-month in aged-PS1/APP mice and littermate controls. We investigate specific mechanisms that may elucidate the molecular link between AD and r-mTBI, focusing primarily on amyloid and tau pathology, amyloid processing, glial activation states, and associated clearance mechanisms. Herein, we demonstrate r-mTBI in aged PS1/APP mice does not augment, glial activation, amyloid burden, or tau pathology (with exception of pS202-positive Tau) 1 month after exposure to the last-injury. However, we observed a decrease in brain soluble Aβ42 levels without any appreciable change in peripheral soluble Aβ42 levels. This was accompanied by an increase in brain insoluble to soluble Aβ42 ratio in injured PS1/APP mice compared with sham injury. A parallel reduction in phagocytic receptor, triggering receptor expressed on myeloid cells 2, was also observed. This study demonstrates very subtle subchronic effects of r-mTBI on a preexisting amyloid pathology background, which may be on a continuum toward a slow and worsening neurodegenerative outcome compared with sham injury, and therefore, have many implications, especially in the elderly population exposed to TBI.

Neurobehavioral, neuropathological and biochemical profiles in a novel mouse model of co-morbid post-traumatic stress disorder and mild traumatic brain injury.
Co-morbid mild traumatic brain injury (mTBI) and post-traumatic stress disorder (PTSD) has become the signature disorder for returning combat veterans. The clinical heterogeneity and overlapping symptomatology of mTBI and PTSD underscore the need to develop a preclinical model that will enable the characterization of unique and overlapping features and allow discrimination between both disorders. This study details the development and implementation of a novel experimental paradigm for PTSD and combined PTSD-mTBI. The PTSD paradigm involved exposure to a danger-related predator odor under repeated restraint over a 21 day period and a physical trauma (inescapable footshock). We administered this paradigm alone, or in combination with a previously established mTBI model. We report outcomes of behavioral, pathological and biochemical profiles at an acute timepoint. PTSD animals demonstrated recall of traumatic memories, anxiety and an impaired social behavior. In both mTBI and combination groups there was a pattern of disinhibitory like behavior. mTBI abrogated both contextual fear and impairments in social behavior seen in PTSD animals. No major impairment in spatial memory was observed in any group. Examination of neuroendocrine and neuroimmune responses in plasma revealed a trend toward increase in corticosterone in PTSD and combination groups, and an apparent increase in Th1 and Th17 proinflammatory cytokine(s) in the PTSD only and mTBI only groups respectively. In the brain there were no gross neuropathological changes in any groups. We observed that mTBI on a background of repeated trauma exposure resulted in an augmentation of axonal injury and inflammatory markers, neurofilament L and ICAM-1 respectively. Our observations thus far suggest that this novel stress-trauma-related paradigm may be a useful model for investigating further the overlapping and distinct spatio-temporal and behavioral/biochemical relationship between mTBI and PTSD experienced by combat veterans.

THE FUNDAMENTALS OF GAZE STABILIZATION – WHAT THE EYES CAN TELL US ABOUT SENSORY INTEGRATION

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Tobias Wibble[1,2], Sten Grillner[2], Tony Pansell[1], Juan Pérez-Fernández[3]
[1]Karolinska Institutet, Clinical Neuroscience, Solna, Sweden, [2]Karolinska Institutet, Neuroscience, Solna, Sweden, [3]University of Vigo, Cinbio, Vigo, Spain

Aims Gaze stabilization is primarily achieved through the optokinetic (OKR) and vestibulo-ocular (VOR) reflexes, which work in constant synergy to compensate for movements across the retina. This project aims to illustrate how these primordial circuits operate using the lamprey animal model, and expand on their relevance in humans using eye-tracking. **Methods** Trials involved participants sitting in a mechanized sled facing a projected visual scene. The scene and the chair would then be rotated with different levels of visual and vestibular intensities while subjects' eyes were recorded. Trials were also performed on an eye-brain preparation of the lamprey exposed to similar stimulations as in the human experiments, which allowed us to map what neural structures were involved in producing gaze-stabilizing eye movements. **Results** The human studies showed that rotational stimulations evoke both torsional and vergence eye movements, and that the torsional response was increased to greater visual clutter (n=13), while the vergence increased to higher accelerations (n=12). We were able to quantify the percentual influence of visual and vestibular input during any given stimulation (n=25). Experiments on the lamprey showed that the mechanisms underlying gaze-stabilization are conserved and performed by circuits in the brainstem, not requiring cortical or cerebellar contributions. **Conclusions** Gaze-stabilization offered clear insights into how the brain integrates sensory information, which is reflected in its fundamental brainstem network. As several aspects of our results are relevant for postural control, ocular torsion and vergence may hold important clinical utility when treating patients with diffuse motion hypersensitivity, particularly visually induced dizziness.

Optokinetic stimulation induces vertical vergence, possibly through a non-visual pathway.
Vertical vergence is generally associated with one of three mechanisms: vestibular activation during a head tilt, induced by vertical visual disparity, or as a by-product of ocular torsion. However, vertical vergence can also be induced by seemingly unrelated visual conditions, such as optokinetic rotations. This study aims to investigate the effect of vision on this latter form of vertical vergence. Eight subjects (4m/4f) viewed a visual scene in head erect position in two different viewing conditions (monocular and binocular). The scene, containing white lines angled at 45° against a black background, was projected at an eye-screen distance of 2 m, and rotated 28° at an acceleration of 56°/s. Eye movements were recorded using a Chronos Eye-Tracker, and eye occlusions were carried out by placing an infrared-translucent cover in front of the left eye during monocular viewing. Results revealed vergence amplitudes during binocular viewing to be significantly lower than those seen for monocular conditions ($p = 0.003$), while torsion remained unaffected. This indicates that vertical vergence to optokinetic stimulation, though visually induced, is visually suppressed during binocular viewing. Considering that vertical vergence is generally viewed as a vestibular signal, the findings may reflect a visually induced activation of a vestibular pathway.

Intensified visual clutter induces increased sympathetic signalling, poorer postural control, and faster torsional eye movements during visual rotation.
Many dizzy patients express a hypersensitivity to visual motion and clutter. This study aims to investigate how exposure to rotating visual clutter affects ocular torsion, vertical skewing, body-sway, the autonomic pupillary response, and the subjective feeling of discomfort to the stimulation. Sixteen healthy subjects were exposed to 20 seconds rotational visual stimulation (72 deg/s; 50 deg visual field). Visual stimuli were comprised of black lines on a white background, presented at low and high intensity levels of visual clutter, holding 19 lines and 38 lines respectively. Ocular torsion and vertical skewing were recorded using the Chronos Eye Tracker, which also measured pupil size as a reflection of the autonomic response. Postural control was evaluated by measuring body-sway area on the Wii Balance Board. Values were compared to data retrieved 20 seconds before and after the optokinetic stimulation, as subjects viewed the stationary visual scene. The high intensity stimulus resulted in significantly higher torsional velocities. Subjects who were exposed to low intensity first exhibited higher velocities for both intensities. Both pupil size and body sway increased for the higher intensity to both the moving and stationary visual scene, and were positively correlated to torsional velocity. In conclusion, exposure to visual clutter was reflected in the eye movement response, changes in postural control, and the autonomic response. This response may hold clinical utility when assessing patients suffering from visual motion hypersensitivity, while also providing some context as to why some healthy people feel discomfort in visually cluttered surroundings.

The role of the optic tectum for visually evoked orienting and evasive movements.
As animals forage for food and water or evade predators, they must rapidly decide what visual features in the environment deserve attention. In vertebrates, this visuomotor computation is implemented within the neural circuits of the optic tectum (superior colliculus in mammals). However, the mechanisms by which tectum decides whether to approach or evade remain unclear, and also which neural mechanisms underlie this behavioral choice. To address this problem, we used an eye-brain-spinal cord preparation to evaluate how the lamprey responds to visual inputs with distinct stimulus-dependent motor patterns. Using ventral root activity as a behavioral readout, we classified 2 main types of fictive motor responses: () a unilateral burst response corresponding to orientation of the head toward slowly expanding or moving stimuli, particularly within the anterior visual field, and () a unilateral or bilateral burst response triggering fictive avoidance in response to rapidly expanding looming stimuli or moving bars. A selective pharmacological blockade revealed that the brainstem-projecting neurons in the deep layer of the tectum in interaction with local inhibitory interneurons are responsible for selecting between these 2 visually triggered motor actions conveyed through downstream reticulospinal circuits. We suggest that these visual decision-making circuits had evolved in the common ancestor of vertebrates and have been conserved throughout vertebrate phylogeny.

DEVELOPMENTAL SWITCH IN VESTIBULO-SPINAL NEURONAL PHENOTYPES DURING THE XENOPUS METAMORPHOSIS.

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Francois Lambert, Gabriel Barrios, Anne Olechowski, Laura Cardoit, Muriel Thoby-Brisson
University of Bordeaux, Incia Cnrs Umr 5287, Bordeaux, France

Vestibular neurons involved in vestibular pathways exhibit distinct intrinsic membrane properties tuned to ensure various sensory-motor tasks. The amphibian metamorphosis represents a relevant neuronal plasticity model to investigate this neural computation. In adult frog, vestibular neurons present two phenotypes according to their discharge dynamic: 1) Phasic neurons exhibiting a high-frequency burst of 1-3 spikes, without subsequent continuous discharge and 2) tonic neurons firing continuously. These neuronal sub-populations act as band-pass and low-pass neuronal filters, respectively. However such a characterization remains unrelated to a specific vestibular function and so far nothing is known about the maturation of these neuronal dynamics. This study aims to investigate the maturation of membrane properties specifically expressed in vestibulospinal neurons involved in postural control, during the complete re-organization of the body induced by the metamorphosis. Discharge dynamics of vestibulospinal neurons were characterized in larval and juvenile *Xenopus laevis* frog. Vestibulo-spinal neurons were identified by retrograde labeling from the spinal cord. Patch-clamp recordings of VST neurons were performed on brainstem slices in voltage and current clamp configurations. Both developmental stages exhibited classical phasic and tonic VST neurons with some variations in their membrane properties. Surprisingly the proportion of tonic and phasic neurons was reversed from larva (70% of tonic) to juvenile (70% of phasic). These results revealed a developmental switch in the expression of neuronal phenotypes dedicated to a specific vestibular function and lead to promising hypothesis: 1/ which maturation mechanism is responsible for such a switch; 2/ does this switch exist in other functional 2°OVN groups?

CHARACTERIZATION OF ANATOMICAL AND FUNCTIONAL VESTIBULOSPINAL PATHWAYS IN LARVAL XENOPUS LAEVIS

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Gabriel Barrios, Laura Cardoit, Didier Le Ray, Francois Lambert
University of Bordeaux, Incia Cnrs Umr 5287, Bordeaux, France

In all vertebrates vestibulo-spinal reflexes participate to postural adjustments needed during passive and active motion. So far this modality of postural control is barely understood in aquatic animals, facing different constrains than terrestrial models. The amphibian metamorphosis, provoking the complete remodeling of the locomotor system, is a developmental context particularly interesting to address this question. This study aims to characterize vestibulo-spinal pathways in larval xenopus laevis. Neuronal tracing of tail axial motoneurons and *synapsin* immunostaining were combined with confocal microscopy to explore anatomical vestibular motor pathways in the larval cord. Vestibular-evoked activity was measured from extracellular nerve recordings of spinal roots activity in response to vestibular nuclei electrical stimulation or galvanic stimulation of horizontal semicircular canal afferents, mimicking head horizontal rotations. Multi-level retrograde labelling from spinal segments (5^{th}, 12^{th} and 16^{th}) revealed that vestibulospinal neurons projected specifically either in conserved or in degenerated spinal regions after metamorphosis, respectively. Both anterograde labelling and electrical stimulation from bilateral vestibulospinal nuclei also showed functional vestibular terminals on rostral, mid-caudal and caudal axial. Galvanic stimulation elicited postural reflexive or various locomotor responses in rostro-caudal spinal motor nerves. Vestibular-induced responses remained in caudal spinal segments despite the blocking of rostral segments, demonstrating independent vestibulospinal pathways from rostral to caudal spinal regions. Altogether, our results showed vestibulospinal functional pathways inducing either reflexive or locomotor postural motor outcomes, suggesting 1/ the implication of other networks (reticular formation, CPGs) and 2/ the existence of a vestibular control specific to larval stage giving a flexible behavioural repertoire.

Aims Visual vertigo is characterized by a heightened sensitivity to visual motion and is often associated with vestibular symptoms. While it is a common sequela after a concussion, many patients receive little rehabilitation, likely due to a limited number of diagnostic tools. This study investigates how optokinetic gaze-stabilization may be used to identify visual vertigo, focusing on ocular torsion (OT) and vertical vergence (VV). **Methods** Nine concussed patients with visual vertigo (7m, 2f; age 36±11.22) and nine healthy controls (7m, 2f; age 39.66±10.06) were recruited. Subjects were exposed to rotational optokinetic stimulations while wearing a head-mounted eye-tracker measuring slow-phase velocities. Stimulations differed in terms of movement coherence between central and peripheral visual fields, rotating either clockwise, counter-clockwise, or randomly. **Results** A generalized estimation equations analysis revealed a significant increase in VV slow phase velocity in the patient group (p = .002), VV peak velocity (p = .002), and OT peak velocity (p = .019). The VV-OT ratio was significantly increased in the patient group during coherent full-field stimulation (p = .029). **Conclusions** Both optokinetic gaze-stabilizing eye movements presented increased velocities in patients, indicating heightened neural sensitivity to visual motion. The VV-OT ratio was increased in patients during full-field rotations, showing that vergence was more readily affected in these patients. Vertical vergence is generally considered a vestibular response, and so a heightened VV velocity may suggest a greater visual influence over the vestibular nuclei. Altogether, vertical vergence may prove a valuable clinical tool when assessing patients with visual vertigo.

CHRONIC STRESS TRIGGERS DISMANTLEMENT OF THE CALYCEAL JUNCTION BETWEEN TYPE I VESTIBULAR HAIR CELLS AND CALYX AFFERENT TERMINALS

POSTER SESSION 02 - SECTION: MOVEMENT: BRAINSTEM AND VESTIBULAR CONTROL

Jordi Llorens[1], Mireia Borrajo[1], Angela Callejo[2], Marta Perez-Grau[2], Emilio Amilibia[2], Francesc Roca-Ribas[2], Elisabeth Castellanos[3], Alberto Maroto[1]
[1]Universitat de Barcelona and IDIBELL, Departament De Ciències Fisiològiques And Institut De Neurociències, Hospitalet de Llobregat, Catalunya, Spain, [2]Institut de Recerca Germans Trias i Pujol (IGTP), Departament D'otorinolaringologia, Badalona, Catalunya, Spain, [3]Institut de Recerca Germans Trias i Pujol (IGTP), Clinical Genomics Research Unit, Badalona, Catalunya, Spain

Reversible synaptic uncoupling between vestibular hair cells (HC) and afferent terminals, including early dismantlement of the calyceal junction in the contact between type I HC (HCI) and calyx afferent terminals, has been described in the IDPN model of sub-chronic ototoxicity in rats. In this study, we evaluated whether this pathological process has wider significance. First, we studied if calyceal junction dismantlement occurs in rats treated with a clinically relevant ototoxin, streptomycin. Weaning rats received streptomycin once or twice a day for 3 to 8 weeks. Vestibular function was assessed using the tail-lift reflex. Sensory epithelia were studied by SEM, TEM, and confocal microscopy. Streptomycin caused reversible loss of vestibular function. In the sensory epithelia, a partial loss of HC occurred. Moreover, decreased expression of CASPR1, denoting calyceal junction dismantlement, was observed in the calyces encasing the surviving HCI. We also recorded reduced numbers of pre-synaptic (ribeye) and post-synaptic (PSD95) puncta per cell, and KCNQ4 mislocalization. After washout, the CASPR1 label revealed junction rebuilding. Second, we studied by confocal microscopy human sensory epithelia from vestibular schwannomma patients; these tumors cause inflammatory stress on the sensory epithelia. Some samples had intact calyceal junctions, but others presented patched label indicating junction dismantlement. In conclusion, dismantlement of the calyceal junction is a common response triggered by chronic stress in the vestibular sensory epithelium. This effect precedes HC loss, is reversible, and may explain, at least in part, reversible function loss. DIFFERENTIAL ENCODING OF ODOR INFORMATION BY DISTINCT SUBPOPULATIONS OF OLFACTORY CORTEX PROJECTION NEURONS

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Simon Daste, Alexander Fleischmann
Brown University, Department Of Neuroscience And The Robert J. And Nancy D. Carney Institute For Brain Science, Providence, United States of America

Sensory cortexes contain a multitude of neuron types projecting to different target areas. Determining their distinct functional properties is essential to better understand how stimulus information is transmitted across brain areas. Piriform cortex (PCx), the main recipient of sensory input from the olfactory bulb, contains neurons that project to numerous areas, including the Olfactory Bulb (PCx_{OB}) and the Medial Prefrontal Cortex (PCx_{mPFC}). Both PCx_{OB} and PCx_{mPFC} cells are deep-layer pyramidal cells, however, whether they selectively encode distinct stimulus information is unknown. Here, we record neuronal activity in the PCx of awake behaving mice using GRIN lens technology and two-photon calcium imaging microscopy. We label PCx_{OB} and PCx_{mPFC}subpopulations using retrogradely transported Adeno-associated virus, and we determine their response properties under passive odor presentation and associative tasks. We show that PCx_{OB} and PCx_{mPFC} subpopulations can accurately be identified based on their odor response profiles. Moreover, odor identity is more efficiently encoded in PCx_{mPFC} neurons compared to PCx_{OB} neurons. Odor coding efficiency dynamically change in both ensembles with behavioral state. Our results suggest that odor information coding differs between PCx neuron types, providing new insights into how olfactory information is routed across brain areas.

Heat But Not Mechanical Hypersensitivity Depends on Voltage-Gated Ca2.2 Calcium Channel Activity in Peripheral Axon Terminals Innervating Skin.
Voltage-gated Ca2.2 calcium channels are expressed in nociceptors at presynaptic terminals, soma, and axons. Ca2.2 channel inhibitors applied to the spinal cord relieve pain in humans and rodents, especially during pathologic pain, but a biological function of nociceptor Ca2.2 channels in processing of nociception, outside presynaptic terminals in the spinal cord, is underappreciated. Here, we demonstrate that functional Ca2.2 channels in peripheral axons innervating skin are required for capsaicin-induced heat hypersensitivity in male and female mice. We show that Ca2.2 channels in TRPV1-nociceptor endings are activated by capsaicin-induced depolarization and contribute to increased intracellular calcium. Capsaicin induces hypersensitivity of both thermal nociceptors and mechanoreceptors, but only heat hypersensitivity depends on peripheral Ca2.2 channel activity, and especially a cell-type-specific Ca2.2 splice isoform. Ca2.2 channels at peripheral nerve endings might be important therapeutic targets to mitigate certain forms of chronic pain. It is generally assumed that nociceptor termini in the spinal cord dorsal horn are the functionally significant sites of Ca2.2 channel in control of transmitter release and the transmission of sensory information from the periphery to central sites. We show that peripheral Ca2.2 channels are essential for the classic heat hypersensitivity response to develop in skin following capsaicin exposure. This function of Ca2.2 is highly selective for heat, but not mechanical hypersensitivity induced by capsaicin exposure, and is not a property of closely related Ca2.1 channels. Our findings suggest that interrupting Ca2.2-dependent calcium entry in skin might reduce heat hypersensitivity that develops after noxious heat exposure and may limit the degree of heat hypersensitivity associated with certain other forms of pain.

NEURAL CIRCUIT BASIS OF AVERSIVE ODOUR PROCESSING IN DROSOPHILA FROM SENSORY INPUT TO DESCENDING OUTPUT

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

How are sensorimotor transformations in the nervous system instantiated in the circuitry of the brain? *Drosophila melanogaster* is a powerful model to answer this question, thanks to its extensive genetic toolkit and the release of multiple synaptic-resolution electron-microscopy volumes (Zheng et al., 2018, Scheffer et al., 2020). Previous work has shown that the Or56a receptor neurons are narrowly tuned to the microbial odorant geosmin. These microbes interrupt egg-development, and female flies avoid it when laying eggs (Stensmyr et al., 2012). This circuit has been characterised using a combination of light and electron microscopy, electrophysiology, functional imaging, and egg-laying assays to establish the necessary behavioural components (Huoviala et al., 2018). Within this circuit multiple levels of convergence have been identified, including an axo-axonic input onto neurons conveying another danger signal, the pheromone of parasitoid wasps. We also observe extensive divergence: second order geosmin neurons connect with a diverse array of ~80 third order cell types. At the next synaptic layer we have shown that a descending neuron (DN) from the brain to the ventral nerve cord (VNC) is required for females to avoid geosmin during egg-laying. Light-activation of this DN triggers backwards movement, and it shares downstream targets in the VNC with Moonwalker neurons (Williamson et al. 2018). These findings show that olfactory pathways from brain to nerve cord may involve as few as 4 synaptic levels, as previously suggested for pheromone responses (Ruta et al., 2010), and fewer than thought to exist in visual escape responses (von Reyn et al., 2017).

Aims: Post-partum olfaction is critical to mother-baby bonding. We compare post-partum olfaction among women with and without prenatal SARS-CoV-2 infection. Methods: We enrolled pregnant women (n=453) in New York, Utah, and Alabama. Participants self-reported history of COVID-19, participated in surveillance for SARS-CoV-2 infection with symptom monitoring, weekly nasal swabs for SARS-CoV-2 PCR-testing, and up to three blood draws for SARS-CoV-2 antibody-testing. A subset completed objective (University of Pennsylvania Smell Identification Test (UPSIT)) and subjective (self-reported smell) measures of olfaction within 6-months post-partum. We compared unadjusted olfactory function among women with (cases) and without (controls) prenatal SARS-CoV-2 infection using chi-square and T-tests. Current analyses excluded women with pre-pregnancy and/or postpartum infections. Mean±SDs are reported. Results: 195 controls and 48 cases completed olfaction testing. Among cases, none were hospitalized and infections were asymptomatic for 8 and symptomatic for 32 (severity missing for 8 cases with self-reported infections prior to surveillance). Olfaction testing was completed 227±12 days post-infection (range: 68-417). Compared to controls, a smaller proportion of cases had olfactory function within the UPSIT normosmic range (25% vs. 48%, chi-square=8.4, p=0.004). Cases also had greater post-partum microsmia severity (1=anosmia: 5=normosmia, 3.92±0.12 vs. 4.31±0.06, p=0.003), lower total UPSIT scores (32.3±0.5 vs. 33.8±0.2 of 40, p=.007, Figure 1a), and larger loss of self-reported sense of smell post-partum compared to pre-pregnancy (vs. -13±3 vs. -2±1 of 100, p=0.00003, Figure 1b). Conclusion: Maternal prenatal SARS-CoV-2 infection is associated with objective and subjective post-partum olfactory dysfunction in unadjusted models, which could have implications for mother-baby

bonding.

γ-SYNCHRONIZATION ENHANCES TRANSMISSION OF SENSORY INFORMATION IN THE BRAIN

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Tal Dalal, Rafi Haddad
Bar-Ilan University, The Gonda Multidisciplinary Brain Research Center, Ramat-Gan, Israel

γ-oscillatory activity is ubiquitous across brain areas, but the ways it contributes to sensory processing and cognitive function remain unclear. Numerous studies and theoretical models have suggested that γ-synchrony should enhance the transmission of sensory information in the brain . However, direct causal evidence is still lacking. Furthermore, γ-oscillations are typically generated by the increased rhythmic activity of inhibitory neurons, which reduces the number of output spikes transmitted to the next brain region, thus raising the question of whether synchrony can compensate for the reduction in firing rate . Here we tested this hypothesis in the mouse olfactory system, where local GABAergic granule cells in the olfactory bulb shape mitral/tufted cell (MTC) excitatory output from the olfactory bulb to downstream piriform cortex. By optogenetically modulating granule cell activity, we successfully dissociated MTC γ-synchronization from MTC firing rates. By recording odor responses in the downstream piriform cortex neurons, we found that increasing MTC γ-synchronization enhanced cortical neurons' odor-evoked firing rates, reduced their response variability, and improved their odor ensemble representation. These improvements occurred despite a reduction in MTC firing rates. Furthermore, reducing MTC γ-synchronization without changing its firing rates via suppression of granule cells activity, degraded piriform cortex odor-evoked responses. Finally, directly or indirectly suppressing MTC firing rates without increasing synchrony degraded piriform cortex odor responses. These findings provide causal evidence that increased γ-synchronization enhances the transmission of sensory information between two brain regions.

GPCR VOLTAGE DEPENDENCE CONTROLS NEURONAL PLASTICITY AND BEHAVIOR

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Moshe Parnas
Tel Aviv University, Physiology And Pharmacology, Tel Aviv, Israel

G-protein coupled receptors (GPCRs) play a paramount role in diverse brain functions. Almost 20 years ago, GPCR activity was shown to be regulated by membrane potential *in vitro*, but whether the voltage dependence of GPCRs contributes to neuronal coding and behavioral output under physiological conditions *in vivo* has never been demonstrated. We show, that muscarinic GPCR mediated neuronal potentiation *in vivo* is voltage dependent. This potentiation voltage dependency is abolished in mutant animals expressing a voltage independent receptor. Depolarization alone, without a muscarinic agonist, resulted in a nicotinic ionotropic receptor potentiation that was mediated by muscarinic receptor voltage dependency. Most important, muscarinic receptor voltage independence caused a strong behavioral effect of increased odor habituation. Together, this study provides the very first demonstration of a physiological role for the voltage dependency of GPCRs by demonstrating crucial involvement of GPCR voltage dependence in neuronal plasticity and behavior. Thus, this study suggests that GPCR voltage dependency plays a role in many diverse neuronal functions including learning and memory and may serve as a target for novel drug development.

Anxiety disorders are a group of mental illnesses that is characterized by feelings of fear or worry. Odor exposure can be used to reduce anxiety; however, the neural basis of this emotional improvement is unclear. In this context, we investigated brain activity and connectivity in mice enriched with pleasant odorants that showed a reduction of anxiety compared to mice enriched with neutral odorants showing no change in anxiety level. Analysis of c-Fos expression across twenty brain regions involved in olfactory and anxiety circuits allowed the identification of a pattern of correlated activity specific of the odor-induced reduction in anxiety. Within the network of correlated activity, we identified key brain structures that could sustain this emotional improvement by presenting important increased connectivity, the paraventricular thalamic nucleus, the hypothalamic paraventricular nucleus and the postero-lateral-cortical amygdaloid area. These finding confirm the efficiency of odorant stimulation on well-being and further propose neural mechanism and regions that may play privileged roles in this process.

INVESTIGATING SPARSE CODING ADAPTATION IN KENYON CELLS OF DROSOPHILA MELANOGASTER

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Katie Greenin-Whitehead
The University of Sheffield, Biosciences, Sheffield, United Kingdom

Stimulus-specificity of associative memories requires sparse coding in the neurons storing the memory. Effective sparse coding requires that the memory-storing neurons have approximately equal probabilities of firing across all stimuli. Otherwise, some cells will be disproportionately active or silent, and thereby be less informative about stimulus identity. We study the problem of how distributed sparse coding is maintained in Kenyon cells (KCs). KCs are the third order olfactory neurons in Drosophila melanogaster that store olfactory associative memories. We are investigating the hypothesis that KCs homeostatically adjust their intrinsic properties to ensure even activity across the population of KCs by using ex-vivo whole-cell patch-clamping, two-photon imaging and genetic manipulation of ion channel expression. Acute overexpression of the bacterial voltage-gated sodium channel, NaChBac, in KCs increases their excitability (as measured by amplitude of odour responses); while chronic expression of NaChBac throughout development paradoxically decreased KC excitability. This suggests KC can compensate for excitability and even overcompensate by homeostatic mechanisms. Calcium imaging results indicate that overexpressing a voltage-gated sodium channel in KCs paradoxically decreases their excitability, as measured by amplitude of odour responses. Additionally, initial results suggest that the inclusion of NaChBac causes the axon initial segment of the KCs to decrease the number of para channels. Lastly, knocking down or disrupting potassium channels appears to either weaken odour responses or have no effect in specific mushroom body lobes. We are currently investigating the acute expression of the potassium channels.

MICE CAN EXTRACT INFORMATION FROM TEMPORALLY COMPLEX ODOUR PLUMES TO LEARN ABOUT DISTANCE TO AN ODOUR SOURCE

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Alina-Cristina Marin[1,2], Tobias Ackels[1,2], Julia Harris[1,2], Debanjan Dasgupta[2], Andrew Erskine[1,2], Tom Warner[1], Sina Tootoonian[1,2], Andreas Schaefer[1,2]
[1]Francis Crick Institute, Sensory Circuits And Neurotechnology Laboratory, London, United Kingdom, [2]University College London, Department Of Neuroscience, Physiology & Pharmacology, London, United Kingdom

Natural odour plumes are shaped by airflow turbulence, resulting in high frequency odour intensity fluctuations that may contain information about odour source location. We aimed to investigate whether mice can extract and use this information in a distance discrimination task. We built a wind tunnel and odour delivery devices to reliably generate and record odour plumes. In addition, we created an “olfactory virtual reality” by replicating the recorded odour plumes with a high-temporal-bandwidth multichannel odour delivery device. In a high-throughput behavioural conditioning system, we trained mice to perform distance discrimination tasks, either in “olfactory virtual reality”, or directly using odour plumes generated in the wind tunnel. Using odour sources placed at different distances in a wind tunnel, we found that mice learnt to respond differently to odour sources based on their distance. In a separate cohort of mice, we performed calcium imaging of neurons in the mouse Olfactory Bulb while presenting distant odour plumes in olfactory virtual reality, and found a subset of Mitral and Tufted Cells that responded differently to different distances. As total odour concentration was kept constant, we suggest these neurons respond to features of the temporal structures of odour plumes, which are informative of source distance. We conclude that mice are able to perform distance discrimination using olfactory information available in temporally complex odour plumes, and that the differential processing of this information can already be observed at the level of the Olfactory Bulb.

STIMULUS DURATION ENCODING BY MOTH OLFACTORY RECEPTOR NEURONS

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Tomas Barta[1,2,3], Abhishek Chatterjee[3], Christelle Montsempès[3], Elodie Demondion[3], Lubomir Kostal[2], Philippe Lucas[3]
[1]Charles University, First Faculty Of Medicine, Prague, Czech Republic, [2]Institute of Physiology, Czech Academy of Sciences, Laboratory Of Computational Neuroscience, Prague, Czech Republic, [3]Institute of Ecology and Environmental Sciences, INRAE, Department Of Sensory Ecology, Versailles, France

Insects heavily rely on olfactory cues in their search for a mate, food, and a suitable place for egg-laying. Flying insects encounter turbulent environments, where chemotaxis along a concentration gradient makes little sense. Detection of the onset and offset of discrete odor pulses is predicted to become crucial for navigation in this environment. It is well understood how the olfactory system encodes the onset, but surprisingly, not the offset, i.e., the duration of the odor pulse. Typically, the reported duration of moth olfactory receptor neuron's (ORN) spike firing response greatly exceeds the pulse duration. We built a precise olfactometer to eliminate possible artefacts caused by low pheromone volatility and performed extracellularly single sensillum recordings from the ORN. We found that the sharp pheromone pulses generated by the new olfactometer evoked firing responses in the ORN that faithfully tracked the pulse duration, provided the pulse lasted at least 200ms. A transient inhibition marked the termination of the pulse and disappeared with shorter pulses. We could precisely predict the firing response from the receptor potential with a linear filter harboring several time constants. Particularly, a slow (±500ms) adaptation of the spike generating mechanism is necessary to reproduce the qualitatively different response to different pulse durations. The observed limits in temporal resolution are in agreement with behavioral studies. Our findings show that moth ORNs are better at encoding stimulus duration than previously thought and help understand how their olfactory system encodes the fine structure of the pheromone plume in the turbulent environment.

Regular spiking in high-conductance states: The essential role of inhibition.
Strong inhibitory input to neurons, which occurs in balanced states of neural networks, increases synaptic current fluctuations. This has led to the assumption that inhibition contributes to the high spike-firing irregularity observed in vivo. We used single compartment neuronal models with time-correlated (due to synaptic filtering) and state-dependent (due to reversal potentials) input to demonstrate that inhibitory input acts to decrease membrane potential fluctuations, a result that cannot be achieved with simplified neural input models. To clarify the effects on spike-firing regularity, we used models with different spike-firing adaptation mechanisms, and we observed that the addition of inhibition increased firing regularity in models with dynamic firing thresholds and decreased firing regularity if spike-firing adaptation was implemented through ionic currents or not at all. This fluctuation-stabilization mechanism provides an alternative perspective on the importance of strong inhibitory inputs observed in balanced states of neural networks, and it highlights the key roles of biologically plausible inputs and specific adaptation mechanisms in neuronal modeling.

The effect of inhibition on rate code efficiency indicators.
In this paper we investigate the rate coding capabilities of neurons whose input signal are alterations of the base state of balanced inhibitory and excitatory synaptic currents. We consider different regimes of excitation-inhibition relationship and an established conductance-based leaky integrator model with adaptive threshold and parameter sets recreating biologically relevant spiking regimes. We find that given mean post-synaptic firing rate, counter-intuitively, increased ratio of inhibition to excitation generally leads to higher signal to noise ratio (SNR). On the other hand, the inhibitory input significantly reduces the dynamic coding range of the neuron. We quantify the joint effect of SNR and dynamic coding range by computing the metabolic efficiency-the maximal amount of information per one ATP molecule expended (in bits/ATP). Moreover, by calculating the metabolic efficiency we are able to predict the shapes of the post-synaptic firing rate histograms that may be tested on experimental data. Likewise, optimal stimulus input distributions are predicted, however, we show that the optimum can essentially be reached with a broad range of input distributions. Finally, we examine which parameters of the used

neuronal model are the most important for the metabolically efficient information transfer.

COMPARATIVE STUDY OF OLFACTORY SYSTEM ONTOGENY IN MUS MUSCULUS AND OCTODON DEGUS

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Daniel Amaya, Peter Mombaerts
Max Planck Institute, Max Planck Research Unit For Neurogenetics, Frankfurt am Main, Germany

Olfaction is critical for survival of the individual. Olfactory reception is mediated by olfactory sensory neurons (OSNs), which are located in convoluted turbinates within the nasal cavity. The axons of OSNs coalesce into globose structures called glomeruli within the olfactory bulb. In mouse, olfactory development begins with the invagination of the olfactory pit at E10.5 and proceeds by establishing the olfactory epithelium. Here, we take a step further in understanding the complexity of the olfactory system by studying its development in a lesser-known species, the *Octodon degus*, a rodent endemic to central Chile with an exceptionally long gestation period. We performed a comparative study to identify differences in the ontogeny of the olfactory system between mouse and degu. First, we compared developmental stage-specific features in mouse and degu. After determining developmentally equivalent stages, mouse and degu embryos were collected and processed for immunofluorescence. With OSN specific markers, we found that the olfactory system is more established at birth in degu than in mouse. Glomeruli in the olfactory bulb are further developed in degu and are akin to glomeruli at later stages in mouse. In addition, the structural organization of turbinates appears more convoluted in degu than in mouse. Several structural differences were also notable at earlier developmental stages, such as glomerular formation and axon/mitral cell connectivity.

BINGE EATING SUPPRESSES FLAVOR REPRESENTATIONS IN THE MOUSE OLFACTORY CORTEX

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Hung Lo[1,2], Anke Schoenherr[2], Malinda Tantirigama[3], Robert Sachdev[3], Katharina Stumpenhorst[4], Marion Rivalan[5], York Winter[4], Dietmar Schmitz[2], Friedrich Johenning[2]
[1]Charité-Universitätsmedizin Berlin, Einstein Center For Neurosciences Berlin, Berlin, Germany, [2]Charité – Universitätsmedizin Berlin, Neuroscience Research Center, Berlin, Germany, [3]Humboldt Universität zu Berlin, Institut Für Biologie, Berlin, Germany, [4]Humboldt Universität zu Berlin, Cognitive Neurobiology, Berlin, Germany, [5]Charité - Universitätsmedizin Berlin, Animal Behavior Phenotyping Facility, Berlin, Germany

Appropriate feeding behavior is the foundation of maintaining homeostasis. Elevated feeding speed (binge eating) is a common trait of eating disorders and is associated with obesity. It is also known that flavor perception has an active role in regulating feeding. However, the effects of feeding speed on flavor sensory feedback remain unknown. By using miniscope in mice, we show that binge eating suppresses neuronal activity in the anterior olfactory (piriform) cortex (aPC). The strength of binge-induced inhibition in the aPC is correlated with animals' appetite. This suppression is partially due to local GABAergic interneurons (PV & SOM) in the aPC. Odor inputs from olfactory bulb mitral cells remain stable upon binge eating, suggesting the suppression is not due to degraded odor inputs. We further excluded the inhibitory effect from serotonergic modulation in the aPC by using *in vivo* serotonin imaging. Taken together, our results provide clear circuit mechanisms of binge-induced flavor modulation, which may explain binge-induced overeating due to suppression of sensory feedback of food items.

Creating clear and informative image-based figures for scientific publications.
Scientists routinely use images to display data. Readers often examine figures first; therefore, it is important that figures are accessible to a broad audience. Many resources discuss fraudulent image manipulation and technical specifications for image acquisition; however, data on the legibility and interpretability of images are scarce. We systematically examined these factors in non-blot images published in the top 15 journals in 3 fields; plant sciences, cell biology, and physiology (n = 580 papers). Common problems included missing scale bars, misplaced or poorly marked insets, images or labels that were not accessible to colorblind readers, and insufficient explanations of colors, labels, annotations, or the species and tissue or object depicted in the image. Papers that met all good practice criteria examined for all image-based figures were uncommon (physiology 16%, cell biology 12%, plant sciences 2%). We present detailed descriptions and visual examples to help scientists avoid common pitfalls when publishing images. Our recommendations address image magnification, scale information, insets, annotation, and color and may encourage discussion about quality standards for bioimage publishing.

Circuit-Specific Dendritic Development in the Piriform Cortex.
Dendritic geometry is largely determined during postnatal development and has a substantial impact on neural function. In sensory processing, postnatal development of the dendritic tree is affected by two dominant circuit motifs, ascending sensory feedforward inputs and descending and local recurrent connections. In the three-layered anterior piriform cortex (aPCx), neurons in the sublayers 2a and 2b display vertical segregation of these two circuit motifs. Here, we combined electrophysiology, detailed morphometry, and Ca imaging in acute mouse brain slices and modeling to study circuit-specific aspects of dendritic development. We observed that determination of branching complexity, dendritic length increases, and pruning occurred in distinct developmental phases. Layer 2a and layer 2b neurons displayed developmental phase-specific differences between their apical and basal dendritic trees related to differences in circuit incorporation. We further identified functional candidate mechanisms for circuit-specific differences in postnatal dendritic growth in sublayers 2a and 2b at the mesoscale and microscale levels. Already in the first postnatal week, functional connectivity of layer 2a and layer 2b neurons during early spontaneous network activity scales with differences in basal dendritic growth. During the early critical period of sensory plasticity in the piriform cortex, our data are consistent with a model that proposes a role for dendritic NMDA-spikes

in selecting branches for survival during developmental pruning in apical dendrites. The different stages of the morphologic and functional developmental pattern differences between layer 2a and layer 2b neurons demonstrate the complex interplay between dendritic development and circuit specificity.

EXPLORING THE ROLE OF THE LATERAL ENTORHINAL CORTEX IN THE MODULATION OF THE PIRIFORM CORTEX NEURONAL ACTIVITY

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

The piriform cortex (PC), the main region of the olfactory cortex, receives afferent sensory inputs from the olfactory bulb through the lateral olfactory tract (LOT), and extensive inputs from higher-order areas such as the lateral entorhinal cortex (LEC). To understand the contribution of LEC to the processing of odors, we study its functional and anatomical connectivity to excitatory and inhibitory neurons in the PC. We infected LEC with adeno-associated virus expressing channelrhodopsin under CamKIIa promoter to activate excitatory LEC afferents arriving to PC. We recorded then, in acute brain slices, postsynaptic currents and spiking in pyramidal L2/3 neurons and interneurons, in response to photostimulation. We found that excitatory long-range projections arriving from LEC evoke different excitation to inhibition balance in each type of neuron. L2 neurons and PV interneurons receive more excitation than inhibition along a 10Hz stimulation train. In addition, we observed that LEC projections preferentially contact L2 pyramidal neurons. We then explored how the PC microcircuit is reorganized in the presence of the cholinergic agonist, carbachol (CBC). We found that a diminished response to LEC activation is due to the reduction in recurrent activity, but the response to the monosynaptic input remains intact after bath infusion of CBC. Last, to assess the role of LEC in the processing of odors in vivo, we conducted experiments to inactivate this region during an odor-visual context associative task and evaluate the effect of LEC silencing after learning this olfactory behavior.

EARLY-LIFE OLFACTORY EXPERIENCE SHAPES THE CONNECTIVITY OF THE ODORANT-RESPONDING BRAIN NETWORK IN MICE

POSTER SESSION 02 - SECTION: OLFACTORY SYSTEM

Mathias Cavelius[1], Théo Brunel[1], Marc Thevenet[2], Anne Didier[2]

Early-life experience shapes behavior and the anatomical and functional organization of the brain with life-long consequences. In this context, olfactory processing and related brain connectivity or plasticity remain poorly documented. Here, we measured brain connectivity based on between-region correlations of c-Fos positive cell density, in different experimental groups including male and female mice, submitted or not to olfactory enrichment from birth to weaning. The pattern of brain connectivity in the adult brain in response to an odorant stimulation was greatly modified by early-life olfactory enrichment in the direction of enhanced connection density in both males and females. Increased connectivity held for both sides of the brain to the exception of enriched females showing a left hemisphere dominance. Increased connectivity expanded beyond olfactory regions to other functional brain systems and this effect was broader in females than in males. Altogether, these findings revealed a strong and long-lasting effect of early-life olfactory enrichment on brain connectivity including lateralization and a sex-related susceptibility to these effects.

Individual recognition in mice is based on the major urinary proteins present in urine, detected by the vomeronasal organ. These signals are processed in the chemosensory amygdala, where the posteromedial cortical nucleus (PMCo) constitutes the primary vomeronasal cortex and influences the hippocampal formation via direct and indirect pathways. Social memory is stored in the ventral hippocampus (vCA1), where PMCo directly projects. In addition, social information is integrated into spatial memory through an amygdalo-entorhino-hippocampal (dCA1) indirect circuit, which is highly activated in female mice exploring male urine. Although hippocampal CA2 region (dCA2) is essential for social memory, its role in vomeronasal processing is still unknown. To assess the effect of urine stimuli on c-Fos activity in the chemosensory amygdala, the vCA1 and the dCA2, we tested the preference of CD1 female mice to investigate male urine or a control odorant (citralva). Behavioral analysis showed that male urine induced a significantly longer exploration, accompanied by a significant increase in c-Fos expression in vCA1 and dCA2. In the chemosensory amygdala, higher c-Fos expression was found in the cortex-amygdala transition area and the dorsal and ventral subdivisions of the posterior medial amygdala. Since male urine induces a preferential exploration, we hypothesized a higher activation of the mesolimbic reward system and the basolateral complex of the amygdala (the interface between the chemosensory amygdala and the reward system). However, our results showed non-significant differences in these structures, where a low level of c-Fos expression was found in both experimental groups.

Integrating pheromonal and spatial information in the amygdalo-hippocampal network.
Vomeronasal information is critical in mice for territorial behavior. Consequently, learning the territorial spatial structure should incorporate the vomeronasal signals indicating individual identity into the hippocampal cognitive map. In this work we show in mice that navigating a virtual environment induces synchronic activity, with causality in both directionalities, between the vomeronasal amygdala and the dorsal CA1 of the hippocampus in the theta frequency range. The detection of urine stimuli induces synaptic plasticity in the vomeronasal pathway and the dorsal hippocampus, even in animals with experimentally induced anosmia. In the dorsal hippocampus, this plasticity is associated with the overexpression of pAKT and pGSK3β. An amygdalo-entorhino-hippocampal circuit likely underlies this effect of pheromonal information on hippocampal learning. This circuit likely constitutes the neural substrate of territorial behavior in mice, and it allows the integration of social and spatial information.

Integrating physiology with structural insights of the same neuronal circuit provides a unique approach to understanding how the mammalian brain computes information. However, combining the techniques that provide both streams of data represents an experimental challenge. When studying glomerular column circuits in the mouse olfactory bulb, this approach involves e.g. recording the neuronal activity with *in vivo* 2-photon (2P) calcium imaging, retrieving the circuit structure with synchrotron X-ray computed tomography with propagation-based phase contrast (SXRT) and/or serial block-face electron microscopy (SBEM) and correlating these datasets. Sample preparation and dataset correlation are two key bottlenecks in this correlative workflow. Here, we first quantify the occurrence of different artefacts when staining tissue slices with heavy metals to generate X-ray or electron contrast. We report improvements in the staining procedure, ultimately achieving perfect staining in ~67% of the 0.6 mm thick olfactory bulb slices that were previously imaged *in vivo* with 2P. Secondly, we characterise the accuracy of the spatial correlation between functional and structural datasets. We demonstrate that direct, single-cell precise correlation between *in vivo* 2P and SXRT tissue volumes is possible and as reliable as correlating between 2P and SBEM. Altogether, these results pave the way for experiments that require retrieving physiology, circuit structure and synaptic signatures in targeted regions. These correlative function-structure studies will bring a more complete understanding of mammalian olfactory processing across length scales and time.

Vomeronasal information plays an essential role in rodents' individual recognition, which is crucial for orienting and navigating through their environment. This particular type of sensory information must necessarily reach the hippocampal formation to provide the identity of the conspecific owner of each territory, constituting the "who" component of episodic memory. Through tract-tracing methods we have investigated neural pathways between the chemosensory amygdala and the hippocampus. Since no direct connection was observed after retrograde tracer (FluoroGold) injection in the dorsal CA1, we looked for indirect projections through the entorhinal cortex. FluoroGold injections in the dorsolateral entorhinal cortex resulted in labelled neurons in all the cortical areas of the chemosensory amygdala (including the posteromedial nucleus of the amygdala). Conversely, the subcortical structures of the chemosensory amygdala (medial amygdala and posteromedial bed nucleus of the stria terminalis) have no direct or indirect connections with the hippocampus. This amygdalo-entorhino-hippocampal circuit may constitute the neural substrate for the integration of pheromonal information into spatial memory. In order to assess the activation of these pathways in social recognition tasks including spatial information, we have designed behavioural experiments to evaluate c-Fos expression in paradigms in which female mice explore social stimulus from different males or objects that change their spatial location over the days.
