Glioblastoma multiforme is an extremely aggressive and invasive form of central nervous system tumor commonly treated with the chemotherapeutic drug Temozolomide. Unfortunately, even with treatment, the median survival time is less than 12 months. 2,9-Di-sec-butyl-1,10-phenanthroline (SBP), a phenanthroline-based ligand originally developed to deliver gold-based anticancer drugs, has recently been shown to have significant antitumor activity in its own right. SBP is hypothesized to initiate tumor cell death via interaction with non-DNA targets, and considering most glioblastoma drugs kill tumors through DNA damage processes, SBP was tested as a potential novel drug candidate against glial-based tumors. In vitro studies demonstrated that SBP significantly inhibited the growth of rodent GL-26 and C6 glioma cells, as well as human U-87, and SW1088 glioblastomas/astrocytomas. Furthermore, using a syngeneic glioma model in mice, in vivo administration of SBP significantly reduced tumor volume and increased survival time. There was no significant toxicity toward nontumorigenic primary murine and human astrocytes in vitro, and limited toxicity was observed in ex vivo tissues obtained from noncancerous mice. Terminal deoxynucleotidyl transferase dUTP nick end labeling staining and recovery assays suggest that SBP induces apoptosis in gliomas. This exploratory study suggests SBP is effective in slowing the growth of tumorigenic cells in the brain while exhibiting limited toxicity to normal cells and tissues and should therefore be further investigated for its potential in glioblastoma treatment.

Functional role of brain-engrafted macrophages against brain injuries.
Brain-resident microglia have a distinct origin compared to macrophages in other organs. Under physiological conditions, microglia are maintained by self-renewal from the local pool, independent of hematopoietic progenitors. Pharmacological depletion of microglia during whole-brain radiotherapy prevents synaptic loss and long-term recognition memory deficits. However, the origin or repopulated cells and the mechanisms behind these protective effects are unknown.

The impact of deep space radiation on cognitive performance: From biological sex to biomarkers to countermeasures.
In the coming decade, astronauts will travel back to the moon in preparation for future Mars missions. Exposure to galactic cosmic radiation (GCR) is a major obstacle for deep space travel. Using multivariate principal components analysis, we found sex-dimorphic responses in mice exposed to accelerated charged particles to simulate GCR (GCRsim); males displayed impaired spatial learning, whereas females did not. Mechanistically, these GCRsim-induced learning impairments corresponded with chronic microglia activation and synaptic alterations in the hippocampus. Temporary microglia depletion shortly after GCRsim exposure mitigated GCRsim-induced deficits measured months after the radiation exposure. Furthermore, blood monocyte levels measured early after GCRsim exposure were predictive of the late learning deficits and microglia activation measured in the male mice. Our findings (i) advance our understanding of charged particle–induced cognitive challenges, (ii) provide evidence for early peripheral biomarkers for identifying late cognitive deficits, and (iii) offer

potential therapeutic strategies for mitigating GCR-induced cognitive loss.

STRUCTURAL PLASTICITY OF DENDRITIC SPINES WITHIN COCAINE-SEEKING NEURONAL ENSEMBLES

POSTER SESSION 01 - SECTION: SYNAPTIC PLASTICITY AND COGNITION

Skylar Hodgins, Levi Flom, Lucio Vaccaro, Ana-Clara Bobadilla
University of Wyoming, Pharmaceutical Sciences, Laramie, United States of America

Background: Effective substance use disorder treatment hinges on successful relapse prevention, which is impeded by our limited knowledge of drug-induced pathology in brain circuits and synaptic physiology (Kuhn et al. 2019). Previous research indicates that relapse and seeking may be driven by morphological changes in nucleus accumbens (NAc) neuronal ensembles, i.e., clusters of neurons coactivated in the reward-seeking and motivation center of the brain (Shen et al. 2011, Gipson et al. 2014). Aim: The proposed study compares the efficacy of spine analysis software SPINEJ to IMARIS and evaluates the structural plasticity of cocaine-seeking ensemble cells in the NAc core. Methods: A short access cocaine self-administration and relapse model combined with genetically modified Ai14xFosTRAP mice was used to induce cocaine-seeking and tag NAc neuronal ensembles with TdTomato. Images of NAc dendritic spines were acquired with confocal microscopy, followed by structural analysis in IMARIS and SPINEJ. Spine plasticity of cocaine-ensemble cells in actively seeking animals was compared to cells of non-seeking animals, as well as non-ensemble cells tagged with an unspecific GFP virus. Results: IMARIS is more accurate and reliable for morphological spine analysis than SPINEJ. Preliminary data on spine plasticity suggests that spine density, but not spine head diameter, is specifically altered in the cocaine-seeking ensemble during seeking. These changes correlate with the strength of cocaine seeking. Conclusion: Characterizing spine morphology in cocaine-seeking ensembles will further our understanding of how the brain processes drug seeking and potentially lead to relapse prevention developments.

ENHANCING DENDRITIC SPINE PLASTICITY BY COUPLING PHYSICAL ACTIVITY WITH NON-INVASIVE BRAIN STIMULATION

POSTER SESSION 01 - SECTION: SYNAPTIC PLASTICITY AND COGNITION

Federica Marchiotto, Arianna Di Giorgio, Marco Cambiaghi, Mario Rosario Buffelli
University of Verona, Neuroscience, Biomedicine And Movement, Verona, Italy

Aim. There is a huge interest in coupling transcranial direct current stimulation (tDCS) and physical activity as an effective strategy to further enhance cortical excitability in physiological and pathological conditions. Nevertheless, the mechanisms underlying this phenomenon are not well known. Animal studies revealed that tDCS affects the motor cortical plasticity by modulating dendritic spines, similarly to voluntary physical exercise. Thus, in this study we investigated the effects of combining tDCS and physical activity in healthy mice. *Methods.*For this purpose, we studied the effects of coupling anodal tDCS and physical activity on the morphological plasticity in primary motor cortex (M1) layer II/III and layer V in young (2-3 months) and middle-aged (14-16 months) mice. *Results.* At both ages, the joining of stimulation and physical activity results in an increased number of activated cells and a higher density in basal and apical dendrites of both hemispheres, compared to single interventions only. Young mice displayed a higher number of mushrooms spines, while middle-aged mice showed an increase of thin spines. *Conclusions.*Altogether, the coupling between tDCS and physical activity results in a significant inter-hemispheric plasticity enhancement in physiological conditions, maintained with aging. However, the spine morphology is differently displayed in young and middle-aged mice, probably indicating a different effect of the combination in the aging.

THE CELLULAR ARCHITECTURE OF MEMORY MODULES IN DROSOPHILA SUPPORTS STOCHASTIC INPUT INTEGRATION

POSTER SESSION 01 - SECTION: SYNAPTIC PLASTICITY AND COGNITION

Rouven Lukas Ziegler[1], Omar Hafez[2], Benjamin Escribano[1], Jan Hirtz[3], Ernst Niebur[4], Jan Pielage[1]
[1]Universität Kaiserslautern, Zoology, Kaiserslautern, Germany, [2]Yale School of Medicine, Md-phd Programme, New Haven, United States of America, [3]TU Kaiserslautern, Physiology Of Neuronal Networks, Kaiserslautern, Germany, [4]Johns Hopkins University, Zanvyl Krieger Mind/brain Institute, Baltimore, MD, United States of America

The ability to associate neutral stimuli with valence information and to store these associations as memories forms the basis for decision making. To determine the underlying computational principles, we build a realistic computational model of a central decision module within the *Drosophila* mushroom body (MB), the fly's center for learning and memory. Our model combines the electron microscopy-based architecture of one MB output neuron (MBON-α3), the synaptic connectivity of its 948 presynaptic Kenyon cells (KCs), and its *in vivo* membrane properties obtained from patch-clamp recordings. We show that this neuron is electrotonically compact and that synaptic input corresponding to simulated odor input robustly drives its spiking behavior. Therefore, sparse innervation by KCs can efficiently control and modulate MBON activity in response to learning with minimal requirements on the specificity of synaptic localization. This architecture allows efficient storage of large numbers of memories using the flexible stochastic connectivity of the circuit.

AUTOMATED HOME-CAGE SYSTEM FOR AUDITORY TRAINING AND PSYCHOPHYSICS IN COMMON MARMOSETS

POSTER SESSION 01 - SECTION: SYNAPTIC PLASTICITY AND COGNITION

Jorge Cabrera-Moreno[1,2,3,4], Antonino Calapai[1,3,5,6], Tobias Moser[2,3,4,7,8], Marcus Jeschke[1,3,4,6]
[1]German Primate Center, Cognitive Hearing In Primates, Göttingen, Germany, [2]University of Göttingen, Göttingen Graduate School For Neuroscience, Biophysics And Molecular Biosciences, Göttingen, Germany, [3]University Medical Center Goettingen, Institute For Auditory Neuroscience, Goettingen, Germany, [4]German Primate Center, Auditory Neuroscience And Optogenetics, Göttingen, Germany, [5]German Primate Center, Cognitive Neuroscience Laboratory, Göttingen, Germany, [6]Leibniz Science Campus, Primate Cognition, Göttingen, Germany, [7]Max Planck Institute for Multidisciplinary Sciences, Auditory Neuroscience Group And Synaptic Nanophysiology Group, Göttingen, Germany, [8]University of Goettingen, Cluster Of Excellence "multiscale Bioimaging: From Molecular Machines To Networks Of Excitable Cells" (mbexc), Goettingen, Germany

The common marmoset (*Callithrix jacchus*) has become an important model for auditory neuroscience. Their large vocal repertoire together with strong similarities of auditory perception with humans opens up the possibility to explore several aspects of the auditory system in non-human primates. In order to assess cognitive aspects of hearing it is crucial to develop and refine experimental and training procedures to improve their reliability, and replicability, while also contributing to animal welfare. In this study, we describe a novel, automated home-cage, operant conditioning device which has been successfully employed for training and testing of audio-visual-cued behaviors in socially housed common marmosets. Through a sequence of four different tasks naïve animals autonomously learned: first, to operate a touchscreen proficiently (14 out of 14 animals); second, to discriminate between a conspecific vocalization from a pure tone (9 out of 11 animals); third, to flexibly transfer learned discrimination behaviour to a set of novel stimuli (4 out of 4 animals); and fourth, to detect the presence or absence of a conspecific vocalization (3 out of 3 animals). Marmosets showed an stable engagement over sessions regardless of: the session duration (1 to 5 hours); the level of difficulty; and the task type - performing on average 120 self-initiated trials per session (SD: 40 trials) - without dietary restriction or social separation. Combined with 3R compatible training principles, our device represents a significant step towards to the development of high-throughput protocols for integrating advanced cognitive and behavioral assessments of common marmosets in the auditory domain.

BEHAVIORAL AND ELECTROPHYSIOLOGICAL CHARACTERIZATION OF DIFFERENT FUNCTIONAL REGIONS OF THE SUBTHALAMIC NUCLEUS IN HEALTHY NON-HUMAN PRIMATES

POSTER SESSION 01 - SECTION: SYNAPTIC PLASTICITY AND COGNITION

Mathilde Bertrand[1], Stephan Chabardes[2], Julien Bastin[1], Brigitte Piallat[1]
[1]Université Grenoble Alpes - Inserm U1216, Grenoble Institut Des Neurosciences, Grenoble, France, [2]2. Univ. Grenoble Alpes, Department of Neurosurgery, Inserm, U1216, Chu Grenoble Alpes, Grenoble Institut Neurosciences, Grenoble, France

Aims Behavior consists of motor activity influenced by cognitive and emotional context. The subthalamic nucleus (STN) is thought to play a central role in behavior and current hypotheses, based on anatomy and tracing technics, suggest a tripartite overlapping division of this nucleus. However, functional characterization of these regions needs to be further studied. Here, we investigated the electrophysiological activity and the impact of directional stimulation of the STN during a behavioral task. Methods Two non-human primates (NHPs) were trained to perform a switching task to evaluate: the motor domain through the response time; the cognitive domain by a decision to either do the default task or to check the proximity of a large reward delivery; allowing the evaluation of the emotional domain. The NHPs were then implanted with a segmented lead into the STN, enabling directional recordings and stimulations, at 4Hz or 130Hz, of different regions during the task. Results We found higher beta oscillations in the dorso-lateral region and specific 130Hz stimulation decreased the motor response time. Alpha oscillations increased in the more ventral and medial regions before making the decision to work. Specific stimulation at 4Hz applied to the ventro-medial part decreased both motor and cognitive response times. Finally, gamma oscillations increased at the large reward delivery. 4Hz stimulation of all the STN, except the dorso-medial region, decreased the motivation to check for the large reward. Conclusion Our results suggest overlapping in the functional regions of the STN and specific behavioral performances can be modulated with directional stimulation.

NOT YOUR FATHER'S SYNAPSE: REVISING THE HEBB SYNAPSE FOR THE 21ST CENTURY

POSTER SESSION 01 - SECTION: SYNAPTIC PLASTICITY AND COGNITION

Richard Brown, Bayla Dolman
Dalhousie University, Psychology And Neuroscience, Halifax, Canada

Aims: Neurobiologists have studied synaptic communication and plasticity for over a century. In 1949, Donald O. Hebb developed his neuropsychological postulate, which proposed that synaptic plasticity was the basis of cognitive function. This postulate involved three neural processes: synaptic modifications (i.e., the Hebb Synapse), the cell assembly, and the phase sequence. The Hebb synapse describes how activity at pre- and post-synaptic neurons modulates the strength of a synapse (and synaptic networks). The discovery of long-term potentiation and long-term depression provided evidence for the existence of the Hebb synapse and guided our understanding of the neurobiology of learning and memory. However, new findings suggest that the concept of the Hebb synapse needs revision to incorporate the role of glial cells, the extracellular matrix (ECM), and the neurovascular unit (NVU). **Methods:** Previous researchers proposed the concepts of the 'tripartite synapse', 'quad-partite synapse', 'tetra-partite synapse' and 'penta-partite synapse' as well as the 'active milieu' to describe synaptic activity. We reviewed existing literature that described the roles of neuronal and non-neuronal cells and cellular components at the synapse. **Results:** We propose a 'hepta-partite' model of the synapse to account for the role of astrocytes, oligodendrocytes, microglia, the ECM, and NVU in the regulation of synaptogenesis and modulation of synaptic activity/plasticity. **Conclusions:** Based on this new information about the synapse, we revise Hebbian theories of synaptic plasticity, the cell assembly, and phase sequence underlying learning and memory to reflect our current understanding of synaptic communication and plasticity, while upholding the legacy of Donald Hebb.

LOW-FREQUENCY PLASTICITY OF OLFACTORY BULB INPUTS MEDIATED BY KV4.2 CHANNELS IN RODENT PIRIFORM CORTEX

POSTER SESSION 01 - SECTION: SYNAPTIC PLASTICITY AND COGNITION

Amit Kumar, Mohammad Sohaib, Jackie Schiller
Technion, Department Of Physiology, Haifa, Israel

Voltage-gated A-type K^+ channel Kv4.2 sub-units are highly expressed in the dendrites of Layer II pyramidal neurons of piriform cortex. They are known to regulate back-propagation of action potentials into the dendrites of pyramidal neurons and thus limiting the Spike-timing dependent plasticity (STDP) of distal LOT inputs. Using slice electrophysiology, Ca^{+2} imaging and optogenetic techniques, we describe a novel form of plasticity in pyramidal neurons in which unpaired low-frequency (0.1 Hz) stimulation of LOT inputs resulted in large and robust potentiation of EPSPs and enhanced local excitability. It also resulted in more efficient propagation of somatic action potentials specifically into the activated dendritic segment. This form of plasticity was exclusive to LOT inputs and did not occur in the more proximal IC inputs. Induction of this plasticity was dependent on activation of Kv4.2 potassium and NMDAR channels, resulted in insertion of AMPAR to postsynaptic membrane of activated dendrites and required internalization of membrane proteins. Upon activation of acetylcholine by bath application of CarbaChol, the potentiation frequency shifted from 0.1 Hz to 1 Hz. This phenomenon was also limited to LOT inputs and was abolished by Nicotine-receptor blockers. This form of plasticity enhances the proximal-distal electrical coupling of activated dendritic segment in a branch-specific manner.

SYNAPSE-SPECIFIC HOMO- AND HETERO-SYNAPTIC LTP-INDUCED MEMORY CONSOLIDATION IN THE AMYGDALA

POSTER SESSION 01 - SECTION: SYNAPTIC PLASTICITY AND COGNITION

Islam Faress[1], Valentina Khalil[1], Wen-Hsien Hou[2], Andrea Moreno[1], Sadegh Nabavi[1]
[1]Aarhus University-Dandrite, Molecular Biology And Genetics, Aarhus C, Denmark, [2]Aarhus University, Biomedicine, Aarhus C, Denmark

The discovery of experience-dependent plasticity at the cortical (C) and thalamic (T) inputs onto the lateral amygdala (LA) induced by cued Pavlovian aversive conditioning (PAC), is a landmark in elucidating the mechanisms of associative learning. Anatomically, C and T inputs converge onto the LA (C-LA and T-LA) neurons, and functionally the neutral conditioned stimulus (CS) and the aversive unconditioned stimulus (US) also converge in the LA. We have investigated the modes of plasticity of the two inputs independently with optogenetics and tested the behavioral effects by using an optimized optical PAC. We showed for the first time that pairing the optical activation T-LA (OCS) with foot-shocks, which served as the US, is sufficient to support PAC, whereby OCS elicits robust freezing as a conditioned response (CR) 24-hours later. We optimized a milder optical PAC protocol that yields virtually no freezing to study the effect of homosynaptic long-term potentiation (Ho-LTP), whereby high-frequency optical stimulation is applied to the T-LA inputs. Ho-LTP applied immediately, or 24-hours after mild PAC yields a higher CR compared to the baseline and the control group. Next, we asked whether T-LA inputs could undergo heterosynaptic LTP (He-LTP). He-LTP has the same effect as Ho-LTP only if applied immediately after conditioning. While the mild optical PAC protocol doesn't involve activation of the C-LA inputs, the potentiated C-LA inputs consistently yield high freezing levels when tested by applying optical activation of C-LA inputs. This finding was confirmed with freely moving in-vivo electrophysiology in combination with behavioral testing.

NMDA RECEPTOR-RELATED MECHANISMS OF DOPAMINERGIC MODULATION OF TDCS-INDUCED NEUROPLASTICITY

POSTER SESSION 01 - SECTION: SYNAPTIC PLASTICITY AND COGNITION

Elham Ghanavati
Leibniz Research Centre for Working Environment and Human Factors, Psychology And Neuroscience, Dortmund, Germany

Dopamine is a key neuromodulator of neuroplasticity, and an important neuronal substrate of learning, and memory formation, which critically involves glutamatergic N-Methyl-D-aspartate (NMDA) receptors. Dopamine modulates NMDA receptor activity via dopamine D1 and D2 receptor subtypes. It is hypothesized that dopamine focuses long term potentiation (LTP)-like plasticity, i.e. reduces diffuse widespread but enhances locally restricted plasticity via a D2 receptor-dependent NMDA receptor activity reduction. Here, we explored NMDA receptor-dependent mechanisms underlying Dopaminergic modulation of LTP-like plasticity induced by transcranial direct current stimulation (tDCS). Eleven healthy, right-handed volunteers received anodal tDCS (1 mA, 13 min) over the left motor cortex combined with Dopaminergic agents (the D2 receptor agonist bromocriptine, levodopa for general dopamine enhancement, or placebo), and the partial NMDA receptor agonist D-cycloserine (dosages of 50, 100 and 200 mg, or placebo). Cortical excitability was monitored by transcranial magnetic stimulation-induced motor-evoked potentials. We found that LTP-like plasticity was abolished or converted into LTD-like plasticity via dopaminergic activation, but re-established under medium-dose D-cycloserine. These results suggest that diffuse LTP-like plasticity is counteracted via D2 receptor-dependent reduction of NMDA receptor activity.

A major problem of cocaine use disorder is the propensity to relapse, even after extended periods of abstinence. The Seizure-related 6 (Sez6) protein, a neuron-specific protein regulating dendritic branching, dendritic spine formation and excitatory synaptic transmission, potentially regulates structural and functional plasticity of nucleus accumbens (NAc) excitatory synapses after repeated cocaine exposure. The Sez6 ectodomain, which is shed by the protease BACE1, may mediate these effects. Aim: To determine Sez6 involvement in cocaine relapse and the effect of BACE inhibition (BACEi). Methods: Sez6 was conditionally deleted in CaMKIIα-expressing neurons (Sez6 cKO). Two models of relapse were utilized – cocaine-primed reinstatement of conditioned place preference (CPP) and cue-induced cocaine seeking following abstinence in a self-administration paradigm. Sez6 cKO and control mice received in-diet BACEi prior to patch-clamp electrophysiology of NAc slices or relapse tests/Rapid Golgi staining. Results: Sez6 cKO mice displayed reduced relapse behaviour compared to controls in both models. After cocaine-primed reinstatement or abstinence from cocaine IVSA, the density of NAc core medium spiny neuron (MSN) dendritic spines was significantly reduced in Sez6 cKO mice (cf. controls). BACEi significantly reduced: i) drug-primed or cue-induced cocaine-seeking, compared to vehicle, in a Sez6-dependent manner; ii) cocaine-induced excitatory synaptic plasticity following extended withdrawal, and iii) mature dendritic spine density on NAc core MSNs after relapse testing. Conclusion: Lack of Sez6 is protective against cocaine relapse and BACE inhibition mitigates excitatory synaptic strengthening in these models. BACE inhibitors, being trialled as Alzheimer's disease therapeutics, are promising therapeutics for relapse prevention in cocaine use disorder.

ROLE OF POSTSYNAPTIC β2-CONTAINING NICOTINIC ACETYLCHOLINE RECEPTORS IN STRIATAL CIRCUITS AND RELATED BEHAVIOR.

POSTER SESSION 01 - SECTION: SYNAPTIC PLASTICITY AND COGNITION

Maxime Assous, Samet Kocaturk, Elif Guven, Fulva Shah, Michael Shiflett, James Tepper
Rutgers University, Cmbn, Newark, United States of America

The striatum possesses the highest density of acetylcholine (ACh) markers in the basal ganglia underlying the importance of ACh in this structure. Striatal cholinergic interneurons (CINs) are tonically active and have an essential role in cognitive flexibility and goal-directed behaviors. While the effects of ACh in the striatum through muscarinic receptors have received a particular attention, nicotinic receptors (NR) function has been less studied. Our main goal is to better understand the role of striatal cholinergic transmission via NR selectively expressed postsynaptically by striatal GABAergic interneurons. Indeed, there is now evidence that CINs are not simply neuromodulatory elements but are integrated in a fast bidirectional synaptic circuitry with several classes of GABAergic interneurons via NR activation. It was demonstrated that optogenetic activation of CINs elicits very large disynaptic GABAergic IPSP/Cs in striatal projection neurons (SPNs) that are secondary to β2-NR activation. Using a double transgenic/double optogenetic strategies, we demonstrated that NR activation of populations of striatal GABAergic interneurons was responsible for the disynaptic inhibition of SPNs. Further, using transgenic β2-floxed mice we are able to delete β2-NR conditionally and specifically contingent on Cre-expression. We demonstrate that the removal of striatal β2-NR, after localized striatal injections, abolishes the disynaptic inhibition of SPNs. Finally, our preliminary behavioral data demonstrate that removing β2-NR in striatal GABAergic interneurons induces significant impairment in cognitive flexibility measured in a reversal learning paradigm when task contingencies are switched. These results demonstrate the importance of striatal NRs, which are selectively expressed postsynaptically by interneurons, in striatal circuits and related behaviors.

NOGO-A IS A MELATONIN-DRIVEN REGULATOR OF CIRCADIAN MEMORY DYNAMICS AND LEARNING

POSTER SESSION 01 - SECTION: SYNAPTIC PLASTICITY AND COGNITION

Jörg Stehle[1], Antje Jilg[1], Philipp Bechstein[1], Laura Hausmann[2]
[1]Goethe University Frankfurt, Institute Of Anatomy Iii, Frankfurt, Germany, [2]University Hospital RWTH Aachen, Department Of Neurology, Aachen, Germany

Synaptic plasticity and subsequent memory formation are time-of-day-dependent processes, with molecular mechanisms unclear. We identified in mouse hippocampus by immunochemistry a circadian oscillation of the neurite-outgrowth-inhibitor Nogo-A, with lowest levels occurring at Zeitgeber Time 2 (ZT2) and highest abundance at ZT14. Low Nogo-A levels at ZT2 coincided with better learning in a food-rewarded spatial memory test, while at highest Nogo-A levels at ZT14 learning was diminished. As in both, melatonin-deficient C57BL mice and in melatonin receptor deficient $MT^{-/-}$ mice hippocampal Nogo-A levels were constantly elevated, we suggested a role of melatonin for the hippocampal Nogo-A rhythm. We extirpated the superior cervical ganglia (SCG) in mice, rendering a knockdown of rhythmic melatonin synthesis. Indeed, in SCGX mice Nogo-A was constantly elevated, and learning showed no day-night differences. When we substituted melatonin at nighttime only in WT-SCGX mice the circadian Nogo-A rhythm re-appeared and the day-night differences in learning was re-established. Our results grant Nogo-A a fundamental and novel function in regulating daily homeostasis of mouse hippocampal signaling, with the rhythm determined by melatonin that temporarily removes constraints on neuronal plasticity, merging into shaping time-of-day-dependent cognitive performance.

DIVERSE GABAERGIC MODULATION OF STDP IN MOUSE CA1 PYRAMIDAL NEURONS ALONG THE LONGITUDINAL AXIS OF THE HIPPOCAMPUS

POSTER SESSION 01 - SECTION: SYNAPTIC PLASTICITY AND COGNITION

Babak Khodaie[1,2], Elke Edelmann[1,2,3], Volkmar Lessmann[1,2,3]
[1]Institute of Physiology, Otto-von-Guericke University, Magdeburg, Germany, [2]OVGU, ESF-funded International Graduate School ABINEP, Magdeburg, Germany, [3]Center for Behavioral Brain Sciences, (CBBS), Magdeburg, Germany

The hippocampus and its associated medial temporal lobe structures develop as a complex micro-network of excitatory and inhibitory synapses to process learning and memory formation. The longitudinal hippocampal axis spans from dorsal to ventral poles, which are differentially involved in spatial and emotional learning. Along this axis GABA, glutamate, and neuromodulatory receptors are differentially expressed, providing diverse synaptic regulation mechanisms. GABAergic inhibition balances excitatory responses and neuromodulatory transmitter release. Due to the non-uniformi expression of $GABA_A$ and $GABA_B$ receptors along the longitudinal axis synaptic plasticity might be differently modulated by this diverse GABAergic inhibition.
STDP is a paradigm based on precise ms delays of action potentials (APs) in pre- and postsynaptic neurons. Patch clamp recorded CA1 neurons were subjected to canonical (1 presynaptic : 1 postsynaptic AP) or burst t-LTP protocols (1:4), repeated 6 times @0.5 Hz in acute mouse hippocampal slices taken from dorsal (DH), intermediate (IH), or ventral (VH) hippocampus to test timing-dependent LTP (t-LTP) induction under diverse settings for GABAergic inhibition. We used either intact GABAergic inhibition, fully blocked inhibition using co-applied $GABA_AR$ (100µM picrotoxin) or $GABA_BR$ antagonists (10µM CGP55845), or recorded in the presence of only picrotoxin.
We found a complex association of excitatory and inhibitory responses depending on stimulation protocols (canonical or burst) and studied regions (DH or VH). While the 6x 1:1 protocol lost its dependency on GABAergic signaling to induce robust t-LTP from DH to VH pole, our 6x 1:4 protocol mainly depended on active $GABA_BR$ signaling during t-LTP induction.

EARLY IMPAIRED CA3-CA1 SYNAPSES IN AN APP KNOCK-IN MICE MODEL OF ALZHEIMER'S DISEASE

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Benjamin Portal[1], Tamer Ayberk Kaya[2], Ipsit Srivastava[2], Per Nilsson[2], Mia Lindskog[1]
[1]Uppsala University, Department For Medical Cell Biology, Uppsala, Sweden, [2]Karolinska Institutet, Department Of Neurobiology, Care Science And Society, Stockholm, Sweden

Synaptic plasticity has been the subject of an intense investigation in the past decades, as it is a mechanism for memory and increased Long Term Potentiation (LTP) at the CA3-CA1 hippocampal synapses is associated with increased cognitive capability. Alzheimer's disease (AD) is the most common neurodegenerative disease with decreased cognition as the main symptom, mostly initiated in the hippocampus. Recently, very early neuronal and synaptic impairments have been unveiled long before the formation of Aβ plaques. The astrocytic contribution at this stage remain yet to be clarified. **AIM**: Our study aims at study neuronal and astrocytic dysfunctions at early stages of AD. **METHODS**: Electrophysiological recordings were used to study synaptic activity and plasticity in hippocampal slices from an APP knock-in mice (APP^{NL-F}) model of AD. Western-blot and immunohistochemistry were used to understand morphological and molecular changes. **RESULTS**: Electrophysiological recordings revealed an overall altered synaptic activity in APP^{NL-F} mice. Whilst neurons look healthy, pre-synaptic activity is reduced and field recordings reveal a facilitated LTP, associated with altered expression with MAPK/ERK signaling pathway. In the meantime, astrocytes seems to express less GFAP and morphological analysis revealed a reduced complexity. **CONCLUSIONS**: We show here that neuronal synaptic transmission as well as astrocytic morphology are altered in the hippocampus at early phases of AD. Interestingly these results contrast with earlier reports showing opposite impairment in older animals. Further functional and molecular studies are therefore needed to better understand the cause of such neuronal and astrocytic early changes.

A missense mutation converts the Na,K-ATPase into an ion channel and causes therapy-resistant epilepsy.
The ion pump Na,K-ATPase is a critical determinant of neuronal excitability; however, its role in the etiology of diseases of the central nervous system (CNS) is largely unknown. We describe here the molecular phenotype of a Trp931Arg mutation of the Na,K-ATPase catalytic α1 subunit in an infant diagnosed with therapy-resistant lethal epilepsy. In addition to the pathological CNS phenotype, we also detected renal wasting of Mg. We found that membrane expression of the mutant α1 protein was low, and ion pumping activity was lost. Arginine insertion into membrane proteins can generate water-filled pores in the plasma membrane, and our molecular dynamic (MD) simulations of the principle states of Na,K-ATPase transport demonstrated massive water inflow into mutant α1 and destabilization of the ion-binding sites. MD simulations also indicated that a water pathway was created between the mutant arginine residue and the cytoplasm, and analysis of oocytes expressing mutant α1 detected a nonspecific cation current. Finally, neurons expressing mutant α1 were observed to be depolarized compared with neurons expressing wild-type protein, compatible with a lowered threshold for epileptic seizures. The results imply that Na,K-ATPase should be considered a neuronal locus minoris resistentia in diseases associated with epilepsy and with loss of plasma membrane integrity.

[Role of astrocytic connexins in the regulation of extracellular glutamate levels: implication for the treatment of major depressive episodes].
Major depression is a psychiatric disorder relying on different neurobiological mechanisms. In particular, a hypersensitivity of the hypothalamic-pituitary-adrenal axis leading to an excess of cortisol in blood and a deficit in monoaminergic neurotransmission have been associated with mood disorders. In keeping with these mechanisms, currently available antidepressant drugs act by increasing the extracellular levels of monoamines in the synaptic cleft. Since the discovery of the

rapid and long-lasting antidepressant effects of ketamine, an NMDA receptor antagonist, a growing attention in psychiatry is paid to the pharmacological tools able to attenuate glutamatergic neurotransmission. Astrocytes play an important role in the excitatory/inhibitory balance of the central nervous system through the regulation of glutamate reuptake and secretion. Interestingly, the release of this excitatory amino acid is controlled, at least in part, by plasma membrane proteins (i.e. connexins) that cluster together to form gap junctions or hemichannels. Preclinical evidence suggests that these functional entities play a critical role in emotional behaviour. After a brief overview of the literature on mood disorders and related treatments, this review describes the role of astrocytes and connexins in glutamatergic neurotransmission and major depression. Moreover, we highlight the arguments supporting the therapeutic potential of connexins blockers but also the practical difficulties to target the hemichannels while maintaining gap junctions intact.

Efficacy of THN201, a Combination of Donepezil and Mefloquine, to Reverse Neurocognitive Deficits in Alzheimer's Disease.
Donepezil (DPZ) is an acetylcholinesterase inhibitor used in Alzheimer's disease to restore cognitive functions but is endowed with limited efficacy. Recent studies pointed out the implication of astroglial networks in cognitive processes, notably via astrocyte connexins (Cxs), proteins involved in gap junction intercellular communications. Hence, we investigated the impact on cognition of pharmacological or genetic modulations of those astrocyte Cxs during DPZ challenge in two rodent models of Alzheimer's disease-like memory deficits. We demonstrated that the Cx modulator mefloquine (MEF) significantly enhanced the procognitive effect of DPZ in both models. In parallel, we determined that MEF potentiated DPZ-induced release of acetylcholine in hippocampus. Finally, local genetic silencing of astrocyte Cxs in the hippocampus was also found to enhance the procognitive effect of DPZ, pointing out the importance of Cx-dependent astrocyte networks in memory processes.

Genetic and pharmacological inactivation of astroglial connexin 43 differentially influences the acute response of antidepressant and anxiolytic drugs.
Astroglial connexins (Cxs) 30 and 43 are engaged in gap junction and hemichannel activities. Evidence suggests that these functional entities contribute to regulating neurotransmission, thereby influencing brain functions. In particular, preclinical and clinical findings highlight a role of Cx43 in animal models of depression. However, the role of these proteins in response to currently available psychotropic drugs is still unknown.

A New Tool for In Vivo Study of Astrocyte Connexin 43 in Brain.
Astrocytes are glial cells organized in dynamic and structured networks in the brain. These plastic networks, involving key proteins such as connexin 43 (Cx43), are engaged in fine neuronal tuning and have recently been considered as emerging therapeutic targets in central nervous system disorders. We developed and validated a new application of the manganese-enhanced magnetic resonance imaging (MEMRI) technique allowing in vivo investigations of astrocyte-neuron interactions through quantification of brain Cx43 functional activity. The proof of concept has been achieved by quantification of MEMRI signals in brain after either local astrocyte-specific Cx43 knockdown with shRNA or systemic administration of Cx43 blockers. Unilateral hippocampal Cx43 genetical silencing was associated with an ipsilateral local increase of MEMRI signal. Furthermore, Cx43 blockers also enhanced MEMRI signal responses in hippocampus. Altogether, these data reveal the MEMRI technique as a tool for quantitative imaging of in vivo Cx43-dependent function in astrocytes under physiological and pathological conditions.

Attenuated Levels of Hippocampal Connexin 43 and its Phosphorylation Correlate with Antidepressant- and Anxiolytic-Like Activities in Mice.
Clinical and preclinical studies have implicated glial anomalies in major depression. Conversely, evidence suggests that the activity of antidepressant drugs is based, at least in part, on their ability to stimulate density and/or activity of astrocytes, a major glial cell population. Despite this recent evidence, little is known about the mechanism(s) by which astrocytes regulate emotionality. Glial cells communicate with each other through gap junction channels (GJCs), while they can also directly interact with neurons by releasing gliotransmitters in the extracellular compartment via an hemichannels (HCs)-dependent process. Both GJCs and HCs are formed by two main protein subunits: connexins (Cx) 30 and 43 (Cx30 and Cx43). Here we

investigate the role of hippocampal Cx43 in the regulation of depression-like symptoms using genetic and pharmacological approaches. The first aim of this study was to evaluate the impact of the constitutive knock-down of Cx43 on a set of behaviors known to be affected in depression. Conversely, the expression of Cx43 was assessed in the hippocampus of mice subjected to prolonged corticosterone (CORT) exposure, given either alone or in combination with an antidepressant drug, the selective serotonin reuptake inhibitor fluoxetine. Our results indicate that the constitutive deficiency of Cx43 resulted in the expression of some characteristic hallmarks of antidepressant-/anxiolytic-like behavioral activities along with an improvement of cognitive performances. Moreover, in a new cohort of wild-type mice, we showed that CORT exposure elicited anxiety and depression-like abnormalities that were reversed by chronic administration of fluoxetine. Remarkably, CORT also increased hippocampal amounts of phosphorylated form of Cx43 whereas fluoxetine treatment normalized this parameter. From these results, we envision that antidepressant drugs may exert their therapeutic activity by decreasing the expression and/or activity of Cx43 resulting from a lower level of phosphorylation in the hippocampus.

AMYLOID-BETA OLIGOMERS INCREASES THE AMPLITUDE AND CHANGES THE FIRING PATTERN OF SPONTANEOUS EXCITATORY POSTSYNAPTIC CURRENTS OF HIPPOCAMPAL NEURONS IN A MODEL OF ALZHEIMER'S DISEASE

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Marcela Cuestas Torres
Universidad de los Andes, Cundinamarca, Cajicá, Colombia

Alzheimer's disease (AD) is a neurodegenerative disorder characterized by the deterioration of memory and learning. Synapses are fundamental to the transfer, coding, and storage of information, and the latest findings indicate that the deterioration of synaptic transmission is caused by the accumulation of amyloid-beta (Aβ), dysregulated Ca2+ homeostasis, increased oxidative stress, and mitochondrial dysfunction. The cellular mechanisms that occur at the presynaptic and postsynaptic levels in hippocampal neurons in the early stages of AD have not been fully characterized, nor have their effects on the encoding of neuronal information by these cells. Spontaneous activity, which is the result of the spontaneous fusion of individual vesicles and the release of quanta/unique neurotransmitter packages, allows us to analyze the presynaptic and postsynaptic elements separately by evaluating their spontaneous firing frequency and amplitude. To characterize the spontaneous electrical activity of hippocampal neurons during the early stages of the neurodegeneration process associated with AD, we studied, through the patch-clamp whole-cell technique, the effect of the presence of Aβ oligomers (Aβo) on the amplitude, firing frequency, and firing pattern of spontaneous excitatory postsynaptic currents (sEPSCs) in hippocampal primary cultures from Wistar rat embryos. We found that exposure to Aβo increased the amplitude of sEPSCs, which indicated alterations at the postsynaptic level, and modified the firing pattern of the cultured hippocampal cells, which indicated changes in the coding of the information. These data expand the basic knowledge on the cellular basis of the early deterioration of synaptic transmission and your implications on the processes of synaptic plasticity

Synaptic plasticity in Alzheimer's disease and healthy aging.
The strength and efficiency of synaptic connections are affected by the environment or the experience of the individual. This property, called synaptic plasticity, is directly related to memory and learning processes and has been modeled at the cellular level. These types of cellular memory and learning models include specific stimulation protocols that generate a long-term strengthening of the synapses, called long-term potentiation, or a weakening of the said long-term synapses, called long-term depression. Although, for decades, researchers have believed that the main cause of the cognitive deficit that characterizes Alzheimer's disease (AD) and aging was the loss of neurons, the hypothesis of an imbalance in the cellular and molecular mechanisms of synaptic plasticity underlying this deficit is currently widely accepted. An understanding of the molecular and cellular changes underlying the process of synaptic plasticity during the development of AD and aging will direct future studies to specific targets, resulting in the development of much more efficient and specific therapeutic strategies. In this review, we classify, discuss, and describe the main findings related to changes in the neurophysiological mechanisms of synaptic plasticity in excitatory synapses underlying AD and aging. In addition, we suggest possible mechanisms in which aging can become a high-risk factor for the development of AD and how its development could be prevented or slowed.

AIR POLLUTION EFFECTS ON SYNAPTIC TRANSMISSION.

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Sara Di Girolamo, Giulia Terribile, Giulio Sancini
University of Milano-Bicocca, Department Of Medicine And Surgery, Monza, Italy

Air pollution (AP) effects are traditionally associated with increased risks for development of pulmonary and cardiovascular disease (Block & Calderón-Garcidueñas, 2009). In recent years, human epidemiological and animal studies show how the Central Nervous System (CNS) is emerging as an important target for adverse health effects of airborne pollutants (Costa et al., 2017; Genc et al., 2012). Moreover, different studies demonstrate how exposure to environmental air pollutants induces synaptic plasticity impairment, both directly and indirectly (Hajipour S. et al., 2020; Bello-Medina P.C. et al., 2019; Woodward N.C. et al., 2017; Davis D.A. et al., 2013; Morgan T.E. et al., 2011). General aim of our experimental project is to investigate how AP modify and invalidate delicate and complex mechanisms on which synaptic plasticity depends, including LTP and multiple neurotransmission signals of hippocampal and cortical neuronal cells, whose function is at the base of the learning and memory process. For this purpose, we use CD-1 mouse models (P8/20), whose brain slices are exposed to Diesel Exhaust Particles (DEP) (Reference Material, 10µg/mL, 2h exposure), which constitute an important component of AP. Electrophysiological recordings experiments are performed using the *Whole-Cell Patch Clamp* technique both in *Voltage* and in *Current Clamp* on pyramidal neurons. The final aim of this project is to achieve a better understanding of the overall effects of AP on physiological mechanisms of cerebral neuro-communication.

LOCALIZATION AND FUNCTION OF ENDOCYTIC ZONES IN NEURONAL DENDRITES IN SITU: RELEVANCE FOR SYNAPTIC PLASTICITY

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Julie Angibaud, Khadija Inam, David Perrais

Post-synaptic receptor trafficking plays an important role in synaptic transmission and plasticity. Receptor internalization occurs at endocytic zones (EZs) marked by clathrin. In neurons in culture, EZs are positioned near post-synaptic densities (PSDs) marking excitatory synapses in dendritic spines as well as in uncharacterized locations on the dendritic shaft. We have recently shown that EZs are stable but produce endocytic vesicles to internalize post-synaptic receptors (Rosendale et al. Cell Reports 2017). We determined the spatial organization and dynamics of EZs in hippocampal brain slices. We expressed by single cell electroporation in CA1 pyramidal neurons CLC-GFP to mark EZs and Homer1c-tdTomato, a marker of PSDs. We imaged these neurons at 15 days in vitro with lattice light sheet microscopy every 4 s for 5-10 minutes and tracked EZs. We show that, in neurons in situ, EZs keep the same general organization as in culture: EZs are distributed in the dendritic shaft and in spines, next to PSDs. However, EZs are much more dynamic, appearing and disappearing within minutes. EZs close to PSDs have longer lifetimes (2.6min) than in the dendritic shaft (1min). We now explore the possible mechanisms for a difference in the dynamics of EZs. In particular, we test the hypothesis that substrate rigidity plays a role by culturing neurons on polyacrylamide gels of controlled stiffness.

Resistance to pharmacotherapy requires the development of novel antiepileptic drugs (AEDs). An adenosine A_1 receptor (A_1R) agonist, MRS5474, possesses anticonvulsant activity (Tosh et al., 2012, J Med Chem, 55:8075), without the cardiac side effects of other A_1R agonists. Hypothesizing that it operates via a novel mechanism, we assessed its influence upon hippocampal excitatory transmission and GABA uptake in control and in status-epilepticus (SE)-induced conditions. Excitatory postsynaptic potentials (fEPSPs), Population Spikes (PS), or GAT-1 mediated [^{3}H]GABA uptake was recorded from hippocampal slices. Status epilepticus (SE) was induced by kainate (10mg/kg, i.p) 4 weeks before hippocampal slice preparation, as approved by the ethics committee. In control slices MRS5474 (120-500nM) was devoid of effect in fEPSPs (n=7, mouse; n=2, rat) or PS (n=2, rat). In contrast, the well-known A1R agonists, CPA (30nM, n=2), or CHA (30nM, n=2), caused the expected marked inhibition (>60%) of fEPSPs. In SE rat slices, MRS5474 (250nM) inhibited (30±6.0%, n=7, $p<0.05$) fEPSP slope and PS amplitude (40±9.6%, n=4, $p<0.05$). MRS5474 (50nM) inhibited GAT-1 mediated [^{3}H]GABA uptake by 52±8.4% (n=6, $p<0.05$) in control slices, but this effect is likely not mediated by A1R since it was not blocked by the A1R antagonist, DPCPX (50nM, % inhibition 46±6.2, n=4, $p>0.05$ vs no DPCPX). In conclusion, MRS5474 does not share properties with canonical A_1R agonists, suggesting that this putative AED may have fewer side effects than other A1R agonists and currently available AEDs. Project funded by FCT, Portugal (PTDC/MED- FAR/30933/2017) and by EU Horizon 2020 research and innovation programme (GA 952455, EpiEpiNet).

EFFECT OF A HIGH-FAT DIET ON HIPPOCAMPAL AREA CA2 AND SOCIAL RECOGNITION MEMORY

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Maud Muller[1], Alice Fermigier[2], Pauline Lafenetre[2], Eva-Gunnel Ducourneau[2], Guillaume Ferreira[3], Rebecca Piskorowski[1], Vivien Chevaleyre[1]

Obesity levels during adolescence is growing at an alarming rate and obese adolescents perform worse in cognitive tasks leading to detrimental academic performance. In mice, the consumption of a diet high in saturated fat (High-Fat Diet: HFD) during adolescence also results in strong deficits in several hippocampal-dependent memory tasks including social recognition memory (SRM). Area CA2 of the hippocampus plays a critical role in SRM. CA2 neuronal activity is enhanced during social interactions and decreasing CA2 pyramidal neuron activity or blocking CA2 transmission onto its targets prevents SRM. Our aim here is to **understand if and how area CA2 activity is altered in HFD-fed mice and whether this underlies their impairments in SRM.** After exposing the mice to 12 weeks of HFD, electrophysiology, chemogenetics and behavioral experiments are used to study the alterations induced by HFD in hippocampal area CA2, and the contribution of these changes on SRM. Decreasing hippocampal pyramidal cell activity throughout the dorsal hippocampus of HFD-fed mice rescued their SRM deficits. In line with this result, we also discovered that CA2 pyramidal neurons are hyper excitable in HFD-fed animals, allowing for CA3 inputs to drive action potentials in CA2 of HFD-fed mice. This hyperexcitability seems to be due to increased presynaptic glutamate release from Schaffer collaterals. HFD during adolescence alters CA2 pyramidal neuron activity possibly underlying SRM deficits. We are currently studying the precise mechanisms underlying the dysfunction as well as whether modulatory signaling such as oxytocin effects are altered in CA2 by HFD consumption.

OPTOGENETIC MAPPING OF THE CELLULAR SPECIFICITY OF THE AFFERENT INPUTS TO THE RETROSPLENIAL CORTEX

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Gabriella Margetts-Smith[1], Andrew Randall[1], John Aggleton[2], Jonathan Witton[1], Michael Craig[3]
[1]University of Exeter, Institute Of Biomedical And Clinical Sciences, Exeter, United Kingdom, [2]Cardiff University, School Of Pyschology, Cardiff, United Kingdom, [3]University of Glasgow, School Of Psychology & Neuroscience, Glasgow, United Kingdom

One of the defining characteristics of the retrosplenial cortex (RSC) is the interconnectivity it shares with a range of brain regions. This connectivity could be critical to its role in learning and memory, as reciprocal connections have been anatomically identified with other memory-associated regions such as the anterior cingulate cortex (ACC), anterior thalamic nuclei (ATN) and dorsal subiculum (dSub). However, the connection probability and strength of these synapses are still relatively unknown; therefore we aimed to characterise and quantify the properties of the afferent pathways to the RSC from these regions. To achieve this, afferent terminals in *ex vivo* C57BL6/J mouse RSC brain slices were optogenetically stimulated following viral expression of channelrhodopsin2(H134R) in the presynaptic regions, and whole-cell patch clamp recordings were undertaken in pyramidal neurons (PYRs) to measure the synaptic properties of these connections. Our findings indicate projection-specific differences in both afferent strength and specificity. Firstly, projections from the ACC elicited responses in a much sparser subset of PYRs than from the ATN and dSub. Secondly, projections from the ATN elicited significantly larger EPSCs than from the other presynaptic regions; although this effect was limited to cells situated in the dysgranular superficial layers. These findings demonstrate that not all RSC afferent pathways are equal in strength and provides an important addition to standard neuroanatomical tracing to provide insights into the distinct roles that these pathways may play in behaviour. Furthermore, characterisation of these pathways provides a physiological baseline for future comparisons of afferent inputs to RSC in different models of disease.

Acute, but not longer-term, exposure to environmental enrichment attenuates Pavlovian cue-evoked conditioned approach and Fos expression in the prefrontal cortex in mice.
Exposure to environmental enrichment can modify the impact of motivationally relevant stimuli. For instance, previous studies in rats have found that even a brief, acute (~1 day), but not chronic, exposure to environmentally enriched (EE) housing attenuates instrumental lever pressing for sucrose-associated cues in a conditioned reinforcement setup. Moreover, acute EE reduces corticoaccumbens activity, as measured by decreases in expression of the neuronal activity marker "Fos." Currently, it is not known whether acute EE also reduces sucrose seeking and corticoaccumbens activity elicited by non-contingent or "forced" exposure to sucrose cues, which more closely resembles cue exposure encountered in daily life. We therefore measured the effects of acute/intermittent (1 day or 6 day of EE prior to test day) versus chronic (EE throughout conditioning lasting until test day) EE on the ability of a Pavlovian sucrose cue to elicit sucrose seeking (conditioned approach) and Fos expression in the medial prefrontal cortex (mPFC), orbitofrontal cortex (OFC), and nucleus accumbens (NAc) in mice. One day, but not 6 day or chronic EE , reduced sucrose seeking and Fos in the deep layers of the dorsal mPFC. By contrast, 1 day, 6 day, and chronic EE all reduced Fos in the shallow layers of the OFC. None of the EE manipulations modulated NAc Fos expression. We reveal how EE reduces behavioral reactivity to sucrose cues by reducing activity in select prefrontal cortical brain areas. Our work further demonstrates the robustness of EE in its ability to modulate various forms of reward-seeking across species.

Extinction of cue-evoked food-seeking recruits a GABAergic interneuron ensemble in the dorsal medial prefrontal cortex of mice.
Animals must quickly adapt food-seeking strategies to locate nutrient sources in dynamically changing environments.

Learned associations between food and environmental cues that predict its availability promote food-seeking behaviors. However, when such cues cease to predict food availability, animals undergo "extinction" learning, resulting in the inhibition of food-seeking responses. Repeatedly activated sets of neurons, or "neuronal ensembles," in the dorsal medial prefrontal cortex (dmPFC) are recruited following appetitive conditioning and undergo physiological adaptations thought to encode cue-reward associations. However, little is known about how the recruitment and intrinsic excitability of such dmPFC ensembles are modulated by extinction learning. Here, we used in vivo 2-Photon imaging in male Fos-GFP mice that express green fluorescent protein (GFP) in recently behaviorally activated neurons to determine the recruitment of activated pyramidal and GABAergic interneuron dmPFC ensembles during extinction. During extinction, we revealed a persistent activation of a subset of interneurons which emerged from a wider population of interneurons activated during the initial extinction session. This activation pattern was not observed in pyramidal cells, and extinction learning did not modulate the excitability properties of activated pyramidal cells. Moreover, extinction learning reduced the likelihood of reactivation of pyramidal cells activated during the initial extinction session. Our findings illuminate novel neuronal activation patterns in the dmPFC underlying extinction of food-seeking, and in particular, highlight an important role for interneuron ensembles in this inhibitory form of learning.

31727794: Brebner LS, Ziminski JJ, Margetts-Smith G, Sieburg MC, Reeve HM, Nowotny T, Hirrlinger J, Heintz TG, Lagnado L, Kato S, Kobayashi K, Ramsey LA, Hall CN, Crombag HS, Koya E

The Emergence of a Stable Neuronal Ensemble from a Wider Pool of Activated Neurons in the Dorsal Medial Prefrontal Cortex during Appetitive Learning in Mice.

Animals selectively respond to environmental cues associated with food reward to optimize nutrient intake. Such appetitive conditioned stimulus-unconditioned stimulus (CS-US) associations are thought to be encoded in select, stable neuronal populations or neuronal ensembles, which undergo physiological modifications during appetitive conditioning. These ensembles in the medial prefrontal cortex (mPFC) control well-established, cue-evoked food seeking, but the mechanisms involved in the genesis of these ensembles are unclear. Here, we used male mice that express green fluorescent protein (GFP) in recently behaviorally activated neurons, to reveal how dorsal mPFC neurons are recruited and modified to encode CS-US memory representations using an appetitive conditioning task. In the initial conditioning session, animals did not exhibit discriminated, cue-selective food seeking, but did so in later sessions indicating that a CS-US association was established. Using microprism-based 2-Photon imaging, we revealed that only a minority of neurons activated during the initial session was consistently activated throughout subsequent conditioning sessions and during cue-evoked memory recall. Notably, using electrophysiology, we found that neurons activated following the initial session exhibited transient hyperexcitability. Chemogenetically enhancing the excitability of these neurons throughout subsequent conditioning sessions interfered with the development of reliable cue-selective food seeking, indicated by persistent, nondiscriminated performance. We demonstrate how appetitive learning consistently activates a subset of neurons to form a stable neuronal ensemble during the formation of a CS-US association. This ensemble may arise from a pool of hyperexcitable neurons activated during the initial conditioning session. Appetitive conditioning endows cues associated with food with the ability to guide food-seeking, through the formation of a food-cue association. Neuronal ensembles in the mPFC control established cue-evoked food-seeking. However, how neurons undergo physiological modifications and become part of an ensemble during conditioning remain unclear. We found that only a minority of dorsal mPFC neurons activated on the initial conditioning session became consistently activated during conditioning and memory recall. These initially activated neurons were also transiently hyperexcitable. We demonstrate the following: (1) how stable neuronal ensemble formation in the dorsal mPFC underlies appetitive conditioning; and (2) how this ensemble may arise from hyperexcitable neurons activated before the establishment of cue-evoked food seeking.

Reward Devaluation Attenuates Cue-Evoked Sucrose Seeking and Is Associated with the Elimination of Excitability Differences between Ensemble and Non-ensemble Neurons in the Nucleus Accumbens.

Animals must learn relationships between foods and the environmental cues that predict their availability for survival. Such cue-food associations are encoded in sparse sets of neurons or "neuronal ensembles" in the nucleus accumbens (NAc). For these ensemble-encoded, cue-controlled appetitive responses to remain adaptive, they must allow for their dynamic updating depending on acute changes in internal states such as physiological hunger or the perceived desirability of food. However, how these neuronal ensembles are recruited and physiologically modified following the update of such learned associations is unclear. To investigate this, we examined the effects of devaluation on ensemble plasticity at the levels of recruitment, intrinsic excitability, and synaptic physiology in sucrose-conditioned mice that express green fluorescent protein (GFP) in recently activated neurons. Neuronal ensemble activation patterns and their physiology were examined using immunohistochemistry and slice electrophysiology, respectively. Reward-specific devaluation following 4 d of sucrose

consumption, but not general caloric devaluation, attenuated cue-evoked sucrose seeking. This suggests that changes in the hedonic and/or incentive value of sucrose, and not caloric need, drove this behavior. Moreover, devaluation attenuated the size of the neuronal ensemble recruited by the cue in the NAc shell. Finally, it eliminated the relative enhanced excitability of ensemble (GFP) neurons against non-ensemble (GFP) neurons observed under non-devalued conditions, and did not induce any ensemble-specific changes in excitatory synaptic physiology. Our findings provide new insights into neuronal ensemble mechanisms that underlie the changes in the incentive and/or hedonic impact of cues that support adaptive food seeking.

Regional Differences in Striatal Neuronal Ensemble Excitability Following Cocaine and Extinction Memory Retrieval in Fos-GFP Mice.
Learned associations between drugs of abuse and the drug administration environment have an important role in addiction. In rodents, exposure to a drug-associated environment elicits conditioned psychomotor activation, which may be weakened following extinction (EXT) learning. Although widespread drug-induced changes in neuronal excitability have been observed, little is known about specific changes within neuronal ensembles activated during the recall of drug-environment associations. Using a cocaine-conditioned locomotion (CL) procedure, the present study assessed the excitability of neuronal ensembles in the nucleus accumbens core and shell (NAc and NAc), and dorsal striatum (DS) following cocaine conditioning and EXT in Fos-GFP mice that express green fluorescent protein (GFP) in activated neurons (GFP+). During conditioning, mice received repeated cocaine injections (20 mg/kg) paired with a locomotor activity chamber (Paired) or home cage (Unpaired). Seven to 13 days later, both groups were re-exposed to the activity chamber under drug-free conditions and Paired, but not Unpaired, mice exhibited CL. In a separate group of mice, CL was extinguished by repeatedly exposing mice to the activity chamber under drug-free conditions. Following the expression and EXT of CL, GFP+ neurons in the NAc (but not NAc and DS) displayed greater firing capacity compared to surrounding GFP- neurons. This difference in excitability was due to a generalized decrease in GFP- excitability following CL and a selective increase in GFP+ excitability following its EXT. These results suggest a role for both widespread and ensemble-specific changes in neuronal excitability following recall of drug-environment associations.

Changes in Appetitive Associative Strength Modulates Nucleus Accumbens, But Not Orbitofrontal Cortex Neuronal Ensemble Excitability.
Cues that predict the availability of food rewards influence motivational states and elicit food-seeking behaviors. If a cue no longer predicts food availability, then animals may adapt accordingly by inhibiting food-seeking responses. Sparsely activated sets of neurons, coined "neuronal ensembles," have been shown to encode the strength of reward-cue associations. Although alterations in intrinsic excitability have been shown to underlie many learning and memory processes, little is known about these properties specifically on cue-activated neuronal ensembles. We examined the activation patterns of cue-activated orbitofrontal cortex (OFC) and nucleus accumbens (NAc) shell ensembles using wild-type and mice, which express green fluorescent protein (GFP) in activated neurons, after appetitive conditioning with sucrose and extinction learning. We also investigated the neuronal excitability of recently activated, GFP+ neurons in these brain areas using whole-cell electrophysiology in brain slices. Exposure to a sucrose cue elicited activation of neurons in both the NAc shell and OFC. In the NAc shell, but not the OFC, these activated GFP+ neurons were more excitable than surrounding GFP- neurons. After extinction, the number of neurons activated in both areas was reduced and activated ensembles in neither area exhibited altered excitability. These data suggest that learning-induced alterations in the intrinsic excitability of neuronal ensembles is regulated dynamically across different brain areas. Furthermore, we show that changes in associative strength modulate the excitability profile of activated ensembles in the NAc shell. Sparsely distributed sets of neurons called "neuronal ensembles" encode learned associations about food and cues predictive of its availability. Widespread changes in neuronal excitability have been observed in limbic brain areas after associative learning, but little is known about the excitability changes that occur specifically on neuronal ensembles that encode appetitive associations. Here, we reveal that sucrose cue exposure recruited a more excitable ensemble in the nucleus accumbens, but not orbitofrontal cortex, compared with their surrounding neurons. This excitability difference was not observed when the cue's salience was diminished after extinction learning. These novel data provide evidence that the intrinsic excitability of appetitive memory-encoding ensembles is regulated differentially across brain areas and adapts dynamically to changes in associative strength.

Daun02 Inactivation of Behaviorally Activated Fos-Expressing Neuronal Ensembles.
Learned associations about salient experiences (e.g., drug exposure, stress) and their associated environmental stimuli are mediated by a minority of sparsely distributed, behaviorally activated neurons coined 'neuronal ensembles.' For many years,

it was not known whether these neuronal ensembles played causal roles in mediating learned behaviors. However, in the last several years the 'Daun02 inactivation technique' in Fos-lacZ transgenic rats has proved very useful in establishing causal links between neuronal ensembles that express the activity-regulated protein Fos and learned behaviors. Fos-expressing neurons in these rats also express the bacterial protein β-galactosidase (β-gal) in strongly activated neurons. When the prodrug Daun02 is injected into the brains of these rats 90 min after a behavior (e.g., drug-seeking) or cue exposure, then Daun02 is converted into daunorubicin by β-gal, which selectively inactivates Fos- and β-gal-expressing neurons that were activated 90 min before the Daun02 injection. This unit presents protocols for breeding the Fos-lacZ rats and conducting appropriate Daun02 inactivation experiments.

Aim NX210c is a disease-modifying dodecapeptide, derived from the subcommissural organ-spondin, under clinical development for the treatment of neurological disorders. Here, we have evaluated the effect of NX210c on synaptic function/dysfunction. **Methods** NX210c (250 µg/mL) was superfused on mouse brain slices to measure (1) NMDAR- and AMPAR-mediated excitatory postsynaptic currents (EPSCs) at hippocampal CA3-CA1 synapses, and (2) extracellular field excitatory postsynaptic potentials (fEPSPs) recordings at hippocampal and thalamocortical synapses. NX210c (5 mg/kg) was injected intraperitoneally in mice with cortical synaptic dysfunctions induced by chronic administrations of the NMDAR antagonist phencyclidine (PCP) to evaluate working memory (% of alternations in the T-maze) and GluN2A-NMDAR and phosphorylated CREB levels in cortical protein extracts (western-blot). **Results** NX210c increased EPSC amplitudes mediated by NMDAR (+79.2%, p=0.0469 *vs* baseline), more specifically GluN2A-NMDAR, and AMPAR (+16.7%, p=0.0191 *vs* baseline), as well as fEPSP slopes (p=0.0356 and p=0.0027 *vs* control for hippocampal and thalamocortical synapses), consistent with the *in silico* docking of NX210c to glutamatergic receptors. Accordingly, a single acute administration of NX210c in PCP-injected mice restored working memory (-35.7 and -13.5% of alternations for vehicle- and NX210c-treated PCP mice compared with control mice). Further, repeated daily administrations of the peptide induced a two-fold increase in GluN2A-NMDAR protein levels and reversed PCP-induced decrease in pCREB, which also restored memory (-4.3% of alternations for NX210c-treated PCP mice compared with control mice). **Conclusions** The action of NX210c on GluN2A-NMDAR and AMPAR represents an innovative therapeutic opportunity to ameliorate outcomes in patients suffering from CNS disorders with crippling synaptic dysfunctions.

Left-right asymmetry is a fundamental feature of higher-order brain structure and function. In the mouse hippocampus, properties of synapses between pyramidal cells depend on the hemispheric location of presynaptic CA3 neurons. In *stratum radiatum*, right-input synapses consist of larger postsynaptic density (PSD) with higher ratio of perforations and lower density NR2B subunits compared with left-input synapses. The major histocompatibility complex class I (MHCI) and immunoglobulin-like receptor B (PirB) are essential for the formation of this input-side dependent asymmetry, implying a potential trans-synaptic signalling via MHCI and PirB. We aimed to investigate if the PirB is necessary for signalling on the input or target side. To this end, we conducted electrophysiological and morphological analysis. NMDA EPSCs at the PirB-deficient mice (KO) pyramidal cell synapses showed no asymmetry in sensitivity to a NR2B-selective antagonist. Postsynaptic, but not presynaptic AAV-mediated PirB expression rescued this asymmetry. However, ultrastructural analysis revealed that conditional KO of PirB in either pre- or postsynaptic neurons abolished the asymmetry. Both left- and right-input synapses showed a low perforation ratio similar to that of wild-type left-input synapses. This suggests that PirB is necessary on both sides of the synapse for the asymmetry formation. Our results indicate that PirB expression in target side is critical for the asymmetry formation. The discrepant results of presynaptic PirB manipulation might be due to its indirect effects on postsynaptic PirB expression. Further work is needed to elucidate how the PirB in the pre and postsynaptic sites work in concert for the generation of hippocampal asymmetry.

GLUCAGON-LIKE PEPTIDE 1 RECEPTOR AGONIST EXENDIN-4 HAS DIVERSE EFFECTS ON NEURONAL ACTIVITY

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Brinda Gurung[1], Andrew Randall[2], Jonathan Brown[2]
[1]University of Exeter, College Of Medicine And Health, Exeter, United Kingdom, [2]University of Exeter, Institute Of Biomedical And Clinical Sciences, Exeter, United Kingdom

Glucagon-like peptide-1 receptor (GLP-1R) is an important G-protein coupled receptor in the periphery, which when activated stimulates the glucose-dependent release of insulin by the pancreatic β-cells to lower blood glucose. As such drugs that are agonists of this receptor are an approved class of drugs used for Type 2 diabetes mellitus (T2DM). T2DM and the neurodegenerative disease Alzheimer's disease (AD) share common pathophysiological characteristics such as insulin resistance and decreased glucose metabolism. The GLP-R agonist liraglutide is under a Phase IIb clinical trial (NCT01843075) in patients with mild AD dementia to examine the drug's effect on the hallmarks of the progression of the disease. Other agonists of this receptor have also shown improved spatial learning and memory in animal models of AD. However, to date the details of the effects this receptor system has at a neural circuit level in the brain is not well known. GLP-1R is expressed in many brain structures but it is most highly expressed in the lateral septum. Therefore, we aim to explore the effects of GLP-1R activation on neuronal activity in the lateral septum. We have used a multi-electrode array approach to show the diverse effects of GLP-1R agonist Exendin-4 on neuronal activity within the lateral septum. Consequently, our work will provide a basis for future works to study whether the effects of GLP-1R activation on neuronal activity is a result of direct or modulatory mechanism, and also how the regulation of neural circuits by this receptor system guides behaviour.

Hippocampal area CA2 plays a central role in the encoding of social information. This small region is targeted by long-range glutamatergic axons from the hypothalamic supramammillary nucleus (SuM) that enable the detection of social novelty. In area CA2, these glutamatergic inputs form synapses with parvalbumin-expressing (PV+) interneurons (INs) and pyramidal neurons (PNs). Using a mouse model of the 22q11.2 deletion syndrome (DS), we have previously described a reduction in PV+ IN density in area CA2 that is similar to observations made in postmortem studies from schizophrenic and bi-polar patients. Furthermore, social memory of these mice is strongly impaired. In this study, we aim to examine the local circuitry between the SuM and area CA2. Specifically, how excitatory and feedforward inhibitory (FFI) transmission from the SuM to CA2 PNs are changed in a 22q11.2 DS model. To answer this question, we have crossed SuM-cre mice with 22q11.2 DS mice (LgDel) and used viral vectors to selectively express channelrhodopsin-2 (ChR2) in SuM neurons. We found that FFI from SuM axons onto CA2 PNs is decreased in both female and male LgDel mice while the direct excitation to PNs is unchanged. Furthermore, we have found a decrease PV+ IN density in the deep pyramidal layer of CA2, where SuM axons are localized. Thus, the ability of SuM inputs to convey social novelty information to the hippocampus is likely compromised by the change in PV+ IN function, leading to compromised social memory.

C-terminal binding protein (CtBP1) is a ubiquitously expressed, NAD+/NADH-dependent, transcriptional corepressor protein that shuttles between nucleus and pre-synapse in neurons. CtBP1 regulates gene expression in the nucleus, while it regulates synaptic recycling in the presynaptic region. It has been shown that CtBP1 also regulates cell cycle progression and cellular survival. Specifically, its deficiency causes sensitivity to neurotoxicity in hippocampal and cortical neurons due to increased cell apoptosis and its absence causes a decrease in pluripotency in human embryonic stem cells (hESCs). However, the molecular phenomenon behind this functional dualism remains unclear. Previously a human *de novo* CtBP1^{R331W} mutation has been linked to HADDTS syndrome characterized by mental retardation, ataxia, and hypotonia. To elucidate the role of CtBP1 in the regulation of neurodevelopment and synaptic plasticity, we established hESCs carrying the CtBP1^{R331W} mutation using CRISPR-Cas9 mediated gene editing. Using these cells, we model the disease phenotype in parallel to CtBP1 KO mice studies. In the disease model, we analyze the transcriptional changes in development- and plasticity-related molecular pathways, neuronal architecture, and synaptic plasticity. Besides, studies including extracellular electrophysiology and transcriptional analysis are being done in hippocampus from CtBP1 KO. Our preliminary data show that CtBP1^{R331W} mutation causes an aberrancy in the transcriptional profile in hESC-derived neurons throughout the development, and loss of CtBP1 causes parallel changes in mice hippocampus together with an impaired LTP phenotype and loss of resilience to stress.

Obesity has become a health problem worldwide. In general, the prevalence of overweight and obesity is higher in women than in men. The correlation between the increase in female obesity, especially at childbearing ages, and the increase in the incidence of metabolic and neurological diseases in both children and adolescents, shows the relevance of maternal nutrition and obesity on neurodevelopment and its cognitive effects in youth and adulthood. The hippocampus is important for learning and memory, and its development is sensitive to the metabolic environment in utero. Recently, it has been suggested that fetal exposure to maternal obesity causes decreased neurogenesis and impaired hippocampal learning, but the implications at the level of synaptic physiology have not been examined in detail. Our main aim was to study whether this adverse prenatal environment impairs hippocampal inhibitory synaptic transmission using a model of maternal obesity induced by a high-fat diet (HFD, 60% Kcal from fat) consumption. We performed electrophysiological recordings in the hippocampal CA1 region of juvenile mouse offspring. We observed that maternal HFD consumption increases the amplitude of inhibitory postsynaptic currents, but not the frequency or release probability. We also found that maternal HFD does not change the membrane passive properties of the CA1 pyramidal neurons. These data suggest that maternal obesity can increase the hippocampal inhibitory efficacy, and this could have important consequences in the excitation/inhibition balance, being able to modify the hippocampal cognitive function in offspring mice.

During adolescence, the maturational processes occurring in the brain are highly sensitive to environmental factors, making it a high-risk stage for the onset of neuropsychiatric diseases such as schizophrenia (SZ). The pathophysiology of SZ has been associated with alterations related to GABAergic interneurons, mainly those expressing parvalbumin protein (PV-INs). In our laboratory, using an animal model such as SZ by ketamine treatment in adolescents, we observed a strong decrease in the number of PV-INs and GABA transmission in the prefrontal cortex, but not in the ventral hippocampus. Considering that hippocampal function varies along its dorsal-ventral axis and that PV-INs in the dentate gyrus (DG) are important in adult neurogenesis, the main objective of this study was to evaluate whether ketamine treatment in adolescence alters GABAergic transmission and adult neurogenesis in the dorsal DG (dDG) of mice. To test this possibility, we used an immunofluorescent and electrophysiological approach in the dDG of adult mice. Our results showed that adolescent ketamine treatment induced a morphofunctional alteration of PV-INs and reduced GABAergic transmission in the dentate granule cell (DGC), which induces a change in the excitation-inhibition balance in the dDG. Furthermore, we found that this treatment reduced the rate of adult neurogenesis in the DG. These results suggest that GABAergic transmission plays an important role in synaptic and structural plasticity and that the hypofunction of PV-INs in adult dDG could be key to understanding cognitive impairment associated with SZ.

Ketamine-Treatment During Late Adolescence Impairs Inhibitory Synaptic Transmission in the Prefrontal Cortex and Working Memory in Adult Rats.
Schizophrenia (SZ) is associated with changes in the structure and function of several brain areas. Several findings suggest that these impairments are related to a dysfunction in γ-aminobutyric acid (GABA) neurotransmission in brain areas such as the medial prefrontal cortex (mPFC), the hippocampus (HPC) and the primary auditory cortex (A1); however, it is still unclear how the GABAergic system is disrupted in these brain areas. Here, we examined the effect of ketamine (Ket) administration during late adolescence in rats on inhibition in the mPFC-, ventral HPC (vHPC), and A1. We observe that Ket treatment reduced the expression of the calcium-binding protein parvalbumin (PV) and the GABA-producing enzyme glutamic acid decarboxylase 67 (GAD67) as well as decreased inhibitory synaptic efficacy in the mPFC. In addition, Ket-treated rats performed worse in executive tasks that depend on the integrity and proper functioning of the mPFC. Conversely, we do not find such changes in vHPC or A1. Together, our results provide strong experimental support for the hypothesis that during adolescence, the function of the mPFC is more susceptible than that of HPC or A1 to NMDAR hypofunction, showing apparent structure specificity. Thus, the impairment of inhibitory circuitry in mPFC could be a convergent primary site of SZ-like behavior during the adulthood.

Environmental enrichment restores the reduced expression of cerebellar synaptophysin and the motor coordination impairment in rats prenatally treated with betamethasone.
Preterm babies treated with synthetic glucocorticoids in utero exhibit behavioural alterations and disturbances in brain maturation during postnatal life. Accordingly, it has been shown in preclinical studies that SGC exposure at a clinical dose

alters the presynaptic and postsynaptic structures and results in synaptic impairments. However, the precise mechanism by which SGC exposure impairs synaptic protein expression and its implications are not fully elucidated. Therefore, the purpose of this study was to investigate the effect of prenatal exposure to a clinical dose of betamethasone on the pre- and postsynaptic proteins expression in the developing rat cerebellum and prefrontal cortex, whose synchronized synaptic activity is crucial for motor control and learning. Consequently, the first objective of the present study was to determine whether prenatal betamethasone -equivalent to the clinically used dose- alters cerebellar vermal and cortical expression of synaptophysin, synaptotagmin I, post-synaptic density protein 95 and gephyrin - four important pre- and post-synaptic proteins, respectively- at a relevant adolescent stage. In addition, our second objective was to assess whether prenatal betamethasone administration induced coordination impairment using a rotarod test. On the other hand, it has been shown that the environmental enrichment is capable of improving synaptic transmission and recovering various behavioural impairments. Nevertheless, there is not enough information about the effect of this non-pharmacological preclinical approach on the regulation of this cerebellar and cortical synaptic proteins. Therefore, the third objective of this study was to examine whether environmental enrichment exposure could recover the possible molecular and behavioural impairments in the offspring at the same developmental stage. The principal data showed that adolescent rats prenatally treated with betamethasone exhibited underexpression of synaptophysin in the vermal cerebellum, but not change in levels of synaptotagmin I, post-synaptic density protein 95 and gephyrin. Analysis of the same pre- and post-synaptic proteins no showed differences in the frontal cortex of the same rats. These results were accompanied by an increase in the number of falls in the rotarod test, when the speed of rotation was fixed and when it was in acceleration, which means motor coordination impairments. Importantly, we found that environmental enrichment restores the betamethasone-induced reduction in the cerebellar synaptophysin together with a recover in the motor coordination impairments in prenatally betamethasone-exposed adolescent rats.

Prenatal glucocorticoid administration persistently increased the immunohistochemical expression of type-1 metabotropic glutamate receptor and Purkinje cell dendritic growth in the cerebellar cortex of the rat.
Several studies have indicated that abnormal prenatal changes in the circulating glucocorticoids (GCs), induced by either maternal stress or exogenous GC administration, significantly alter the development of Purkinje cells (PCs). Among the suggested mechanisms that could mediate this GC-dependent PC susceptibility are changes in the expression of type-1 metabotropic glutamate receptors (mGluR1). In the current study, we analyzed whether a single course of prenatally administered betamethasone phosphate (BET) in pregnant rats increased the immunohistochemical expression of mGluR1 in PCs and decreased PC dendritic growth. The data obtained showed that in utero BET exposure resulted in a significant immunohistochemical overexpression of mGluR1 and a significant reduction in Purkinje cell dendritic outgrowth during postnatal life.

Influence of antenatal synthetic glucocorticoid administration on pyramidal cell morphology and microtubule-associated protein type 2 (MAP2) in rat cerebrocortical neurons.
Previous animal studies have indicated that excessive prenatal circulating glucocorticoid (GC) levels induced by the antenatal administration of synthetic GC (sGC) significantly alter neuronal development in the cerebellar and hippocampal neurons of the offspring. However, it is unknown whether antenatal sGC administration results in long-term neocortical pyramidal cell impairment. In the current study, we examined whether an equivalent therapeutic dose of antenatal betamethasone phosphate (BET) in pregnant rats alters the Golgi-stained basilar dendritic length and histochemical expression of dendritic microtubule-associated protein 2 (MAP2) of neocortical pyramidal cells in infant, adolescent, and young adult offspring. The results obtained showed that BET exposure resulted in a significant reduction in the basilar dendritic length per neuron and a transient reduction in histochemical MAP2 immunoreactivity. Consistent with previous hippocampal and cerebellar data, the present findings suggest that prenatal BET administration alters the dendritic growth of cerebrocortical pyramidal cells.

BRAIN ESTROGEN SYNTHESIS BY AROMATASE REGULATES SYNAPTIC INHIBITION IN THE FEMALE HIPPOCAMPUS

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Alicia Hernandez-Vivanco[1], Nuria Cano-Adamuz[1], Íñigo Azcoitia[2], Alba González-Alonso[1], Pablo Mendéz[1]
[1]Cajal Institute (CSIC), Dept. Functional And Systems Neurobiology, Madrid, Spain, [2]Universidad Complutense de Madrid, Dept. Cellular Biology, Madrid, Spain

In addition to ovarian production, estrogens are synthesized within the brain by neurons that express the enzyme aromatase. In the hippocampus, neuron-derived estrogen regulates excitatory synaptic function and plasticity. In addition to excitatory neurons, the hippocampus is populated by a diverse array of inhibitory neurons (INs). INs regulate synaptic plasticity and organize several forma of hippocampal network activity. Despite their critical role for hippocampal function, the impact of brain-derived estrogen on INs physiology is unknown. Here, we present evidence supporting estrogen (17ß-estradiol) synthesis in female CA1 parvalbumin (PV) expressing neurons, a mayor class of hippocampal INs. Moreover, our *patch-clamp* experiments revealed that brain aromatase regulates CA1 synaptic inhibition through a mechanism that involves modification of perineuronal nets enwrapping PV INs. Interestingly, this regulation of CA1 inhibition by estrogen synthesis is female-specific, determined by the perinatal gonadal hormone milieu and independent of the genetic sex of the brain. *In vivo* fiber photometry experiments revealed that estrogen modulates the activity of PV INs and their coupling to animal behavior. Our results reveal sex differences in hippocampal inhibition that may be related to the female-specific regulation of PV INs by brain synthesized estrogen. Since aromatase inhibitors are widely used in clinics, our results have implications for understanding their effects on cognitive functions in humans.

SYNAPTIC COMMUNICATION WITHIN THE MICROCIRCUITS OF PYRAMIDAL NEURONS AND BASKET CELLS IN THE MOUSE PREFRONTAL CORTEX

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Zsuzsanna Fekete[1,2], Filippo Weisz[1], Mária Karlócai[3], Judit Veres[1], Tibor Andrási[1], Norbert Hájos[1]
[1]ELRN Institute of Experimental Medicine, 'lendület' Laboratory Of Network Neurophysiology, Budapest, Hungary, [2]Semmelweis University, János Szentágothai Doctoral School Of Neurosciences, Budapest, Hungary, [3]ELRN Institute of Experimental Medicine, Laboratory Of Cellular Neurophysiology, Budapest, Hungary

Parvalbumin- and cholecystokinin-containing basket cells (PVBCs and CCKBCs) are GABAergic interneurons that are able to efficiently control the spiking of their postsynaptic partners. Here, we investigated the intrinsic electrophysiological features and synaptic properties within the networks of basket cells and pyramidal neurons (PNs) in the mouse medial prefrontal cortex (mPFC) to determine the organizational principles of their microcircuits. *In vitro* whole-cell recordings were performed in brain slices prepared from transgenic mice that allowed us to target basket cells. Single-cell features of these interneurons showed major differences regarding both their active and passive membrane properties. By performing paired recordings we uncovered that PVBCs receive larger and faster unitary excitatory postsynaptic currents from PNs than CCKBCs and that PVBCs provide stronger and more reliable synaptic inputs onto PNs than the other basket cell type. In addition, the amplitude of unitary postsynaptic responses between PVBCs were found to be larger than those observed between CCKBCs. Short term-dynamics of connections were also characteristic for the cell type of synaptic partners. Finally, our anatomical data together with electrophysiological recordings combined with pharmacology and optogenetics revealed that there is synaptic communication between the two types of basket cells. Our data provide the first detailed description of connectivity within the networks of pyramidal neurons and basket cells in the mPFC. These results imply that PVBCs may have a larger impact at the microcircuit level than CCKBCs, thus, smaller changes in PVBC function can substantially contribute to altered circuit operation in the mPFC, often linked to psychiatric diseases.

Total Number and Ratio of GABAergic Neuron Types in the Mouse Lateral and Basal Amygdala.
GABAergic neurons are key circuit elements in cortical networks. Despite growing evidence showing that inhibitory cells play a critical role in the lateral (LA) and basal (BA) amygdala functions, neither the number of GABAergic neurons nor the ratio of their distinct types has been determined in these amygdalar nuclei. Using unbiased stereology, we found that the ratio of GABAergic neurons in the BA (22%) is significantly higher than in the LA (16%) in both male and female mice. No difference was observed between the right and left hemispheres in either sex. In addition, we assessed the ratio of the major inhibitory cell types in both amygdalar nuclei. Using transgenic mice and a viral strategy for visualizing inhibitory cells combined with immunocytochemistry, we estimated that the following cell types together compose the vast majority of GABAergic cells in the LA and BA: axo-axonic cells (5.5%-6%), basket cells expressing parvalbumin (17%-20%) or cholecystokinin (7%-9%), dendrite-targeting inhibitory cells expressing somatostatin (10%-16%), NPY-containing neurogliaform cells (14%-15%), VIP and/or calretinin-expressing interneuron-selective interneurons (29%-38%), and GABAergic projection neurons expressing somatostatin and neuronal nitric oxide synthase (5.5%-8%). Our results show that these amygdalar nuclei contain all major GABAergic neuron types as found in other cortical regions. Furthermore, our data offer an essential reference for future studies aiming to reveal changes in GABAergic cell number and in inhibitory cell types typically observed under different pathologic conditions, and to model functioning amygdalar networks in health and disease. GABAergic cells in cortical structures, as in the lateral and basal nucleus of the amygdala, have a determinant role in controlling circuit operation. In this study, we provide the first estimate for the total number of inhibitory cells in these two amygdalar nuclei. In addition, our study is the first to define the ratio of the major GABAergic cell types present in these cortical networks. Taking into account that hyperexcitability in the amygdala, arising from the imbalance between excitation and inhibition typifies many altered brain functions, including anxiety, post-traumatic stress disorder, schizophrenia, and autism, uncovering the number and ratio of distinct amygdalar inhibitory cell types offers a solid base for comparing the changes in inhibition in pathologic brain states.

Striatal cholinergic interneurons (CINs) respond to salient or reward prediction-related stimuli after conditioning with brief pauses in their activity, implicating them in learning and action selection. This pause is lost in animal models of Parkinson's disease. How this signal regulates the functioning of the striatum remains an open question. To address this issue, we examined the impact of CIN firing inhibition on glutamatergic transmission between the cortex and the medium-sized spiny projection neurons expressing dopamine D1 receptors (D1 MSNs). Brief interruption of CIN activity had no effect in control condition whereas it increased glutamatergic responses in D1 MSNs after nigrostriatal dopamine denervation. This potentiation was dependent upon M4 muscarinic receptor and protein kinase A. Decreasing CIN firing by opto/chemogenetic strategies *in vivo* rescued long-term potentiation in some MSNs and alleviated motor learning deficits in parkinsonian mice. Taken together, our findings demonstrate that the control exerted by CINs on corticostriatal transmission and striatal-dependent motor-skill learning depends on the integrity of dopaminergic inputs.

Mounting evidence identifies layer 1 (L1) as a central site of memory in sensory neocortex. While this work revealed plasticity in several excitatory brain-wide afferent systems, the existence, connectivity and memory-related signaling of long-range inhibitory input to L1 remains elusive. We report that inhibitory afferents from zona incerta project specifically to auditory cortex L1, where they connect selectively to interneurons to disinhibit the cortical circuit and facilitate behavioral memory. Chronic calcium imaging of these synapses identifies a balanced form of plasticity that develops rapidly during threat learning and is characterized by the *de novo* appearance of negative stimulus responses which transmit most information. Our results therefore pinpoint malleability of long-range (dis)inhibitory afferents to L1 as a key factor for the exquisite computational flexibility of this unique layer.

MOLECULAR MECHANISMS OF DRUG-INDUCED SYNAPTOGENESIS

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Paloma Huguet-Rodriguez, Oliver M. Schlüter
University Medical Center Göttingen, Department Of Psychiatry And Psychotherapy, Goettingen, Germany

Relapse is a major challenge to the treatment of substance use disorder, mainly triggered by drug-associated memories, which contrary to physiological memories, exhibit an exceedingly rigid and long-lasting nature as a product of maladaptive plasticity. Repetitive cocaine exposure generates *de novo* silent synapses in the nucleus accumbens, whose maturation underlies drug-associated behaviors. As silent synapses provide novel synaptic opportunities, we hypothesize that drug-induced synaptogenesis reorganizes neural networks to change the connection patterns morphologically and functionally, and as a result encode drug-associated memories with rigid and long-lasting features. Using the electrophysiology procedure of minimal stimulation, we describe repetitive cocaine exposure has more generalized implications than previously reported, as we found that silent synapses are generated in additional brain areas, including the dorsal striatum. Obtaining a blueprint of the molecular mechanisms underlying silent synapse generation will help to unveil the consequences of silent synapse-based network reorganization in substance use disorders. We report that viral vector-mediated knockdown of α2δ1 and integrin-β3 prevented the synaptogenic effect of cocaine in the dorsal striatum, suggesting a glial-neuron signaling pathway for the generation of silent synapses.

Microglia Actively Remodel Adult Hippocampal Neurogenesis through the Phagocytosis Secretome.
During adult hippocampal neurogenesis, most newborn cells undergo apoptosis and are rapidly phagocytosed by resident microglia to prevent the spillover of intracellular contents. Here, we propose that phagocytosis is not merely passive corpse removal but has an active role in maintaining neurogenesis. First, we found that neurogenesis was disrupted in male and female mice chronically deficient for two phagocytosis pathways: the purinergic receptor P2Y12, and the tyrosine kinases of the TAM family Mer tyrosine kinase (MerTK)/Axl. In contrast, neurogenesis was transiently increased in mice in which MerTK expression was conditionally downregulated. Next, we performed a transcriptomic analysis of the changes induced by phagocytosis in microglia and identified genes involved in metabolism, chromatin remodeling, and neurogenesis-related functions. Finally, we discovered that the secretome of phagocytic microglia limits the production of new neurons both and Our data suggest that microglia act as a sensor of local cell death, modulating the balance between proliferation and survival in the neurogenic niche through the phagocytosis secretome, thereby supporting the long-term maintenance of adult hippocampal neurogenesis. Microglia are the brain professional phagocytes and, in the adult hippocampal neurogenic niche, they remove newborn cells naturally undergoing apoptosis. Here we show that phagocytosis of apoptotic cells triggers a coordinated transcriptional program that alters their secretome, limiting neurogenesis both and In addition, chronic phagocytosis disruption in mice deficient for receptors P2Y12 and MerTK/Axl reduces adult hippocampal neurogenesis. In contrast, inducible MerTK downregulation transiently increases neurogenesis, suggesting that microglial phagocytosis provides a negative feedback loop that is necessary for the long-term maintenance of adult hippocampal neurogenesis. Therefore, we speculate that the effects of promoting engulfment/degradation of cell debris may go beyond merely removing corpses to actively promoting regeneration in development, aging, and neurodegenerative diseases.

STRAIN-DEPENDENT EFFECTS OF PHYSICAL EXERCISE ON MITOCHONDRIAL, NEUROTROPHIC AND NEUROGENIC MEASURES IN THE BRAIN IN C57BL/6J AND C57BL/6N MICE

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Aastha Singla[1], Pratik Chaudhari[2], Darshana Kapri[2], Sashaina Fanibunda[2,3], Vidita Vaidya[2], Ullas Kolthur-Seetharam[2]

Physical exercise evokes neurotrophic and neurogenic changes in specific parts of the central nervous system and evokes bioenergetic changes involving mitochondria. These changes have been reported in diverse rodent models but it is unclear whether genetic background plays a role in modulating the nature, pattern, and magnitude of effects evoked by exercise. In the present study, we look at two widely used strains of C57BL/6 mice namely C57BL/6J (B6J) and C57BL/6N (B6N), with the former carrying a null mutation in the *NNT* gene (nicotinamide nucleotide transhydrogenase). NNT is an essential mitochondrial redox regulatory protein and its absence in B6J mice leads to a metabolic profile distinct from B6N mice. Hence, we investigated whether the effects of seven days of voluntary wheel running on mitochondrial, neurotrophic, and neurogenic measures in limbic brain circuits are different, based on the strain of C57BL/6 mice used. We find that while both B6J and B6N mice show similar wheel running activity and weight profile changes, there are multiple distinct strain-specific effects. In the hippocampus, we see an improvement in mitochondrial biogenesis and function in B6J but not in B6N, as assessed by mitochondrial-DNA copy number, ATP levels, and gene expression changes. Further, we see a differential extent of upregulation in growth factor expression and adult neurogenesis in the hippocampus, between B6J and B6N in response to exercise. These results highlight the importance of being watchful of strain differences in animal models while interpreting data across studies and to keep in mind the genetic background of knockout mouse lines, several of which have been backcrossed onto C57BL/6J.

PLACE-FIELD DYNAMICS AS A WINDOW ON SYNAPTIC PLASTICITY IN THE HIPPOCAMPUS

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Antoine Madar, Can Dong, Mark Sheffield
University of Chicago, Neurobiology, Chicago, United States of America

Despite decades of research, the rules of synaptic plasticity governing hippocampal representations during memory formation and familiarization remain unclear. We considered the trial-by-trial dynamics of these representations as an indirect indicator of ongoing plasticity. Using 2-photon calcium imaging in mice navigating through virtual environments, we recorded CA1 and CA3 pyramidal neurons and measured how the spatial modulation of their activity (place fields) evolved lap-by-lap[1]. During exploration of a novel environment, a majority of CA1 place fields (less in CA3) continuously shifted, mostly backwards. The proportion of shifting cells and the shift speeds decreased with the level of familiarity to the environment. To determine the mechanisms supporting these shifting dynamics, we designed computational models of spiking neurons with synapses following different plasticity rules. In contrast to early models, we found that classic Hebbian spike-timing-dependent-plasticity is too weak and has too short of a timescale to produce strong backward shifting, especially when realistic firing rates are maintained. The recently discovered Behavioral Timescale Synaptic Plasticity (BTSP), with its large amplitude and long time-constants, is an alternative candidate mechanism. Our model of BTSP combined with homeostatic synaptic normalization produces both forward and backward shifting dynamics that match our experimental data. Overall, our study suggests BTSP as the main plasticity mechanism underlying the dynamics of spatial representations in the hippocampus. Exploration of our model's parameter space and mining of our experimental data for BTSP signatures will refine our understanding of the phenomenology of BTSP during memory formation and familiarization. 1-Dong, Madar & Sheffield, (2021) https://doi.org/10.1038/s41467-021-23260-3

MOLECULAR SIGNATURES OF THE INTERACTION OF KARS WITH G-PROTEINS

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

M. Isabel Aller, Marija Gjorgoska, Juan Lerma
Instituto de Neurociencias, Csic-umh, Alicante, Spain

Kainate receptors (KARs) are found ubiquitously in the CNS and are present presynaptically and postsynaptically regulating synaptic transmission and excitability. Functional studies have proven that KARs act as ion channels as well as potentially activating G-proteins, thus indicating the existance of a dual signaling system for KARs. Previous studies in our laboratory demonstrated a direct interaction of the $GluK1_{2b}$ subunit of KARs with the Gαo-protein, showing that GluK1 and Go proteins are natural partners, accounting for the metabotropic effects of KARs. In this context we have focused on studying which part of the carboxy-terminal domain (CTD) of the $GluK1_{2b}$ subunit is important in this interaction. The CTD of the $GluK1_{2b}$ subunit has a region enriched in Lysine (K) and Arginine (R), similar to that identified as critical for the coupling of muscarinic receptors to G-proteins. Therefore, we generated several $GluK1_{2b}$ subunit mutants, which either lack a part of the CTD (Δ930, Δ914, Δ900) o have the positively charged K an R residues replaced by Alanines (A) and assessed whether the interaction with Gαo was prevented using Biomolecular fluorescence complementation (BiFC). We observed that all mutant forms lacking the positively-charged-poly K-R region (($GluK1_{2b}$, Δ914, Δ900) have reduced interaction with Gαo. Further, the complete substitution of K's and R's in the 15-amino acids-stretch ($GluK1_{2b}$ 914-928K-A), results in a reduction of this interaction to a similar extent as when the entire CTD was removed, supporting the critical role of these residues in the GluK1 to Gαo coupling.

Fyn is a Src family kinase implicated in learning and memory and is responsible for controlling signalling cascades in neurons. The postsynaptic enrichment of Fyn underpins synaptotoxicity in Alzheimer's Disease (AD) and frontotemporal lobar degeneration (FTLD). Expression of pathogenic FTLD tau promotes nanoclustering of Fyn in the dendrites and spines of hippocampal neurons (Padmanabhan et al., 2019). However, the mechanism underpinning such clustering and the link to altered signalling is unknown. Here, we used single particle tracking photoactivated localization microscopy (sptPALM) to demonstrate that the transition of Fyn into an open, primed conformation promotes nanoclustering in dendritic spines of live hippocampal neurons. Entry into an open conformation was achieved by disrupting the auto-inhibitory, closed conformation of Fyn through phospho-inhibition (Y531F) and perturbing Fyn's SH3 domain. We demonstrate that the resulting entry into an open conformation is required to initiate the Fyn/ERK/S6 signalling cascade, a pathway implicated in AD-related neurodegeneration and synaptotoxicity (Li et al., 2017). In isolation, alteration of Fyn's catalytic SH1 domain through pharmacological and phospho-inhibition (Y420F) did not affect Fyn mobility. Together these findings demonstrate that Fyn fluctuates between a closed and an open conformation, the latter being enzymatically active and conducive to nanoclustering. Our results highlight a tantalizing role of nanoclustering in promoting intracellular signalling and suggest that long term alterations of Fyn clustering and ensued intracellular signalling could contribute to the development of AD and FTLD.

THE ROLE OF ENDOPLASMIC RETICULUM IN DENDRITIC SPINE INDIVIDUALIZATION

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Leena-Stiina Kontturi, Ellinoora Elomaa, Juha Saarikangas
University of Helsinki, Molecular And Integrative Biosciences Research Program, Helsinki, Finland

The ability of dendritic spines to individualize from the rest of the neuron is a key feature in synapse-specific functions, but the underlying mechanisms are unclear. The endoplasmic reticulum (ER) is the largest cellular organelle with key functions in protein and calcium homeostasis as well as compartmentalization of biochemical reactions. In neurons, ER forms a continuous network that has been reported to localize to a subset of dendritic spines, but its functions in spines remain poorly understood. Here we combined diverse imaging methods to study the potential compartmentalization of ER in dendritic spines and its role in spine individualization. Interestingly, our fluorescence loss in photobleaching measurements show that in a subset of spines, the ER is compartmentalized. Approximately 30% of the ER-containing spines displayed restricted diffusion of ER-bound proteins between the spine and dendritic ER, while in 70% of the ER-containing spines, diffusion was rapid and non-restricted (average half-lives 480 s and 6 s, respectively). Importantly, preliminary results indicate that the compartmentalization of spine ER potentiates synaptic calcium signaling. Spines with restricted diffusion of ER-bound proteins showed larger increase in synaptic calcium levels after glutamate uncaging than spines with non-compartmentalized ER or spines without ER. Together, these results suggest that the diffusion of ER-bound molecules at the synapses can be constricted, which may underlie synaptic individualization and plasticity in synaptic function.

Light-Triggered Cellular Delivery of Oligonucleotides.
The major challenge in the therapeutic applicability of oligonucleotide-based drugs is the development of efficient and safe delivery systems. The carriers should be non-toxic and stable in vivo, but interact with the target cells and release the loaded oligonucleotides intracellularly. We approached this challenge by developing a light-triggered liposomal delivery system for oligonucleotides based on a non-cationic and thermosensitive liposome with indocyanine green (ICG) as photosensitizer. The liposomes had efficient release properties, as 90% of the encapsulated oligonucleotides were released after 1-minute light exposure. Cell studies using an enhanced green fluorescent protein (EGFP)-based splicing assay with HeLa cells showed light-activated transfection with up to 70%⁻80% efficacy. Moreover, free ICG and oligonucleotides in solution transfected cells upon light induction with similar efficacy as the liposomal system. The light-triggered delivery induced moderate cytotoxicity (25%⁻35% reduction in cell viability) 1⁻2 days after transfection, but the cell growth returned to control levels in 4 days. In conclusion, the ICG-based light-triggered delivery is a promising method for oligonucleotides, and it can be used as a platform for further optimization and development.

Encapsulated cells for long-term secretion of soluble VEGF receptor 1: Material optimization and simulation of ocular drug response.
Anti-angiogenic therapies with vascular endothelial growth factor (VEGF) inhibiting factors are effective treatment options for neovascular diseases of the retina, but these proteins can only be delivered as intravitreal (IVT) injections. To sustain a therapeutic drug level in the retina, VEGF inhibitors have to be delivered frequently, every 4-8weeks, causing inconvenience for the patients and expenses for the healthcare system. The aim of this study was to investigate cell encapsulation as a delivery system for prolonged anti-angiogenic treatment of retinal neovascularization. Genetically engineered ARPE-19 cells secreting soluble vascular endothelial growth factor receptor 1 (sVEGFR1) were encapsulated in a hydrogel of cross-linked collagen and interpenetrating hyaluronic acid (HA). The system was optimized in terms of matrix composition and cell density, and long-term cell viability and protein secretion measurements were performed. sVEGFR1 ARPE-19 cells in the optimized hydrogel remained viable and secreted sVEGFR1 at a constant rate for at least 50days. Based on pharmacokinetic/pharmacodynamic (PK/PD) modeling, delivery of sVEGFR1 from this cell encapsulation system is expected to lead only to modest VEGF inhibition, but improvements of the protein structure and/or secretion rate should result in strong

and prolonged therapeutic effect. In conclusion, the hydrogel matrix herein supported the survival and protein secretion from the encapsulated cells. The PK/PD simulation is a convenient approach to predict the efficiency of the cell encapsulation system before in vivo experiments.

An injectable, in situ forming type II collagen/hyaluronic acid hydrogel vehicle for chondrocyte delivery in cartilage tissue engineering.
In this study, chondrocytes were encapsulated into an injectable, in situ forming type II collagen/hyaluronic acid (HA) hydrogel cross-linked with poly(ethylene glycol) ether tetrasuccinimidyl glutarate (4SPEG) and supplemented with the transforming growth factor β1 (TGFβ1). The chondrocyte-hydrogel constructs were cultured in vitro for 7 days and studied for cell viability and proliferation, morphology, glycosaminoglycan production, and gene expression. Type II collagen/HA/4SPEG formed a strong and stable hydrogel, and the chondrocytes remained viable during the encapsulation process and for the 7-day culture period. In addition, the encapsulated cells showed spherical morphology characteristic for chondrocytic phenotype. The cells were able to produce glycosaminoglycans into their extracellular matrix, and the gene expression of type II collagen and aggrecan, genes specific for differentiated chondrocytes, increased over time. The results indicate that the studied composite hydrogel with incorporated chondrogenic growth factor TGFβ1 is able to maintain chondrocyte viability and characteristics, and thus, it can be regarded as potential injectable cell delivery vehicle for cartilage tissue engineering.

A laboratory-scale device for the straightforward production of uniform, small sized cell microcapsules with long-term cell viability.
Microencapsulated and genetically engineered cells may be used for prolonged delivery of therapeutically active proteins. The objective of this study was to develop a simple, inexpensive and flexible laboratory-scale device for the production of cell microcapsules, especially capsules of small diameter (<300 μm). Many microencapsulation devices are expensive, difficult to assemble and to use, and often more suitable for large-scale experiments. However, the simplicity and low price of the encapsulation system should not limit the quality of capsules and reproducibility of the process: for successful in vitro and in vivo experiments it is important to be able to produce uniform, spherical microcapsules without deformities with high reproducibility. In addition, an advantage of the present procedure compared to other similar, co-axial laminar gas flow systems is the possibility to produce also small microcapsules, less than 200 μm in diameter, with narrow size distribution. First, design, optimization and reproducibility testing of this custom-built device were carried out. Second, microencapsulated retinal pigment epithelial cells (ARPE-19) capable of secreting soluble vascular endothelial growth factor receptor 1 (sVEGFR1) were engineered. The cells remained viable in alginate-poly-L-lysine-alginate microcapsules and secreted sVEGFR1 for prolonged periods.

The cerebellar GABAAR α6-R100Q polymorphism alters ligand binding in outbred Sprague-Dawley rats in a similar manner as in selectively bred AT and ANT rats.
The alcohol-tolerant AT and alcohol-nontolerant ANT rat lines have been selectively bred for innate sensitivity to ethanol-induced motor impairment. The cerebellar GABAA receptor (GABAAR) α6 subunit alleles α6-100R and α6-100Q are segregated in the AT and ANT rats, respectively. This α6 polymorphism might explain various differences in pharmacological properties and density of GABAARs between the rat lines. In the present study, we have used nonselected outbred Sprague-Dawley rats homozygous for the α6-100RR (RR) and α6-100QQ (QQ) genotypes to show that these RR and QQ rats display similar differences between genotypes as AT and ANT rat lines. The genotypes differed in their affinity for [3H]Ro 15-4513 and classic benzodiazepines (BZs) to cerebellar "diazepam-insensitive" (DZ-IS) binding sites, in density of cerebellar [3H]muscimol binding and in the antagonizing effect of furosemide on GABA-induced inhibition of [3H]EBOB binding. The results suggest the involvement of α6-R100Q polymorphism in these line differences and in the differences previously found between AT and ANT rats. In addition, the α6-R100Q polymorphism induces striking differences in [3H]Ro 15-4513 binding kinetics to recombinant α6β3γ2s receptors and cerebellar DZ-IS sites. Association of [3H]Ro 15-4513 binding was ~10-fold faster and dissociation was ~3-4-fold faster in DZ-IS α6βγ2 receptors containing the α6-100Q allele, with a resulting change of ~2.5-fold in equilibrium dissociation constant (KD). The results indicate that in addition to the central role of the homologous α6-100R/Q (α1-101H) residue in BZ binding and efficacy, this critical BZ binding site residue has a major impact on BZ binding kinetics.

Chondrogenic differentiation of human bone marrow-derived mesenchymal stromal cells in a three-dimensional environment.

Cell therapy combined with biomaterial scaffolds is used to treat cartilage defects. We hypothesized that chondrogenic differentiation bone marrow-derived mesenchymal stem cells (BM-MSCs) in three-dimensional biomaterial scaffolds would initiate cartilaginous matrix deposition and prepare the construct for cartilage regeneration in situ. The chondrogenic capability of human BM-MSCs was first verified in a pellet culture. The BM-MSCs were then either seeded onto a composite scaffold rhCo-PLA combining polylactide and collagen type II (C2) or type III (C3), or commercial collagen type I/III membrane (CG). The BM-MSCs were either cultured in a proliferation medium or chondrogenic culture medium. Adult human chondrocytes (ACs) served as controls. After 3, 14, and 28 days, the constructs were analyzed with quantitative polymerase chain reaction and confocal microscopy and sulfated glycosaminoglycans (GAGs) were measured. The differentiated BM-MSCs entered a hypertrophic state by Day 14 of culture. The ACs showed dedifferentiation with no expression of chondrogenic genes and low amount of GAG. The CG membrane induced the highest expression levels of hypertrophic genes. The two different collagen types in composite scaffolds yielded similar results. Regardless of the biomaterial scaffold, culturing BM-MSCs in chondrogenic differentiation medium resulted in chondrocyte hypertrophy. Thus, caution for cell fate is required when designing cell-biomaterial constructs for cartilage regeneration.

Characterization of CDNF-Secreting ARPE-19 Cell Clones for Encapsulated Cell Therapy.
Cerebral dopamine neurotrophic factor (CDNF) shows beneficial effects in rodent models of Parkinson's and Alzheimer's disease. The brain is a challenging target for protein therapy due to its exclusive blood-brain barrier. Hence, the therapeutic protein should be delivered directly to the brain parenchyma. Implantation of encapsulated mammalian cells that constantly secrete CDNF is a potential approach for targeted and long-term protein delivery to the brain. In this study, we generated several CDNF-secreting cell clones derived from human retinal pigment epithelial cell line ARPE-19, and studied CDNF secretion from the clones maintained as monolayers and in polymeric microcapsules. The secretion of wild type (wt) CDNF transgene was low and the majority of the produced protein remained intracellular, locating mainly to the endoplasmic reticulum (ER). The secretion of wtCDNF decreased to even lower levels when the clones were in a non-dividing state, as in the microcapsules. Both codon optimization and deletion of the putative ER-retrieval signal (four last amino acids: KTEL) improved CDNF secretion. More importantly, the secretion of KTEL-deleted CDNF remained constant in the non-dividing clones. Thus, cells expressing KTEL-deleted CDNF, in contrast to wtCDNF, can be considered for cell encapsulation applications if the KTEL-deleted CDNF is proven to be biologically active .

Light activated liposomes: Functionality and prospects in ocular drug delivery.
Ocular drug delivery, especially to the retina and choroid, is a major challenge in drug development. Liposome technology may be useful in ophthalmology in enabling new routes of delivery, prolongation of drug action and intracellular drug delivery, but drug release from the liposomes should be controlled. For that purpose, light activation may be an approach to release drug at specified time and site in the eye. Technical advances have been made in the field of light activated drug release, particularly indocyanine green loaded liposomes are a promising approach with safe materials and effective light triggered release of small and large molecules. This review discusses the liposomal drug delivery with light activated systems in the context of ophthalmic drug delivery challenges.

Indocyanine Green-Loaded Liposomes for Light-Triggered Drug Release.
Light-triggered drug delivery systems enable site-specific and time-controlled drug release. In previous work, we have achieved this with liposomes containing gold nanoparticles in the aqueous core. Gold nanoparticles absorb near-infrared light and release the energy as heat that increases the permeability of the liposomal bilayer, thus releasing the contents of the liposome. In this work, we replaced the gold nanoparticles with the clinically approved imaging agent indocyanine green (ICG). The ICG liposomes were stable at storage conditions (4-22 °C) and at body temperature, and fast near-infrared (IR) light-triggered drug release was achieved with optimized phospholipid composition and a 1:50 ICG-to-lipid molar ratio. Encapsulated small molecular calcein and FITC-dextran (up to 20 kDa) were completely released from the liposomes after light exposure for 15 s. Location of ICG in the PEG layer of the liposomes was simulated with molecular dynamics. ICG has important benefits as a light-triggering agent in liposomes: fast content release, improved stability, improved possibility of liposomal size control, regulatory approval to use in humans, and the possibility of imaging the in vivo location of the liposomes based on the fluorescence of ICG. Near-infrared light used as a triggering mechanism has good tissue penetration and safety. Thus, ICG liposomes are an attractive option for light-controlled and efficient delivery of small and large drug molecules.

Photothermally Triggered Lipid Bilayer Phase Transition and Drug Release from Gold Nanorod and Indocyanine Green Encapsulated Liposomes.
In light-activated liposomal drug delivery systems (DDSs), the light sensitivity can be obtained by a photothermal agent that converts light energy into heat. Excess heat increases the drug permeability of the lipid bilayer, and drug is released as a result. In this work, two near-IR responsive photothermal agents in a model drug delivery system are studied: either gold nanorods (GNRs) encapsulated inside the liposomes or indocyanine green (ICG) embedded into the lipid bilayer. The liposome system is exposed to light, and the heating effect is studied with fluorescent thermometers: laurdan and CdSe quantum dots (QDs). Both photothermal agents are shown to convert light into heat in an extent to cause a phase transition in the surrounding lipid bilayer. This phase transition is also proven with laurdan generalized polarization (GP). In addition to the heating results, we show that the model drug (calcein) is released from the liposomal cavity with both photothermal agents when the light power is sufficient to cause a phase transition in the lipid bilayer.

ROLE OF NEURON-DERIVED EXTRACELLULAR VESICLES IN SYNAPTIC PLASTICITY

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Julia Solana Balaguer[1,2,3], Albert Coll Manzano[1,2,3,4], Genís Campoy Campos[1,2,3], Leticia Pérez Sisqués[1,2,3,5], Núria Martín Flores[1,2,3,6], Jordi Alberch[1,2,3,4], Jordi Soriano[7,8], Mercè Masana[1,2,3,4], Cristina Malagelada[1,2,3]

Neurodegenerative diseases induce an impairment in synaptic plasticity which eventually leads to cognitive symptoms in patients. Extracellular vesicles, which are involved in intercellular communication, have been suggested to be involved in synaptic processes, as they are carriers of bioactive miRNAs, proteins and lipids that can influence firing rate in recipient neurons. The aim of this study is to investigate whether neuronal EVs have a direct role in the regulation of synaptic plasticity. Extracellular vesicles were isolated from rat cortical neurons culture media, by ultracentrifugation, and used to treat sister cultures for 24h. Samples were subjected to immunohistochemistry, Western blotting and calcium imaging analysis. We found that EVs are taken up by neurons both in the soma and in dendrites, and even in synaptic spines. We found that neuronal EVs carry synaptic proteins and enhance the consolidation of glutamatergic synapses in recipient neurons. We also observed a mild effect of EVs over neural network dynamics. Moreover, EVs had a trophic effect in neurons under nutrient deprivation conditions. All these data put neuronal EVs in the spotlight to understand synaptic plasticity impairment in neurodegenerative conditions and use them as a possible therapeutic approach.

RTP801/REDD1 Is Involved in Neuroinflammation and Modulates Cognitive Dysfunction in Huntington's Disease.
RTP801/REDD1 is a stress-regulated protein whose levels are increased in several neurodegenerative diseases such as Parkinson's, Alzheimer's, and Huntington's diseases (HD). RTP801 downregulation ameliorates behavioral abnormalities in several mouse models of these disorders. In HD, RTP801 mediates mutant huntingtin (mhtt) toxicity in in vitro models and its levels are increased in human iPSCs, human postmortem putamen samples, and in striatal synaptosomes from mouse models of the disease. Here, we investigated the role of RTP801 in the hippocampal pathophysiology of HD. We found that RTP801 levels are increased in the hippocampus of HD patients in correlation with gliosis markers. Although RTP801 expression is not altered in the hippocampus of the R6/1 mouse model of HD, neuronal RTP801 silencing in the dorsal hippocampus with shRNA containing AAV particles ameliorates cognitive alterations. This recovery is associated with a partial rescue of synaptic markers and with a reduction in inflammatory events, especially microgliosis. Altogether, our results indicate that RTP801 could be a marker of hippocampal neuroinflammation in HD patients and a promising therapeutic target of the disease.

RTP801/REDD1 contributes to neuroinflammation severity and memory impairments in Alzheimer's disease.
RTP801/REDD1 is a stress-regulated protein whose upregulation is necessary and sufficient to trigger neuronal death. Its downregulation in Parkinson's and Huntington's disease models ameliorates the pathological phenotypes. In the context of Alzheimer's disease (AD), the coding gene for RTP801, DDIT4, is responsive to Aβ and modulates its cytotoxicity in vitro. Also, RTP801 mRNA levels are increased in AD patients' lymphocytes. However, the involvement of RTP801 in the pathophysiology of AD has not been yet tested. Here, we demonstrate that RTP801 levels are increased in postmortem hippocampal samples from AD patients. Interestingly, RTP801 protein levels correlated with both Braak and Thal stages of

the disease and with GFAP expression. RTP801 levels are also upregulated in hippocampal synaptosomal fractions obtained from murine 5xFAD and rTg4510 mice models of the disease. A local RTP801 knockdown in the 5xFAD hippocampal neurons with shRNA-containing AAV particles ameliorates cognitive deficits in 7-month-old animals. Upon RTP801 silencing in the 5xFAD mice, no major changes were detected in hippocampal synaptic markers or spine density. Importantly, we found an unanticipated recovery of several gliosis hallmarks and inflammasome key proteins upon neuronal RTP801 downregulation in the 5xFAD mice. Altogether our results suggest that RTP801 could be a potential future target for theranostic studies since it could be a biomarker of neuroinflammation and neurotoxicity severity of the disease and, at the same time, a promising therapeutic target in the treatment of AD.

Understanding information storage and processing in the brain remains one of the grand challenges in neuroscience. Reducing the complexity in the study of neuronal systems could help understanding fundamental properties of information processing in the brain. Low-density cultures of neurons with controlled topology presents a simple yet robust experimental platform for studying neuronal communication. The bottom-up approach has proved fruitful in investigating network's electrical properties wtih high spatiotemporal resolution [1], [2], [3]. To study mechanisms of spike-timing dependent plasticity in particular, we designed a PDMS microstructure consisting of two input nodes with axons guided symmetrically around the output node. To control number and location of synaptic connections, the nodes are interconnected with nanochannels, too narrow for axons but allowing for synapse formation [4]. We place the microstructures on top of microelectrode arrays (MEAs) and use a combination of stimulation and recording to analyze how the input-node activity affects the output node. Additionally, we use functional imaging to achieve a high spatial resolution for analyzing signal propagation. In parallel, we develop an *in silico* equivalent that would enable efficient testing of various stimulation patterns. Based on the experimental activity we tune the model parameters and use it to give predictions we can directly test *in vitro*. [1] Duru, et al., *Frontiers*, 2022

PRE-GESTATIONAL STRESS AND PERINATAL TREATMENT WITH ANTIDEPRESSANTS IN RATS AFFECT LEVELS OF SYNAPSE-RELATED PROTEINS IN HIPPOCAMPUS OF ADULT OFFSPRING IN A SEX-DEPENDENT MANNER

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Aim: Prenatal maternal stress has been linked to impaired cognitive development of offspring. Mirtazapine and bupropion are new generation antidepressants with different mechanism of action. We aimed to identify possible sex differences in markers of hippocampal synaptic plasticity, i.e., BDNF, PSD-95 and AMPAR during adulthood in offspring of mothers exposed to pre-gestational stress and/or antidepressant treatment. Method: Female Wistar rats were subjected to chronic unpredictable stress for three weeks to evoke a depressive-like condition and were subsequently mated. Bupropion (30 mg/kg/day) or mirtazapine (10 mg/kg/day) were administered from gestation day 10 until weaning on day 21 post-partum. Hippocampal tissues were collected from both sexes of adult offspring for Western-blot analysis to assess levels of BDNF, PSD-95 and AMPA proteins. Results: We observed significant effect of both pre-gestational stress and/or mirtazapine and bupropion treatment on the levels of BDNF protein in the hippocampus of adult offspring. Levels of PSD-95 were increased in both treatments and stress only in male offspring. Levels of AMPAR were affected only by stress, showing higher mean values in males compared to females, however bupropion treatment counteracted this effect. Conclusions: We found that pre-gestational stress and/or treatment with selected antidepressants altered hippocampal levels of synaptic plasticity markers BDNF, PSD-95 and AMPAR in a sex-dependent manner. These changes may relate to neurobehavioral and cognitive dysfunctions in adulthood. Study was supported by the grants VEGA 2/0124/19 and APVV-19-0435.

Long-term effects of pre-gestational stress and perinatal venlafaxine treatment on neurobehavioral development of female offspring.
Preclinical studies suggest that stress-related disorders even prior gestation can cause long-term changes at the level of neurobehavioral adaptations. Therefore, it is critical to consider undergoing antidepressant therapy which could reverse the negative consequences in the offspring. Venlafaxine is widely used in clinical practice; however insufficient amount of well-controlled studies verified the safety of venlafaxine therapy during gestation and lactation. The aim of this work was to investigate the effects of perinatal venlafaxine therapy on selected neurobehavioral variables in mothers and their female offspring using a model of maternal adversity. Pre-gestational stressed and non-stressed Wistar rat dams were treated with either venlafaxine (10 mg/kg/day) or vehicle during pregnancy and lactation. We have shown that pre-gestational stress decreased the number of pups with a significant reduction in the number of males but not females. Furthermore, we found that offspring of stressed and treated mothers exhibited anxiogenic behavior in juvenile and adolescent age. However, during adulthood pre-gestational stress significantly increased anxiety-like behavior of female, with venlafaxine treatment normalizing the state to control levels. Additionally, we found that even maternal stress prior gestation can have long-term impact on adult number of hippocampal immature neurons of the female offspring. A number of questions related to the best treatment options for maternal depression still remains, however present data may provide greater insight into the possible outcomes associated with perinatal venlafaxine therapy.

Sex- and age- dependent effect of pre-gestational chronic stress and mirtazapine treatment on neurobehavioral development of Wistar rat offspring.
Hormonal fluctuations, such as the perinatal period, may increase susceptibility of women to depression, which in turn exert a negative impact on child's neurodevelopment, becoming a risk factor in development of neuropsychiatric disorders. Moreover, the use of antidepressants during this critical period presents a serious health concern for both the mother and the child, due to the consequences of treatment in terms of the reliability and safety for the proper neurodevelopment of the organism being

not well known. Atypical antidepressants, such as mirtazapine, that targets both serotonergic and noradrenergic systems in the central nervous system (CNS), represent a novel focus of research due to its unique pharmacological profile. The aim of this work was to study the effects of maternal depression and/or perinatal antidepressant mirtazapine treatment on the neurobehavioral development of the offspring. Pre-gestationally chronically stressed or non-stressed Wistar rat dams were treated with either mirtazapine (10 mg/kg/day) or vehicle during pregnancy and lactation followed by analysis of offspring's behavior at juvenile and adolescent age. We found mirtazapine induced significant alterations of nursing behavior. In offspring, pregestational stress (PS) had an anxiogenic effect on adolescent males ($p \leq 0.05$) and increased their active behavior in forced swim test ($p \leq 0.01$). Interaction between pregestational stress and mirtazapine treatment variously induced anxiolytic changes of juvenile ($p \leq 0.05$) and adolescent ($p \leq 0.05$) females and impairment of spatial memory ($p \leq 0.01$) in adolescent females as well. Hippocampal density of synaptophysin, pre-synaptic protein marker, was decreased mainly by mirtazapine treatment. In conclusion, our results show mirtazapine induced significant alterations in maternal behavior and several sex- and age-dependent changes in neurobehavioral development of offspring caused by both prenatal mirtazapine treatment and/or chronic pregestational stress.

RHYTHMIC WHISKER STIMULATION CHANGES THE ACTIVITY OF NEOCORTICAL PYRAMIDAL NEURONS

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Leena Williams[1], Laura Bussien[2], Stephane Pagès[3], Tanika Bawa[2], Anthony Holtmaat[2]

Sensory experience and learning are thought to be associated with brain plasticity. Previously, we have demonstrated in anesthetized mice that a brief period (1min) of passive rhythmic whisker stimulation (RWS, 8Hz) induces long-term potentiation (LTP) of L2/3 Pyramidal Neuron (PN) synapses in the barrel cortex (BC). The potentiated amplitude of sensory-evoked post synaptic potentials (PSPs) in PNs remained mostly below spiking threshold, which is consistent with previous findings that PNs in supragranular layers of the BC rarely spike, but it may also be the consequence of anesthesia. To assess whether L2/3 PN activity is modulated as a consequence of LTP, we monitored whisker-evoked calcium responses in GCaMP6s-expressing L2/3 PNs in awake mice before, during and after RWS (10min - hours). We found that RWS induced a strong, 2 hour-lasting increase in whisker-evoked L2/3 PN population activity. This effect was specific for RWS of the PNs' principal whisker and was not observed for whiskers that functionally project onto distant barrel columns. Previously, we showed that RWS-evoked plasticity is dependent upon activation of vasoactive intestinal peptide-expressing (VIP) interneurons. Therefore, in a separate set of mice, we monitored the activity of GCaMP6s-expressing VIP interneurons and found that VIP interneurons increased their firing for a sustained period during RWS, which suggests that disinhibition-facilitated plasticity may have triggered the transient increase in L2/3 PN activity. Altogether, this work indicates that the cortical representation of sensory input is dynamic and can be modulated over hours by repetitive sensory stimulation, via mechanisms that may involve cortical disinhibitory circuit motifs.

IF HYPERACTIVE, RELAX WITH AGE? AGING MICE AND LACK OF MITF

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Pétur Henry Petersen[1], Fatich Mechmet[1,2], Eiríkur Steingrímsson[2]
[1]University of Iceland, Faculty of Medicine, School of Health Sciences, Biomedical Center, Department Of Anatomy, Reykjavík, Iceland, [2]University of Iceland, Faculty of Medicine, Biomedical Center, School of Health Sciences, Department Of Biochemistry And Molecular Biology, Reykjavík, Iceland

Age-related decline occurs in many brain structures and sensory systems. One example is the olfactory bulb (OB), the first brain structure that mediates olfactory information, which deteriorates with age leading to reduced olfactory ability. A decrease in olfactory ability is also an early symptom of neuropathologies such as Alzheimer´s disease (AD) and Parkinson´s disease (PD). However, the pathophysiology underlying olfactory dysfunction is often unclear. Microphthalmia-associated transcription factor (Mitf), the master regulator of melanocyte development and an important oncogene in melanoma, has distinct expression in the projection neurons, mitral and tufted (M/T) cells, of the OB. We have shown that mutant primary M/T cells are hyperactive and that the expression of key potassium channel subunit, Kv4.3 is reduced in M/T neurons of Mitf mutant mice. This suggest a role for Mitf in homestatic intrinsic plasticity. Neuronal hyperactivity is a frequent first step towards neurodegeneration and the goal of the current study is to determine whether lack of Mitf during aging leads to detrimental effects. OB from aged mice were analysed with regards to neuronal and glia morphology using the Golgi-COX method and immunohistochemistry, as well as gene expression and olfactory ability. Olfaction was affected, however, changes in protein markers and gene expression changes showed no evidence of inflammation or neurodegeneration in aged Mitf mutant mice. Importantly, there was an increased expression of neuronal genes which play an inhibitive role in OB´s neuronal network. This suggest that neuronal hyperactivity in younger animals is buffered or equilized through compensatory mechanisms in aging animals.

Aim: Microglia are the resident macrophages of the central nervous system (CNS) and are involved in brain homeostasis, synapse formation, plasticity, cognition and learning. Several studies have implicated microglia as important players in regulating experience-dependent synaptic plasticity. In order to better understand the mechanisms through which microglia respond to experience-dependent plasticity, we aim to analyse the microglial transcriptome in the visual cortex after induction of experience-dependent plasticity in adult murine brain. For this, we developed a protocol for RNA extraction from microglia using the RiboTag approach. Method: To characterize the microglia transcriptome from the visual cortex , we first optimized the RiboTag protocol for isolation of mRNA from small brain tissue sections using the microglia-specific RiboTag-based mouse line (Cx3cr1Cre$^{ERT2/+}$;Rpl22$^{HA/+}$), RT-PCR, Western blot and immunostaining. We determined the effect of various tamoxifen-mediated Cre-recombinase activation times and tissue amounts on the RNA-extraction yield. In addition, we evaluated the impact of Qiazol and the RNA precipitant LPA (linear polyacrylamide) on the yield and integrity of the immunoprecipitated mRNA using Agilent-based analyses. Result: an extended period of 30 d after tamoxifen delivery in combination with Qiazol/LPA-mediated extraction and immunoprecipitation led to an increased yield of mRNA from microglia as indicated by qubit measurement and enrichment of microglia genes. The mRNA obtained was of good quality as indicated by RIN values between 7.0-9.0. Conclusion: Our results indicate that the RiboTag approach can be used to selectively obtain mRNA from microglia in specific murine brain regions for downstream applications including RNA-seq

VULNERABILITY TO COCAINE ADDICTION INDUCED BY CHRONIC STRESS: IMPACT OF VAL66MET POLYMORPHISM IN THE BDNF GENE

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

María Julieta Boezio[1], Daiana Rigoni[1], Milena Jandar Paz[2], Liliana Cancela[1], Mariano Bisbal[2], Agustín Anastasia[2], Flavia Bollati[1]

Brain-derived neurotrophic factor (BDNF) is a neurotrophin widely expressed in the brain and it has a primary role in the development, differentiation, maturation and plasticity of the developing nervous system. BDNF is involved in synaptic plasticity, learning and it has a critical role in the neuronal plasticity leading to drug abuse. In the last decades, a single nucleotide polymorfism (SNP) in BDNF gene which results in the substitution of the amino acid Valine by Methionine at codon 66 (Val66Met) in the BDNF prodomain region, has been widely studied. This polymorphism affects intracellular processing and secretion of BDNF. The aim of the present study is evaluate the involvement of Met-prodomain BDNF (Met-pBDNF) in the impact of stress on vulnerability to cocaine addiction. Through an intracranial injection of lentiviral (LV) particles expressing the Val or Met variant of pBDNF in the nucleus accumbens core (NAc), we were able to observe an enhancement of locomotor activity in stressed animals microinjected with Met-pBDNF after a cocaine injection. Moreover, this enhancement is significantly more pronounced in stress Met-pBDNF compared with stressed Val-pBDNF animals. These results suggest that Met-pBDNF could induce an enhancement in the vulnerability to cocaine abuse and play an important role in the development of substance use disorders induced by chronic stress.

Stress-induced vulnerability to develop cocaine addiction depends on cofilin modulation.
Actin dynamics in dendritic spines can be associated with the neurobiological mechanisms supporting the comorbidity between stress exposure and cocaine increase rewards. The actin cytoskeleton remodeling in the nucleus accumbens (NA) has been implicated in the expression of stress-induced cross-sensitization with cocaine. The present study evaluates the involvement of cofilin, a direct regulator of actin dynamics, in the impact of stress on vulnerability to cocaine addiction. We assess whether the neurobiological mechanisms that modulate repeated-cocaine administration also occur in a chronic restraint stress-induced cocaine self-administration model. We also determine if chronic stress induces alterations in dendritic spines through dysregulation of cofilin activity in the NA core. Here, we show that the inhibition of cofilin expression in the NA core using viral short-hairpin RNA is sufficient to prevent the cocaine sensitization induced by chronic stress. The reduced cofilin levels also impede a-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor surface expression enhancement and promote the reduction of head diameter in animals pre-exposed to stress after a cocaine challenge in the NA core. Moreover, downregulation of cofilin expression prevents facilitation of the acquisition of cocaine self-administration (SA) in male rats pre-exposed to chronic stress without modifying performance in sucrose SA. These findings reveal a novel, crucial role for cofilin in the neurobiological mechanisms underpinning the comorbidity between stress exposure and addiction-related disorders.

EB3 PROTEIN POTENTIATES ENDOPLASMIC RETICULUM LOCALIZATION IN HIPPOCAMPAL DENDRITIC SPINES AND MAKES THEM RESILIENT TO BETA-AMYLOID TOXICITY

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Ekaterina Pchitskaya[1], Anastasiya Rakovskaya[1], Margarita Chigray[1], Ilya Bezprozvanny[1,2]
[1]Peter the Great St.Petersburg Polytechnic University, Laboratory Of Molecular Neurodegeneration, Saint-Petersburg, Russian Federation, [2]UT Southwestern Medical Center at Dallas, Department Of Physiology, Dallas, United States of America

EB3 protein is expressed abundantly in the nervous system and transiently enters the dendritic spines at the tip of the growing microtubule. Nevertheless, the role of dynamic microtubules, and particularly EB3 protein, in synapse function is still elusive. We have shown, that this protein is important for normal dendritogenesis – both EB3 overexpression and knockout reduces hippocampal neurons dendritic branching and total dendritic length. Some of the spines contain endoplasmic reticulum (ER) inside it, which is able to form spine apparatus. EB3 overexpression leads to a dramatic increase in dendritic spines head area, number of ER containing spines and ER area inside the spine. EB3 knockout oppositely reduces spine head area and increases spine neck length and spine neck/spine length ratio, alters ER presence in spines. The same effect is observed in conditions of amyloid-beta toxicity, modelling Alzheimer`s disease. Neck elongation is supposed to be a common detrimental effect on the spine's shape, which makes them biochemically and electrically less connected to the dendrite. According to preliminary results EB3 potentates ER movement in dendritic spines through associating with ER resident calcium sensor protein STIM2. EB3 also potentiates the formation of presynaptic protein Synapsin clusters and CaMKII-alpha preferential localization in spines rather than in dendrites of hippocampal neurons, while its downregulation has an opposite effect and reduces the size of Synapsin and PSD95 protein clusters. EB3 overexpression makes dendritic spines resilient to amyloid-beta toxicity and restores its detrimental effects on spines. Supported by RNF № 21-74-00028.

Neuronal Store-Operated Calcium Entry and Mushroom Spine Loss in Amyloid Precursor Protein Knock-In Mouse Model of Alzheimer's Disease.
Alzheimer's disease (AD) is the most common reason for elderly dementia in the world. We proposed that memory loss in AD is related to destabilization of mushroom postsynaptic spines involved in long-term memory storage. We demonstrated previously that stromal interaction molecule 2 (STIM2)-regulated neuronal store-operated calcium entry (nSOC) in postsynaptic spines play a key role in stability of mushroom spines by maintaining activity of synaptic Ca(2+)/calmodulin kinase II (CaMKII). Furthermore, we demonstrated previously that the STIM2-nSOC-CaMKII pathway is downregulated in presenilin 1 M146V knock-in (PS1-M146V KI) mouse model of AD, leading to loss of hippocampal mushroom spines in this model. In the present study, we demonstrate that hippocampal mushroom postsynaptic spines are also lost in amyloid precursor protein knock-in (APPKI) mouse model of AD. We demonstrated that loss of mushroom spines occurs as a result of accumulation of extracellular β-amyloid 42 in APPKI culture media. Our results indicate that extracellular Aβ42 acts by overactivating mGluR5 receptor in APPKI neurons, leading to elevated Ca(2+) levels in endoplasmic reticulum, compensatory downregulation of STIM2 expression, impaired synaptic nSOC, and reduced CaMKII activity. Pharmacological inhibition of mGluR5 or overexpression of STIM2 rescued synaptic nSOC and prevented mushroom spine loss in APPKI hippocampal neurons. Our results indicate that downregulation of synaptic STIM2-nSOC-CaMKII pathway causes loss of mushroom synaptic spines in both presenilin and APPKI mouse models of AD. We propose that modulators/activators of this pathway may have a potential therapeutic value for treatment of memory loss in AD. Significance statement: A direct connection between amyloid-induced synaptic mushroom spine loss and neuronal store-operated calcium entry pathway is shown. These results provide strong support for the calcium hypothesis of neurodegeneration and further validate the synaptic store-operated calcium entry pathway as a potential therapeutic target for Alzheimer's disease.

Store-Operated Calcium Channel Complex in Postsynaptic Spines: A New Therapeutic Target for Alzheimer's Disease

Treatment.
Mushroom dendritic spine structures are essential for memory storage and the loss of mushroom spines may explain memory defects in aging and Alzheimer's disease (AD). The stability of mushroom spines depends on stromal interaction molecule 2 (STIM2)-mediated neuronal-store-operated Ca influx (nSOC) pathway, which is compromised in AD mouse models, in aging neurons, and in sporadic AD patients. Here, we demonstrate that the Transient Receptor Potential Canonical 6 (TRPC6) and Orai2 channels form a STIM2-regulated nSOC Ca channel complex in hippocampal mushroom spines. We further demonstrate that a known TRPC6 activator, hyperforin, and a novel nSOC positive modulator, NSN21778 (NSN), can stimulate activity of nSOC pathway in the spines and rescue mushroom spine loss in both presenilin and APP knock-in mouse models of AD. We further show that NSN rescues hippocampal long-term potentiation impairment in APP knock-in mouse model. We conclude that the STIM2-regulated TRPC6/Orai2 nSOC channel complex in dendritic mushroom spines is a new therapeutic target for the treatment of memory loss in aging and AD and that NSN is a potential candidate molecule for therapeutic intervention in brain aging and AD.

Calcium signaling, excitability, and synaptic plasticity defects in a mouse model of Alzheimer's disease.
Alzheimer's disease (AD) and aging result in impaired ability to store memories, but the cellular mechanisms responsible for these defects are poorly understood. Presenilin 1 (PS1) mutations are responsible for many early-onset familial AD (FAD) cases. The phenomenon of hippocampal long-term potentiation (LTP) is widely used in studies of memory formation and storage. Recent data revealed long-term LTP maintenance (L-LTP) is impaired in PS1-M146V knock-in (KI) FAD mice. To understand the basis for this phenomenon, in the present study we analyzed structural synaptic plasticity in hippocampal cultures from wild type (WT) and KI mice. We discovered that exposure to picrotoxin induces formation of mushroom spines in both WT and KI cultures, but the maintenance of mushroom spines is impaired in KI neurons. This maintenance defect can be explained by an abnormal firing pattern during the consolidation phase of structural plasticity in KI neurons. Reduced frequency of neuronal firing in KI neurons is caused by enhanced calcium-induced calcium release (CICR), enhanced activity of calcium-activated potassium channels, and increased afterhyperpolarization. As a result, "consolidation" pattern of neuronal activity converted to "depotentiation" pattern of neuronal activity in KI neurons. Consistent with this model, we demonstrated that pharmacological inhibitors of CICR (dantrolene), of calcium-activated potassium channels (apamin), and of calcium-dependent phosphatase calcineurin (FK506) are able to rescue structural plasticity defects in KI neurons. Furthermore, we demonstrate that incubation with dantrolene or apamin also rescued L-LTP defects in KI hippocampal slices, suggesting a role for a similar mechanism. This proposed mechanism may be responsible for memory defects in AD but also for age-related memory decline.

Stim2-Eb3 Association and Morphology of Dendritic Spines in Hippocampal Neurons.
Mushroom spines form strong synaptic contacts and are essential for memory storage. We have previously demonstrated that neuronal store-operated calcium entry (nSOC) in hippocampal neurons is regulated by STIM2 protein. This pathway plays a key role in stability of mushroom spines and is compromised in different mice models of Alzheimer's disease (AD). Actin was thought to be the sole cytoskeleton compartment presented in dendritic spines, however, recent studies demonstrated that dynamic microtubules with EB3 capped plus-ends transiently enter spines. We showed that STIM2 forms an endoplasmic reticulum (ER) Ca -dependent complex with EB3 via Ser-x-Ile-Pro aminoacid motif and that disruption of STIM2-EB3 interaction resulted in loss of mushroom spines in hippocampal neurons. Overexpression of EB3 causes increase of mushroom spines fraction and is able to restore their deficiency in hippocampal neurons obtained from PS1-M146V-KI AD mouse model. STIM2 overexpression failed to restore mushroom dendritic spines after EB3 knockdown, while in contrast EB3 overexpression rescued loss of mushroom spines resulting from STIM2 depletion. We propose that EB3 is involved in regulation of dendritic spines morphology, in part due to its association with STIM2, and that modulation of EB3 expression is a potential way to overcome synaptic loss during AD.

STIM2 protects hippocampal mushroom spines from amyloid synaptotoxicity.
Alzheimer disease (AD) is a disease of lost memories. Mushroom postsynaptic spines play a key role in memory storage, and loss of mushroom spines has been proposed to be linked to memory loss in AD. Generation of amyloidogenic peptides and accumulation of amyloid plaques is one of the pathological hallmarks of AD. It is important to evaluate effects of amyloid on stability of mushroom spines.

Dendritic Spines Shape Analysis-Classification or Clusterization? Perspective.
Dendritic spines are small protrusions from the dendrite membrane, where contact with neighboring axons is formed in order to receive synaptic input. Changes in size, shape, and density of synaptic spines are associated with learning and memory, and observed after drug abuse in a variety of neurodegenerative, neurodevelopmental, and psychiatric disorders. Due to the preeminent importance of synaptic spines, there have been major efforts into developing techniques that enable visualization and analysis of dendritic spines in cultured neurons, in fixed slices and in intact brain tissue. The classification of synaptic spines into predefined morphological groups is a standard approach in neuroscience research, where spines are divided into fixed categories such as thin, mushroom, and stubby subclasses. This study examines accumulated evidence that supports the existence of dendritic spine shapes as a continuum rather than separated classes. Using new approaches and software tools we reflect on complex dendritic spine shapes, positing that understanding of their highly dynamic nature is required to perform analysis of their morphology. The study discusses and compares recently developed algorithms that rely on clusterization rather than classification, therefore enabling new levels of spine shape analysis. We reason that improved methods of analysis may help to investigate a link between dendritic spine shape and its function, facilitating future studies of learning and memory as well as studies of brain disorders.

Dysregulation of neuronal calcium homeostasis in Alzheimer's disease - A therapeutic opportunity?
Alzheimer's disease (AD) is the disease of lost memories. Synaptic loss is a major reason for memory defects in AD. Signaling pathways involved in memory loss in AD are under intense investigation. The role of deranged neuronal calcium (Ca) signaling in synaptic loss in AD is described in this review. Familial AD (FAD) mutations in presenilins are linked directly with synaptic Ca signaling abnormalities, most likely by affecting endoplasmic reticulum (ER) Ca leak function of presenilins. Excessive ER Ca release via type 2 ryanodine receptors (RyanR2) is observed in AD spines due to increase in expression and function of RyanR2. Store-operated Ca entry (nSOC) pathway is disrupted in AD spines due to downregulation of STIM2 protein. Because of these Ca signaling abnormalities, a balance in activities of Ca-calmodulin-dependent kinase II (CaMKII) and Ca-dependent phosphatase calcineurin (CaN) is shifted at the synapse, tilting a balance between long-term potentiation (LTP) and long-term depression (LTD) synaptic mechanisms. As a result, synapses are weakened and eliminated in AD brains by LTD mechanism, causing memory loss. Targeting synaptic calcium signaling pathways offers opportunity for development of AD therapeutic agents.

Dynamic Microtubules in Alzheimer's Disease: Association with Dendritic Spine Pathology.
Alzheimer's disease (AD) is the most common incurable neurodegenerative disorder that affects the processes of memory formation and storage. The loss of dendritic spines and alteration in their morphology in AD correlate with the extent of patient's cognitive decline. Tubulin had been believed to be restricted to dendritic shafts, until recent studies demonstrated that dynamically growing tubulin microtubules enter dendritic spines and promote their maturation. Abnormalities of tubulin cytoskeleton may contribute to the process of dendritic spine shape alteration and their subsequent loss in AD. In this review, association between tubulin cytoskeleton dynamics and dendritic spine morphology is discussed in the context of dendritic spine alterations in AD. Potential implications of these findings for the development of AD therapy are proposed.

Dysregulation of Intracellular Calcium Signaling in Alzheimer's Disease.
Calcium (Ca) hypothesis of Alzheimer's disease (AD) gains popularity. It points to new signaling pathways that may underlie AD pathogenesis. Based on calcium hypothesis, novel targets for the development of potential AD therapies are identified. Recent Advances: Recently, the key role of neuronal store-operated calcium entry (nSOCE) in the development of AD has been described. Correct regulation of nSOCE is necessary for the stability of postsynaptic contacts to preserve the memory formation. Molecular identity of hippocampal nSOCE is defined. Perspective nSOCE-activating molecule, prototype of future anti-AD drugs, is described.

28728834: Pchitskaya E, Popugaeva E, Bezprozvanny I
Calcium signaling and molecular mechanisms underlying neurodegenerative diseases.
Calcium (Ca) is a ubiquitous second messenger that regulates various activities in eukaryotic cells. Especially important role calcium plays in excitable cells. Neurons require extremely precise spatial-temporal control of calcium-dependent processes because they regulate such vital functions as synaptic plasticity. Recent evidence indicates that neuronal calcium signaling is abnormal in many of neurodegenerative disorders such as Alzheimer's disease (AD), Huntington's disease (HD) and Parkinson's disease (PD). These diseases represent a major medical, social, financial and scientific problem, but despite

enormous research efforts, they are still incurable and only symptomatic relief drugs are available. Thus, new approaches and targets are needed. This review highlight neuronal calcium-signaling abnormalities in these diseases, with particular emphasis on the role of neuronal store-operated Ca entry (SOCE) pathway and its potential relevance as a therapeutic target for treatment of neurodegeneration.

MITF REGULATES GENES WHICH DEFINE MIDDLE TUFTED NEURONS OR REDUCE NEURONAL ACTIVITY

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Fatich Mechmet[1], Alba Sabaté San José[1], Snævar Sigurðsson[1], Eiríkur Steingrímsson[2], Pétur Henry Petersen[1]
[1]University of Iceland, Faculty of Medicine, School of Health Sciences, Biomedical Center, Department Of Anatomy, Reykjavík, Iceland, [2]University of Iceland, Faculty of Medicine, Biomedical Center, School of Health Sciences, Department Of Biochemistry And Molecular Biology, Reykjavík, Iceland

The olfactory bulb (OB) is the first relay center in the brain that mediates olfactory information. Its distinct organization and defined neuronal subtypes make the OB attractive to study neuroplasticity. Micropthalmia-associated transcription factory (MITF) is regarded as a master regulator of the melanocyte lineage. It has a broad variety of target genes involved in various cellular processes in melanocytes and melanoma. MITF is also expressed in the projection neurons, mitral and tufted (M/T) cells, of the OB suggesting a putative role in olfaction. However, little is known regarding target genes of MITF in the central nervous system (CNS). Here, we aim to identify potential MITF target genes in the projection neurons of the OB using bulk RNA-sequencing and RNA in situ hybridization. Electrophysiological analysis of primary M/T cells from *Mitf* null mice (*Mitf* $^{mi\text{-}vga9/mi\text{-}vga9}$) showed hyperexcitability. This has been linked to reduced expression of a key potassium voltage-gated channel subunit, Kv4.3. The current transcriptomic data shows reduction in gene expression of genes which are specifically expressed in middle tufted cells of the OB, as well as genes which are known or likely to reduce neuronal activity. RNA in situ hybridization confirmed the expression changes of selected genes in different OB layers of mice. The presence of MITF binding sites in a gene underpins this direct interaction. MITF thus appears to regulate genes involved in neuronal acitivity through multiple mechanisms, subsequent hyperactivity in mutant mice likely leads to changes in expression of other genes sensitive towards increased activity.

Distribution of mast cells within the mouse heart and its dependency on Mitf.
Although mast cell distribution has been described in both human and canine hearts, cardiac mast cells in mice have yet to be categorically localized. We therefore sought to describe mast cell distribution within the mouse heart and characterize their dependence on the Microphthalmia-associated transcription factor (Mitf). Cardiac mast cells were visualized using Toluidine Blue and avidin staining, and their distribution within the heart described. Cardiac mast cells were most prevalent in the epicardium (50%) or myocardium (45%). Less frequently, mast cells were noted in the endocardium (5%). Within the myocardium, 31% of the mast cells had perivascular location. By studying two different Mitf mutant strains, Mitf and Mitf, we demonstrated that these mutations led to near-complete deficiency of cardiac mast cells. Accordingly, expression of the mMCP-4 and mMCP-5 genes was lost and chymase enzyme activity was severely reduced. Additionally, hearts from mice heterozygous for these Mitf mutations contained significantly fewer mast cells compared to wild-type mice. Our results demonstrated that the distribution of cardiac mast cells in mice is different from humans and dogs. Cardiac mast cells are dependent on Mitf expression, with loss-of-function mutation in the Mitf gene leading to near-complete lack of cardiac mast cells. Loss of a single Mitf allele is sufficient for relative mast cell deficiency.

Restoring brain cholesterol turnover improves autophagy and has therapeutic potential in mouse models of spinocerebellar ataxia.
Spinocerebellar ataxias (SCAs) are devastating neurodegenerative disorders for which no curative or preventive therapies are available. Deregulation of brain cholesterol metabolism and impaired brain cholesterol turnover have been associated with several neurodegenerative diseases. SCA3 or Machado-Joseph disease (MJD) is the most prevalent ataxia worldwide. We show that cholesterol 24-hydroxylase (CYP46A1), the key enzyme allowing efflux of brain cholesterol and activating brain cholesterol turnover, is decreased in cerebellar extracts from SCA3 patients and SCA3 mice. We investigated whether reinstating CYP46A1 expression would improve the disease phenotype of SCA3 mouse models. We show that administration

of adeno-associated viral vectors encoding CYP46A1 to a lentiviral-based SCA3 mouse model reduces mutant ataxin-3 accumulation, which is a hallmark of SCA3, and preserves neuronal markers. In a transgenic SCA3 model with a severe motor phenotype we confirm that cerebellar delivery of AAVrh10-CYP46A1 is strongly neuroprotective in adult mice with established pathology. CYP46A1 significantly decreases ataxin-3 protein aggregation, alleviates motor impairments and improves SCA3-associated neuropathology. In particular, improvement in Purkinje cell number and reduction of cerebellar atrophy are observed in AAVrh10-CYP46A1-treated mice. Conversely, we show that knocking-down CYP46A1 in normal mouse brain impairs cholesterol metabolism, induces motor deficits and produces strong neurodegeneration with impairment of the endosomal-lysosomal pathway, a phenotype closely resembling that of SCA3. Remarkably, we demonstrate for the first time both in vitro, in a SCA3 cellular model, and in vivo, in mouse brain, that CYP46A1 activates autophagy, which is impaired in SCA3, leading to decreased mutant ataxin-3 deposition. More broadly, we show that the beneficial effect of CYP46A1 is also observed with mutant ataxin-2 aggregates. Altogether, our results confirm a pivotal role for CYP46A1 and brain cholesterol metabolism in neuronal function, pointing to a key contribution of the neuronal cholesterol pathway in mechanisms mediating clearance of aggregate-prone proteins. This study identifies CYP46A1 as a relevant therapeutic target not only for SCA3 but also for other SCAs.

INTRACELLULAR ACTIVITY OF CORTICAL PYRAMIDAL NEURONS ACROSS THE WAKE-SLEEP CYCLE

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Tiago Campelo, Thomas Rusterholz, Antoine Adamantidis
University of Bern, Center For Experimental Neurology, Dept Of Neurology, Bern, Switzerland

Sleep is a rapid reversible behavioural state and an essential biological need for higher vertebrates. Amassing experimental evidence implicate sleep-wake promoting and oscillatory networks in the control of sleep-wake states and ultimately sleep-dependent functions, including synaptic plasticity and memory refinement. Yet, the precise synaptic and subcellular mechanisms occurring during sleep, in particular rapid-eye movement sleep (REMS), remains unclear. Here, we recorded cortical neurons across the wake-sleep cycle using in vivo whole-cell patch-clamp recordings in head-fixed and naturally sleeping mice. We found that the intracellular activity of L2/3 pyramidal neurons from prefrontal (PFC) and retrosplenial (RSP) cortices remarkably differed between wakefulness, REMS and non-REMS (NREMS), likely resulting from alterations in intrinsic excitability, synaptic activities and local excitation/inhibition balance. Indeed, the membrane potential (Vm) recorded during NREMS showed a biphasic slow oscillation (~2 Hz) between DOWN (~ -65 mV) and UP (~ 45 mV) states and was similar between PFC and RSP. On the other hand, the recorded Vm during REMS was remarkably different between cortical regions, with PFC being defined by a fast and low amplitude fluctuation and RSP by a long-lasting somatic depolarization. Collectively, our results are consistent with previous studies and suggest that the excitability of cortical neurons during NREMS and REMS at either postsynaptic and somatic level might provide a mechanism for sleep-dependent synaptic plasticity essential to the optimization of behaviour.

HUMAN CPEB3, A FUNCTIONAL PRIONOID WITH A REMARKABLE CONFORMATIONAL POLYMORPHISM

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Maria Eugenia Vaquero Morales, Nora Serrano Bengoechea, Paula López-García, Mariano Carrión-Vázquez
Cajal Institute (CSIC), Molecular, Cellular And Developmental Neurobiology, Madrid, Spain

The Cytoplasmic Polyadenylation Element Binding protein 3, CPEB3, is a functional amyloid that plays a crucial role in memory consolidation. The starting point and a key determinant of the aggregation cascade is the conformational change that occurs on the monomeric protein. Here we analyse the mechanical properties of the amyloid region of human CPEB3 (hCPEB3) by atomic force microscopy-based single molecule force spectroscopy (AFM-SMFS) to monitor its conformational polymorphism at monomer level. We have analysed the first 200 residues of the intrinsically disordered region (IDR) of hCPEB3 since this region has been reported to be the amyloid-forming domain. For our unequivocal nanomechanical analysis we use a protein-engineering mechanical-protection strategy. We first validate this strategy using far-UV circular dichroism, immunoreactivity against conformational antibodies and fibrillation studies by Thioflavin-T binding, corroborating the amyloidogenic properties of $hCPEB3_{1-200}$. The AFM-SMFS results indicated that $hCPEB3_{1-200}$ displayed a rich conformational polymorphism at the monomer level with 29.3% non-mechanically resistant events and 68.9% mechanostable conformers. $hCPEB3_{1-200}$ has showed the highest number of mechanostable events out of the fifteen amyloidogenic IDRs analysed so far in our laboratory by AFM-SMFS, including its CPEB orthologs from *Aplysia* (42.1%) and *Drosophila* (37.7%). Considering that an elevated mechanostability is related with an increased acquisition of secondary structure within the intrinsically disorder region, the higher structuring of hCPEB3 may be related to an evolutionary step to fulfil its biological function.

Properties, structure, and applications of microbial sterol esterases.
According to their substrate preferences, carboxylic ester hydrolases are organized in smaller clusters. Among them, sterol esterases (EC 3.1.1.13), also known as cholesterol esterases, act on fatty acid esters of cholesterol and other sterols in aqueous media, and are also able to catalyze synthesis by esterification or transesterification in the presence of organic solvents. Mammalian cholesterol esterases are intracellular enzymes that have been extensively studied since they are essential in lipid metabolism and cholesterol absorption, and the natural role of some microbial sterol esterases is supposed to be similar. However, besides these intracellular enzymes, a number of microbes produce extracellular sterol esterases, which show broad stability, selectivity, or wide substrate specificity, making them interesting for the industry. In spite of this, there is little information about microbial sterol esterases, and only a small amount of them have been characterized. Some of the most commercially exploited cholesterol esterases are produced by Pseudomonas species and by Candida rugosa, although in the last case they are usually described and named as "high substrate versatility lipases." From a structural point of view, most of them belong to the α/β-hydrolase superfamily and have a conserved "catalytic triad" formed by His, an acidic amino acid and a Ser residue that is located in a highly conserved GXSXG sequence. In this review, the information available on microbial sterol esterases has been gathered, taking into account their origin, production and purification, heterologous expression, structure, stability, or substrate specificity, which are the main properties that make them attractive for different applications. Moreover, a comprehensive phylogenetic analysis on available sequences of cholesterol esterases has been done, including putative sequences deduced from public genomes.

Structural traits and catalytic versatility of the lipases from the Candida rugosa-like family: A review.
Lipases and sterol esterases are enzymes with broad biotechnological applications, which catalyze the hydrolysis or synthesis of long-chain acylglycerols and sterol esters, respectively. In this paper, we review the current knowledge on the so-called Candida rugosa-like family of enzymes, whose members display in most cases affinity against the two substrates mentioned above. The family includes proteins with the α/β-hydrolase folding, sharing conserved motifs in their sequences, and common structural features. We will go through their production and purification, relate their described structures and

catalytic activity, and discuss the influence of the hydrophobic character of these lipases on their aggregation state and activity. On the basis of the few crystal structures available, the role of each of the functional areas in catalysis will be analyzed. Considering the particular characteristics of this group, we propose their classification as "Versatile Lipases" (EC 3.1.1.x).

A novel calb-type lipase discovered by fungal genomes mining.
The fungus Pseudozyma antarctica produces a lipase (CalB) with broad substrate specificity, stability, high regio- and enantio-selectivity. It is active in non-aqueous organic solvents and at elevated temperatures. Hence, CalB is a robust biocatalyst for chemical conversions on an industrial scale. Here we report the in silico mining of public metagenomes and fungal genomes to discover novel lipases with high homology to CalB. The candidates were selected taking into account homology and conserved motifs criteria, as well as, phylogeny and 3D model analyses. The most promising candidate (PlicB) presented interesting structural properties. PlicB was expressed in a heterologous host, purified and partially characterized. Further experiments will allow finding novel catalytic properties with biotechnological interest.

Expression and properties of three novel fungal lipases/sterol esterases predicted in silico: comparison with other enzymes of the Candida rugosa-like family.
Lipases from the Candida rugosa-like family are enzymes with great biotechnological interest. In a previous work, several enzymes from this family were identified by in silico mining of fungal genomes. Here, we describe the cloning, expression, and characterization of putative lipases from the genomes of Nectria haematococca, Trichoderma reesei, and Aspergillus niger and compared their catalytic properties with those of OPE, a well-characterized sterol esterase/lipase from Ophiostoma piceae. All of them hydrolyzed p-nitrophenol esters and triglycerides with different efficiency, but their activity against sterol esters was dissimilar, and the enzyme from A. niger was unable of hydrolyzing these substrates while OPE showed the best k cat values, which in general leads to an improved catalytic efficiency. Similarly, OPE was the best catalyst in the synthesis of β-sitostanyl oleate, followed by the commercial CRL from C. rugosa, while the A. niger enzyme was unable to produce this compound. When the enzymes were evaluated for caprolactone oligomerization, the A. niger enzyme gave similar results than CRL, being OPE slightly more efficient. The expression of the putative selected proteins allowed their functional validation, suggesting that the hydrophobicity of the lid region may be an important factor, although the enzymatic efficiency is also influenced by other parameters, as the aggregation state and the size and morphology of the tunnel, where substrate recognition and catalysis takes place.
Appl Microbiol Biotechnol, 2015; 99

Heterologous expression of a fungal sterol esterase/lipase in different hosts: Effect on solubility, glycosylation and production.
Ophiostoma piceae secretes a versatile sterol-esterase (OPE) that shows high efficiency in both hydrolysis and synthesis of triglycerides and sterol esters. This enzyme produces aggregates in aqueous solutions, but the recombinant protein, expressed in Komagataella (synonym Pichia) pastoris, showed higher catalytic efficiency because of its higher solubility. This fact owes to a modification in the N-terminal sequence of the protein expressed in Pichia pastoris, which incorporated 4-8 additional amino acids, affecting its aggregation behavior. In this study we present a newly engineered P. pastoris strain with improved protein production. We also produced the recombinant protein in the yeast Saccharomyces cerevisiae and in the prokaryotic host Escherichia coli, corroborating that the presence of these N-terminal extra amino acids affected the protein's solubility. The OPE produced in the new P. pastoris strain presented the same physicochemical properties than the old one. An inactive form of the enzyme was produced by the bacterium, but the recombinant esterase from both yeasts was active even after its enzymatic deglycosylation, suggesting that the presence of N-linked carbohydrates in the mature protein is not essential for enzyme activity. Although the yield in S. cerevisiae was lower than that obtained in P. pastoris, this work demonstrates the importance of the choice of the heterologous host for successful production of soluble and active recombinant protein. In addition, S. cerevisiae constitutes a good engineering platform for improving the properties of this biocatalyst.

Crystal structures of Ophiostoma piceae sterol esterase: structural insights into activation mechanism and product release.
Sterol esterases are able to efficiently hydrolyze both sterol esters and triglycerides and to carry out synthesis reactions in the presence of organic solvents. Their high versatility makes them excellent candidates for biotechnological purposes. Sterol esterase from fungus Ophiostoma piceae (OPE) belongs to the family abH03.01 of the Candida rugosa lipase-like proteins. Crystal structures of OPE were solved in this study for the closed and open conformations. Enzyme activation involves a

large displacement of the conserved lid, structural rearrangements of loop α16-α17, and formation of a dimer with a large opening. Three PEG molecules are placed in the active site, mimicking chains of the triglyceride substrate, demonstrating the position of the oxyanion hole and the three pockets that accommodate the sn-1, sn-2 and sn-3 fatty acids chains. One of them is an internal tunnel, connecting the active center with the outer surface of the enzyme 30 Å far from the catalytic Ser220. Based on our structural and biochemical results we propose a mechanism by which a great variety of different substrates can be hydrolyzed in OPE paving the way for the construction of new variants to improve the catalytic properties of these enzymes and their biotechnological applications.

Sugar recoveries from wheat straw following treatments with the fungus Irpex lacteus.
Irpex lacteus is a white-rot fungus capable of increasing sugar recovery from wheat straw; however, in order to incorporate biopretreatment in bioethanol production, some process specifications need to be optimized. With this objective, I. lacteus was grown on different liquid culture media for use as inoculums. Additionally, the effect of wheat straw particle size, moisture content, organic and inorganic supplementations, and mild alkali washing during solid-state fermentation (SSF) on sugar yield were investigated. Wheat thin stillage was the best medium for producing inoculums. Supplementation of wheat straw with 0.3mM Mn(II) during SSF resulted in glucose yields of 68% as compared to yields of 62% and 33% for cultures grown without supplementation or on untreated raw material, respectively after 21 days. Lignin loss, wheat straw digestibility, peroxidase activity, and fungal biomass were also correlated with sugar yields in the search for biopretreatment efficiency indicators.

Aims Our aim was to study the adverse effect of maternal depression and perinatal treatment with atypical antidepressant bupropion and mirtazapine on the levels of selected synapse-related proteins in adolescent rats. Methods Wistar rat dams were randomly assigned to control or stress group. The stress group was subjected to chronic unpredictable stress schedule for 3 weeks. Dams were mated with males and from gestational day 10 until day 21 post-partum were treated by bupropion (30 mg/kg/day) or mirtazapine (10 mg/kg/day), respectively. Adolescent offspring was sacrificed, hippocampi were extracted, and subsequently Western-blot analysis was carried-out for selected synapse-related protein level detection. Results In adolescent malesthe BDNF levels in the hippocampus was negatively effected by maternal depression as well as by both antidepressant treatments alone, while treatment after stress with both bupropion and mirtazapine lead to restoration of the BDNF to control levels.PSD-95 levels were lowered in males of stressed dams and restored by both treatment options. In adolescent females highest PSD-95 levels were manifested in control groups with either antidepressant treatment.In both males and females the negative effect of maternal depression on levels of AMPAR Glu1 subunit was compensated by perinatal bupropion and mirtazapine treatment. Conclusions Our results showed negative effect of maternal depression on synaptic related proteins in the hippocampus of adolescent rats. Perinatal antidepressant treatment seemed to mitigate and even compensate the negative effects on neural plasticity and neurogenesis, although the effects appeared to be sex specific. Study was supported by the grants VEGA 2/0124/19 and APVV-19-0435.

Sex- and age- dependent effect of pre-gestational chronic stress and mirtazapine treatment on neurobehavioral development of Wistar rat offspring.
Hormonal fluctuations, such as the perinatal period, may increase susceptibility of women to depression, which in turn exert a negative impact on child's neurodevelopment, becoming a risk factor in development of neuropsychiatric disorders. Moreover, the use of antidepressants during this critical period presents a serious health concern for both the mother and the child, due to the consequences of treatment in terms of the reliability and safety for the proper neurodevelopment of the organism being not well known. Atypical antidepressants, such as mirtazapine, that targets both serotonergic and noradrenergic systems in the central nervous system (CNS), represent a novel focus of research due to its unique pharmacological profile. The aim of this work was to study the effects of maternal depression and/or perinatal antidepressant mirtazapine treatment on the neurobehavioral development of the offspring. Pre-gestationally chronically stressed or non-stressed Wistar rat dams were treated with either mirtazapine (10 mg/kg/day) or vehicle during pregnancy and lactation followed by analysis of offspring's behavior at juvenile and adolescent age. We found mirtazapine induced significant alterations of nursing behavior. In offspring, pregestational stress (PS) had an anxiogenic effect on adolescent males ($p \leq 0.05$) and increased their active behavior in forced swim test ($p \leq 0.01$). Interaction between pregestational stress and mirtazapine treatment variously induced anxiolytic changes of juvenile ($p \leq 0.05$) and adolescent ($p \leq 0.05$) females and impairment of spatial memory ($p \leq 0.01$) in adolescent females as well. Hippocampal density of synaptophysin, pre-synaptic protein marker, was decreased mainly by mirtazapine treatment. In conclusion, our results show mirtazapine induced significant alterations in maternal behavior and several sex- and age-dependent changes in neurobehavioral development of offspring caused by both prenatal mirtazapine treatment and/or chronic pregestational stress.

Maternal immune activation in rats attenuates the excitability of monoamine-secreting neurons in adult offspring in a sex-

specific way.
Higher risk of depression and schizophrenia in descendants of mothers experienced acute infection during the pregnancy has been reported. Since monoamines are fundamental in mentioned psychopathologies, it is possible that maternal immune activation leads to impaired functioning of serotonin (5-HT), noradrenaline, and dopamine neurons in offspring. To test this hypothesis, we examined the effect of maternal immune activation by lipopolysaccharide (LPS) in rats on the excitability of monoamine-secreting neurons in the offspring. LPS was administered during days 15-19 of the gestation in the rising doses of 20-80 µg/kg; control dams received vehicle. During days 53-63 postpartum, rats were anesthetized and electrodes were inserted into the dorsal raphe nucleus, locus coeruleus, and ventral tegmental area for in vivo excitability assessment of 5-HT, noradrenaline, and dopamine neurons. Maternal immune activation suppressed the firing rate of 5-HT neurons in both sexes and stimulated the firing rate of dopamine neurons in males. Decrease in the firing rate of 5-HT neurons was accompanied with an increase, and increase in the firing rate of dopamine neurons with a decrease, in the density of spontaneously active cells. Maternal immune activation also decreased the variability of interspike intervals in 5-HT and dopamine neurons. It is possible that the alteration of excitability of 5-HT and dopamine neurons by maternal immune activation is involved in the psychopathologies induced by infectious disease during the pregnancy. Stimulation of dopamine excitability in males might be a compensatory mechanism secondary to the maternal immune challenge-induced suppression of 5-HT neurons.

Electrophysiology and Behavioral Assessment of the New Molecule SMe1EC2M3 as a Representative of the Future Class of Triple Reuptake Inhibitors.
SMe1EC2M3 is a pyridoindole derivative related to the neuroleptic drug carbidine. Based on the structural similarities of SMe1EC2M3 and known serotonin (5-HT), norepinephrine, and dopamine reuptake inhibitors, we hypothesized that this compound may also have triple reuptake inhibition efficacy and an antidepressant-like effect. PreADMET and Dragon software was used for in silico prediction of pharmacokinetics and pharmacodynamics of SMe1EC2M3. Forced swim test was used to evaluate its antidepressant-like effects. Extracellular in vivo electrophysiology was used to assess 5-HT, norepinephrine, and dopamine reuptake inhibition efficacy of SMe1EC2M3. PreADMET predicted reasonable intestinal absorption, plasma protein binding, and blood-brain permeability for SMe1EC2M3. Dragon forecasted its efficiency as an antidepressant. Using behavioral measurements, it was found that SMe1EC2M3 decreased immobility time and increase swimming time during the forced swim test (FST). Electrophysiological investigations showed that SMe1EC2M3 dose-dependently suppressed the excitability of 5-HT neurons of the dorsal raphe nucleus (DRN), norepinephrine neurons of the locus coeruleus (LC), and dopamine neurons of the ventral tegmental area (VTA). The SMe1EC2M3-induced suppression of 5-HT, norepinephrine, and dopamine neurons was reversed by the antagonists of serotonin-1A (5-HT; WAY100135), α-2 adrenergic (α, yohimbine), and dopamine-2 receptors (D, haloperidol), respectively. We conclude that SMe1EC2M3 is prospective triple 5-HT, norepinephrine, and dopamine reuptake inhibitor with antidepressant-like properties, however future studies should be performed to complete the pharmacological profiling of this compound.

Pre-gestational stress impacts excitability of hippocampal cells in vitro and is associated with neurobehavioral alterations during adulthood.
Chronic stress during pregnancy or even prior to gestation can negatively affect offspring´s neurobehavioural development. Several studies have shown, that offspring who had experienced excessive stress during gestation had higher rates of cognitive and mood disorders later during adolescence or in adulthood. Hippocampal neurons play a crucial role in the regulation of behavior, mainly in anxiety-related behaviors and spatial learning and memory. Recently, it has been shown, that excessive stress even prior to gestation could interfere with sensitive developmental processes in the brain and may affect hippocampal functioning with severe neurobehavioural consequences in later life. The aim of this work was to investigate the effects of pre-gestational stress of the rat dams on the hippocampal excitability of the pups right after the birth. Neurobehavioural consequences of pre-gestational stress were analyzed during adolescence (35-40 postnatal days) and in early adulthood (75-80 postnatal days). We have shown that even pre-gestational chronic maternal stress increased resting membrane potential, suppressed depolarization-activated action potential firing, and increased spontaneous activity of hippocampal cells from newborn offspring. Altered function of hippocampus was reflected at the behavioural level. Adolescent male offspring of dams exposed stress prior to conception showed hyperactivity-like behaviour in a new stressful environment and increased anxiety-like behaviour during adulthood compared to adult males from non-stress group. Together, this work suggests, that chronic stress even prior to gestation can interfere with functional brain development of the offspring and can cause long-term behavioural changes at the level of neurobehavioural adaptations.

Animal tests for anxiety-like and depression-like behavior in rats.
An animal model of human behavior represents a complex of cognitive and/or emotional processess, which are translated from animals to humans. A behavioral test is developed primarily and specifically to verify and support a theory of cognition or emotion; it can also be used to verify a theory of a psychopathology, but it is not developed for a particular type of psychopathology. The paper reviews tests commonly used in novel drug discovery research. Focus is especially on tests which can evaluate anxiety-like (openfield test, novelty suppressed feeding, elevated plus maze, light/dark box, stressinduced hyperthermia) and depression-like behaviors (forced swim test, tail suspension test, sucrose preference test) as they represent an important methodological tool in pre-clinical as well as in behavioral toxicology studies.

Animal models of maternal depression for monitoring neurodevelopmental changes occurring in dams and offspring.
Depression is one of the most prevalent and life-threatening forms of mental illness affecting about 20% of the population. Depressive disorder as a biochemical phenomenon, was first recognized in the mid-20 century of research, however the etiology of this disease is still not well understood. Although the need to investigate depressive disorders has emerged from the needs of clinical practice, there are many preclinical studies, which brought new insights into this field of research. During experimental work it was crucial to develop appropriate animal models, where the neurohumoral mechanism was similar to humans. In the past decades, several animal models of maternal depression have been developed. We describe the three most popular rodent models of maternal depression which are based on 1. stress prior to gestation, 2. prenatal stress and 3. early life stress. The above-mentioned animal models appear to fulfill many criteria for a relevant animal model of depression; they alter the regulation of the HPA, induce signs of depression-like behavior and several antidepressant treatments can reverse the state induced by maternal stress. Although, they are not able to model all aspects of maternal depression, they are useful models for monitoring neurodevelopmental changes occurring in dams and offspring.

Risks of using SSRI / SNRI antidepressants during pregnancy and lactation.
At present, affective disorders are among the most commonly diagnosed mental diseases. In pregnancy, they can occur as pre-delivery depression, recurrent depressive disorder or postnatal depression. The estimated prevalence of depressive disorders in pregnancy is approximately 9-16%, with some statistics reporting up to 20%. Approximately 2-3% of pregnant women take antidepressants during pregnancy, and the number of mothers treated increases by birth to 5-7%. Treatment of depression during pregnancy and breastfeeding is a controversial issue, as antidepressants can negatively affect the developing fetus. According to epidemiological studies, the effects of treated depression in pregnancy are related to premature birth, decreased body weight of the child, intrauterine growth retardation, neonatal adaptive syndrome, and persistent pulmonary hypertension. However, untreated depression can adversely affect maternal health and increase the risk of preeclampsia and eclampsia, as well as of subsequent postnatal depression, which can lead to disruption of the mother-child relationship. Based on the above mentioned facts, the basic question arises as to whether or not to treat depression during pregnancy and lactation.

Effect of Physical Exercise and Acute Escitalopram on the Excitability of Brain Monoamine Neurons: In Vivo Electrophysiological Study in Rats.
The antidepressant effect of physical exercise has been reported in several clinical and animal studies. Since serotonin, norepinephrine, and dopamine play a central role in depression, it is possible that the beneficial effects of physical exercise are mediated via monoamine pathways. This study investigates the effects of voluntary wheel running on the excitability of monoamine neurons.

THE EFFECT OF HIGH INTENSITY WHITE NOISE ON THE ULTRASTRUCTURE OF LIMBIC AREAS ON IN RATS. ELECTRON MICROSCOPE STUDY

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Mzia Zhvania[1,2], Nino Gogokhia[2], Nadezhda Japaridze[1,3]
[1]I. Beritashvili center of Experimental Biomedicine, Lab Of Brain Of Ultrastructure And Nanoarchitechtonics, Tbilisi, Georgia, [2]Ilia State University, Cellular Neuroscience, Tbilisi, Georgia, [3]New Vision University, Medical School, Tbilisi, Georgia

Noise pollution is a major growing concern, negatively impacting public health. People are continually and increasingly exposed to harmful noise levels, originating from traffic, loud music, home appliances, etc. Impaired cognitive functions, such as language acquisition, memory and other functions are greatly compromised. In the present study, we assessed the ultrastructural alterations in selective auditory pathways of the rat brain following high intensity white noise exposure. In addition, learning, anxiety-like behavior and locomotor activity were assessed. Adult male rats were exposed to 100 dB noise, one hour daily, for 10 consecutive days. Exposure to noise did not affect learning or the components of locomotor activity. However, it induced anxietylike behavior as evidenced by time spent in the closed arm of elevated-plus maze. Concomitantly, ultrastructural changes in medial geniculate body, as well as in the hippocampus and basolateral amygdala. Specifically, noise resulted in neuronal apoptosis, chromatolysis, cytoplasmic organelle destruction, and glial activation in medial geniculate body and hippocampus, as well as mild alterations in amygdala. Such results suggest that due to continuous transmission, the majority of vesicles are unable to replenish their cargo via transporters. Evaluation of synaptic vesicles size undertaken in the current electron microscopic study has advanced the understanding of the pathophysiology of white noise exposure on auditory brain processing regions, in addition to our understanding of fractional neurotransmitter release at the nerve terminal and on overall brain function. This work was supported: Shota Rustaveli National Science Foundation of Georgia DP2016_17 and I. Beritashvili Center of Experimental Biomedicine.

Toluene addiction is a worldwide public health problem. The use of toluene-containing volatile inhalants is widespread among adolescents, young people and adults. Although the relationships between brain structure and emotions may alter across the life span, this relationship is of particular importance during aging when significant alterations in emotions may be manifested. Understanding the structural-behavioral relationship could not only provide a neurobiological basis of these changes, but could also suggest potential intervention. We undertook this study to determine the extent of associated ultra-structural changes in the amygdala. The goal of the study is using high resolution transmission electron microscope(TEM), to evaluate immediate and persisting effect of toluene chronic exposure on the ultrastructure/presynaptic architecture of the the central nucleus of amygdala (CNA) in adolescent and male Wistar rats; EM revealed the age-dependent effect of toluene misuse on hippocampal and amygdala structure. Specifically, in adolescent rats significant cell loss was observed only immediately after the end of inhalation. Therefore, in adolescents the alterations do not progress during 90 days period of withdrawal. In opposite, in adult rats more numerous alterations were observed after 90 days of withdrawal. Therefore, in these animals the alterations progressed during 90 days period of withdrawal. The most prominent alterations were detected in the CA1 area. Toluene chronic exposure affects the structure/ultrastructure of the amygdala–brain area involved in learning and memory. Persisting and long-term effects were almost the same. We suggest that in the case of withdrawal the e ultrastructure of regions can be restored.

Electron microscopy demonstrating noise exposure alters synaptic vesicle size in the inferior colliculus of cat.
White noise is known to have detrimental effects on different brain regions, especially auditory regions, including inferior colliculus. Although the basis for such alterations has been hypothesized to result from abnormalities in neurotransmitter release, the mechanism is unclear. The final step in neurotransmission is the docking and transient fusion of synaptic vesicles at the base of cup-shaped lipoprotein structures called porosomes at the presynaptic membrane and the consequent release of neurotransmitters. Earlier studies in cat brain document altered morphology of the secretory portal the porosome at nerve terminals in the inferior colliculus following white noise exposure. The current study was performed to test the hypothesis of possible changes to synaptic vesicle size in the colliculus, following white noise exposure.

Behavioral and neuroanatomical effects on exposure to White noise in rats.
Noise pollution is a severe public health problem as continuous exposure to even moderate noise levels between 55-65 dB can lead to various pathologies, including neurological states. In the present study, we assessed the ultrastructural alterations in selective auditory pathways of the rat brain following high intensity white noise exposure. In addition, learning, anxiety-like behavior and locomotor activity were assessed. Adult male rats were exposed to 100 dB noise, one hour daily, for 10 consecutive days. The evaluations were performed on day 11. Exposure to noise did not affect learning or the components of locomotor activity. However, it induced anxiety-like behavior as evidenced by time spent in the closed arm of elevated-plus maze. Concomitantly, ultrastructural changes in medial geniculate body, considered an integral component of classical auditory pathway, as well as in the hippocampus and basolateral amygdala, considered important structures of non-classical auditory pathway were noted. Specifically, noise resulted in neuronal apoptosis, chromatolysis, cytoplasmic organelle destruction, and glial activation in medial geniculate body and hippocampus, as well as mild alterations in amygdala. These results provide further evidence of detrimental consequences following exposure to loud noise.

Age-related behavioral and ultrastructural changes in the rat amygdala.
Although the relationships between brain structure and emotions may alter across the life span, this relationship is of particular importance during aging when significant alterations in emotions may be manifested. Understanding the structural-behavioral relationship could not only provide a neurobiological basis of these changes, but could also suggest potential intervention. Since anxiety is commonly observed in aging population, we undertook this study to determine the extent of this behavioral manifestations as well as the associated ultrastructural changes in the amygdala. Rats of various age groups, adolescent, adult, and aged were tested for anxiety-like behavior and the ultrastructure/presynaptic architecture of the central nucleus of amygdala (CNA) were evaluated using transmission electron microscopy (EM). Aged rats were consistently more anxious than the other groups as evidenced by their scores in the elevated plus maze. Morphometric EM analysis of axodendritic synapses revealed that the aged rats had a lower presynaptic area as well as number of synapses, but unexpectedly a higher number of presynaptic mitochondria in CNA. Since presynaptic mitochondria are known to provide the energy for neurotransmission, it may be concluded that compensatory mechanisms are still operational during aging, and hence, may be a target for therapeutic intervention at this stage of life span.

Effect of propionic acid on the morphology of the amygdala in adolescent male rats and their behavior.
Autism spectrum disorder is a group of life-long developmental syndromes, characterized by stereotypic behavior, restricted, communication deficits, cognitive and social impairments. Autism spectrum disorder is heritable state, provided by the mutations of well-conserved genes; however, it has been increasingly accepted, that most of such states are the result of complex interaction between individual's genetic profile and the environment that he/she is exposed to. Gut microbiota plays one of the central roles in the etiology of autism. Propionic acid is one of the most abundant short-chain fatty acids, made by enteric bacteria. Propionic acid has many positive functions and acts as the main mediator between nutrition, gut microbiota and brain physiology. However, increased level of propionic acid is associated with various neurological pathologies, including autism. It is proposed that some types of autism might be partially related with alterations in propionic acid metabolism. The amygdala, the main component of social brain, via its large interconnections with fronto-limbic neural system, plays one of the key roles in social communications, emotional memory and emotional processing. Social behavior is a hot topic in autism research. As to anxiety, it is not the main characteristics of ASD, but represents one of the most common its co morbidities. Several theoretical reasons compatible with amygdala dysfunction have been suggested to account for socio-emotional disturbances in autism. In the present study, using adolescent male Wistar rats, the effect of acute administration of low dose of propionic acid on social behavior, anxiety-like behavior and the structure/ultrastructure of central nucleus of amygdale was described. In addition to qualitative analysis, on electron microscopic level the quantitative analysis of some parameters of synapses was performed. Behavior was assessed 2, 24 and 48 hours after treatment. The results revealed that even single and relatively low dose of propionic acid is sufficient to produce fast and relatively long lasting (48 h after treatment) decrease of social motivation, whereas asocial motivation and emotional sphere remain unaffected. Morphological analyses of propionic acid-treated brain revealed the reduced neuron number and the increase of the number of glial cells. Electron microscopically, in some neurons the signs of apoptosis and chromatolysis were detected. Glial alterations were more common. Particularly, the activation of astrocytes and microglia were often observed. Pericapillary glia was the most changed. Neuronal, glial and presynaptic mitochondria showed substantial structural diversities, mainly in terms of size and form. Total number of the area of presynaptic profile was significantly decreased. Some axons were moderately demyelinated. In general, the data indicate that even low dose of propionic acid produces in adolescent rodents immediate changes in social behavior, and structural/ultrastructural alterations in amygdala. Ultrastructural alterations may reflect moderate modifications in functional networks of social brain.

DEVELOPMENTAL AND ADULT MEMORY CAPACITY CONTROL VIA INTERPLAY BETWEEN NON-CONVENTIONAL GLUN3A-NMDA RECEPTORS AND MTOR SIGNALING

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Oscar Elia-Zudaire[1], Federica Giona[1], Remy Verhaeghe[1], Luis García-Rabaneda[1,2], Agnès Gruart[3], Jose M. Delgado-García[3], Isabel Perez-Otaño[1]

GluN3A-containing NMDA receptors ensure appropriate synapse selection during the postnatal refinement of neural circuits by limiting synapse plasticity and stabilization and promoting pruning. While massively down-regulated in most brain areas after postnatal stages, significant GluN3A expression is retained in selected areas of the adult brain where it seems to play roles in controlling the types of memories that are persistently stored (Murillo et al 2021; Conde-Dusman et al 2021). In line with this work, humans with low levels of GRIN3A (human gene encoding GluN3A) perform better in cognitive tasks. Using constitutive and inducible knockout mice, we investigated how GluN3A expression influences the emergence of memory capacities throughout adolescence into adulthood and explored the underlying mechanisms in vivo. We found that genetic removal of GluN3A facilitates long-term associative memory formation in postnatal (P20-P25) and adult (3-6 month-old) mice. Deletion of GluN3A from adult excitatory neurons using CamKII-Cre-ERT2 mice was sufficient for the memory enhancement, whereas deletion in somatostatin interneurons did not recapitulate the phenotype. The enhancement correlated with longer-lasting long-term potentiation (up to 72 hours in GluN3A knockout mice, but only a few hours in wild-types) measured in vivo and di novo protein synthesis measured in vivo, and was blocked by the mTOR inhibitor rapamycin and the general protein synthesis blocker anisomycin. These findings identify GluN3A as regulator of synaptic translational control during memory encoding, and offer a potentially selective target for cognitive modulation. Further work is directed to determine whether memory domains such as memory discrimination or flexibility are compromised.

Control of protein synthesis and memory by GluN3A-NMDA receptors through inhibition of GIT1/mTORC1 assembly.
De novo protein synthesis is required for synapse modifications underlying stable memory encoding. Yet neurons are highly compartmentalized cells and how protein synthesis can be regulated at the synapse level is unknown. Here, we characterize neuronal signaling complexes formed by the postsynaptic scaffold GIT1, the mechanistic target of rapamycin (mTOR) kinase, and Raptor that couple synaptic stimuli to mTOR-dependent protein synthesis; and identify NMDA receptors containing GluN3A subunits as key negative regulators of GIT1 binding to mTOR. Disruption of GIT1/mTOR complexes by enhancing GluN3A expression or silencing GIT1 inhibits synaptic mTOR activation and restricts the mTOR-dependent translation of specific activity-regulated mRNAs. Conversely, GluN3A removal enables complex formation, potentiates mTOR-dependent protein synthesis, and facilitates the consolidation of associative and spatial memories in mice. The memory enhancement becomes evident with light or spaced training, can be achieved by selectively deleting GluN3A from excitatory neurons during adulthood, and does not compromise other aspects of cognition such as memory flexibility or extinction. Our findings provide mechanistic insight into synaptic translational control and reveal a potentially selective target for cognitive enhancement.

TRANSIENT MOLECULAR CHANGES AND LASTING SYNAPTIC EFFECTS IN THE CEREBELLUM OF THE NEONATAL PHENCYCLIDINE MOUSE MODEL OF SCHIZOPHRENIA

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Beetsi Urrieta-Chavez[1], Maxime Veleanu[1], Séverine Sigoillot[1], Maela Paul[1], Fekrije Selimi[2]
[1]Collège de France-CIRB, 75, Paris, France, [2]Collège de France, Cirb, Paris, France

Environmental perturbations during the first years of life are a major factor in psychiatric diseases. Phencyclidine (PCP), a drug of abuse, has psychomimetic effects, and neonatal subchronic administration of PCP in rodents leads to long-term behavioral changes relevant for schizophrenia. The cerebellum is increasingly recognized for its role in diverse cognitive functions. However, little is known about potential cerebellar changes in models of schizophrenia. Here, we analyzed the characteristics of the cerebellum in the neonatal subchronic PCP model. We found that, while the global cerebellar cytoarchitecture and Purkinje cell spontaneous spiking properties are unchanged, climbing fiber/Purkinje cell synaptic connectivity is increased in juvenile mice. Neonatal subchronic administration of PCP is accompanied by increased cFos expression, a marker of neuronal activity, and transient modification of the neuronal surfaceome in the cerebellum. The largest change is the increased expression of *Ctgf*, a gene previously suggested as a biomarker for schizophrenia. However, *Ctgf* overexpression driven by transient increased neuronal activity in the cerebellum using chemogenetics does not lead to increased climbing fiber/Purkinje cell connectivity. Thus other molecular signaling pathways modulated by PCP lead to the long-term modification of Purkinje cell innervation. Overall, our study shows that administration of the drug of abuse PCP during the developmental period of intense synaptogenesis and circuit remodeling has long-term and specific effects on Purkinje cell connectivity, and warrants the search for this type of synaptic changes in psychiatric diseases.

Functional recovery following incomplete spinal cord injury depends, among others, on circuit plasticity of supraspinal connections onto spinal relay neurons. Which molecules can promote synaptogenesis and circuit plasticity following spinal cord injury is still unclear. FGF22 is a presynaptic organizer that mediates synaptogenesis in the developing and mature nervous system. Its absence is associated with decreased synapse formation and maturation during post-injury circuit rewiring. Here we identify FGF22 as a powerful enhancer of synaptogenesis during post-injury circuit rewiring and demonstrate that targeted gene therapy with FGF22 to specific subsets of spinal interneurons allows for precise synaptogenesis, synapse maturation and functional recovery following injury. We also demonstrate that therapeutic treatment with FGF22 restores functional recovery with a critical therapeutic window of 1 day. This study highlights the use of pre-synaptic organizers as therapeutic agents following spinal cord injury.

A deep learning-based toolbox for Automated Limb Motion Analysis (ALMA) in murine models of neurological disorders.
In neuroscience research, the refined analysis of rodent locomotion is complex and cumbersome, and access to the technique is limited because of the necessity for expensive equipment. In this study, we implemented a new deep learning-based open-source toolbox for Automated Limb Motion Analysis (ALMA) that requires only basic behavioral equipment and an inexpensive camera. The ALMA toolbox enables the consistent and comprehensive analyses of locomotor kinematics and paw placement and can be applied to neurological conditions affecting the brain and spinal cord. We demonstrated that the ALMA toolbox can (1) robustly track the evolution of locomotor deficits after spinal cord injury, (2) sensitively detect locomotor abnormalities after traumatic brain injury, and (3) correctly predict disease onset in a multiple sclerosis model. We, therefore, established a broadly applicable automated and standardized approach that requires minimal financial and time commitments to facilitate the comprehensive analysis of locomotion in rodent disease models.

Corticospinal circuit remodeling after central nervous system injury is dependent on neuronal activity.
The remodeling of supraspinal axonal circuits mediates functional recovery after spinal cord injury. This process critically depends on the selection of appropriate synaptic connections between cortical projection and spinal relay neurons. To unravel the principles that guide this target selection, we used genetic and chemogenetic tools to modulate NMDA receptor (NMDAR) integrity and function, CREB-mediated transcription, and neuronal firing of relay neurons during injury-induced corticospinal remodeling. We show that NMDAR signaling and CREB-mediated transcription maintain nascent corticospinal tract (CST)-relay neuron contacts. These activity-dependent signals act during a defined period of circuit remodeling and do not affect mature or uninjured circuits. Furthermore, chemogenetic modulation of relay neuron activity reveals that the regrowing CST axons select their postsynaptic partners in a competitive manner and that preventing such activity-dependent shaping of corticospinal circuits limits motor recovery after spinal cord injury.

Combining molecular intervention with in vivo imaging to untangle mechanisms of axon pathology and outgrowth following spinal cord injury.
In vivo imaging of the spinal cord has allowed the observation of single axons over relatively long periods in the living mouse.

After spinal cord injury, this methodology has helped to differentiate several pathological stages and tissue processes which impact axon morphology. In addition, the combination of in vivo imaging techniques with particular molecular intervention has shown that specific pathological axon changes can respond to distinct treatments. Combining in vivo imaging with molecular interventions is, hence, a powerful approach to extend our knowledge of the pathological processes leading to axonal loss. It also allows testing possible treatment options to, for example, increase axonal outgrowth. This review will provide a detailed description and critical examination of several studies that have combined the two methodologies in spinal cord injury research and pinpoints the specificities of the approach.

HYDROGEN PEROXIDE DIFFUSIVITY IN VIVO IN THE BRAIN EXTRACELLULAR SPACE SUPPORTS VOLUME NEUROTRANSMISSION

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Ana Ledo, Eliana Fernandes, João Laranjinha, Rui Barbosa
University of Coimbra, Faculty of Pharmacy, Center For Neuroscience And Cell Biology, Coimbra, Portugal

A role for hydrogen peroxide (H_2O_2) as an intercellular signaling molecule and neuromodulator in the brain has become increasingly apparent, with evidence showing this biological oxidant to regulate neuronal polarity, connectivity, synaptic transmission, and tuning of neuronal networks. This notion is rooted in its ability to diffuse in the extracellular space, from the source of production to target. It is crucial to understand extracellular H_2O_2 concentration dynamics in the living brain and which intra and extracellular factors shape its diffusion pattern and half-life. We have achieved this by using a novel microsensor to measure H_2O_2 diffusivity in the brain extracellular matrix, as well as uptake and removal kinetics governed by the main antioxidant enzymatic systems. Extracellular H_2O_2 is rapidly removed and degraded intracellularly by glutathione peroxidase and peroxiredoxins in neural cells, and also by catalase in erythrocytes. This rapid uptake and removal results in an average half-life in the extracellular space of $t_{1/2}$ = 2.19 s. We determined the effective diffusion coefficient of H_2O_2 to be D^* = 2.49 x 10^{-5} cm^2 s^{-1}. This allows it to diffuse over 100 µm in the extracellular space within its half-life. Considering this, we can tentatively place H_2O_2 within the class of volume transmitters connecting all cell types with the complex network of brain tissue, regardless of whether the cells are physically connected. These quantitative details allow us to interpret the physiology of the redox signal and lay the pavement to address dysregulation in redox homeostasis associated with disease processes in the brain.

FUNCTIONAL ANALYSIS OF MICRORNAS IN AUDITORY BRAINSTEM OF MICE

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Faiza Altaf, Hans Nothwang, Lena Ebbers
Carl-von-Ossietzky Universität Oldenburg, Department Of Neuroscience | Ag Neurogenetics, Oldenburg, Germany

MicroRNAs are small non-coding RNAs that posttranscriptionally regulate gene expression. They repress the translation of mRNAs into proteins via complementary base pairing to their target mRNAs.The microRNA 183 cluster, comprising of miRs-183, -96 and -182, plays an important role in the development and function of sensory systems. To gain insights into its function within the central auditory system we previously investigated a *Mir-183/96dko* mouse model in which miR-183 and miR-96 are deleted. Our data showed that *Mir-183/96* play a key role for proper development of auditory brainstem structures and synaptic transmission in an excitatory synapse of the auditory brainstem. Immunohistochemical analysis of AMPA receptor subunit GluA1, which is responsible for excitatory synaptic transmission and is also an established target of the miR-96, revealed significantly increased expression levels of GluaA1 at the calyx of Held, a central synapse in the auditory brainstem, of *Mir-183/96dko*. Here we set out to investigate the effects of *Mir-183/96* deficiency on inhibitory neurotransmission in the auditory brainstem, as miR-96 also targets many mRNAs important for inhibitory neurotransmission. To do so, we focused on synapses in the lateral superior olive (LSO) of the brainstem, which receives inhibitory input. By means of immunohistochemistry, we quantified the expression of miR-96 targeted genes important for inhibitory neurotransmission in the *Mir-183/96dko* mice. So far, our data revealed no significant differences in the expression of *KCC2* which is a critical mediator of synaptic inhibitory neurotransmission speculating there might be additional elements playing a role in its regulation besides microRNAs.

NOVEL METHOD FOR RELIABLY MEASURING MINIATURE AND SPONTANEOUS POSTSYNAPTIC POTENTIALS/CURRENTS IN WHOLE-CELL PATCH CLAMP RECORDINGS

POSTER SESSION 01 - SECTION: SYNAPTIC TRANSMISSION AND PLASTICITY IN HEALTH AND DISEASE

Martynas Dervinis
Cardiff University, School Of Biosciences, Cardiff, United Kingdom

Aims: Measurements of amplitudes of miniature postsynaptic currents (mPSCs) or potentials (mPSPs) (minis), recorded with action potentials blocked, are commonly used to investigate synaptic transmission. Combined with measurements of cell membrane potential noise fluctuations, somatic minis' amplitudes offer a technically straightforward way to estimate distributions of quantal sizes, a key synaptic transmission parameter, as generally each mini is thought to be elicited by the spontaneous release of a single neurotransmitter vesicle. As the first step in devising such a method, we developed and described a novel mPSP/mPSC detection algorithm as part of our quantal analysis software called 'minis'. **Methods:** We tested the performance of the algorithm in detecting real minis and simulated minis added to real noise, using data from rat cortical slice whole-cell recordings, and compared it to two the most commonly-used minis detection algorithms in the field of synaptic function research: Mini Analysis (Blue Cell) and Clampfit (Molecular Devices). **Results:** This benchmarking analysis revealed superior detection performance by our algorithm. The release version of our software also offers great flexibility as it can be controlled through graphical and programming interfaces making it suitable for the needs of most individual researchers studying the synapse function. **Conclusions:** By highlighting common methodological pitfalls surrounding spontaneous synaptic signalling research and offering a transparent and objectively evaluated algorithm to minimise their impact, we hope to set an important methodological standard for the comparative assessment of other algorithms in the field of synaptic function research and contribute to increased openness and reproducibility in science.

Gemelli, Rome, Italy, [2]Università Cattolica del Sacro Cuore, Department Of Neuroscience, Rome, Italy, [3]National Research Council (CNR), Institute Of Translational Pharmacology, Rome, Italy, [4]Istituto Superiore di Sanità, Department Of Infectious Diseases, Rome, Italy, [5]Laboratory affiliated to Istituto Pasteur Italia - Cenci Bolognetti Foundation, Department Of Public Health And Infectious Diseases, Sapienza University Of Rome, Rome, Italy

Aims: We recently developed a mouse model of multiple Herpes Simplex Virus Type-1 (HSV-1) replications within the brain exhibiting typical AD hallmarks, including amyloid-β and pTau accumulation, neuroinflammation. Here, we investigated the role of the interleukin 1β (IL-1β) to the HSV-1-induced synaptic dysfunction and cognitive decline. **Methods**: HSV-1 was inoculated via lip scarification in 1-month-old male C57BL/6 mice. After thermal stresses (TS) inducing virus reactivation, the AD-like phenotype was studied by behavioral tests, electrophysiology, Golgi staining and molecular analyses. **Results**: Mice undergone 2TS exhibited synaptic dysfunction assessed by deficits of: i) memory and learning; ii) long-term potentiation (LTP) at CA3-CA1 synapses; iii) pre- and post-synaptic proteins; iv) dendritic spine density; v) expression of plasticity-related genes. These effects were associated with increased levels of IL-1β (20.9±1.1 *vs*. 5.8±2.1 pg/mg in controls, $p<0.05$) that may negatively impinge on plasticity-related genes expression by modulating transcriptional repressors. In HSV-1-infected mice we found significant increases of MeCP2 and REST at both protein (+59% and +95%, respectively *vs*. mock, $p<0.05$) and mRNA (+4.8 and +3.8 folds, respectively *vs*. mock, $p<0.05$) levels. The pathogenic role of IL-1β on these effects was assessed by blocking IL-1 receptor with Anakinra. This treatment: i) counteracted the HSV-1-induced increases in MeCP2 and REST levels; ii) rescued plasticity-related genes expression; iii) ameliorated LTP (87.2±10.5% *vs*. 58.2±7.9%, in HSV-1; $p<0.05$) and memory performance (assessed by NOR test: 63.0±2.7% *vs*. 52.2±.1.8% in HSV-1; $p<0.05$). **Conclusions**: Our results suggest that IL-1β-activated pathways contributing to an AD-like phenotype in HSV-1-infected mice probably via MeCP2 and REST upregulation.

ANTEROGRADE DELIVERY OF RAB10-ORGANELLES REGULATES THE SORTING OF INTERNALISED TRKB FOR RETROGRADE AXONAL TRANSPORT.

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

Oscar Marcelo Lazo, Giampietro Schiavo
University College London, Ucl Queen Square Institute Of Neurology And Uk Dementia Research Institute At Ucl, London, United Kingdom

Neurons process real-time information coming from axon terminals to coordinate complex cellular responses, including gene expression, growth and plasticity. Input from distal axons is encoded as a stream of endocytic organelles termed signalling endosomes, which are targeted to the soma. Formation of these organelles depends on target-derived molecules, such as brain-derived neurotrophic factor (BDNF), which is recognised by TrkB receptors on the plasma membrane, endocytosed and transported to the soma along the microtubules network. Notwithstanding its physiological and neuropathological importance, the mechanism controlling the sorting of TrkB to signalling endosomes is currently unknown. In this work, we used primary mouse brain neurons and advanced confocal microscopy to uncover the small GTPase Rab10 as critical for TrkB sorting and propagation of BDNF signalling from axon terminals to the soma. We manipulated the expression and activity of Rab10 in neurons cultured in microfluidic devices, and study axonal transport, sorting of receptors and recruitment of motor proteins. Our data demonstrate that Rab10 defines a class of axonal organelles, which are rapidly mobilised towards the axon terminal upon BDNF stimulation, enabling the axon to fine-tune retrograde signalling depending on BDNF availability at the synapse. These results help to clarify the neuroprotective phenotype recently associated to Rab10 polymorphisms in Alzheimer's disease, providing novel therapeutic targets for neurodegenerative conditions.

The Rab5-Rab11 Endosomal Pathway is Required for BDNF-Induced CREB Transcriptional Regulation in Hippocampal Neurons.
Brain-derived neurotrophic factor (BDNF) is a key regulator of the morphology and connectivity of central neurons. We have previously shown that BDNF/TrkB signaling regulates the activity and mobility of the GTPases Rab5 and Rab11, which in turn determine the postendocytic sorting of signaling TrkB receptors. Moreover, decreased Rab5 or Rab11 activity inhibits BDNF-induced dendritic branching. Whether Rab5 or Rab11 activity is important for local events only or for regulating nuclear signaling and gene expression is unknown. Here, we investigated, in rat hippocampal neuronal cultures derived from embryos of unknown sex, whether BDNF-induced signaling cascades are altered when early and recycling endosomes are disrupted by the expression of dominant-negative mutants of Rab5 and Rab11. The activity of both Rab5 and Rab11 was required for sustained activity of Erk1/2 and nuclear CREB phosphorylation, and increased transcription of a BDNF-dependent program of gene expression containing CRE binding sites, which includes activity-regulated genes such as , , , , and , and growth and survival genes such as and Based on our results, we propose that early and recycling endosomes provide a platform for the integration of neurotrophic signaling from the plasma membrane to the nucleus in neurons, and that this mechanism is likely to regulate neuronal plasticity and survival. BDNF is a neurotrophic factor that regulates plastic changes in the brain, including dendritic growth. The cellular and molecular mechanisms underlying this process are not completely understood. Our results uncover the cellular requirements that central neurons possess to integrate the plasma membrane into nuclear signaling in neurons. Our results indicate that the endosomal pathway is required for the signaling cascade initiated by BDNF and its receptors at the plasma membrane to modulate BDNF-dependent gene expression and neuronal dendritic growth mediated by the CREB transcription factor. CREB is a key transcription factor regulating circuit development and learning and memory.

The evolution of the axonal transport toolkit.
Neurons are highly polarized cells that critically depend on long-range, bidirectional transport between the cell body and

synapse for their function. This continual and highly coordinated trafficking process, which takes place via the axon, has fascinated researchers since the early 20th century. Ramon y Cajal first proposed the existence of axonal trafficking of biological material after observing that dissociation of the axon from the cell body led to neuronal degeneration. Since these first indirect observations, the field has come a long way in its understanding of this fundamental process. However, these advances in our knowledge have been aided by breakthroughs in other scientific disciplines, as well as the parallel development of novel tools, techniques and model systems. In this review, we summarize the evolution of tools used to study axonal transport and discuss how their deployment has refined our understanding of this process. We also highlight innovative tools currently being developed and how their addition to the available axonal transport toolkit might help to address key outstanding questions.

The many disguises of the signalling endosome.
Neurons are highly complex and polarised cells that must overcome a series of logistic challenges to maintain homeostasis across their morphological domains. A very clear example is the propagation of neurotrophic signalling from distal axons, where target-released neurotrophins bind to their receptors and initiate signalling, towards the cell body, where nuclear and cytosolic responses are integrated. The mechanisms of propagation of neurotrophic signalling have been extensively studied and, eventually, the model of a 'signalling endosome', transporting activated receptors and associated complexes, has emerged. Nevertheless, the exact nature of this organelle remains elusive. In this Review, we examine the evidence for the retrograde transport of neurotrophins and their receptors in endosomes, outline some of their diverse physiological and pathological roles, and discuss the main interactors, morphological features and trafficking destinations of a highly flexible endosomal signalling organelle with multiple molecular signatures.

Venlafaxine treatment after endothelin-1-induced cortical stroke modulates growth factor expression and reduces tissue damage in rats.
Neuromodulators, such as antidepressants, may contribute to neuroprotection by modulating growth factor expression to exert anti-inflammatory effects and to support neuronal plasticity after stroke. Our objective was to study whether early treatment with venlafaxine, a serotonin-norepinephrine reuptake inhibitor, modulates growth factor expression and positively contributes to reducing the volume of infarcted brain tissue resulting in increased functional recovery. We studied the expression of BDNF, FGF2 and TGF-β1 by examining their mRNA and protein levels and cellular distribution using quantitative confocal microscopy at 5 days after venlafaxine treatment in control and infarcted brains. Venlafaxine treatment did not change the expression of these growth factors in sham rats. In infarcted rats, BDNF mRNA and protein levels were reduced, while the mRNA and protein levels of FGF2 and TGF-β1 were increased. Venlafaxine treatment potentiated all of the changes that were induced by cortical stroke alone. In particular, increased levels of FGF2 and TGF-β1 were observed in astrocytes at 5 days after stroke induction, and these increases were correlated with decreased astrogliosis (measured by GFAP) and increased synaptophysin immunostaining at twenty-one days after stroke in venlafaxine-treated rats. Finally, we show that venlafaxine reduced infarct volume after stroke resulting in increased functional recovery, which was measured using ladder rung motor tests, at 21 days after stroke. Our results indicate that the early oral administration of venlafaxine positively contributes to neuroprotection during the acute and late events that follow stroke.

The p75 neurotrophin receptor evades the endolysosomal route in neuronal cells, favouring multivesicular bodies specialised for exosomal release.
The p75 neurotrophin receptor (p75, also known as NGFR) is a multifaceted signalling receptor that regulates neuronal physiology, including neurite outgrowth, and survival and death decisions. A key cellular aspect regulating neurotrophin signalling is the intracellular trafficking of their receptors; however, the post-endocytic trafficking of p75 is poorly defined. We used sympathetic neurons and rat PC12 cells to study the mechanism of internalisation and post-endocytic trafficking of p75. We found that p75 internalisation depended on the clathrin adaptor protein AP2 and on dynamin. More surprisingly, p75 evaded the lysosomal route at the level of the early endosome, instead accumulating in two different types of endosomes, Rab11-positive endosomes and multivesicular bodies (MVBs) positive for CD63, a marker of the exosomal pathway. Consistently, depolarisation by KCl induced the liberation of previously endocytosed full-length p75 into the extracellular medium in exosomes. Thus, p75 defines a subpopulation of MVBs that does not mature to lysosomes and is available for exosomal release by neuronal cells.

Spatiotemporal intracellular dynamics of neurotrophin and its receptors. Implications for neurotrophin signaling and neuronal function.
Neurons possess a polarized morphology specialized to contribute to neuronal networks, and this morphology imposes an important challenge for neuronal signaling and communication. The physiology of the network is regulated by neurotrophic factors that are secreted in an activity-dependent manner modulating neuronal connectivity. Neurotrophins are a well-known family of neurotrophic factors that, together with their cognate receptors, the Trks and the p75 neurotrophin receptor, regulate neuronal plasticity and survival and determine the neuronal phenotype in healthy and regenerating neurons. Is it now becoming clear that neurotrophin signaling and vesicular transport are coordinated to modify neuronal function because disturbances of vesicular transport mechanisms lead to disturbed neurotrophin signaling and to diseases of the nervous system. This chapter summarizes our current understanding of how the regulated secretion of neurotrophin, the distribution of neurotrophin receptors in different locations of neurons, and the intracellular transport of neurotrophin-induced signaling in distal processes are achieved to allow coordinated neurotrophin signaling in the cell body and axons.

BDNF regulates Rab11-mediated recycling endosome dynamics to induce dendritic branching.
Dendritic arborization of neurons is regulated by brain-derived neurotrophic factor (BDNF) together with its receptor, TrkB. Endocytosis is required for dendritic branching and regulates TrkB signaling, but how postendocytic trafficking determines the neuronal response to BDNF is not well understood. The monomeric GTPase Rab11 regulates the dynamics of recycling endosomes and local delivery of receptors to specific dendritic compartments. We investigated whether Rab11-dependent trafficking of TrkB in dendrites regulates BDNF-induced dendritic branching in rat hippocampal neurons. We report that TrkB in dendrites is a cargo for Rab11 endosomes and that both Rab11 and its effector, MyoVb, are required for BDNF/TrkB-induced dendritic branching. In addition, BDNF induces the accumulation of Rab11-positive endosomes and GTP-bound Rab11 in dendrites and the expression of a constitutively active mutant of Rab11 is sufficient to increase dendritic branching by increasing TrkB localization in dendrites and enhancing sensitization to endogenous BDNF. We propose that Rab11-dependent dendritic recycling provides a mechanism to retain TrkB in dendrites and to increase local signaling to regulate arborization.

Cholinergic abnormalities, endosomal alterations and up-regulation of nerve growth factor signaling in Niemann-Pick type C disease.
Neurotrophins and their receptors regulate several aspects of the developing and mature nervous system, including neuronal morphology and survival. Neurotrophin receptors are active in signaling endosomes, which are organelles that propagate neurotrophin signaling along neuronal processes. Defects in the Npc1 gene are associated with the accumulation of cholesterol and lipids in late endosomes and lysosomes, leading to neurodegeneration and Niemann-Pick type C (NPC) disease. The aim of this work was to assess whether the endosomal and lysosomal alterations observed in NPC disease disrupt neurotrophin signaling. As models, we used i) NPC1-deficient mice to evaluate the central cholinergic septo-hippocampal pathway and its response to nerve growth factor (NGF) after axotomy and ii) PC12 cells treated with U18666A, a pharmacological cellular model of NPC, stimulated with NGF.

An agonistic mAb directed to the TrkC receptor juxtamembrane region defines a trophic hot spot and interactions with p75 coreceptors.
The D5 domain of TrkC receptors is a docking site for Neurotrophin-3 (NT-3), but other domains may be relevant for function or harmonizing signals with p75(NTR) coreceptors. We report a monoclonal antibody (mAb) 2B7 targeting the juxtamembrane domain of TrkC. mAb 2B7 binds to murine and human TrkC receptors and is a functional agonist that affords activation of TrkC, AKT, and MAPK. These signals result in cell survival but not in cellular differentiation. Monomeric 2B7 Fabs also affords cell survival. Binding of 2B7 mAb and 2B7 Fabs to TrkC are blocked by NT-3 in a dose-dependent manner but not by pro-NT-3. Expression of p75(NTR) coreceptors on the cell surface block the binding and function of mAb 2B7, whereas NT-3 binding and function are enhanced. mAb 2B7 defines a previously unknown neurotrophin receptor functional hot spot; that exclusively generates survival signals; that can be activated by non-dimeric ligands; and potentially unmasks a site for p75-TrkC interactions.

Axotomy-induced neurotrophic withdrawal causes the loss of phenotypic differentiation and downregulation of NGF signalling, but not death of septal cholinergic neurons.

Septal cholinergic neurons account for most of the cholinergic innervations of the hippocampus, playing a key role in the regulation of hippocampal synaptic activity. Disruption of the septo-hippocampal pathway by an experimental transection of the fimbria-fornix drastically reduces the target-derived trophic support received by cholinergic septal neurons, mainly nerve growth factor (NGF) from the hippocampus. Axotomy of cholinergic neurons induces a reduction in the number of neurons positive for cholinergic markers in the medial septum. In several studies, the reduction of cholinergic markers has been interpreted as analogous to the neurodegeneration of cholinergic cells, ruling out the possibility that neurons lose their cholinergic phenotype without dying. Understanding the mechanism of cholinergic neurodegeneration after axotomy is relevant, since this paradigm has been extensively explored as an animal model of the cholinergic impairment observed in neuropathologies such as Alzheimer's disease.The principal aim of this study was to evaluate, using modern quantitative confocal microscopy, neurodegenerative changes in septal cholinergic neurons after axotomy and to assess their response to delayed infusion of NGF in rats.

SUCELLULAR NETWORKS OF SECOND MESSENGERS SHAPE THE CONNECTIVITY OF THE VISUAL SYSTEM.

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

Sarah Baudet
Institut de la Vision, Biologie Du Dévelopement, Paris, France

Retinal ganglion cell (RGC) wiring into the brain requires axon pathfinding molecules and their downstream signaling pathways actors including cGMP, cAMP and calcium. These second messengers are also involved in a wide range of cellular processes. How they achieve specificity for each of their downstream pathway remains elusive. The spatial regulation of second messengers appeared as a flexible strategy to specifically activate downstream effectors. Using cell compartment-restricted biosensors and genetically-encoded scavengers to probe and manipulate second messengers with subcellular resolution, we identified the spatio-temporal features of cGMP, cAMP and calcium signals shaping RGC axon connectivity. Focusing on two axon repellents, slit1 and ephrinA5, and investigating lipid rafts, a microdomain of the plasma membrane, we demonstrated that these guidance molecules control second messengers in distinct compartments. Whereas the repellent activity of ephrinA5 requires the modulation of cGMP, cAMP and calcium concentration in the vicinity of lipid rafts, the signals critical for slit1-dependent axon repulsion sit in the membrane excluded from this domain. In addition, combining local biosensors and scavengers enabled to demonstrate that seconds messengers interactions differ in and outside lipid rafts. Finally, recent data suggest that altering lipid raft-restricted calcium and cGMP signaling *in vivo* affects the terminal arbors of RGC axons, in agreement with a role in ephrinA signaling. Overall, these results pave the way to understand how a limited set of signaling molecules specifically regulate their downstream cellular processes. It also provides a description of the signals involved in axonal response to repellent cues, together with their interactions.

PYK2 AND MBD2 NUCLEAR TRANSLOCATION AND INTERACTION IN HIPPOCAMPAL NEURONS

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

Tiago Mendes[1,2], Margot Chouchana[1,2], Albert Giralt[1,2], Jean-Antoine Girault[1,2]
[1]Inserm UMR-S 1270, Institut Du Fer à Moulin, Paris, France, [2]Sorbonne University, Science And Engineering Faculty, Paris, France

Pyk2 is a non-receptor calcium-dependent protein-tyrosine kinase, highly expressed in the hippocampus and able to translocate to the nucleus upon neuronal activity. MBD2 is a protein from the methyl-CpG binding domain (MBD) family, which can indirectly repress transcription and was shown to interact with Pyk2 in osteocytes. Here we aimed to assess the impact of glutamate stimulation of hippocampal neurons on (i) the nuclear translocation of Pyk2 and MBD2, (ii) their interaction, and (iii) to dissect the signaling pathway(s) involved. We observed that Pyk2 accumulates in the nucleus of hippocampal neurons in culture following stimulation of glutamate receptors, in a NMDA receptors- and calcineurin-dependent manner. MBD2 showed a similar translocation pattern. We assessed the interaction between Pyk2 and MBD2 with a proximity ligation assay (PLA) and found it was increased by glutamate stimulation. Translocation and increased interaction between Pyk2 and MBD2, may be a mechanism by which synaptic activity leads to changes in gene transcription and long-lasting alterations of neuronal properties.

ENHANCING POTASSIUM-CHLORIDE CO-TRANSPORTER-2 (KCC2) FUNCTION IN NEURONS BY TARGETING PROTEIN-PROTEIN INTERACTIONS

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

Vineeth Andisseryparambil Raveendran[1], Jessica C. Pressey[1], Satra Nim[2], Carles Corbi-Verge[2], Philip Kim[2], Melanie Woodin[1]
[1]University of Toronto, Department Of Cell And Systems Biology, Ramsay Wright Biological Laboratories, Toronto, Canada, [2]University of Toronto, Donnelly Centre For Cellular And Biomolecular Research, Toronto, Canada

Fast synaptic inhibition in the adult brain is mediated by the neurotransmitter γ-aminobutyric acid (GABA). The hyperpolarizing action of GABA requires low intracellular chloride (Cl^-) which is maintained by the potassium-chloride co-transporter 2 (KCC2) in mature neurons. KCC2 protein expression and/or function can be regulated by its interactome, which can affect its ability to extrude Cl^- ions. Altered Cl^- homeostasis is associated with various neurological disorders including autism spectrum disorder (ASD). Using two different approaches, we are investigating strategies to promote KCC2 function by targeting its interaction with novel interacting partners, namely Protein kinase C and casein kinase substrate in neurons protein 1 (PACSIN1) and 14-3-3. Our first approach used peptide-based protein-protein interaction inhibitors (PPI inhibitors) which prevent KCC2-PACSIN1 interaction. PACSIN1 is a neuron-specific protein that has been identified as a negative regulator of KCC2. Therefore, inhibiting KCC2-PACSIN1 interaction using PPI inhibitors can provide a neuron-specific therapeutic strategy to rescue KCC2. I have identified and validated two PPI inhibitors that result in hyperpolarized E_{GABA} in primary neurons indicating enhanced KCC2 function. The second approach used genetic manipulation of the ε, γ, and θ isoforms of 14-3-3 which interact with KCC2 in co-immunoprecipitation assay. Overexpression of 14-3-3 γ isoform resulted in reduced KCC2 expression in primary neurons, revealing potential targets for the development of new PPI inhibitors. The remainder of this study will examine the mechanisms underlying regulation of KCC2 by these interacting partners and further development of PPI inhibitors to treat disrupted KCC2 function in neurological disorders.

Neuronal Preconditioning Requires the Mitophagic Activity of C-terminus of HSC70-Interacting Protein.
The C terminus of HSC70-interacting protein (CHIP,) is a ubiquitously expressed cytosolic E3-ubiquitin ligase. CHIP-deficient mice exhibit cardiovascular stress and motor dysfunction before premature death. This phenotype is more consistent with animal models in which master regulators of autophagy are affected rather than with the mild phenotype of classic E3-ubiquitin ligase mutants. The cellular and biochemical events that contribute to neurodegeneration and premature aging in CHIP KO models remain poorly understood. Electron and fluorescent microscopy demonstrates that CHIP deficiency is associated with greater numbers of mitochondria, but these organelles are swollen and misshapen. Acute bioenergetic stress triggers CHIP induction and relocalization to mitochondria, where it plays a role in the removal of damaged organelles. This mitochondrial clearance is required for protection following low-level bioenergetic stress in neurons. CHIP expression overlaps with stabilization of the redox stress sensor PTEN-inducible kinase 1 (PINK1) and is associated with increased LC3-mediated mitophagy. Introducing human promoter-driven vectors with mutations in either the E3 ligase or tetracopeptide repeat domains of CHIP in primary neurons derived from CHIP-null animals enhances CHIP accumulation at mitochondria. Exposure to autophagy inhibitors suggests that the increase in mitochondrial CHIP is likely due to diminished clearance of these CHIP-tagged organelles. Proteomic analysis of WT and CHIP KO mouse brains (four male, four female per genotype)

reveals proteins essential for maintaining energetic, redox, and mitochondrial homeostasis undergo significant genotype-dependent expression changes. Together, these data support the use of CHIP-deficient animals as a predictive model of age-related degeneration with selective neuronal proteotoxicity and mitochondrial failure. Mitochondria are recognized as central determinants of neuronal function and survival. We demonstrate that C terminus of HSC70-Interacting Protein (CHIP) is critical for neuronal responses to stress. CHIP upregulation and localization to mitochondria is required for mitochondrial autophagy (mitophagy). Unlike other disease-associated E3 ligases such as Parkin and Mahogunin, CHIP controls homeostatic and stress-induced removal of mitochondria. Although CHIP deletion results in greater numbers of mitochondria, these organelles have distorted inner membranes without clear cristae. Neuronal cultures derived from animals lacking CHIP are more vulnerable to acute injuries and transient loss of CHIP renders neurons incapable of mounting a protective response after low-level stress. Together, these data suggest that CHIP is an essential regulator of mitochondrial number, cell signaling, and survival.

The Vps10p domain receptor family consists of Sortilin, SorLA, SorCS1, SorCS2 and SorCS3, which all convey intracellular sorting and internalization of specific cargo proteins in somatodendritic compartments of neurons. They interact with their N-terminal Vps10p domains with several ligands, such as neurotrophic factors and neuropeptides, and bind different cytosolic adaptor proteins with their cytoplasmic moiety. Malfunctioning of Vps10p domain receptors has been associated with a number of neurological and neuropsychological diseases including Alzheimer's disease, Huntington's disease and epilepsy. The investigation of specific cellular functions of these receptors is crucial to understand neuronal intracellular sorting mechanisms and their impact on brain function and dysfunction. To study these receptors *in vivo* e.g. in live cell imaging experiments, and without the need of specific antibodies, we established fully functional fluorophore tagged recombinant versions of all family members. Accordingly, tag positioning had to be selected carefully in order to not interfere with any function of the receptors domains. Since simple N- or C-terminal tags are not applicable due to the functional interaction sites of the receptors at either terminus an internal non-interfering insertion site for the fluorophore tag was chosen. To ensure correct protein folding the structures of the recombinant receptors were predicted computationally, expression constructs generated and exit of tagged receptors from the endoplasmic reticulum was shown in transfected cells. With these recombinant proteins we then demonstrated the subcellular localizations of the different receptors and their ability to internalize the brain derived neurotrophic factor (BDNF) independent of the tropomyosin receptor kinase B (TrkB).

The adaptor protein PICK1 targets the sorting receptor SorLA.
SorLA is a member of the Vps10p-domain (Vps10p-D) receptor family of type-I transmembrane proteins conveying neuronal endosomal sorting. The extracellular/luminal moiety of SorLA has a unique mosaic domain composition and interacts with a large number of different and partially unrelated ligands, including the amyloid precursor protein as well as amyloid-β. Several studies support a strong association of SorLA with sporadic and familial forms of Alzheimer's disease (AD). Although SorLA seems to be an important factor in AD, the large number of different ligands suggests a role as a neuronal multifunctional receptor with additional intracellular sorting capacities. Therefore, understanding the determinants of SorLA's subcellular targeting might be pertinent for understanding neuronal endosomal sorting mechanisms in general. A number of cytosolic adaptor proteins have already been demonstrated to determine intracellular trafficking of SorLA. Most of these adaptors and several ligands of the extracellular/luminal moiety are shared with the Vps10p-D receptor Sortilin. Although SorLA and Sortilin show both a predominant intracellular and endosomal localization, they are targeted to different endosomal compartments. Thus, independent adaptor proteins may convey their differential endosomal targeting. Here, we hypothesized that Sortilin and SorLA interact with the cytosolic adaptors PSD95 and PICK1 which have been shown to bind the Vps10p-D receptor SorCS3. We observed only an interaction for SorLA and PICK1 in mammalian-two-hybrid, pull-down and cellular recruitment experiments. We demonstrate by mutational analysis that the C-terminal minimal PDZ domain binding motif VIA of SorLA mediates the interaction. Moreover, we show co-localization of SorLA and PICK1 at vesicular structures in primary neurons. Although the physiological role of the interaction between PICK1 and SorLA remains unsolved, our study suggests that PICK1 partakes in regulating SorLA's intracellular itinerary.

Converging roles of PSENEN/PEN2 and CLN3 in the autophagy-lysosome system.
PSENEN/PEN2 is the smallest subunit of the γ-secretase complex, an intramembrane protease that cleaves proteins within their transmembrane domains. Mutations in components of the γ-secretase underlie familial Alzheimer disease. In addition to its proteolytic activity, supplementary, γ-secretase independent, functions in the macroautophagy/autophagy-lysosome system have been proposed. Here, we screened for PSENEN-interacting proteins and identified CLN3. Mutations in are causative for juvenile neuronal ceroid lipofuscinosis, a rare lysosomal storage disorder considered the most common neurodegenerative disease in children. As mutations in the and genes cause different neurodegenerative diseases, understanding shared cellular functions of both proteins might be pertinent for understanding general cellular mechanisms underlying neurodegeneration. We hypothesized that CLN3 modulates γ-secretase activity and that PSENEN and CLN3 play associated roles in the autophagy-lysosome system. We applied CRISPR gene-editing and obtained independent isogenic HeLa knockout cell lines for and . Following previous studies, we demonstrate that PSENEN is essential for forming a functional γ-secretase complex and is indispensable for γ-secretase activity. In contrast, CLN3 does not modulate γ-secretase activity to a significant degree. We observed in - and -knockout cells corresponding alterations in the autophagy-lysosome system. These include reduced activity of lysosomal enzymes and lysosome number, an increased number of autophagosomes, increased lysosome-autophagosome fusion, and elevated levels of TFEB (transcription factor EB). Our study strongly suggests converging roles of PSENEN and CLN3 in the autophagy-lysosome system in a γ-secretase activity-independent manner, supporting the idea of common cytopathological processes underlying different neurodegenerative diseases.

Age-Dependent Heterogeneity of Murine Olfactory Bulb Astrocytes.
Astrocytes have a high impact on the structure of the central nervous system, as they control neural activity, development, and plasticity. Heterogeneity of astrocytes has been shown before, but so far only a few studies have demonstrated heterogeneous morphology of astrocytes concerning aging. In this study, we examined morphologic differences of astrocyte subpopulations in adult mice and the progression of these differences with age. We surveyed astrocytes in olfactory bulb slices of mice aged 3 months, 1 year and 2 years (three animals each age group), based on their appearance in anti-GFAP immunostaining. Based on this data we established three different types of astrocytes: type I (stellate), type II (elliptic), and type III (squid-like). We found that with the advanced age of the mice, astrocytes grow in size and complexity. Major changes occurred between the ages of 3 months and 1 year, while between 1 and 2 years no significant development in cell size and complexity could be detected. Our results show that astrocytes in the olfactory bulb are heterogeneous and undergo morphological transformation until late adolescence but not upon senescence. Structural plasticity is further substantiated by the expression of vimentin in some astrocyte processes in all age groups.

LATERAL SODIUM DIFFUSION IN SPINY DENDRITES

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

Joel Nelson, Niklas Gerkau, Jan Meyer, Christine Rose
Heinrich Heine University Düsseldorf, Neurobiology, Duesseldorf, Germany

During glutamatergic synaptic transmission, influx of Na^+ through voltage- and ligand gated ion channels drives the depolarization of the postsynaptic site. A fast clearance of Na^+ from its point of entry is crucial for the cell, as prolonged increased intracellular Na^+ concentrations lead to persistent depolarizations. Previous work from our laboratory has established that efficient recovery from global Na^+ increases requires activity of the Na^+/K^+-ATPase, whereas local Na^+ increases are mainly cleared via lateral diffusion (Mondragão *et al.,* J Physiol 2016*).* Based on these findings, the goal of the present study was to determine the apparent diffusion constant of Na^+ along dendrites. To this end, we performed local glutamate iontophoresis coupled with whole cell patch-clamp and two-photon Na^+ imaging in the line-scan mode of CA1 pyramidal neurons in organotypic slices of the mouse brain. Combining Na^+ imaging with 3D-reconstructions of dendrites allowed us to analyze the influence of morphological properties on Na^+ dynamics. We found that Na^+ diffuses with an apparent diffusion coefficient (D_{Na+}) of 200-400 µm²/s along spiny dendrites, which is considerably less than values reported from muscle cells (600 µm²/s; Kushmerick and Podolsky 1969) or along large lizard axons (1300 µm²/s; David et al. 1997). Furthermore, our data indicate that D_{Na+} is dependent on spine density. Taken together, our study demonstrates that Na^+ diffusion along dendrites is much slower than previously thought. Moreover, it provides evidence that the presence and density of spines shape the spatiotemporal dynamics of activity-induced Na^+ signals in dendrites.

SATELLITE GLIAL CELL-PROPRIOCEPTOR INTERACTIONS IN DORSAL ROOT GANGLIA

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

Pauline Meriau[1], Sophie Guinoiseau[1], Charlène Joséphine[2], Alexis Bemelmans[2], Cendra Agulhon[1]
[1]Glia-Glia and Glia Neuron Interactions Group, Integrative Neuroscience And Cognition Centre, Umr8002, Université De Paris, Paris, France, [2]Molecular Imaging Research Center, Mircen/cea, Fontenay-aux-Roses, France

Proprioception is a sensory modality that informs the central nervous system about the precise body and limb position in order to estimate the state of movements. Thus, proprioceptive neurons play a major role in locomotion and posture. Their cell bodies are located in the dorsal root ganglia (DRG) and are tightly enwrapped by satellite glial cells (SGCs). SGCs can sense neuronal activity through their Gq protein coupled receptors (GqGPCRs) located at their plasma membrane. Under physiological conditions, SGCs maintain neuronal extracellular homeostasis *via* their hemichannels, channels, transporters. Our laboratory has found that *ex vivo* activation of GqGPCR Ca^{2+} signaling in SGCs leads to activation of proprioceptors *via* a purinergic system. To examine whether such SGC-induced Ca^{2+} elevations in proprioceptors could impact proprioceptive function in a more physiologically-relevant *in vivo* context, we used a transgenic mouse line expressing a DREADD receptor under the control of the GFAP promoter. We observed several abnormal limb positioning in DREADD mice as compared to controls, suggesting that SGC GqGPCR Ca^{2+} signaling alters sensorimotor function *in vivo*. However, a contribution of astrocytes on spinal interneuron and/or motor neuron functions or on brain cannot be excluded. To overcome this technical limitation, we have developed an approach based on Adeno-Associated Viral delivery of transgene selectively in SGCs of single DRG *in vivo*. This approach will allow us to avoid possible confounding results due to DREADD expression in glial cells elswhere than in DRG. Our results have implications in diseases with DRG SGC impairments and sensorimotor disorders.

BIOPHYSICAL PROPERTIES OF HIPPOCALCIN SIGNALING IN DIFFERENT SUB-CELLULAR COMPARTMENTS

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

Borys Olifirov[1], Sonia Nevelchuk[2], Polina Koval[2], Pavel Belan[1]
[1]Bogomoletz Institute of Physiology, Department Of Molecular Biophysics, Kyiv, Ukraine, [2]State Research Institution "Kyiv Academic University", Department Of Biophysics And Molecular Physiology, Kyiv, Ukraine

Hippocalcin (HPCA) is a neuronal calcium sensor protein controlling neuronal functions in many types of cells. Ca^{2+} binding of HPCA leads to its conformational changes and highly heterogeneous translocation from a cytosol to different sub-cellular compartments. In spite of the importance of HPCA signaling in neuronal functioning, biophysical properties of HPCA translocation in a physiological range of Ca^{2+} concentrations in the cytosol ($[Ca^{2+}]_i$) have not been studied yet. In this work, high-resolution confocal microscopy was used to follow and quantify spatio-temporal patterns of both $[Ca^{2+}]_i$ and translocation of fluorescently-labeled HPCA in HEK 293 cells. Laser-induced Ca^{2+} uncaging from NP-EGTA was used to control $[Ca^{2+}]_i$. Fast homogeneous increase in $[Ca^{2+}]_i$, induced by the uncaging, resulted in heterogeneous HPCA translocation to certain sites in the plasma membrane and trans-Golgi network indicating diverse affinity of different membranous loci to Ca^{2+}-bound HPCA. Slow decay of $[Ca^{2+}]_i$. after uncaging allowed to obtain a Ca^{2+}-dependency of HPCA translocation to different plasma membrane regions and trans-Golgi network. Half-maximal translocation for all regions was observed in a physiological range of $[Ca^{2+}]_i$ with different parameters obtained by fitting the Ca^{2+}-dependency by Hill equation. We also demonstrated a substantially stronger translocation to the plasma membrane compared to the trans-Golgi network with virtually no translocation to other intracellular membranes. We have concluded that in a physiological range of Ca^{2+} concentrations in the cytosol HPCA can function as a compartment-specific Ca^{2+} sensor having a wide dynamic range for a precise decoding of complex spatio-temporal patterns of $[Ca^{2+}]_i$ changes.

MODULATING AGE-DEPENDENT CHANGES OF NEURAL MECHANICAL PROPERTIES AFFECTS MECHANOSIGNALING AND SYNAPTIC INTEGRITY IN NEURON-GLIA COCULTURES

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

Anke Müller[1,2]
[1]Center for Behavioural Brain Sciences, Cbbs, Magdeburg, Germany, [2]Otto von Guericke University, Institute For Pharmacology And Toxicology, Magdeburg, Germany

The ability to sense mechanical stimuli and confer this information into adaptive cellular responses is relevant for many biological processes. In neurons, changes of extracellular matrix composition, ion homeostasis or cytoskeletal rearrangements within cells also generate mechanical forces. Disease features of trauma, inflammation or neurodegenerative diseases include alterations in mechanical properties of the brain and also pharmacological treatment or natural aging processes change membrane lipid composition and brain tissue rigidity but little is known about resulting consequences for cellular signaling and function. Here, we use several strategies to model alterations in brain tissue rigidity and mechanical properties of neuronal membranes to elucidate possible impacts on neuronal function. Neuron-glia cocultures were either grown on hydrogels with adjustable stiffness grades to model different tissue mechanical properties or pharmacological treatment was applied to reduce the cholesterol content of neuronal membranes in order to mimic age-related changes of neuronal membrane properties. We characterized neuron-glia cocultures based on morphological features, protein synthesis rates and key players in mechanosignaling cascades with cells either grown on altered substrate rigidity or with reduced cholesterol content. Indeed, we can confirm the dependency of synaptic integrity on membrane cholesterol and we identify alteration in the activation of key players in mechanosignaling cascades. These results further support the notion that mechanosignaling is relevant for age- and disease-induced changes in the central nervous system cells contributing to changes in neuronal function and survival in disease conditions and in the aging brain.

Biased agonism, the ability of agonists to differentially activate downstream signaling pathways by stabilizing specific receptor conformations, is a key issue for G protein-coupled receptor (GPCR) signaling. The C-terminal domain might influence this functional selectivity of GPCRs as it engages G proteins, GPCR kinases, b-arrestins, and several other proteins. Thus, the aim of this paper is to compare the agonist-dependent selectivity for intracellular pathways in a heterologous system expressing the fulllength (A2AR) and a C-tail truncated (A2A D40R lacking the last 40 amino acids) adenosine A2A receptor, a GPCR that is already targeted in Parkinson's disease using a first-in-class drug. Experimental data such as ligand binding, cAMP production, b-arrestin recruitment, ERK1/2 phosphorylation and dynamic mass redistribution assays, which correspond to different aspects of signal transduction, were measured upon the action of structurally diverse compounds (the agonists adenosine, NECA, CGS-21680, PSB-0777 and LUF-5834 and the SCH-58261 antagonist) in cells expressing A2AR and A2A D40R. The results show that taking cAMP levels and the endogenous adenosine agonist as references, the main difference in bias was obtained with PSB-0777 and LUF-5834. The C-terminus is dispensable for both G-protein and barrestin recruitment and also for MAPK activation. Unrestrained molecular dynamics simulations, at the ls timescale, were used to understand the structural arrangements of the binding cavity, triggered by these chemically different agonists, facilitating G protein binding with different efficacy.

CNRS UMR8022 - University of Paris, Integrative Neuroscience & Cognition Center, Paris, France

Proprioception is mediated by proprioceptive neurons and is crucial for important motor functions such as standing and walking. Proprioceptor cell bodies reside within the peripheral dorsal root ganglia and are tightly enveloped by satellite glial cells (SGCs). SCGs express a number of G_q protein-coupled receptors (G_q GPCRs), but their functional consequences on proprioceptor activity is unknown. We hypothesized that activation of SGC G_q GPCR-mediated Ca^{2+} signaling induces the release of neuroactive molecules from SGCs to modulate proprioceptor functions. Using 2-photon microscopy, chemogenetics, and novel genetic tools, we have discovered that SGC GPCR signaling drives proprioceptor Ca^{2+} activity through a purinergic pathway, which might alter sensorimotor functions. These findings suggest a new role for SGCs in shaping sensory information processing.

Connexins are the building blocks of electrical synapses formed between neurons and/or neurons and glial cells. This coupling is suggested to serve as a fundamental circuit element for neuronal communication and has important functional implications for network oscillations. However, most of the evidence pointing towards the formation of bona fide axonal gap junctions is based on recordings and only limited structural evidence has been presented so far. A recent study showed connexin clusters at pyramidal axon initial segments (AIS), however, their subcellular composition, potential contact points and developmental profile remain unknown. Here we provide evidence that connexin puncta indeed appear at the AIS of a vast majority of M1 pyramidal neurons. Surprisingly, they colocalize with synaptopodin, an actin-binding protein essential for the formation of the cisternal organelle, an intra- axonal Ca2+ store. Using multi-channel immunofluorescence, confocal microscopy and 3D reconstruction, we show that in 86% of all pyramidal neurons investigated, connexin43 (Cx43) is expressed at the AIS in direct proximity to synaptopodin-positive intra-axonal structures. In an attempt to better understand the subcellular distribution of connexins, protein expansion microscopy (ProExM) and 3D-PAINT superresolution microscopy were used to visualize nanoscale structural interactions between synaptopodin-positive cisternal organelles and axonal structures immunoreactive for Cx43, Cx36 and Cx45. Our future directive will be to elucidate whether the observed Cx43 staining refers to actual gap junctions with robust intercellular connections and whether or not they are of functional relevance for action potential initiation at the AIS.

MODULATION OF POINT CONTACT SIGNALING BY SUBCELLULARLY-RESTRICTED CAMP SIGNALS IN RETINAL AXONS

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

Johann Becret, Fiona Roche, Sandrine Couvet, Yvrick Zagar, Xavier Nicol
Institut de la Vision, Ile-de-france, Paris, France

Retinal ganglion cells (RGCs) exit the retina and project into the brain in a highly stereotypic manner. The establishment of these connections involves axon pathfinding and terminal arbor refinement, two processes relying on guidance cues. Intracellular integration of guidance molecules requires several molecular mechanisms, such as local second messenger signaling and cellular adhesion modulation. However, the way those processes interact with each other in axon pathfinding remains elusive. In this regard, we identified a cAMP signal in the vicinity of point contact (PC) in response to ephrin-A5, a repulsive cue. PCs are macromolecular complexes representing one of the main modalities of cellular adhesion in developing axons. Using genetically-encoded chelator, named cAMP-Sponge, we managed to buffer cAMP specifically in PCs. Hence, buffering PC-restricted cAMP signals reduces axonal retraction induced by ephrin-A5. Moreover, we provide evidence that this reduction is linked to a decrease of focal adhesion kinase (FAK) phosphorylation on its tyrosine 925. FAK is key actor of PC dynamic, and its phosphorylation on the tyrosine 925 is linked to PC disassembly. Further investigation will explore if this type of PC disassembly could explain our reduced-axonal retraction phenotype. Taken together, those results give new insights into the fine mechanisms driving RGCs axon pathfinding.

Aim: The role of synaptic SNAREs VAMP2, Syntaxin 1 and SNAP-25 in membrane fusion has been established by a large set of *in vivo* and *in vitro* experiments, particularly reconstitution assays using artificial membranes. **Method**: Here we took advantage of the generation of membrane cisternae by caveolin expression in *E. coli* to develop an assay based on co-expression of SNAREs via a polycistronic vector. We show that Syntaxin 1 formed protein complexes with VAMP2 and SNAP-25 which were regulated by co-expression of Munc-18a. Syntaxin1 interacted with caveolin and Syntaxin 1/SNAP-25/VAMP2 complexes were observed and regulated by Munc-18a in the presence of caveolin. Expression of Syntaxin1/SNAP-25/VAMP2 led to increased bacterial cell elongation in the presence of caveolin, but not in its absence. SNAP-25 was required for cell growth and the light chain of tetanus neurotoxin inhibited this process. DAPI staining further showed that increased bacterial cell elongation was not due to a defect of cell fission. Electron microscopy and super-resolution light microscopy showed that synaptic SNARE expression together with caveolin led to the partial loss of the cisternae suggesting their efficient fusion with the cytoplasmic membrane. **Result**: We propose that this assay reconstitutes membrane fusion in a simple organism with an easy-to-observe phenotype amenable to structure-function studies of SNAREs.

Neurotransmission at tripartite synapses results in Ca^{2+} signals in astrocytes, that are essential to brain function and impaired in brain disorders. The majority of astrocytic Ca^{2+} signals result from Ca^{2+} fluxes from the endoplasmic reticulum. As most perisynaptic astrocytic processes (PAPs) are below the diffraction limit, the presence of ER in PAPs and its involvement in local Ca^{2+} activity is unclear and highly debated. Here, we reconstruct 3D meshes of hippocampal tripartite synapses from electron microscopy. We find that 75% of PAPs contain some ER, which can be as close as 72 nm from the synapse. We further quantify the geometrical properties of the ER in PAPs, highlighting its diversity. Reaction-diffusion simulations in the realistic 3D PAP meshes were then performed to test the effect of ER shape on Ca^{2+} activity in PAPs. To discern the effect of ER distribution from ER shape, we provide an algorithm that automatically creates realistic 3D PAP meshes with various ER distributions and constant shape. Simulations in those realistic 3D meshes reveal the complex interplay between the clustering of Ca^{2+} channels, the ER surface-volume ratio, Ca^{2+} buffering and the size of ER-PM contact sites that shapes the spatio-temporal properties of Ca^{2+} signals in PAPs. Overall, this study provides key insights into the mechanisms that regulate astrocyte activity at tripartite synapses.

Simulation of calcium signaling in fine astrocytic processes: Effect of spatial properties on spontaneous activity.
Astrocytes, a glial cell type of the central nervous system, have emerged as detectors and regulators of neuronal information processing. Astrocyte excitability resides in transient variations of free cytosolic calcium concentration over a range of temporal and spatial scales, from sub-microdomains to waves propagating throughout the cell. Despite extensive experimental approaches, it is not clear how these signals are transmitted to and integrated within an astrocyte. The localization of the main molecular actors and the geometry of the system, including the spatial organization of calcium channels IP3R, are deemed essential. However, as most calcium signals occur in astrocytic ramifications that are too fine to be resolved by conventional light microscopy, most of those spatial data are unknown and computational modeling remains the only methodology to study this issue. Here, we propose an IP3R-mediated calcium signaling model for dynamics in such small sub-cellular volumes. To account for the expected stochasticity and low copy numbers, our model is both spatially explicit and particle-based. Extensive simulations show that spontaneous calcium signals arise in the model via the interplay between excitability and stochasticity. The model reproduces the main forms of calcium signals and indicates that their frequency crucially depends on the spatial organization of the IP3R channels. Importantly, we show that two processes expressing exactly the same calcium channels can display different types of calcium signals depending on the spatial organization of the channels. Our model with realistic process volume and calcium concentrations successfully reproduces spontaneous calcium signals that we measured in calcium micro-domains with confocal microscopy and predicts that local variations of calcium indicators might contribute to the diversity of calcium signals observed in astrocytes. To our knowledge, this model is the first model suited to investigate calcium dynamics in fine astrocytic processes and to propose plausible mechanisms responsible for their variability.

Modulation of astrocyte reactivity improves functional deficits in mouse models of Alzheimer's disease.

Astrocyte reactivity and neuroinflammation are hallmarks of CNS pathological conditions such as Alzheimer's disease. However, the specific role of reactive astrocytes is still debated. This controversy may stem from the fact that most strategies used to modulate astrocyte reactivity and explore its contribution to disease outcomes have only limited specificity. Moreover, reactive astrocytes are now emerging as heterogeneous cells and all types of astrocyte reactivity may not be controlled efficiently by such strategies.Here, we used cell type-specific approaches in vivo and identified the JAK2-STAT3 pathway, as necessary and sufficient for the induction and maintenance of astrocyte reactivity. Modulation of this cascade by viral gene transfer in mouse astrocytes efficiently controlled several morphological and molecular features of reactivity. Inhibition of this pathway in mouse models of Alzheimer's disease improved three key pathological hallmarks by reducing amyloid deposition, improving spatial learning and restoring synaptic deficits.In conclusion, the JAK2-STAT3 cascade operates as a master regulator of astrocyte reactivity in vivo. Its inhibition offers new therapeutic opportunities for Alzheimer's disease.

UNRAVELING THE MOLECULAR CONTROL OF INTRAORGANELLAR CA2+ FLUXES USING NOVEL CA2+ INTEGRATORS

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

Lorenzo Calzado-Reyes[1], Aurélien Boré[2], Michel Wassef[2], Raphaël Margueron[2], Eric Schreiter[3], Jaime De Juan-Sanz[1]
[1]Sorbonne Université, Institut du Cerveau - Paris Brain Institute - ICM, Inserm, CNRS, APHP, Hôpital de la Pitié Salpêtrière, Neurophysiology Department, PARIS, France, [2]PSL Research University, Institut Curie, Crispr'it, Platform For Genetic Screens, Inserm U934, Cnrs Umr3215, Paris, France, [3]Howard Hughes Medical Institiute, Janelia Research Campus, Ashburn, United States of America

Although the endoplasmic reticulum (ER) extends throughout all locations in neurons and neuronal ER dysfunction is implicated in numerous neurological diseases, the molecular control of ER Ca^{2+} fluxes remains poorly understood. Sarco-endoplasmic reticulum Ca^{2+}-ATPase (SERCA) is constitutively active and transports Ca^{2+} continuosly inside the ER, counteracting the action of an unknown mechanism that leaks Ca^{2+} from the ER into the cytosol. Blocking SERCA pharmacologically, causes a quick depletion of the ER Ca^{2+}, resulting in a state in which the lack of ER Ca^{2+} severely affects neurotransmission. Despite the vital importance of the ER Ca^{2+} leak pathway for neurons, however, the molecular identity of the protein driving this process remains a mistery. We developed a new optical tool that can generate a temporally-precise "ER Ca^{2+} content snapshot". This tool, named ER-CaMPARI, undergoes efficient and irreversible green-to-red conversion only when ER Ca^{2+} is at normal levels and UV illumination coincide at the same time. Conversely, such tool does not convert to red after thapsigargin-induced depletion, which allows to isolate cells that are resistant to ER Ca^{2+} depletion. Combining this sensor with a genome-wide CRISPR-Cas9 knockout screen, we aim to identify the driving mechanisms of ER Ca^{2+} depletion, as we can match the lack of a particular gene with the resistance to ER Ca^{2+} depletion. The use of organelle-specific CaMPARI variants should prove useful in identifying the molecular basis of neuronal disease states associated with organelle Ca^{2+} dyshomeostasis, and as an example we have also generated Mito-CaMPARIs, optimized to explore mitochondrial Ca^{2+} biology.

VIRUS-MEDIATED ASTROCYTE CAMP QUANTIFICATION

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

Valentin Ritou[1], Bruna Rubino[1], Cendra Agulhon[1], Alexis Bemelmans[2]
[1]Integrative Neuroscience and Cognition Center, CNRS, UMR8002, Université de Paris, France, Glia-glia And Glia Neuron Interactions Group, Paris, France, [2]Molecular Imaging Research Center, MIRCen, Cea, Fontenay-aux-Roses cedex, France

Astrocytes are the most abundant glial cell type in the central nervous system. They can express many different receptors, such as G-Protein Coupled Receptors (GPCRs). The activation of Gi and Gs GPCRs leads to a decrease or increase of cAMP concentration, respectively. cAMP-dependant pathways are known to modulate synaptic plasticity and memory, and thus constitute crucial components of the glia-neuron relationship. Dysregulations of the aforementioned astrocytic pathways might be implicated in the aetiology of many psychiatric disorders. Investigating astrocyte cAMP dynamics *in* and *ex vivo* is thus critical. So far, only a few tools are available to quantify specifically astrocytic changes in cAMP. Here, we present the characterisation of an adeno-associated viral tool that can be stereotaxically injected and allows *in/ex vivo* visualisation and quantification of astrocyte cAMP dynamics.

MECHANISTIC INSIGHTS INTO VAMP7-DEPENDENT UNCONVENTIONAL SECRETION IN NEURON-GLIOBLASTOMA CELL COMMUNICATION

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

Somya Vats[1], Sebastien Nola[1], Thibaud Martial[1], Eric Chevet[2], Thierry Galli[1,3]
[1]Université Paris Cité, Institut de Psychiatrie et Neurosciences de Paris, INSERM U1266, Membrane Trafficking In Healthy And Diseased Brain, Paris, France, [2]Inserm U1242, Université de Rennes, Centre De Lutte Contre Le Cancer Eugène Marquis, Rennes, France, [3]GHU PARIS psychiatrie & neurosciences, Hospital Centre Sainte Anne, Paris, France

Aim: To study VAMP7-dependent unconventional secretion in neuron-glioblastoma cell communication Methods: Secretome analysis, Proteomics, genetic alterations, super-resolution microscopy Description and results: Communication between cells, particularly neuronal and non-neuronal cells is important for proper development and function. Conventional secretion which is ER-Golgi mediated relies on secretory vesicles. In the brain, that involves synaptic vesicle and secretory granule mediated release of classical neurotransmitters. However, the molecules released by the vesicular late-endosome mediated unconventional secretion in the brain and their effects are largely unidentified. Recent work by our lab has characterized a new secretory autophagy-like pathway dependent on VAMP7, a tetanus neurotoxin insensitive v-SNARE. We show that ER and mitochondrial elements can be incorporated into late endosomes and can later be released by a secretory mechanism. This process is more efficient in the absence of degradative autophagy. We further observed that in this scenario, neurites grow longer and the neuronal polarity is altered. Conclusions: We combine genetic alterations in the rat, lipidomics, proteomics, metabolomics, and super-resolution microscopy to dissect the mechanisms regulating the VAMP7 dependent secretion. Furthermore, VAMP7 has also recently been linked to various cancers. As VAMP7 is a bridge connecting secretion, cancer migration and invasion and neuronal growth, we are studying the effects of VAMP7 dependent secretion on glioblastoma particularly towards understanding the effect of neuronal VAMP7 dependent secretion on glioblastoma and vice versa.

SELENOT IS A GUARDIAN OF ER HOMEOSTASIS IN POMC NEURONS

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

Isabelle Lihrmann[1], Dorthe Cartier[1], Christine Bucharles[1], Carole Burel[2], Marie-Laure Wallet-Balieu[3], Philippe Chan Tchi Song[3], Muriel Bardor[2], Youssef Anouar[1], Cédric Jehan[1]

POMC neurons in the hypothalamus play an anorexigenic role in the regulation of food intake via the release of α-MSH derived from post-translational cleavage of POMC in response to various metabolic signals such as lipids, hormones or carbohydrates. In a mouse model of obesity induced by a high-fat diet, ER stress is observed in these neurons, as well as an accumulation of POMC in the ER leading to a defect in α-MSH secretion. In this study, we examined the role of a selenoprotein, SELENOT, in POMC neurons physiology, given its essential role in ER homeostasis and its neuroprotective effect in some models of neurodegenerative diseases. To this end, SELENOT was silenced and ER homeostasis, neuronal differentiation and secretion were examined. We found major defects in SELENOT KO neurons compared to wild-type neurons, including increased ER and cell volume, altered disulfide isomerase distribution, loss of ER/plasma membrane contacts, defects in adhesion, vesicle trafficking, neuritogenesis, and increased senescence. To go further, a thiol trapping approach was performed to identify SELENOT partners. Immunoprecipitation of SELENOT followed by mass spectrometry analysis revealed significant enrichment of partners involved in ER protein folding and N-glycosylation. Comparison of N-glycomes between wild-type and KO cells revealed the species-specific loss of sialylated polysaccharides. Several potential redox partners have been identified and ongoing studies are aimed at determining the nature and role of their interaction with SELENOT in the secretory pathway.

LOSS OF KINESIN KIF2A CAUSES PREMATURE NEURODEGENERATION.

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

Nuria Ruiz Reig[1], Georges Chehade[1], Janne Hakanen[1], Keimpe Wierda[2], Joris De Wit[3], Laurent Nguyen[4], Philippe Gailly[5], Fadel Tissir[1,6]
[1]Université catholique de Louvain (UCLouvain), Institute Of Neuroscience, Laboratory Of Developmental Neurobiology, Brussels, Belgium, [2]VIB-KU Leuven Center for Brain & Disease Research, Electrophysiology Expert Unit, Leuven, Belgium, [3]VIB Center for Brain & Disease Research, Ku Leuven, Department Of Neurosciences, Leuven, Belgium, [4]University of Liège, C.H.U., Giga-stem Cells, Interdisciplinary Cluster For Applie Genoproteomics (giga-r), Liège, Belgium, [5]Université catholique de Louvain (UCLouvain), Institute Of Neuroscience, Laboratory Of Cell Physiology, Brussels, Belgium, [6]Hamad Bin Khalifa University, College Of Health And Life Sciences, Doha, Qatar

KIF2A is a microtubule-dependent Kinesin that has the capacity to depolymerize microtubules. Patients with dysfunctional KIF2A present microcephaly and intellectual disability, and this has been ascribed to its role in mitotic progression, progenitors fate determination, and neuron production. In this study, we report that KIF2A is necessary for postnatal stages to assemble and maintain cortical circuitries; and that KIF2A-related microcephaly results from connectivity defects and premature neurodegeneration rather than impaired neurogenesis. Cortical neurons, with specific ablation of KIF2A, displayed abnormalities in polarity, neuritogenesis, and synaptogenesis. These neurons exhibited aberrant electrophysiological properties, failed to connect properly, and eventually died. Mechanistically, we show that lack of KIF2A alters the intracellular transport of lysosomes and distribution of insulin-like growth factor-1 receptor, which compromises the PI3K/Akt/mTOR and Erk survival pathways and leads to premature loss of neurons.

The Celsr3-Kif2a axis directs neuronal migration in the postnatal brain.
The tangential migration of immature neurons in the postnatal brain involves consecutive migration cycles and depends on constant remodeling of the cell cytoskeleton, particularly in the leading process (LP). Despite the identification of several proteins with permissive and empowering functions, the mechanisms that specify the direction of migration remain largely unknown. Here, we report that planar cell polarity protein Celsr3 orients neuroblasts migration from the subventricular zone (SVZ) to olfactory bulb (OB). In Celsr3-forebrain conditional knockout mice, neuroblasts loose directionality and few can reach the OB. Celsr3-deficient neuroblasts exhibit aberrant branching of LP, de novo LP formation, and decreased growth rate of microtubules (MT). Mechanistically, we show that Celsr3 interacts physically with Kif2a, a MT depolymerizing protein and that conditional inactivation of Kif2a in the forebrain recapitulates the Celsr3 knockout phenotype. Our findings provide evidence that Celsr3 and Kif2a cooperatively specify the directionality of neuroblasts tangential migration in the postnatal brain.

DIAPH3 deficiency links microtubules to mitotic errors, defective neurogenesis, and brain dysfunction.
Diaphanous (DIAPH) three (DIAPH3) is a member of the formin proteins that have the capacity to nucleate and elongate actin filaments and, therefore, to remodel the cytoskeleton. DIAPH3 is essential for cytokinesis as its dysfunction impairs the contractile ring and produces multinucleated cells. Here, we report that DIAPH3 localizes at the centrosome during mitosis and regulates the assembly and bipolarity of the mitotic spindle. DIAPH3-deficient cells display disorganized cytoskeleton and multipolar spindles. DIAPH3 deficiency disrupts the expression and/or stability of several proteins including the kinetochore-associated protein SPAG5. DIAPH3 and SPAG5 have similar expression patterns in the developing brain and overlapping subcellular localization during mitosis. Knockdown of SPAG5 phenocopies DIAPH3 deficiency, whereas its overexpression rescues the DIAHP3 knockdown phenotype. Conditional inactivation of in mouse cerebral cortex profoundly disrupts

neurogenesis, depleting cortical progenitors and neurons, leading to cortical malformation and autistic-like behavior. Our data uncover the uncharacterized functions of DIAPH3 and provide evidence that this protein belongs to a molecular toolbox that links microtubule dynamics during mitosis to aneuploidy, cell death, fate determination defects, and cortical malformation.

Linking Cell Polarity to Cortical Development and Malformations.
Cell polarity refers to the asymmetric distribution of signaling molecules, cellular organelles, and cytoskeleton in a cell. Neural progenitors and neurons are highly polarized cells in which the cell membrane and cytoplasmic components are compartmentalized into distinct functional domains in response to internal and external cues that coordinate polarity and behavior during development and disease. In neural progenitor cells, polarity has a prominent impact on cell shape and coordinate several processes such as adhesion, division, and fate determination. Polarity also accompanies a neuron from the beginning until the end of its life. It is essential for development and later functionality of neuronal circuitries. During development, polarity governs transitions between multipolar and bipolar during migration of postmitotic neurons, and directs the specification and directional growth of axons. Once reaching final positions in cortical layers, neurons form dendrites which become compartmentalized to ensure proper establishment of neuronal connections and signaling. Changes in neuronal polarity induce signaling cascades that regulate cytoskeletal changes, as well as mRNA, protein, and vesicle trafficking, required for synapses to form and function. Hence, defects in establishing and maintaining cell polarity are associated with several neural disorders such as microcephaly, lissencephaly, schizophrenia, autism, and epilepsy. In this review we summarize the role of polarity genes in cortical development and emphasize the relationship between polarity dysfunctions and cortical malformations.

Developmental Requirement of Homeoprotein Otx2 for Specific Habenulo-Interpeduncular Subcircuits.
The habenulo-interpeduncular system (HIPS) is now recognized as a critical circuit modulating aversion, reward, and social behavior. There is evidence that dysfunction of this circuit leads to psychiatric disorders. Because psychiatric diseases may originate in developmental abnormalities, it is crucial to investigate the developmental mechanisms controlling the formation of the HIPS. Thus far, this issue has been the focus of limited studies. Here, we explored the developmental processes underlying the formation of the medial habenula (MHb) and its unique output, the interpeduncular nucleus (IPN), in mice independently of their gender. We report that the homeobox gene is essential for the proper development of both structures. We show that MHb and IPN neurons require at different developmental stages and, in both cases, deletion leads to disruption of HIPS subcircuits. Finally, we show that Otx2 neurons tend to be preferentially interconnected. This study reveals that synaptically connected components of the HIPS, despite radically different developmental strategies, share high sensitivity to expression. Brain reward circuits are highly complex and still poorly understood. In particular, it is important to understand how these circuits form as many psychiatric diseases may arise from their abnormal development. This work shows that , a critical evolutionary conserved gene implicated in brain development and a predisposing factor for psychiatric diseases, is required for the formation of the habenulo-interpeduncular system (HIPS), an important component of the reward circuit. Otx2 deletion affects multiple processes such as proliferation and migration of HIPS neurons. Furthermore, neurons expressing are preferentially interconnected. Therefore, expression may represent a code that specifies the connectivity of functional subunits of the HIPS. Importantly, the conditional knock-out animals used in this study might represent a new genetic model of psychiatric diseases.

The caudo-ventral pallium is a novel pallial domain expressing Gdf10 and generating Ebf3-positive neurons of the medial amygdala.
In rodents, the medial nucleus of the amygdala receives direct inputs from the accessory olfactory bulbs and is mainly implicated in pheromone-mediated reproductive and defensive behaviors. The principal neurons of the medial amygdala are GABAergic neurons generated principally in the caudo-ventral medial ganglionic eminence and preoptic area. Beside GABAergic neurons, the medial amygdala also contains glutamatergic Otp-expressing neurons cells generated in the lateral hypothalamic neuroepithelium and a non-well characterized Pax6-positive population. In the present work, we describe a novel glutamatergic Ebf3-expressing neuronal subpopulation distributed within the periphery of the postero-ventral medial amygdala. These neurons are generated in a pallial domain characterized by high expression of Gdf10. This territory is topologically the most caudal tier of the ventral pallium and accordingly, we named it Caudo-Ventral Pallium (CVP). In the absence of Pax6, the CVP is disrupted and Ebf3-expressing neurons fail to be generated. Overall, this work proposes a novel model of the neuronal composition of the medial amygdala and unravels for the first time a new novel pallial subpopulation originating from the CVP and expressing the transcription factor Ebf3.

Rostro-Caudal and Caudo-Rostral Migrations in the Telencephalon: Going Forward or Backward?
The generation and differentiation of an appropriate number of neurons, as well as its distribution in different parts of the brain, is crucial for the proper establishment, maintenance and plasticity of neural circuitries. Newborn neurons travel along the brain in a process known as neuronal migration, to finalize their correct position in the nervous system. Defects in neuronal migration produce abnormalities in the brain that can generate neurodevelopmental pathologies, such as autism, schizophrenia and intellectual disability. In this review, we present an overview of the developmental origin of the different telencephalic subdivisions and a description of migratory pathways taken by distinct neural populations traveling long distances before reaching their target position in the brain. In addition, we discuss some of the molecules implicated in the guidance of these migratory paths and transcription factors that contribute to the correct migration and integration of these neurons.

Lateral Thalamic Eminence: A Novel Origin for mGluR1/Lot Cells.
A unique population of cells, called "lot cells," circumscribes the path of the lateral olfactory tract (LOT) in the rodent brain and acts to restrict its position at the lateral margin of the telencephalon. Lot cells were believed to originate in the dorsal pallium (DP). We show that Lhx2 null mice that lack a DP show a significant increase in the number of mGluR1/lot cells in the piriform cortex, indicating a non-DP origin of these cells. Since lot cells present common developmental features with Cajal-Retzius (CR) cells, we analyzed Wnt3a- and Dbx1-reporter mouse lines and found that mGluR1/lot cells are not generated in the cortical hem, ventral pallium, or septum, the best characterized sources of CR cells. Finally, we identified a novel origin for the lot cells by combining in utero electroporation assays and histochemical characterization. We show that mGluR1/lot cells are specifically generated in the lateral thalamic eminence and that they express mitral cell markers, although a minority of them express ΔNp73 instead. We conclude that most mGluR1/lot cells are prospective mitral cells migrating to the accessory olfactory bulb (OB), whereas mGluR1+, ΔNp73+ cells are CR cells that migrate through the LOT to the piriform cortex and the OB.

Molecular control of two novel migratory paths for CGE-derived interneurons in the developing mouse brain.
GABAergic interneurons are highly heterogeneous and originate in the subpallium mainly from the medial (MGE) and caudal (CGE) ganglionic eminences according to a precise temporal sequence. MGE-derived cells disperse dorsally and migrate towards all regions of the cortex, but little is known about how CGE-derived cells reach their targets during development. Here, we unravel the existence of two novel CGE caudo-rostral migratory streams, one located laterally (LMS) and the other one more medially (MMS), that, together with the well-known caudal migratory stream (CMS), contribute to populate the neocortex, hippocampus and amygdala. These paths appear in a precise temporal sequence and express a distinct combination of transcription factors, such as SP8, PROX1, COUP-TFI and COUP-TFII. By inactivating COUP-TFI in developing interneurons, the lateral and medial streams are perturbed and expression of SP8 and COUP-TFII affected. As a consequence, adult mutant neocortices have laminar-specific alterations of distinct cortical interneuron subtypes. Overall, we propose that the existence of spatially and temporally regulated migratory paths in the subpallium contributes to the laminar distribution and specification of distinct interneuron subpopulations in the adult brain.

Zic2 Controls the Migration of Specific Neuronal Populations in the Developing Forebrain.
Human mutations in ZIC2 have been identified in patients with holoprosencephaly and schizophrenia. Similarly, Zic2 mutant mice exhibit holoprosencephaly in homozygosis and behavioral and morphological schizophrenic phenotypes associated with forebrain defects in heterozygosis. Despite the devastating effects of mutations in Zic2, the cellular and molecular mechanisms that provoke Zic2-deficiency phenotypes are yet unclear. Here, we report a novel role for this transcription factor in the migration of three different types of forebrain neurons: the Cajal-Retzius cells that populate the surface of the telencephalic vesicles, an amygdaloid group of cells originated in the caudal pole of the telencephalic pallium, and a cell population that travels from the prethalamic neuroepithelium to the ventral lateral geniculate nucleus. Our results also suggest that the receptor EphB1, previously identified as a Zic2 target, may mediate, at least partially, Zic2-dependent migratory events. According to these results, we propose that deficiencies in cell motility and guidance contribute to most of the forebrain pathologies associated with Zic2 mutations.

Oral self-administration of buprenorphine in the diet for analgesia in mice.

Postsurgical oral self-administration of analgesics in rodents is an interesting technique of providing analgesia, avoiding the negative effects of manipulation. Several strategies, using gelatin or nutella, have already been described. However, rodents require some habituation period to reach a good intake because of their neophobic behavior. The current study aimed to explore whether buprenorphine when mixed with an extruded diet offers a potential treatment option in the pain management of mice using a triple approach: by measuring the spontaneous intake in healthy animals; by using the hot-plate test; and finally by assessing the drug's ability to provide postoperative analgesia in a surgical intervention of moderate severity (intra-utero electroporation). Mice consumed during 20 hours, similar amounts of extruded diet alone, mixed with glucosaline, and mixed with buprenorphine (0.03 mg per pellet) or meloxicam (0.25 mg per pellet) both of which were diluted in glucosaline, showing that no neophobia was associated with these administrations. Relative increase from baseline latency (% maximal possible effect) in the hot-plate test at 20 h of administration was significantly higher for oral buprenorphine in diet 0.03 mg/pellet, and diet 0.15 mg/pellet, compared with placebo and no differences were found between those oral administrations and subcutaneous buprenorphine 0.1 mg/kg measured 3 h later. The treatment was also effective in attenuating the reductions in food consumption and body weight that occur after surgery. These data suggest that providing buprenorphine with the diet is a feasible and effective way of self-administration of analgesia in mice and does not cause neophobia and may easily contribute to the refinement of surgical procedures.

AUTOPHAGY AND MICROTUBULES-MEDIATED CYTOSKELETON DYNAMICS IN UBIQUITIN LIGASE E3A (UBE3A)-DEFICIENT NEURONS

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

Ilaria Tonazzini[1,2], Edwin Mientjes[1], Ype Elgersma[1], Marco Cecchini[2]
[1]Erasmus Medical Center, Department Of Neuroscience, Rotterdam, Netherlands, [2]Istituto Nanoscienze Consiglio Nazionale delle Ricerche (CNR) and Scuola Normale Superiore, National Enterprise For Nanoscience And Nanotechnology (nest), Pisa, Italy

Ubiquitin E3A ligase (**UBE3A**) has crucial functions in the brain and changes in its expression levels lead to neurodevelopmental disorders, to Angelman Syndrome (**AS**) or 15duplication-autisms. We investigated neuronal guidance *in vitro* in UBE3A-deficient neurons, model of AS, by using micro-grooved substrates (GRs) that can induce specific directional stimuli to cells. We found deficits in topographical contact guidance in AS neurons, linked to a dysregulated focal adhesions' sensing and cytoskeleton polarization, with an aberrant axonal branching on GRs. Recently, it emerged that cytoskeleton and autophagy processes are connected, and of pivotal importance for neuronal homeostasis and development. The cytoskeleton has an important role in autophagy, the process by which cellular waste is isolated inside specialized vesicles called autophagosomes for recycling and degradation. Here, we investigate the trafficking of cytoskeletal cargos along microtubules and the autophagy process in primary AS neurons, under control and stimulated conditions. The migration behaviour of wild-type and AS neurons, under control or stimulated conditions, is also shown, with the aim to clarify UBE3A role during neurodevelopment. We show that the loss of axonal guidance in AS neurons is related to an impairment in the microtubules-mediated process and that the autophagy flux is dysregulated in AS neurons. Overall, cytoskeleton dynamics and autophagy response emerge as players in UBE3A-mediated pathogenesis. These results support the view that UBE3A-related deficits in early neuronal morphogenesis and homeostasis may lead to defective neuronal connectivity and plasticity. This work was supported by MSCA-IF-2017 grant Neuroguide-795948.

A crucial step in the assembly of neuronal circuits lies in the accurate growth and navigation of developing axons toward their appropriate targets. These axon outgrowth and pathfinding processes involve fine tuned and synchronized modifications of actin filament (F-actin) and microtubule dynamics/structure inside the growth cone. However, the numerous players that coordinate the remodelling of both cytoskeletons to drive growth cone steering remain largely unknown. We previously uncovered the microtubule-associated ATPase fidgetin-like1 (fignl1) as a key regulator of microtubule plus-end dynamics required for zebrafish spinal motor axon navigation. We here aim to investigate the role of this ATPase in the microtubule/actin crosstalk underlying axon guidance in the mammalian central nervous system, using the visual system as a model. We showed that fignl1 is highly expressed in retinal axons at the pick phase of axon navigation at the optic chiasm (E15). Using primary cultures of mouse retinal explants, we further showed that fignl1 overexpression drastically impairs retinal axon outgrowth and leads to ectopic branching while its knockdown reduces axon extension. Moreover, we demonstrated that Fignl1-GFP localizes to F-actin-rich regions in retinal growth cones where it moves with the actin retrograde flow. Consistently, recombinant Fignl1 binds F-actin in *in vitro* co-peletting assays. To further dissect the roles of this microtubule- and F-actin-binding protein in visual circuit wiring, we generated a retinal-specific fignl1 conditional mutant. Extensive characterization of the physiological, cellular and molecular phenotypes of fignl1-deficient embryos should shed new lights on the basic mechanisms governing the microtubule/F-actin crosstalk underlying neuronal connectivity.

VISUALIZATION OF MAP6-POSITIVE MICROTUBULES THROUGHOUT THE NEURONAL MT NETWORK: INPUT OF EXPANSION MICROSCOPY

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

Sylvie Gory-Fauré, Eric Denarier, Isabelle Arnal, Annie Andrieux
Grenoble Institut Neuroscience - INSERM U1216 - CEA IRIG, Team Neurocytoskeleton Dynamics And Structure, Grenoble, France

The shaft of neuron extensions contains bundles of microtubules allowing the continuity of cellular space to reach a length of one meter in humans. In neurons, microtubules properties and functions are regulated by a myriad of accessory proteins including microtubules associated proteins (MAPs) such as Tau, MAP1B or MAP6. Microtubule stability relies on 1/post-translational modifications of tubulin with tyrosinated and detyrosinated/acetylated tubulin isotypes associated with dynamic and stable microtubules, respectively 2/the binding of MAPs. Here we focus on the neuronal protein MAP6 able to protect microtubules against drug- and cold-induced depolymerization and recently shown to localize in microtubule lumen. We charted dynamic and stable microtubules as well as MAP6-positive microtubules throughout the neuronal microtubule network. To reach this objective we have combined 8X expansion microscopy and super-resolution light imaging allowing to visualize individual microtubules in neuronal shafts of cultured hippocampal neurons. We observed tyrosinated microtubules at neurites borders whereas detyrosinated/acetylated microtubules are present in the central part of neurites. MAP6-positive microtubules preferentially co-localized with detyrosinated/acetylated microtubules. Thanks to MAP6 deficient neurons, we investigate possible causal roles of MAP6 in the segregation of dynamic and stable microtubules populations. Also, in rescue experiments with a MAP6 mutant unable to enter microtubule lumen, we are investigating if MAP6 luminal localization dictate its presence on stable microtubules. Deciphering the sub-cellular localisation and organisation of various kinds of microtubules within the whole neuronal network should establish the respective and combined contributions of tubulin isotypes and MAPs to microtubule identity and stability.

Ependymal cells have multiple apical cilia that line the ventricular surfaces and the central canal of spinal cord. In cancer, the loss of ependymal cell polarity promotes the formation of different types of tumors, such as supratentorial anaplastic ependymomas, which are highly aggressive in children. IIIG9 (PPP1R32) is a protein restricted to adult ependymal cells located in cilia and in the apical cytoplasm and has unknown function. In this work, we studied the expression and localization of IIIG9 in the adherens junctions (cadherin/β-catenin-positive junctions) of adult brain ependymal cells using confocal and transmission electron microscopy. Through in vivo loss-of-function studies, ependymal denudation (single-dose injection experiments of inhibitory adenovirus) was observed, inducing the formation of ependymal cells with a “balloon-like” morphology. These cells had reduced cadherin expression (and/or delocalization) and cleavage of the cell death marker caspase-3, with “cilia rigidity” morphology (probably vibrational beating activity) and ventriculomegaly occurring prior to these events. Finally, after performing continuous infusions of adenovirus for 14 days, we observed total cell denudation and reactive parenchymal astrogliosis. Our data confirmed that IIIG9 is essential for the maintenance of adherens junctions of polarized ependymal cells. Eventually, altered levels of this protein in ependymal cell differentiation may increase ventricular pathologies, such as hydrocephalus or neoplastic transformation.

DIFFERENTIAL AXONAL TRAFFICKING OF NEUROPEPTIDE Y-, LAMP1- AND RAB7-TAGGED ORGANELLES IN VIVO

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

Joris Paul Nassal
VU University Amsterdam and VU University Medical Center, Departments Of Functional Genomics And Clinical Genetics, Center For Neurogenomics And Cognitive Research (cncr), Amsterdam, Netherlands

A variety of neuronal organelles with diverse functions are transported throughout the axons. The precise delivery of cargo is crucial for neurons to function. The mechanism of organelle trafficking and positioning has been the target of recent studies. Organelle trafficking is typically studied in in vitro model systems, which lack the full complexity of intact brain tissue. We utilized simultaneous dual colour 2-photon microscopy to visualize the trafficking of Neuropeptide Y-, Lamp1- and Rab7-tagged organelles in thalamocortical axons imaged in mouse cortex in vivo. The parallel imaging revealed that Lamp1- and Rab7-tagged organelles move faster than NPY tagged organelles. NPY is also trafficked more selectively in anterograde direction. By the use of a synapse marker and a calcium sensor we further investigated the transport dynamics of NPY-tagged organelles. We found that NPY-tagged organelles, which are transported in anterograde direction slow down at synapses. In contrast to previous in vitro studies, no significant change of transport speed was observed during spontaneously occurring activity and elevated calcium levels in vivo as well as electrically stimulated activity in acute brain slices.

ELUCIDATING THE ROLE OF STIM PROTEINS IN NEURONAL ER-PM CONTACTS AND THEIR ROLE IN SYNAPTIC PLASTICITY AND ARCHITECTURE.

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

Arun Chhikara[1], Filip Maciag[1], Martin Heine[1], Kay Grünewald[2], Karin Ruban[2]
[1]Johannes Gutenberg University of Mainz, Institut Für Entwicklungsbiologie Und Neurobiologie (idn), Mainz, Germany, [2]Institute of Biochemistry and Molecular Biology, University of Hamburg, Centre For Structural Systems Biology (cssb), Hamburg, Germany

The physical proximity of the endoplasmic reticulum (ER) and the plasma membrane (PM) at contact sites, i.e., ER-PM junctions, enables ER and PM proteins to interact directly. These junctions perform vital functions like store-operated Ca2+ entry (SOCE) and lipid transfer. The functional and structural roles of proteins present in neuronal ER-PM junctions are not well understood. One of these proteins are STIMs (Stromal Interaction Molecule), sensors of Ca2+ in the ER that activate in response to a drop in ER Ca2+ concentration. Activated STIMs open CRAC and TRPC channels in the PM to allow Ca2+ influx from the extracellular space. STIMs were also shown to interact with several other targets at the PM. We aim to understand the role of STIMs in regulating the activity-dependent structural architecture at the ER-PM junctions using TIRF microscopy. We also perform Ca2+ imaging to elucidate the role of STIMs in both pre-and postsynaptic compartments. We perform single-particle tracking experiments to uncover individual STIM molecules' spatial and temporal mobility patterns. Our preliminary data indicate differential mobility patterns for STIM1 and STIM2. STIM2, the more Ca2+ sensitive and dominating STIM homolog in hippocampal neurons, appears to be more mobile in axons and less so in dendrites. The pattern of STIM1 mobility was more uniform within the whole neuron. Both STIM1 and STIM2 seems to change their mobility and localization in response to activity. We expand these findings to understand the events in which STIMs enter the pre or postsynaptic compartment.

The neuronal cytoskeleton, composed of actin filaments (F-actin), microtubules (MTs) and neurofilaments, is crucial for neuronal polarization, growth cone steering or dendritic branching that take place during neuronal differentiation and function. These processes rely on a very precise balance between the dynamicity and the stability of the cytoskeleton and are under control of associated proteins that bind directly to these filaments. One of this protein is the Microtubule-Associated-Protein 6 (MAP6) which is known for its strong ability to stabilize MTs in neurons. Recent work from the team has also shown that MAP6 is involved in synaptic plasticity through its ability to stabilize actin dynamics in dendritic spines. Using cell-free assays, we analyzed the role of MAP6 in the regulation of actin and MTs dynamics and identify MAP6 as a nucleator and bundling factor of F-actin. Moreover, we found that MAP6 is also able to nucleate MTs. Finally, we showed that MAP6 can simultaneously nucleate and crosslink together F-actin and MTs. Such ability to nucleate F-actin and MTs at the same time has never been describe so far and could play a role in neuronal branching or spine formation. MAP6, that has been observed in growth cone and dendritic spines, could be involved in these structures by promoting the invasion of MTs along actin filaments. Experiments are ongoing to assign a cellular function of our in vitro findings.

FORMIN-MEDIATED ACTIN FILAMENT REGULATION IN THE AXON INITIAL SEGMENT OF HIPPOCAMPAL NEURONS

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

David Micinski
Minerva Foundation Institute of Medical Research, Cellular Neuroscience, Helsinki, Finland

The location of the axon initial segment (AIS) at the junction between the soma and axon of neurons makes it instrumental in maintaining neural polarity and serving as the site for action potential generation. Recent research suggests actin structures are involved in AIS activity dependent structural plasticity, maintenance, and vesicle sorting. Thus, our aim is to elucidate how actin is regulated in the AIS mainly, but also how this might affect processes throughout the axon. For this, we have been utilizing pharmacological treatments to modify expression or activity of actin-binding proteins. We are also using super-resolution microscopy, as the specific organization of proteins at the nanoscale is crucial to understanding how the AIS performs its physiological functions. We have examined the stability of the AIS by testing how treatment with the formin inhibiting drug, small molecule inhibitor of formin homology domain 2 (SMIFH2), affected the AIS actin cytoskeleton. From this we learned that some components of the AIS, like Ankyrin-G and actin rings, are unaffected by formin inhibition. We also showed that other, longitudinal actin filaments are lost with this same treatment and that actin patches appear in greater numbers, potentially as a compensatory mechanism. The exact role of these longitudinal filaments is unknown, though they have been described before. To further understand the regulation of these filaments, we have more recently been examining how they respond to changes in neuronal excitability.

Measuring Properties of the Membrane Periodic Skeleton of the Axon Initial Segment using 3D-Structured Illumination Microscopy (3D-SIM).
The axon initial segment (AIS) is the site at which action potentials initiate and constitutes a transport filter and diffusion barrier that contribute to the maintenance of neuronal polarity by sorting somato-dendritic cargo. A membrane periodic skeleton (MPS) comprising periodic actin rings provides a scaffold for anchoring various AIS proteins, including structural proteins and different ion channels. Although recent proteomic approaches have identified a considerable number of novel AIS components, details of the structure of the MPS and the roles of its individual components are lacking. The distance between individual actin rings in the MPS (~190 nm) necessitates the employment of super-resolution microscopy techniques to resolve the structural details of the MPS. This protocol describes a method for using cultured rat hippocampal neurons to examine the precise localization of an AIS protein in the MPS relative to sub-membranous actin rings using 3D-structured illumination microscopy (3D-SIM). In addition, an analytical approach to quantitively assess the periodicity of individual components and their position relative to actin rings is also described.

Tropomyosin Tpm3.1 Is Required to Maintain the Structure and Function of the Axon Initial Segment.
The axon initial segment (AIS) is the site of action potential initiation and serves as a cargo transport filter and diffusion barrier that helps maintain neuronal polarity. The AIS actin cytoskeleton comprises actin patches and periodic sub-membranous actin rings. We demonstrate that tropomyosin isoform Tpm3.1 co-localizes with actin patches and that the inhibition of Tpm3.1 led to a reduction in the density of actin patches. Furthermore, Tpm3.1 showed a periodic distribution similar to sub-membranous actin rings but Tpm3.1 was only partially congruent with sub-membranous actin rings. Nevertheless, the inhibition of Tpm3.1 affected the uniformity of the periodicity of actin rings. Furthermore, Tpm3.1 inhibition led to reduced accumulation of AIS structural and functional proteins, disruption in sorting somatodendritic and axonal proteins, and a reduction in firing frequency. These results show that Tpm3.1 is necessary for the structural and functional maintenance of the AIS.

Sub-membranous actin rings in the axon initial segment are resistant to the action of latrunculin.
The axon initial segment (AIS) comprises a sub-membranous lattice containing periodic actin rings. The overall AIS structure is insensitive to actin-disrupting drugs, but the effects of actin-disrupting drugs on actin rings lack consensus. We examined the effect of latrunculin A and B on the actin cytoskeleton of neurons in culture and actin rings in the AIS. Both latrunculin A and B markedly reduced the overall amount of F-actin in treated neurons in a dose-dependent manner, but the periodicity of actin rings remained unaffected. The insensitivity of AIS actin rings to latrunculin suggests they are relatively stable.

L-cysteine supplementation upregulates glutathione (GSH) and vitamin D binding protein (VDBP) in hepatocytes cultured in high glucose and in vivo in liver, and increases blood levels of GSH, VDBP, and 25-hydroxy-vitamin D in Zucker diabetic fatty rats.
Vitamin D binding protein (VDBP) status has an effect on and can potentially improve the status of 25(OH) vitamin D and increase the metabolic actions of 25(OH) vitamin D under physiological and pathological conditions. Diabetes is associated with lower levels of glutathione (GSH) and 25(OH) vitamin D. This study examined the hypothesis that upregulation of GSH will also upregulate blood levels of VDBP and 25(OH) vitamin D in type 2 diabetic rats.
Mol Nutr Food Res, 2016; 60

Relationship between hydrogen sulfide levels and HDL-cholesterol, adiponectin, and potassium levels in the blood of healthy subjects.
Hydrogen sulfide (H(2)S) is an important signaling molecule whose blood levels have been shown to be lower in certain disease states. Increasing evidence indicates that H(2)S plays a potentially significant role in many biological processes and that malfunctioning of H(2)S homeostasis may contribute to the pathogenesis of vascular inflammation and atherosclerosis. This study examined the fasting blood levels of H(2)S, HDL-cholesterol, LDL-cholesterol, triglycerides, adiponectin, resistin, and potassium in 36 healthy adult volunteers. There was a significant positive correlation between blood levels of H(2)S and HDL-cholesterol ($r = 0.49$, $p = 0.003$), adiponectin ($r = 0.36$, $p = 0.04$), and potassium ($r = 0.34$, $p = 0.047$), as well as a significant negative correlation with LDL/HDL levels ($r = -0.39$, $p = 0.02$). This is the first demonstration of an association of circulating levels of H(2)S with the HDL, LDL, and adiponectin homeostasis in the blood of healthy humans.

Vitamin D upregulates glutamate cysteine ligase and glutathione reductase, and GSH formation, and decreases ROS and MCP-1 and IL-8 secretion in high-glucose exposed U937 monocytes.
Glutathione is a major endogenous antioxidant and its deficiency is implicated in the etiology and progression of a number of human diseases. Vitamin D is important for the prevention of osteoporosis, cardiovascular disease, diabetes, autoimmune diseases, and some cancers. Using a monocyte cell model, this study examined the hypothesis that vitamin D upregulate glutamate cysteine ligase (GCLC) and glutathione reductase (GR), which catalyzes GSH biosynthesis.
Biochem Biophys Res Commun, 2013; 437
31172369: Kanikarla-Marie P, Micinski D, Jain SK
Hyperglycemia (high-glucose) decreases L-cysteine and glutathione levels in cultured monocytes and blood of Zucker diabetic rats.
L-Cysteine (LC) is an essential precursor of GSH biosynthesis. GSH is a major physiological antioxidant, and its depletion increases oxidative stress. Diabetes is associated with lower blood levels of LC and GSH. The mechanisms leading to a decrease in LC in diabetes are not entirely known. This study reports a significant decrease in LC in human monocytes exposed to high glucose (HG) concentrations as well as in the blood of type 2 diabetic rats. Thus, a significant decrease in the level of LC in response to exposure to HG supports the assertion that uncontrolled hyperglycemia contributes to a reduction of blood levels of LC and GSH seen in diabetic patients. Increased requirement of LC to replace GSH needed to scavenge excess ROS generated by hyperglycemia can result in lower levels of LC and GSH. Animal and human studies

report that LC supplementation improves GSH biosynthesis and is beneficial in lowering oxidative stress and insulin resistance. This suggests that hyperglycemia has a direct role in the impairment of LC and GSH homeostasis in diabetes.

In African American type 2 diabetic patients, is vitamin D deficiency associated with lower blood levels of hydrogen sulfide and cyclic adenosine monophosphate, and elevated oxidative stress?
African Americans (AA) have a higher incidence of cardiovascular disease and vitamin D (VD) deficiency compared with Caucasians. Hydrogen sulfide (H(2)S) is an important signaling molecule. This study examined the hypothesis that blood levels of H(2)S are lower in AA type 2 diabetic patients (T2D). Fasting blood was obtained from T2D and healthy controls. Results showed a significant decrease in plasma levels of cyclic adenosine monophosphate (cAMP) and H(2)S in AA T2D but not in Caucasian T2D when compared with those of respective age- and race-matched healthy controls. Plasma VD levels were significantly lower in AA T2D compared with Caucasian T2D. Cell culture studies demonstrate that 1,25(OH)(2)-VD supplementation significantly increased expression of cystathionine-γ-lyase (CSE), H(2)S formation, and cAMP secretion, but decreased reactive oxygen species in high glucose-treated U937 monocytes. This suggests that VD supplementation upregulates CSE and H(2)S formation and decreases oxidative stress, and that VD deficiency may contribute to the malfunctioning of H(2)S signaling and thus a higher incidence of vascular inflammation in AA. These results lead to the hypothesis that VD supplementation can replenish blood concentrations of H(2)S and cAMP and lower oxidative stress and cardiovascular disease in AA T2D.

Hydrogen sulfide upregulates glutamate-cysteine ligase catalytic subunit, glutamate-cysteine ligase modifier subunit, and glutathione and inhibits interleukin-1β secretion in monocytes exposed to high glucose levels.
Glutathione (GSH) deficiency and interleukin-1β (IL-1β) upregulation are linked to the progression of vascular inflammation and atherosclerosis. The consumption of sulfide-rich vegetables is known to lower the risk of atherosclerosis. This study examined the hypothesis that hydrogen sulfide (H2S) upregulates the glutamate-cysteine ligase catalytic subunit (GCLC) and GSH and inhibits IL-1β in a monocyte cell model. U937 monocytes were supplemented with H2S (0-12.5 μM) for 2 hr and then exposed to a control or high glucose (HG, 25 mM) for 22 hr. Levels of GCLC and glutamate-cysteine ligase modifier subunit (GCLM) expression were determined by western blotting and GSH using high-performance liquid chromatography (HPLC), and IL-1β using enzyme-linked immunoassay (ELISA). H2S significantly ($P<0.05$) upregulated expression of GCLC and GCLM, and formation of GSH, and inhibited IL-1β secretion in controls and HG-treated monocytes. This is the first demonstration of H2S upregulation of GCLC and GSH and inhibition of IL-1β levels, which may be what mediates the beneficial effects of H2S-rich compounds in mitigating the pathogenesis of metabolic syndrome and atherosclerosis.

POLYGLUTAMYLATION OF MICROTUBULES DRIVES MOTOR AXON REMODELLING

POSTER SESSION 01 - SECTION: SUBCELLULAR STRUCTURE AND MECHANISMS INVOLVED IN NEURAL ACTIVITY

Antoneta Gavoci[1], Mengzhe Wang[1], Maria Magiera[2], Carsten Janke[2], Thomas Misgeld[1], Monika Leischner-Brill[1]
[1]Technical University Munich, Institute Of Neuronal Cell Biology, Munich, Germany, [2]Institut Curie, Department Genome Integrity, Rna And Cancer, Orsay, France

Microtubules are dynamic cytoskeletal structures build from tubulin dimers, which can carry a range of post-translational modifications (PTMs). Together with associated proteins, PTMs establish a ‘code’, endowing the microtubule scaffold with specific and local functionality, such as regulating microtubule length and dynamics and microtubule-dependent transport. However, how this code translates into shaping cell- or tissue-level events, remains largely unexplored.
We investigate how polyglutamylation, a PTM enriched on neuronal microtubules, regulates postnatal motor axon remodelling: a regressive process in which ~90% of terminal branches prune, involving spastin-mediated loss of microtubules. While spastin is known to preferentially sever polyglutamylated microtubules, it remains elusive whether branch-specific polyglutamylation drives pruning.
Consistent with an instructive role of polyglutamylation, motoneurons ablated of deglutamylases CCP1&6 accelerate axon dismantling, while deletion of chain-elongating glutamylase TTLL1, delayed axonal remodelling. Further measurements of polyglutamylation, microtubule mass and dynamics corroborate the predicted branch-specific regulation of microtubule stability, hinting at a rheostatic regulation of spastin-mediated severing and hence axonal remodelling. Surprisingly, deleting TTLL7, which ‘seeds’ the first glutamate residue, had no effect on polyglutamylation, suggesting several layers of regulation that are engrained in parallel or consecutive steps of editing the tubulin code.
Together, a specific tubulin PTM—polyglutamylation—acts as an instructive signal for spastin-mediated severing, which in turn paces developmental axon pruning. The ‘tubulin code’ could thus control specific morphogenetic events during nervous system development. Future work tries to unravel if synaptic activity coordinates glutamylases and deglutamylases and whether similar mechanisms determine axon stability in central neurons and during disease-related remodelling.

Microexons are an unusual form of alternative splicing characterized by small size and high evolutionary conservation, however, their functions are still far from being understood. In this work, we focused on a neuronal-specific microexon that modulates the structure of the FH2 domain of DAAM1, a protein important for actin dynamics. Using TIRF microscopy approaches we demonstrated that microexon inclusion directly impacts actin nucleation and polymerization capabilities of the FH2 domain, suggesting a modulatory effect on DAAM1´s function. Actin dynamics is an important factor in neuronal differentiation and function. Our results demonstrate higher neuronal activity upon microexon removal, both in an in vitro system of differentiated glutamatergic neurons and in vivo, in a microexon KO mouse model. This presumably synaptic-driven phenotype translated into further developmental imbalances in young mice, and later on, motor and learning impairments in adulthood. These results thus reveal a highly conserved and splicing-driven control mechanism of neuronal functioning, involved in higher cognitive abilities.

ALTERED MICROGLIA SIGNALING IN MOUSE MODELS OF SCHIZOPHRENIA

POSTER SESSION 01 - SECTION: BRAIN INFLAMMATION, NEURODEVELOPMENT AND DISEASE

Anne Günther, Mattia Chini, Jastyn Pöpplau, Ileana Hanganu-Opatz
University Medical Center Hamburg-Eppendorf, ZMNH, Institute For Developmental Neurophysiology, Hamburg, Germany

Microglia, the resident macrophages of the brain, play crucial roles in neuronal development. They directly modulate neuronal connectivity and synaptic density by synaptic pruning, relying on highly specific signaling cascades on the neuronal and on the microglial side. In the context of neurodevelopmental disorders (NDDs), specific elements of microglial signaling cascades have been shown to contribute to network disruption. However, it remains unclear how specific signaling molecules might be involved in the miswiring of neuronal networks in early development of NDDs, specifically on the level of individual synapses. Here, we combined analysis on the RNA level and protein level with computational analysis of morphology and microglia reactivity to assess the role of microglia in early development. We specifically focused on the prefrontal cortex, an area that is involved in cognitive processes which are particularly sensitive to disruption in NDDs. High-throughput quantitative PCR revealed a subset of microglial signaling molecules, which were expressed in a particularly differential manner in early development. Advanced immunohistochemistry confirmed distinct expression patterns on the level of individual synapses, revealing a complex interplay between microglial and neuronal signaling in the context of synaptic maintenance and pruning. Furthermore, we could show disrupted expression of specific signaling molecules in a mouse model of schizophrenia, where morphological analysis revealed a clear redistribution of microglia reactive states, specifically when comparing layer 2/3 and layer 5/6 of the PFC. Taken together, our data provide insights regarding the mechanisms that might underlie the neuronal miswiring characteristic to models of neurodevelopmental disorders.

COMPLEMENT RECEPTORS C3AR AND CR3 MEDIATE LOSS OF SYNAPTIC INPUTS AND NMDAR HYPOFUNCTION IN A MOUSE MODEL OF SCHIZOPHRENIA-ASSOCIATED HIGH C4 EXPRESSION

POSTER SESSION 01 - SECTION: BRAIN INFLAMMATION, NEURODEVELOPMENT AND DISEASE

Nayadoleni Nieves Rivera[1,2], Mélanie Druart[3], Nala Gockel[4], Stefanie Poll[4], Martin Fuhrmann[4], Corentin Le Magueresse[1,2,5]
[1]Sorbonne Université, Sorbonne Sciences, Paris, France, [2]Institut du Fer a Moulin, Serotonin Microglia Plasticity And Pathology, Paris, France, [3]New York University, Neuroscience, New York, United States of America, [4]German Center for Neurodegenerative Diseases (DZNE), Neuroimmunology And Imaging, Bonn, Germany, [5]INSERM, Umr-s 1270, Paris, France

The complement system is a set of proteins contributing to normal immune responses. Over the last two decades studies have revealed key functions of these components in synaptic pruning, a process by which synapses in excess are eliminated during brain maturation. Interestingly, convergent studies point to a loss of dendritic spines in neurons in the cortex of schizophrenic patients, which could reflect disturbances of the normal process of synaptic pruning. High-expression variants of complement component 4 (C4) gene constitute a major risk factor of schizophrenia. We and others have found that over-expressing C4 in the mouse cortex recapitulates several schizophrenia-associated phenotypes, including synapse loss.
To assess the role of complement pathways on brain circuit development during elevated C4 expression, we over-expressed C4 in the prefrontal cortex using in utero electroporation of a C4-encoding plasmid in two different transgenic mouse lines lacking complement receptors CR3 or C3aR, which are both expressed in microglial cells. Using patch-clamp in layer III pyramidal cells of the PFC, we observed that the absence of CR3, but not C3aR, leads to alterations in functional excitatory transmission. Furthermore, C4-induced changes in synaptic transmission, such as decreased glutamatergic input and altered AMPA/NMDA ratio, were normalized in mice lacking either CR3 or C3aR. Given the known role of CR3 and C3aR in microglial cells, these results suggest that the effects of C4 overexpression may involve both recognition of opsonized synaptic material by CR3 and microglial activation by C3aR.

Background Microglia support neurons during postnatal development and in homeostatic conditions and this is altered in pathological conditions. Microglia invade and colonize the developing brain before the start of corticogenesis and accumulate when synapses start to form in the foetal cortex, however the role of immune cells in prenatal development is not well understood. Clinical data from first and second trimester maternal infections indicate changes in brain development and function by the increased risk of manifestation of neuropsychiatric conditions. Moreover, patients with mutated CSF1R show highly reduced microglia survival and severe developmental brain malformations. Aims We hypothesized that microglia could support neuronal maturation and network formation during prenatal development before the generation of astrocytes and oligodendrocytes. Results We established a highly enriched TBR1 positive human cortical neuron culture system where we can control cell density and neuronal birthdates and tested the role of microglia in neuronal maturation. We found that microglia promote neuronal maturation in multiple ways. First by augment voltage gated sodium and potassium channel densities and thus the generation of action potentials. Second microglia also increase synapse formation and activity before the generation of astrocytes. Conclusion Our results demonstrate that microglia can enhance neuronal maturation and synaptic connectivity during prenatal development.

Periods of synchronized myelin changes shape brain function and plasticity.
Myelin, a lipid membrane that wraps axons, enabling fast neurotransmission and metabolic support to axons, is conventionally thought of as a static structure that is set early in development. However, recent evidence indicates that in the central nervous system (CNS), myelination is a protracted and plastic process, ongoing throughout adulthood. Importantly, myelin is emerging as a potential modulator of neuronal networks, and evidence from human studies has highlighted myelin as a major player in shaping human behavior and learning. Here we review how myelin changes throughout life and with learning. We discuss potential mechanisms of myelination at different life stages, explore whether myelin plasticity provides the regenerative potential of the CNS white matter, and question whether changes in myelin may underlie neurological disorders.

MICROGLIA ONTOGENY AND EARLY-LIFE STRESS: MICROGLIAL AND BEHAVIORAL SEX-SPECIFIC RESPONSES IN PREPUBESCENT MICE TO MATERNAL SEPARATION DURING INFANCY

POSTER SESSION 01 - SECTION: BRAIN INFLAMMATION, NEURODEVELOPMENT AND DISEASE

Bruna Resende, Laila Árabe, Ana Luiza Reis, Beatriz Codo, Camila Brito, André Oliveira, Bruno Souza
Federal University of Minas Gerais, Physiology And Biophysics, Belo Horizonte, Brazil

Early-life stress is etiologically linked to many neuropsychiatric disorders, and several emerge during adolescence, another sensitive developmental window. One common feature of both periods is neuronal circuit-remodeling in response to environmental inputs. Microglia is highly responsive and involved in developmental processes, and its malfunctioning is seen in neurodevelopmental disorders. Aim: To evaluate the effects of maternal separation (MS) on microglia and behavior of prepubescent male and female CX3CR1:GFP+/- mice. Pups were subjected to 3 hours of MS (P2-P14), and tested for anxiety- and depressive-like behaviors at P30; other subgroups were euthanized at P15 or P30, and hippocampal tissue was collected. Microglial numbers and morphology were analyzed by confocal microscopy. Data were analyzed using Student's *t-test* or Two-Way ANOVA and Tukey test. Results: Decreased microglial numbers from P15 to P30 in males; females do not follow this pattern and have fewer microglia already at P15. Female microglia had longer dendrites than male's at P30. They also responded differently to MS: males had smaller cells, whereas females had a decrease in cell complexity. We also see anxiety- and depressive-like behavioral phenotypes in MS-males, whereas MS-females were less responsive and exhibited only an increase in exploratory-motor behavior. Conclusions: We observed sex-specific ontogeny pathways in microglial morphology, and sex-specific responses to MS, with a decrease in cell complexity only in females; we also identified sex-specific behavioral effects after MS (stronger effect in males). Further investigations of the mechanisms behind sex- and stress-related differences are needed to understand how microglial physiology interferes in developmental pathways.

LACK OF LIPOCALIN 2 EXPRESSION DURING PRENATAL INFECTION AFFECTS BRAIN DEVELOPMENT

POSTER SESSION 01 - SECTION: BRAIN INFLAMMATION, NEURODEVELOPMENT AND DISEASE

Martyna Pekala, Leszek Kaczmarek, Katarzyna Kalita
Nencki Institute of Experimental Biology, Polish Academy of Sciences, Braincity, Laboratory Of Neurobiology, Warsaw, Poland

Aims Epidemiological studies indicate that maternal infection during pregnancy is a risk factor for neurodevelopmental disorders. However, the mechanisms underlying this phenomenon remain unclear. One of the highly expressed proteins in the adult brain in response to infection is lipocalin 2 (Lcn2), an innate immune response protein. Our studies aim to characterize the role of Lcn2 in the regulation of neuronal circuitry development during prenatal infection. **Methods** To mimic maternal infection we used a model of maternal immune activation where the pregnant mice received i.p. injections of lipopolysaccharide on E16-18. To evaluate Lcn2 mRNA expression we performed qRT-PCR on fetal (E19) and adolescent (P14) hippocampus. To address how lack of Lcn2 during prenatal infection may influence electrophysiological properties of neurons in the adult brain, we performed excitability and miniature excitatory postsynaptic currents (mEPSC) recordings from hippocampal CA1 pyramidal cells on acute brain slices from Lcn2 WT and KO offspring after the LPS challenge. **Results and Conclusions** Our results indicate that Lcn2 mRNA is significantly upregulated in the hippocampus in response to prenatal infection in the fetal and adolescent brain. We also observed that the absence of Lcn2 in the developing brain leads to higher intrinsic excitability of hippocampal pyramidal neurons in the adult brain, but only in mice exposed to prenatal infection. Moreover, lack of Lcn2 resulted in decreased synaptic strength of hippocampal CA1 neurons manifested by decreased mEPSC amplitude. These findings suggest that lipocalin 2 could be a promising link between the immune response and brain development.

The Positive and Negative Outcome of Morphine and Disulfiram Subacute Co-Administration in Rats in the Absence of Ethanol Challenge.
Recently, a well-known anti-alcohol agent, disulfiram (DSF), has gain much interest, as it was found to be effective in the treatment of cocaine abusers, thus also giving hope for patients addicted to opioids and other illicit drugs. Therefore, this study was aimed to investigate the possible outcome that might occur within the subacute co-administration of both morphine (MRF) and DSF in rats, but in the absence of ethanol challenge. As observed, intraperitoneal DSF dose-dependently enhanced MRF-mediated analgesia with the maximal efficacy at a dose of 100 mg/kg. Furthermore, MRF-induced tolerance and aggressive behavior were significantly reduced by DSF (100 mg/kg, i.p.) in comparison to MRF solely. Nonetheless, significant blood biochemical markers of hepatotoxicity were found (i.e., alteration in the levels of glutathione, blood urea nitrogen, etc.), following a combination of both drugs. Likewise, histological analysis of liver tissue revealed severe changes in the group of DSF + MRF, which includes swelling, cell death, damage to certain vessels, and hemorrhages into the liver parenchyma. Our findings indicate that DSF should be used with extreme caution, especially within the course of subacute concomitant use with MRF, as several possible side effects may take place.

Impact of maternal immune activation on dendritic spine development.
Dendritic spines are small dendritic protrusions that harbor most excitatory synapses in the brain. The proper generation and maturation of dendritic spines are crucial for the regulation of synaptic transmission and formation of neuronal circuits. Abnormalities in dendritic spine density and morphology are common pathologies in autism and schizophrenia. According to epidemiological studies, one risk factor for these neurodevelopmental disorders is maternal infection during pregnancy. This review discusses spine alterations in animal models of maternal immune activation in the context of neurodevelopmental disorders. We describe potential mechanisms that might be responsible for prenatal infection-induced changes in the dendritic spine phenotype and behavior in offspring.

Loss of serum response factor in mature neurons in the dentate gyrus alters the morphology of dendritic spines and hippocampus-dependent behavioral tasks.
Serum response factor (SRF) is a major transcription factor that regulates the expression of several plasticity-associated genes in the brain. Although the developmental expression of SRF in excitatory neurons is crucial for establishing proper hippocampal circuitry, no substantial evidence of its role in unstimulated mature neurons has been provided. The present study used time-controlled, conditional SRF knockout mice and found that the lack of SRF in adult neurons led to decreased actin levels and inactivation of the actin-severing protein cofilin 1 through its increase in phosphorylation at Ser3. The augmentation of cofilin 1 phosphorylation correlated with an alteration of dendritic spine morphology in the dentate gyrus, which was reflected by an increase in the number of spines that clustered into the long-spine category. The changes in spine morphology coincided with a lower amplitude and frequency of miniature excitatory postsynaptic currents. Moreover, SRF knockout animals were hyperactive and exhibited impairments in hippocampus-dependent behaviors, such as digging, marble burying, and nesting. Altogether, our data indicate that the adult deletion of neuronal SRF leads to alterations of spine morphology and function and hippocampus-dependent behaviors. Thus, SRF deletion in adult neurons recapitulates some aspects of morphological, electrophysiological, and behavioral changes that are observed in such psychiatric disorders as schizophrenia and autism spectrum disorders.

DYNAMIC NEURONAL IL-1R1 EXPRESSION IN NEURODEVELOPMENT

POSTER SESSION 01 - SECTION: BRAIN INFLAMMATION, NEURODEVELOPMENT AND DISEASE

Nuran Kocak[1], Ning Quan[2]
[1]FLORIDA ATLANTIC UNIVERSITY, Stiles-nicholson Brain Institute, Jupiter, United States of America, [2]FLORIDA ATLANTIC UNIVERSITY, Stiles-nicholson Brain Institute, JUPITER, United States of America

The signaling of the inflammatory cytokine, interleukin-1 (Il-1), through its receptor interleukin-1 receptor-1 (IL-1R1), plays diverse and critical roles in the central nervous system including memory consolidation, neuroinflammation, and mood control. The role of this signaling system has been mainly studied in adults, whereas its influences on brain development and the relevance of such influences to developmentally related neuropsychiatric disorders are unknown. Recently, we discovered IL-1R1 expression in neurons during development. We hypothesize that activities mediated by neuronal IL-1R1 (nIL-1R1) contribute to behavioral abnormalities of neurodevelopmental disorders. In this study, we investigated the spatiotemporal patterns of nIL-1r1 expression in order to lay a foundation for understanding the role of nIL-1R1 in neurodevelopment. To this end, we used our global IL-1R1 reporter mouse line as well as lines in which we restricted the expression of IL-1R1 to specific neuronal or non-neuronal cell types. We found that nIL-1R1 expression is very dynamic during brain development and changes dramatically in various brain regions (dentate gyrus-DG, dorsal raphe nucleus-DRN, thalamic nuclei) in a short time period. nIL-1R1 expression is not detected until P7 in DG while is detectable as early as P4 in DRN. The expression starts in the inner layer of the granular cell layer and progressively increases throughout of mouse life course. These changes are associated with the development of the memory, sensory, and mood-related circuitry of the brain. Moreover, we found that endothelial cells and T cells contribute to nIL-1R1 expression. These findings suggest that nIL-1R1 is tightly regulated during brain development.

IN VIVO EVALUATION OF THE ANTI-INFLAMMATORY ACTIVITY OF ALGINATE IN THE TEMPORAL LOBE EPILEPTIC RAT BRAIN

POSTER SESSION 01 - SECTION: BRAIN INFLAMMATION, NEURODEVELOPMENT AND DISEASE

Stefania Bartoletti[1], Elisa Ren[1], Federica Raimondi[1], Giulia Della Rosa[2], Alessandra Campanelli[3], Ilaria Decimo[3], Gemma Palazzolo[2], Giulia Curia[4]
[1]University of Modena e Reggio Emilia, Department Of Biomedical, Metabolic, And Neural Sciences, modena, Italy, [2]Italian Institute of Technology, Laboratory Of Enhanced Regenerative Medicine, Genova, Italy, [3]Laboratory of Pharmacology, Department Of Diagnostics And Public Health, Verona, Italy, [4]University of Modena e Reggio Emilia, Department Of Biomedical, Metabolic, And Neural Sciences, Modena, Italy

Aim Temporal Lobe Epilepsy (TLE) is the most common type of drug-resistant epilepsy in adults, and mesial TLE, characterized by hippocampal sclerosis, is the most severe TLE form. Neural stem cell (NSC) therapy has been considered a promising intervention to treat seizures. Since inflammation is a hallmark of epileptic brain, **targeting inflammation represents an important tool to generate a microenvironment suitable for brain regeneration**. The vegetal polysaccharide alginate has been used *in vivo* in central nervous system regeneration approaches as NSC delivery system as well as scaffold providing both structural support and neuroprotective cues to promote axonal regrowth and functional recovery. In this study, we aim to investigate the *in vivo* anti-inflammatory activity of the alginate hydrogel when co-injected with NSCs in a lesioned epileptic brain. **Methods** Adult pilocarpine-treated Sprague-Dawley male rats were transplanted with NSCs with or without alginate in the ventral CA3 area. To avoid an increase in intracranial pressure, rats were previously lesioned with the injection of the cytotoxic agent ibotenic acid. Nine weeks after transplantation, immunofluorescence analyses were performed to investigate astrocytic and microglial activation. **Results and Conclusions** Rat brain tissue transplanted with NSCs and alginate show a thinner glial scar and smaller microglial cell body size compared to brain tissue injected with NSCs alone. These results indicate an anti-inflammatory effect of alginate in the lesioned epileptic brain.

ANTIBIOTICS ADMINISTRATION DURING GESTATION MAY AFFECT MEMORY AND BRAIN STRUCTURE IN YOUNG OFFSPRING MICE

POSTER SESSION 01 - SECTION: BRAIN INFLAMMATION, NEURODEVELOPMENT AND DISEASE

Dmytro Shepilov[1], Dmytro Ilienko[2], Iryna Osadchenko[1], Tetiana Kovalenko[1], Kateryna Smozhanyk[1], Galyna Skibo[1]

Aims. The present study aimed to evaluate whether antibiotic treatment during gestation can trigger memory decline and brain structural alterations in mouse offspring. **Methods.** C57BL/6J female mice were divided into two groups (n=3/group): 1) *Control* – drank sterile water over the entire gestation, and 2) *Antibiotics* – consumed amoxicillin (205 mg/kg bw/day) and azithromycin (51 mg/kg bw/day) in sterile water during the 3rd week of gestation. 4-week-old mice born from those dams were conducted behavioral tests, immunohistochemistry of the hippocampus, and electron microscopy of the corpus callosum. **Results.** We revealed that the Antibiotics group had significantly higher latency to find a hidden platform on the 2nd and 3rd days of acquisition and less time spent in the target quadrant during probe test in Morris water maze. Novel object recognition test, in turn, did not show a significant difference in associative memory between groups. At the morphological level, mice of the Antibiotics group were characterized by a decrease in the density of CA1 pyramidal neurons and astrocytes in the hippocampus, as well as a thinning of myelin sheaths and a tendency to reduce the number of myelinated axons in the corpus callosum, compared to the Control animals. **Conclusions.** Antibiotic treatment during gestation was demonstrated to impact the developing brain which resulted in spatial reference memory impairments, changed hippocampal cellular structure, and signs of demyelination in young offspring mice.

ABERRANT INFLAMMATORY ACTIVITY OF MICROGLIA INFLUENCES NEURONAL CONNECTIVITY AND ACTIVITY IN SCHIZOPHRENIA IN VITRO

POSTER SESSION 01 - SECTION: BRAIN INFLAMMATION, NEURODEVELOPMENT AND DISEASE

Johanna Heider, Ricarda Breitmeyer, Sabrina Vogel, Hansjürgen Volkmer
NMI Natural and Medical Sciences Institute at the University of Tübingen, Molecular Neurobiology, Reutlingen, Germany

Schizophrenia is a complex neuropsychiatric disorder often signified by impairments of synaptic transmission. One hypothesis assigns a role for activated microglia to mediate aberrant synaptic pruning. However, interaction between human neurons and microglia in a co-culture exclusively composed of iPSC-derived cells has not been studied so far. Here, we demonstrate increased inflammatory activation in a neuron-microglia co-culture model derived from patients with schizophrenia. A reduction of the presynaptic marker synapsin is accompanied by increased uptake of synapsin-positive terminals by microglia. Interestingly, pre-treatment of microglia with the pro-inflammatory agent LPS replicated the decreased synaptic densities in neuron-glia cultures whilst stimulation with the anti-inflammatory drug Minocycline rescued the observed synaptic pruning deficits of schizophrenia microglia. Neuronal activity was studied after additional inclusion of iPSC-derived GABAergic interneurons in the cultures, leading to robustly observable single-cell activity. When schizophrenia microglia were co- cultured with healthy neurons, we observed a strong reduction in neuronal peak frequency during calcium imaging. Concurrent with our previous results, a reduction of excitatory presynapses was observed in co-cultures of healthy neurons and patient microglia. In conclusion, we generated a 2D *in vitro* human cellular test system to study neuron-microglia interactions in schizophrenia. We observed an inflammatory phenotype in patient microglia, potentially resulting in aberrant synaptic pruning and decreased neuronal activity in neuron-glia cultures. The observed anti-inflammatory effect of the drug Minocycline provides evidence for the usability of our model system to study mechanisms of disease candidate drugs.

Human iPSC-Derived Glia as a Tool for Neuropsychiatric Research and Drug Development.
Neuropsychiatric disorders such as schizophrenia or autism spectrum disorder represent a leading and growing burden on worldwide mental health. Fundamental lack in understanding the underlying pathobiology compromises efficient drug development despite the immense medical need. So far, antipsychotic drugs reduce symptom severity and enhance quality of life, but there is no cure available. On the molecular level, schizophrenia and autism spectrum disorders correlate with compromised neuronal phenotypes. There is increasing evidence that aberrant neuroinflammatory responses of glial cells account for synaptic pathologies through deregulated communication and reciprocal modulation. Consequently, microglia and astrocytes emerge as central targets for anti-inflammatory treatment to preserve organization and homeostasis of the central nervous system. Studying the impact of neuroinflammation in the context of neuropsychiatric disorders is, however, limited by the lack of relevant human cellular test systems that are able to represent the dynamic cellular processes and molecular changes observed in human tissue. Today, patient-derived induced pluripotent stem cells offer the opportunity to study neuroinflammatory mechanisms in vitro that comprise the genetic background of affected patients. In this review, we summarize the major findings of iPSC-based microglia and astrocyte research in the context of neuropsychiatric diseases and highlight the benefit of 2D and 3D co-culture models for the generation of efficient in vitro models for target screening and drug development.

INFLAMMATORY PAIN INDUCES MICROGLIAL DEREGULATION WITHIN THE MESOCORTICOLIMBIC SYSTEM: IMPACT ON MU-OPIOID RECEPTOR INTERNALISATION AND ACTIVATION

POSTER SESSION 01 - SECTION: BRAIN INFLAMMATION, NEURODEVELOPMENT AND DISEASE

Javier Cuitavi[1], Paula Andrés-Herrera[1], David Meseguer[1], Duart-Abadia[2], Julie Sanchez[3], Jesús David Lorente[1], Isabel Fariñas[2], Meritxell Canals[3], Lucía Hipólito[1]

Background and aims Chronic pain is a complex health burden that is increasingly affecting patients worldwide. Interestingly, microglia play a pivotal role in pain management in the spinal cord through neuron-glial interactions. Nevertheless, little is known of this interaction within the mesocorticolimbic system (MCLS) which modulates motivation, reward, and aversion. Pain is usually associated with other pathologies such as depression, anxiety, and addiction, so studying how pain modulates microglial activity in the MCLS could clarify the biochemical substrate of such comorbidities. The present work studies how inflammatory pain regulates microglial activation in the MCLS and observes if microglial activation modulates Mu-Opioid Receptor (MOR), one of the key receptors in pain management and addiction, activation and internalisation. Methods Complete Freund Adjuvant (CFA) inflammatory pain animal model was used in Sprague Dawley rats by subcutaneously injecting CFA and saline in the hind paw. A week after the injection animals were sacrificed and IBA1 Immunohistochemistry was used to assess microglial activation in the areas of the MCLS. Bioluminescence Resonance Energy Transfer (BRET) was used to study changes in neuronal MORs internalisation and activation induced by microglial activation in cultured cells. Results Inflammatory pain alters microglial activation in the MCLS and MORs activation and internalisation is enhanced by microglia in presence of an agonist. Conclusions Although further research is necessary to clarify the mechanisms that underlie pain-induced microglial modulation of the neuronal MORs, understanding these events in the MCLS could be crucial to create new therapeutical strategies to approach pain comorbidities.

CHONDROITIN SULPHATE PROTEOGLYCANS POTENTIALLY INDUCES REACTIVE ASTROGLIOSIS

POSTER SESSION 01 - SECTION: BRAIN INFLAMMATION, NEURODEVELOPMENT AND DISEASE

Cihan Civas[1], Jessica Kwok[1,2]
[1]University of Leeds, Biomedical Sciences, Leeds, United Kingdom, [2]Czech Academy of Sciences, Institute Of Experimental Medicine, Prague, Czech Republic

Astrocytes are the essential glial cells important for the maintenance of homeostasis and functions, including energy homeostasis, neurotransmitter recycling and synaptic activity, of the central nervous system. In addition, astrocytes regulate the synthesis and degradation of extracellular matrix (ECM) structures, and with ECM, astrocytes build up tetrapartite structure to maintain pre and post synaptic processes. After spinal cord injury, astrocytes undergo morphological and functional changes called reactive astrogliosis, and migrate to injury area to form the glial scar. During this process, expression, and secretion of chondroitin sulphate proteoglycans (CSPGs) are increased by astrocytes. CSPGs are ECM molecules and regulate axonal pathfinding and circuitry consolidation. CSPGs synthesis during glial scar formation are mostly inhibitory and studies showed that degradation of CSPGs by chondroitinase ABC after spinal cord injury enhances axonal regeneration and functional recovery. However, the effect of secreted CSPGs on astrocytes themselves is unclear. In our study, we have investigated the effect of aggrecan, one of the key CSPGs in CNS, on primary cortical astrocytes *in vitro*. Our results reveal that aggrecan induces cellular migration and inhibits cellular adhesion. Also, our preliminary quantification analysis showed that expression of GLAST and GFAP increases under the soluble aggrecan treatment and causes morphological changes. These results suggest that CSPGs may induces the reactive astrogliosis and we propose that CSPGs may induce expression of CSPGs in an autocrine loop. Further experiment and analysis are ongoing to prove this hypothesis.

Inactivation of Magel2 suppresses oxytocin neurons through synaptic excitation-inhibition imbalance.
Prader-Willi and the related Schaaf-Yang Syndromes (PWS/SYS) are rare neurodevelopmental disorders characterized by overlapping phenotypes of high incidence of autism spectrum disorders (ASD) and neonatal feeding difficulties. Based on clinical and basic studies, oxytocin pathway defects are suggested to contribute disease pathogenesis but the mechanism has been poorly understood. Specifically, whether the impairment in oxytocin system is limited to neuropeptide levels and how the functional properties of broader oxytocin neuron circuits affected in PWS/SYS have not been addressed. Using cell type specific electrophysiology, we investigated basic synaptic and cell autonomous properties of oxytocin neurons in the absence of MAGEL2; a hypothalamus enriched ubiquitin ligase regulator that is inactivated in both syndromes. We observed significant suppression of overall ex vivo oxytocin neuron activity, which was largely contributed by altered synaptic input profile; with reduced excitatory and increased inhibitory currents. Our results suggest that dysregulation of oxytocin system goes beyond altered neuropeptide expression and synaptic excitation inhibition imbalance impairs overall oxytocin pathway function.

INFLAMMATORY EXOSOMES TRANSFER DANGER SIGNALS AND INDUCE GLIAL DYSFUNCTIONAL CALCIUM DYNAMICS IN NAïVE SPINAL CULTURED EXPLANTS

POSTER SESSION 01 - SECTION: BRAIN INFLAMMATION, NEURODEVELOPMENT AND DISEASE

Christian Memo[1], Pietro Parisse[2], Loredana Casalis[2], Clara Ballerini[3], Laura Ballerini[4]
[1]SISSA, Neurobiology, Trieste, Italy, [2]Elettra Sincrotrone Trieste, Nanoinnovation Lab, Basovizza, Italy, [3]Università di Firenze, Dipartimento Di Medicina Sperimentale E Clinica, Firenze, Italy, [4]International School for Advanced Studies (ISAS), Neurobiology, Trieste, Italy

Neuroinflammation is a shared hallmark of almost every pathology in the central nervous system (CNS), from ischemic or traumatic injury to neurodegenerative diseases. Despite the increasing knowledge of the molecular and cellular mechanisms contributing to neuroinflammatory pathways, the understanding of shared mediators underlying neuroinflammation for the development of novel therapeutic strategies is still lacking. Extracellular vesicles released by astrocytes, the CNS prevalent cells, are key vectorized systems able to spread and actively transfer signalling molecules, modulating target cell functions. We isolated exosomes from LPS-treated (inflamed) organotypic spinal cord slices to investigate vesicle ability to induce glial cell reactivity and inflammation in naïve organotypic spinal slices. The slices were obtained from E13 mouse embryos, cultured *in vitro* for two weeks and treated for 24 h with lipopolysaccharide (LPS 1 µg/ml), to induce spinal neuroinflammation. Upon medium collection and centrifugation, we isolated for the first time exosomes from cultured slices which were used to treat naive slices. LPS-induced neuroinflammation was documented by immunofluorescence and confocal microscopy quantifying glial reactivity by GFAP and Iba1 staining. Exosomes were characterised by Nanoparticle Tracking Analysis (NTA), Atomic Force Microscopy and western-blot analysis and their impact on healthy spinal tissue was assessed with similar approaches while dysfunctional Ca^{2+} signalling in reactive astrocytes was monitored by AAV5. gfaABC1D-cyto-GCaMP6f, a genetically encoded calcium indicator. Confocal microscopy and live imaging documented the ability of exosomes to activate reactive responses in healthy astrocytes. The results obtained strongly indicate that exosomes enable inflammatory danger signalling transfer from treated to naïve tissue.

Synthetic and natural small molecule TLR4 antagonists inhibit motoneuron death in cultures from ALS mouse model.
Increasing evidence indicates that inflammatory responses could play a critical role in the pathogenesis of motor neuron injury in amyotrophic lateral sclerosis (ALS). Recent findings have underlined the role of Toll-like receptors (TLRs) and the involvement of both the innate and adaptive immune responses in ALS pathogenesis. In particular, abnormal TLR4 signaling in pro-inflammatory microglia cells has been related to motoneuron degeneration leading to ALS. In this study the effect of small molecule TLR4 antagonists on in vitro ALS models has been investigated. Two different types of synthetic glycolipids and the phenol fraction extracted from commercial extra-virgin olive oil (EVOO) were selected since they efficiently inhibit TLR4 stimulus in HEK cells by interacting with the TLR4·MD-2 complex and CD14 co-receptor. Here, TLR4 antagonists efficiently protected motoneurons from LPS-induced lethality in spinal cord cultures, and inhibited the interleukine-1β production by LPS-stimulated microglia. In motoneurons/glia cocultures obtained from wild type or SOD1 G93A mice, motoneuron death induced by SOD1mut glia was counteracted by TLR4 antagonists. The release of nitric oxide by LPS treatment or SOD1mut glia was also inhibited by EVOO, suggesting that the action of this natural extract could be mainly related to the modulation of this inflammatory mediator.

Diverse inflammatory threats modulate astrocytes Ca signaling via connexin43 hemichannels in organotypic spinal slices.
Neuroinflammation is an escalation factor shared by a vast range of central nervous system (CNS) pathologies, from neurodegenerative diseases to neuropsychiatric disorders. CNS immune status emerges by the integration of the responses of resident and not resident cells, leading to alterations in neural circuits functions. To explore spinal cord astrocyte reactivity to inflammatory threats we focused our study on the effects of local inflammation in a controlled micro-environment, the organotypic spinal slices, developed from the spinal cord of mouse embryos. These organ cultures represent a complex in

vitro model where sensory-motor cytoarchitecture, synaptic properties and spinal cord resident cells, are retained in a 3D fashion and we recently exploit these cultures to model two diverse immune conditions in the CNS, involving different inflammatory networks and products. Here, we specifically focus on the tuning of calcium signaling in astrocytes by these diverse types of inflammation and we investigate the mechanisms which modulate intracellular calcium release and its spreading among astrocytes in the inflamed environment. Organotypic spinal cord slices are cultured for two or three weeks in vitro (WIV) and exposed for 6 h to a cocktail of cytokines (CKs), composed by tumor necrosis factor alpha (TNF-α), interleukin-1 beta (IL-1 β) and granulocyte macrophage-colony stimulating factor (GM-CSF), or to lipopolysaccharide (LPS). By live calcium imaging of the ventral horn, we document an increase in active astrocytes and in the occurrence of spontaneous calcium oscillations displayed by these cells when exposed to each inflammatory threat. Through several pharmacological treatments, we demonstrate that intracellular calcium sources and the activation of connexin 43 (Cx43) hemichannels have a pivotal role in increasing calcium intercellular communication in both CKs and LPS conditions, while the Cx43 gap junction communication is apparently reduced by the inflammatory treatments.

Microglia are the resident immune cells of the central nervous system in which they play a crucial role in homeostasis and disease. Moreover, they are implicated in brain development, neuronal interactions, and higher brain functions such as learning mechanisms. Microglia are highly motile cells that constantly scan the brain parenchyma with their protrusions. The cellular mechanisms underlying these dynamic changes in shape remain to be further elucidated. The cytoskeleton proteins actin depolymerizing factor and cofilin 1 (ADF/Cfl1) have been shown to be crucially involved in neuronal development, function and cell cycle control by actin filament organization. However, their role in microglia remains unknown. We generated a mouse line that conditionally lacks ADF/Cfl1 in microglia in the adult brain. Chronic *in vivo* two photon imaging of ADF/Cfl1-KO microglia in the cortex revealed altered microglia morphology and motility. Additionally, long-term monitoring of microglia migration towards a lesion site was affected in absence of ADF/Cfl1 in microglia. Furthermore, an associative learning task indicated a role of microglial ADF/Cfl1 in learning and memory. Our results assign a crucial role of ADF/Cfl1 to the diverse microglia functions in health and disease. Moreover, our data suggest that microglial integrity in presence of ADF/Cfl1 is important for higher brain network processes that impact cognition.

AQP4 EXPRESSION LEVEL AND AGGREGATION STATE AFFECT ASTROCYTE MIGRATION IN AN IN VITRO MODEL OF REACTIVE GLIOSIS

POSTER SESSION 01 - SECTION: BRAIN INFLAMMATION, NEURODEVELOPMENT AND DISEASE

Barbara Barile[1], Maria Grazia Mola[1], Guido Mogni[1], Antonio Cibelli[1], Antonio Frigeri[2,3], Grazia Paola Nicchia[1,3]
[1]University of Bari Aldo Moro, Department Of Bioscience, Biotechnology And Biopharmaceutics, Bari, Italy, [2]University of Bari Aldo Moro, School Of Medicine, Department Of Basic Medical Sciences, Neuroscience And Sense Organs, Bari, Italy, [3]A. Einstein College of Medicine, Yeshiva University, Neuroscience Department, New York, United States of America

The water channel Aquaporin-4 (AQP4) is physiologically assembled in Central Nervous System (CNS) astrocytes into large molecular aggregates known as Orthogonal Arrays of Particles (OAPs). Astrocytes are resident cells but can migrate under inflammatory conditions, where it has been reported that AQP4 is upregulated. The aim of this study is to investigate the physiological impact of AQP4 and its supra-molecular level of aggregation in astrocytes migration in an *in vitro* model of reactive gliosis. To this end, we promoted an inflammatory phenotype by co-stimulating primary cultured astrocytes obtained from WT and OAP-null mice with TNFα and IL1β. Astrocyte activation was assessed by morphometric analysis, RT-qPCR and Western Blot of pro-inflammatory markers, while water transport and wound healing assays were used to correlate astrocyte water permeability to migratory ability. We found that, independently from the genotype, reactive astrocytes undergo hypertrophy of intermediate filaments, increase the cell area and display pro-inflammatory gene profile. However, they unexpectedly exhibit low levels of AQP4, as well as Cx43 and GFAP, compared to controls. Wound healing assays of non-reactive astrocytes showed that OAP-null migrate at a higher speed than WT, but both cell types remain almost immotile after 24 hours. Moreover, they both exhibit slow water transport rates under inflammatory conditions, as predicted by the expression levels of AQP4. Altogether these findings show that AQP4 aggregation state drives cell migration, which is impaired when AQP4 is downregulated, and provide new insights on astrocyte role in health and disease.

DECIPHERING THE ROLE OF MECHANICAL CUES ON ACTIVATION OF MICROGLIAL CELLS

POSTER SESSION 01 - SECTION: BRAIN INFLAMMATION, NEURODEVELOPMENT AND DISEASE

Anthony Proces[1], Sylvain Gabriele[2], Laurence Ris[3]
[1]University of Mons, Research Institute For Health Sciences And Technology, Mons, Belgium, [2]University of Mons, Mechanobiology And Soft Matter Group - Research Institute For Biosciences, Mons, Belgium, [3]University of Mons, Neuroscience, Mons, Belgium

In brain tissues, mechanical stresses can lead to complex neuroinflammation events. Both microglia and astrocytes play a significant role in mediating the progression of a mechanical damage. Classic ways of microglia activation can be triggered by antigen presentation like chemokines, damaged-associated molecular patterns (DAMPs) or pathogen particles. However, while the impact of chemical signaling on astrocytes and microglia function has been studied in much detail, the current understanding of mechanical signaling, induced by brain injuries, is very limited. To address this challenge, we studied in vitro the role of mechanically injured microglia. Microglial cells were cultivated on elastic membranes and mechanically activated by a rapid single stretch (< 1 sec) in order to mimic *in vivo* condition as we found during a traumatic brain injury (TBI). All experiments were conducted 24 hours post-injury. Our findings indicate that 20% stretch of microglial cells does induce an activation through the increase of IBA1 protein level as well as an increase of actin fluorescence signal. This activation state is found to be simultaneous with the stiffening of BV2 cells as we measure it using a ferule-top nanoindenter. In addition, preliminary results of migration show a change in cell behavior suggesting that immune glial cells are mechanosensitive and can adopt an activated state in response to a single mechanical stretch. Additional experiments have been conducted to decipher the role of Piezo1 mechanosensitive ion channel on the mechano-activation of microglial cells.

Microglia, the resident immune cells of the CNS, have been implicated in brain plasticity and function. However, the underlying mechanisms remain largely unknown. Here, we show that Cre-dependent removal of the RelA subunit of the NF-κB transcription factor from adult microglia results in impaired learning and long-term potentiation. Depletion of RelA elicits changes in chromatin accessibility and transcriptome landscapes of microglia associated with specific gene regulatory programs driving the activation of specific microglia phenotypes. Our findings suggest that NF-κB drive specific microglia phenotypes modulating neuronal circuits for learning and memory.

EXPOSURE TO EARLY-LIFE STRESS PROMOTES SEX-DEPENDENT CHANGES IN MICROGLIA MORPHOLOGY AND PHAGOCYTIC ACTIVITY IN THE PREFRONTAL CORTEX

POSTER SESSION 01 - SECTION: BRAIN INFLAMMATION, NEURODEVELOPMENT AND DISEASE

Ana Luísa Cardoso[1,2], Jéssica Costa[1,2], Solange Martins[1], Pedro Ferreira[1,3], Carolina Lebre[1,3], Joana Guedes[1,2], João Peça[1,3]

Exposure to early life stress (ELS) induces maladaptive behaviors and increases the vulnerability to mental illness later in life. ELS can trigger changes in immune effectors, such as microglia cells, contributing to the disruption of microglia's homeostatic functions and interfering with the shaping of neuronal circuits. In this work, we have employed a maternal separation and unpredictable stress model (MSUS) to study the impact of ELS in microglia morphology and phagocytic activity in the pre-frontal cortex (PFC), a brain region implicated in decision making and impulse control. Exposure to the MSUS protocol between P2 and P14 drives sex-dependent changes in microglia morphology and number across the PFC. While an increase in microglia ramification and total number was apparent in P10 female MSUS mice, male MSUS mice failed to present any microglia adaptation at this age, but show significant alterations at P40, including a hyper-ramified phenotype. In addition, a decrease in the volume of CD68 positive structures in PFC microglia of P10 MSUS mice was also observed. In males, this result could be further correlated with a decrease in the number of microglia exhibiting one or more phagocytic cups, particularly in the internal layers of the medial orbital cortex, suggesting a region and layer-specific decrease in microglia phagocytic activity. This reduction in phagocytosis can, in turn, jeopardize the elimination of key cellular populations within the PFC, such as PV+ inhibitory neurons. Overall, this work points towards a differential response of male microglia to ELS, ultimately contributing to shed light on the higher susceptibility of males to this type of stress.

INVESTIGATING THE ROLE OF MICROGLIAL TDP-43 IN BRAIN DEVELOPMENT

POSTER SESSION 01 - SECTION: BRAIN INFLAMMATION, NEURODEVELOPMENT AND DISEASE

Anne-Claire Compagnion[1], Ileana Jelescu[2], Valerio Zerbi[3,4], Rosa Paolicelli[1]
[1]University of Lausanne, Department Of Biomedical Sciences, Lausanne, Switzerland, [2]Lausanne University Hospital, Department Of Radiology, Lausanne, Switzerland, [3]EPFL, Institute Of Bioengineering (ibi), Lausanne, Switzerland, [4]ETH Zurich, Department Of Health Sciences And Technology, Zurich, Switzerland

Microglia, the innate immune cells of the brain, contribute to neural circuits refinement by removing unnecessary synapses during brain development. Recent studies indicate that microglia are also responsible for pathological synapse elimination in neurodegeneration. TDP-43, encoded by the *TARDBP* gene, is a highly conserved DNA/RNA binding protein that shuttles between the nucleus and the cytoplasm. Its aberrant cytoplasmic aggregation, commonly associated with depletion of nuclear TDP-43, is a hallmark of Amyotrophic Lateral Sclerosis (ALS) and frontotemporal lobar degeneration (FTLD). We previously showed that microglial TDP-43 regulates phagocytosis and that conditional knockout (cKO) mice selectively lacking TDP-43 in microglia display pathological synapse loss and defective motor behavior. Here, we hypothesize that microglial TDP-43 plays important roles in shaping neuronal circuitries during early brain development, thus providing susceptibility for developing neurological disorders later in life. To investigate possible developmental defects we used $Cx3cr1^{CREert2}$;$Tardbp^{floxed/floxed}$ (cKO)and $Cx3cr1^{CREert2}$;$Tardbp^{wt/wt}$ (control) mice at post-natal day 15 (P15). Unbiased diffusion MRI analysis of the whole brain revealed sex-dependent microstructure alterations specifically in the somatosensory and motor cortex of cKO mice. Such structural changes were associated with decreased density in microglia and in Olig2-positive cells with myelin abnormalities in the somatosensory-motor area. Further analyses are ongoing to elucidate the mechanisms underlying the specific cortical defects mediated by microglial TDP-43 depletion. Overall, these findings suggest that microglia dysfunction induced by the lack of TDP-43 can influence the maturation of the postnatal motor-somatosensory cortex, and be causally implicated in the pathogenesis of brain disorders.

Glucocorticoid receptor in astrocytes regulates midbrain dopamine neurodegeneration through connexin hemichannel activity.
The precise contribution of astrocytes in neuroinflammatory process occurring in Parkinson's disease (PD) is not well characterized. In this study, using GR mice that are conditionally inactivated for glucocorticoid receptor (GR) in astrocytes, we have examined the actions of astrocytic GR during dopamine neuron (DN) degeneration triggered by the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). The results show significantly augmented DN loss in GR mutant mice in substantia nigra (SN) compared to controls. Hypertrophy of microglia but not of astrocytes was greatly enhanced in SN of these astrocytic GR mutants intoxicated with MPTP, indicating heightened microglial reactivity compared to similarly-treated control mice. In the SN of GR astrocyte mutants, specific inflammation-associated transcripts ICAM-1, TNF-α and Il-1β as well as TNF-α protein levels were significantly elevated after MPTP neurotoxicity compared to controls. Interestingly, this paralleled increased connexin hemichannel activity and elevated intracellular calcium levels in astrocytes examined in acute midbrain slices from control and mutant mice treated with MPP+ . The increased connexin-43 hemichannel activity was found in vivo in MPTP-intoxicated mice. Importantly, treatment of MPTP-injected GR mutant mice with TAT-Gap19 peptide, a specific connexin-43 hemichannel blocker, reverted both DN loss and microglial activation; in wild-type mice there was partial but significant survival effect. In the SN of post-mortem PD patients, a significant decrease in the number of astrocytes expressing nuclear GR was observed, suggesting the participation of astrocytic GR deregulation of inflammatory process in PD. Overall, these data provide mechanistic insights into GR-modulated processes in vivo, specifically in astrocytes, that contribute to a pro-inflammatory state and dopamine neurodegeneration in PD pathology.

TLR9 activation via microglial glucocorticoid receptors contributes to degeneration of midbrain dopamine neurons.
Inflammation is a characteristic feature of Parkinson's disease (PD). We examined the role of TLR9 and its regulation by glucocorticoid receptors (GRs) in degeneration of substantia nigra dopamine neurons (DNs). TLR9 agonist, CpG-ODN, induced DN degeneration in mice lacking GR in microglia but not in controls. TLR9 deletion reduced DN loss in neurotoxin, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) mouse model of PD. GR regulates TLR9 activation during MPTP neurotoxicity as TLR9 antagonist suppressed increased DN loss in microglia/macrophage GR mutant mice. GR absence in microglia enhanced TLR9 translocation to endolysosomes and facilitated its cleavage leading to pro-inflammatory gene expression. GR-dependent TLR9 activation also triggered DN loss following intranigral injection of mitochondrial DNA. Finally, microglial GR sensitivity to A53T-alpha-synuclein induced DN degeneration as well as decreased microglial GR expression observed in SN of PD brain samples, all suggest that reduced microglial GR activity in SN can stimulate TLR9 activation and DN loss in PD pathology.

Background: Chronic hyperammonemia, a main contributor to hepatic encephalopathy, leads to neuroinflammation which alters neurotransmission leading to cognitive impairment. Currently there are no specific treatments for the neurological alterations in hepatic encephalopathy. Extracellular vesicles (EVs) from mesenchymal stem cells (MSCs) reduce neuroinflammation in some pathological conditions. **Aims:** The aim of this work was to assess if treatment of hyperammonemic rats with EVs from MSCs reduces neuroinflammation, improves neurotransmission in hippocampus and restores cognitive function and to study the mechanisms involved. **Methods:** Treatment of EVs from MSCs was performed *in vivo* by i.v. injection and *ex vivo* in hippocampal slices from hyperammonemic or control rats. Effects on neuroinflammation (microglia and astrocytes activation and content of inflammatory markers in hippocampus) were assessed by immunohistochemistry, immunofluorescence and western blot. Learning and memory were assessed using the following tests: object location, object recognition, Y maze and radial maze. **Results:** The EVs injected reached the hippocampus. Hyperammonemia induced neuroinflammation in hippocampus and impaired learning and memory in the tests performed. Treatment with EVs reduced microglia and astrocytes activation, the content of IL-1β and NF-kB activation and restored performance of hyperammonemic rats in all the behavioral tests. Studies adding EVs to hippocampal slices ex vivo showed that these beneficial effects were dependent on TGFβ contained in the EVs, which reduced NF-kB activation and the subsequent neuroinflammation. **Conclusions:** EVs from MSCs reduce neuroinflammation in hippocampus and restore cognitive function in hyperammonemic rats. EVs from MSCs may be useful to improve cognitive function in patients with MHE.

Chlamydia pneumoniae is a respiratory tract pathogen but can also infect the central nervous system (CNS). Recently, the link between C. pneumoniae CNS infection and late-onset dementia has become increasingly evident. In mice, CNS infection has been shown to occur weeks to months after intranasal inoculation. By isolating live C. pneumoniae from tissues and using immunohistochemistry, we show that C. pneumoniae can infect the olfactory and trigeminal nerves, olfactory bulb and brain within 72 hours in mice. C. pneumoniae infection also resulted in dysregulation of key pathways involved in Alzheimer's disease pathogenesis at 7 and 28 days after inoculation. Interestingly, amyloid beta accumulations were also detected adjacent to the C. pneumoniae inclusions in the olfactory system. Furthermore, injury to the nasal epithelium resulted in increased peripheral, but decreased CNS infection. In vitro, C. pneumoniae was able to infect peripheral nerve and CNS glia. In summary, the nerves extending between the nasal cavity and the brain constitute invasion paths by which C. pneumoniae can rapidly invade the CNS likely by surviving in glia and leading to Aβ deposition.

In vitro modulation of Schwann cell behavior by VEGF and PDGF in an inflammatory environment.
Peripheral glial cell transplantation with Schwann cells (SCs) is a promising approach for treating spinal cord injury (SCI). However, improvements are needed and one avenue to enhance regenerative functional outcomes is to combine growth factors with cell transplantation. Vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF) are neuroprotective, and a combination of these factors has improved outcomes in rat SCI models. Thus, transplantation of SCs combined with VEGF and PDGF may further improve regenerative outcomes. First, however, we must understand how the two factors modulate SCs. In this in vitro study, we show that an inflammatory environment decreased the rate of SC-mediated phagocytosis of myelin debris but the addition of VEGF and PDGF (alone and combined) improved phagocytosis. Cytokine expression by SCs in the inflammatory environment revealed that addition of PDGF led to significantly lower level of

pro-inflammatory cytokine, TNF-α, but IL-6 and anti-inflammatory cytokines (TGF-β and IL-10), remained unaltered. Further, PDGF was able to decrease the expression of myelination associated gene Oct6 in the presence of inflammatory environment. Overall, these results suggest that the use of VEGF and/or PDGF combined with SC transplantation may be beneficial in SCI therapy.

Antimicrobial responses of peripheral and central nervous system glia against Staphylococcus aureus.
Staphylococcus aureus infections of the central nervous system are serious and can be fatal. S. aureus is commonly present in the nasal cavity, and after injury to the nasal epithelium it can rapidly invade the brain via the olfactory nerve. The trigeminal nerve constitutes another potential route of brain infection. The glia of these nerves, olfactory ensheathing cells (OECs) and trigeminal nerve Schwann cells (TgSCs), as well as astrocytes populating the glia limitans layer, can phagocytose bacteria. Whilst some glial responses to S. aureus have been studied, the specific responses of different glial types are unknown. Here, we compared how primary mouse OECs, TgSCs, astrocytes and microglia responded to S. aureus. All glial types internalized the bacteria within phagolysosomes, and S. aureus-conjugated BioParticles could be tracked with subtle but significant differences in time-course of phagocytosis between glial types. Live bacteria could be isolated from all glia after 24 h in culture, and microglia, OECs and TgSCs exhibited better protection against intracellular S. aureus survival than astrocytes. All glial types responded to the bacteria by cytokine secretion. Overall, OECs secreted the lowest level of cytokines, suggesting that these cells, despite showing strong capacity for phagocytosis, have immunomodulatory functions that can be relevant for neural repair.

Can Invade the Central Nervous System the Olfactory and Trigeminal Nerves and Infect Peripheral Nerve Glial Cells.
can infect the brain and has been linked to late-onset dementia. , which infects mice, is often used to model human chlamydial infections. While it has been suggested to be also important for modelling brain infection, nervous system infection by has not been reported in the literature. has been shown to infect the olfactory bulb in mice after intranasal inoculation, and has therefore been suggested to invade the brain the olfactory nerve; however, nerve infection has not been shown to date. Another path by which certain bacteria can reach the brain is the trigeminal nerve, but it remains unknown whether species can infect this nerve. Other bacteria that can invade the brain the olfactory and/or trigeminal nerve can do so rapidly, however, whether spp. can reach the brain earlier than one-week post inoculation remains unknown. In the current study, we showed that can within 48 h invade the brain the olfactory nerve, in addition to infecting the trigeminal nerve. We also cultured the glial cells of the olfactory and trigeminal nerves and showed that readily infected the cells, constituting a possible cellular mechanism explaining how the bacteria can invade the nerves without being eliminated by glial immune functions. Further, we demonstrated that olfactory and trigeminal glia differed in their responses to , with olfactory glia showing less infection and stronger immune response than trigeminal glia.

Burkholderia pseudomallei invades the olfactory nerve and bulb after epithelial injury in mice and causes the formation of multinucleated giant glial cells in vitro.
The infectious disease melioidosis is caused by the bacterium Burkholderia pseudomallei. Melioidosis is characterised by high mortality and morbidity and can involve the central nervous system (CNS). We have previously discovered that B. pseudomallei can infect the CNS via the olfactory and trigeminal nerves in mice. We have shown that the nerve path is dependent on mouse strain, with outbred mice showing resistance to olfactory nerve infection. Damage to the nasal epithelium by environmental factors is common, and we hypothesised that injury to the olfactory epithelium may increase the vulnerability of the olfactory nerve to microbial insult. We therefore investigated this, using outbred mice that were intranasally inoculated with B. pseudomallei, with or without methimazole-induced injury to the olfactory neuroepithelium. Methimazole-mediated injury resulted in increased B. pseudomallei invasion of the olfactory epithelium, and only in pre-injured animals were bacteria found in the olfactory nerve and bulb. In vitro assays demonstrated that B. pseudomallei readily infected glial cells isolated from the olfactory and trigeminal nerves (olfactory ensheathing cells and trigeminal Schwann cells, respectively). Bacteria were degraded by some cells but persisted in other cells, which led to the formation of multinucleated giant cells (MNGCs), with olfactory ensheathing cells less likely to form MNGCs than Schwann cells. Double Cap mutant bacteria, lacking the protein BimA, did not form MNGCs. These data suggest that injuries to the olfactory epithelium expose the primary olfactory nervous system to bacterial invasion, which can then result in CNS infection with potential pathogenic consequences for the glial cells.

Single nucleotide polymorphisms and genotypes of transient receptor potential ion channel and acetylcholine receptor genes from isolated B lymphocytes in myalgic encephalomyelitis/chronic fatigue syndrome patients.
Objective The pathomechanism of chronic fatigue syndrome/myalgic encephalomyelitis (CFS/ME) is unknown; however, a small subgroup of patients has shown muscarinic antibody positivity and reduced symptom presentation following anti-CD20 intervention. Given the important roles of calcium (Ca) and acetylcholine (ACh) signalling in B cell activation and potential antibody development, we aimed to identify relevant single nucleotide polymorphisms (SNPs) and genotypes in isolated B cells from CFS/ME patients. Methods A total of 11 CFS/ME patients (aged 31.82 ± 5.50 years) and 11 non-fatigued controls (aged 33.91 ± 5.06 years) were included. Flow cytometric protocols were used to determine B cell purity, followed by SNP and genotype analysis for 21 mammalian TRP ion channel genes and nine mammalian ACh receptor genes. SNP association and genotyping analysis were performed using ANOVA and PLINK analysis software. Results Seventy-eight SNPs were identified in nicotinic and muscarinic acetylcholine receptor genes in the CFS/ME group, of which 35 were in mAChM3. The remaining SNPs were identified in nAChR delta (n = 12), nAChR alpha 9 (n = 5), TRPV2 (n = 7), TRPM3 (n = 4), TRPM4 (n = 1) mAChRM3 2 (n = 2), and mAChRM5 (n = 3) genes. Nine genotypes were identified from SNPs in TRPM3 (n = 1), TRPC6 (n = 1), mAChRM3 (n = 2), nAChR alpha 4 (n = 1), and nAChR beta 1 (n = 4) genes, and were located in introns and 3' untranslated regions. Odds ratios for these specific genotypes ranged between 7.11 and 26.67 for CFS/ME compared with the non-fatigued control group. Conclusion This preliminary investigation identified a number of SNPs and genotypes in genes encoding TRP ion channels and AChRs from B cells in patients with CFS/ME. These may be involved in B cell functional changes, and suggest a role for Ca dysregulation in AChR and TRP ion channel signalling in the pathomechanism of CFS/ME.

Dysregulation of Protein Kinase Gene Expression in NK Cells from Chronic Fatigue Syndrome/Myalgic Encephalomyelitis Patients.
The etiology and pathomechanism of chronic fatigue syndrome/myalgic encephalomyelitis (CFS/ME) are unknown. However, natural killer (NK) cell dysfunction, in particular reduced NK cytotoxic activity, is a consistent finding in CFS/ME patients. Previous research has reported significant changes in intracellular mitogen-activated protein kinase pathways from isolated NK cells. The purpose of this present investigation was to examine whether protein kinase genes have a role in abnormal NK cell intracellular signaling in CFS/ME.

Human Chlamydia pneumoniae isolates demonstrate ability to recover infectivity following penicillin treatment whereas animal isolates do not.
Chlamydia pneumoniae strains have recently been demonstrated to have substantially different capacities to enter and recover from IFN-γ-induced persistence, depending on whether they are from human or animal host sources. Here, we examined the ability of two human and two animal strains to enter and be rescued from penicillin-induced persistence. The ability to form inclusions after the addition of penicillin was much reduced in the two animal isolates (koala LPCoLN, bandicoot B21) compared to the two human isolates (respiratory AR39 and heart A03). The penicillin treatment resulted in a dose-dependent loss of infectious progeny for all isolates, with the human strains failing to produce infectious progeny at lower doses of penicillin than the animal strains. The most remarkable finding however was the contrasting ability of the isolates to recover infectious progeny production after rescue by removal of the penicillin (at 72 h) and continued culture. The animal isolates both showed virtually no recovery from the penicillin treatment conditions. In contrast, the human isolates showed a significant ability to recovery infectivity, with the heart isolate (A03) showing the most marked recovery. Combined, these data further support the hypothesis that the ability to establish and recover from persistence appears to be enhanced in human C. pneumoniae strains compared to animal strains.

24989637: Chacko A, Barker CJ, Beagley KW, Hodson MP, Plan MR, Timms P, Huston WM
Increased sensitivity to tryptophan bioavailability is a positive adaptation by the human strains of Chlamydia pneumoniae. One of the most significant activities induced by interferon-gamma against intracellular pathogens is the induction of IDO (indoleamine 2,3-dioxygenase) expression, which subsequently results in the depletion of tryptophan. We tested the hypothesis that human strains of Chlamydia pneumoniae are more sensitive to tryptophan limitation than animal C. pneumoniae strains. The human strains were significantly more sensitive to IFN-γ than the animal strains in a lung epithelia cell model (BEAS-2B), with exposure to 1 U ml(-1) IFN-γ resulting in complete loss of infectious yield of human strains, compared to the animal strains where reductions in infectious progeny were around 3.5-4.0 log. Strikingly, the IFN-γ induced

loss of ability to form infectious progeny production was completely rescued by removal of the IFN-γ and addition of exogenous tryptophan for the human strains, but not the animal strains. In fact, a human heart strain was more capable of entering a non-infectious, viable persistent stage when exposed to IFN-γ and was also more effectively rescued, compared to a human respiratory strain. Exquisite susceptibility to IFN-γ, specifically due to tryptophan availability appears to be a core adaptation of the human C. pneumoniae strains, which may reflect the chronic nature of their infections in this host.
Mol Microbiol, 2014; 93
24682324: Huston WM, Barker CJ, Chacko A, Timms P
Evolution to a chronic disease niche correlates with increased sensitivity to tryptophan availability for the obligate intracellular bacterium Chlamydia pneumoniae.
The chlamydiae are obligate intracellular parasites that have evolved specific interactions with their various hosts and host cell types to ensure their successful survival and consequential pathogenesis. The species Chlamydia pneumoniae is ubiquitous, with serological studies showing that most humans are infected at some stage in their lifetime. While most human infections are asymptomatic, C. pneumoniae can cause more-severe respiratory disease and pneumonia and has been linked to chronic diseases such as asthma, atherosclerosis, and even Alzheimer's disease. The widely dispersed animal-adapted C. pneumoniae strains cause an equally wide range of diseases in their hosts. It is emerging that the ability of C. pneumoniae to survive inside its target cells, including evasion of the host's immune attack mechanisms, is linked to the acquisition of key metabolites. Tryptophan and arginine are key checkpoint compounds in this host-parasite battle. Interestingly, the animal strains of C. pneumoniae have a slightly larger genome, enabling them to cope better with metabolite restrictions. It therefore appears that as the evolutionarily more ancient animal strains have evolved to infect humans, they have selectively become more "susceptible" to the levels of key metabolites, such as tryptophan. While this might initially appear to be a weakness, it allows these human C. pneumoniae strains to exquisitely sense host immune attack and respond by rapidly reverting to a persistent phase. During persistence, they reduce their metabolic levels, halting progression of their developmental cycle, waiting until the hostile external conditions have passed before they reemerge.

The Purkinje Cell Degeneration (PCD) mouse presents a mutation in the *Ccp1* gene that produces the selective post-natal death of both Purkinje cells in the cerebellum and mitral cells in the olfactory bulb (OB). Along with this neuronal loss, a strong microgliosis takes place in the cerebellum whereas a moderate microgliosis occurs in the OB. Therefore, the PCD is an excellent animal model to analyze microglial response, because it has two different neurodegenerative scenarios at different ages and with different degenerative time-courses. Therefore, we analyze the evolution of microglia in these regions at different ages with several techniques. For this purpose, microglial cells and tissue slices were obtained from the cerebellum and OB of both wild-type and PCD mice. Subsequently, qPCR analyses and immunofluorescence techniques were performed to characterize microglia by studying gene and protein expression. Likewise, the morphology, motility and phagocytosis of microglia were analyzed in both cell cultures and in cerebellar and OB slices. The results obtained suggested that the microglia of PCD mice presents a differential gene expression for the analyzed genes. Besides, a higher inflammatory protein expression was observed in PCD mice. Finally, the motility and phagocytosis were more evident in PCD than in wild-type microglia in cultured cells as well as in cerebellar and OB slices. It can be concluded that both the mutation of *Ccp1* gene and the neurodegenerative environment affects microglial features related to gene and protein expression, morphology, motility and phagocytosis cell. **Support:** MICINN, JCyL, USAL, Banco Santander **E-mail:** dpb@usal.es, ddiaz@usal.es, ewp@usal.es

CEREBELLAR INFLAMMATION SUPPORTS AUTISM-RELATED BEHAVIORS IN THE CNTNAP2 MOUSE MODEL OF AUTISM SPECTRUM DISORDERS

POSTER SESSION 01 - SECTION: BRAIN INFLAMMATION, NEURODEVELOPMENT AND DISEASE

Luca Pangrazzi, Luigi Balasco, Enrica Cerilli, Gabriele Chelini, Caterina Tobia, Yuri Bozzi
University of Trento, Cimec, Rovereto, Italy

Autism spectrum disorders (ASDs) are a heterogeneous group of neurodevelopmental disorders associated to social communication deficits and repetitive sensory–motor behaviors. These symptoms affect children from the early childhood and produce clinically significant developmental impairments. Immune dysfunction has recently emerged as major contributor to the neurodevelopmental deficits observed in people with ASD. This condition is often linked with a strong inflammatory state, which contributes to neurodegeneration and impairments in synaptic plasticity. Cntnap2$^{-/-}$ mice have widely been considered a robust animal model of ASD. In the current study, we analyzed the expression of classical pro-inflammatory molecules in the cerebral cortex, hippocampus and cerebellum of mutant mice. mRNA and protein expression of IL-6, TNF, IFNγ and IL-1β were increased in the cerebellum of Cntnap2$^{-/-}$ mice, in comparison with their WT littermates. In addition, increased levels of the same molecules were found in the blood of both mutant mice. Finally, a link could be identified between inflammation within cerebellum and impaired social and motor behaviors (common ASD-related features) in these mice. Taken together, these results suggest that cerebellar inflammation may support ASD-like behaviors in autism.

T cells, aging and senescence.
The T cell compartment undergoes characteristic changes with age, which contribute to increased incidence and severity of infections and reduced immunogenicity and efficacy of many vaccines in the older population. Production of naïve T cells is severely impaired due to a decreased output of lymphoid cells from the bone marrow and the involution of the thymus. At the same time, antigen-experienced, highly differentiated T cells accumulate resulting in a diminished T cell receptor repertoire. These cells show some similarities with senescent cells, such as shorter telomers, accumulated DNA damage and metabolic changes. Latent infection with Cytomegalovirus also impacts the T cell compartment and aggravates several of its age-associated changes. Loss of CD28 expression is one hallmark of T cells after repeated antigenic stimulation, but CD28 T cells cannot be considered truly senescent as e.g. they are still able to proliferate upon adequate stimulation. Several additional markers have been suggested in order to define a potential fully senescent T cell population, but no consensus definition has been reached so far. It has been postulated that highly differentiated senescent-like T cells are unable to eliminate other senescent cell types. Removal of senescent non-immune cells has been shown to be beneficial for the organism and a reliable definition of senescent T cells is essential for an extension of this concept to T cells.

Natural Antioxidants: A Novel Therapeutic Approach to Autism Spectrum Disorders?
Autism spectrum disorders (ASD) are a group of neurodevelopmental syndromes with both genetic and environmental origins. Several recent studies have shown that inflammation and oxidative stress may play a key role in supporting the pathogenesis and the severity of ASD. Thus, the administration of anti-inflammatory and antioxidant molecules may represent a promising strategy to counteract pathological behaviors in ASD patients. In the current review, results from recent literature showing how natural antioxidants may be beneficial in the context of ASD will be discussed. Interestingly, many antioxidant molecules available in nature show anti-inflammatory activity. Thus, after introducing ASD and the role of the vitamin E/vitamin C/glutathione network in scavenging intracellular reactive oxygen species (ROS) and the impairments observed with ASD, we discuss the concept of functional food and nutraceutical compounds. Furthermore, the effects of well-known nutraceutical compounds on ASD individuals and animal models of ASD are summarized. Finally, the importance of nutraceutical compounds as support therapy useful in reducing the symptoms in autistic people is discussed.

Oxidative Stress and Immune System Dysfunction in Autism Spectrum Disorders.
Autism Spectrum Disorders (ASDs) represent a group of neurodevelopmental disorders associated with social and behavioral impairments. Although dysfunctions in several signaling pathways have been associated with ASDs, very few molecules have been identified as potentially effective drug targets in the clinic. Classically, research in the ASD field has focused on the characterization of pathways involved in neural development and synaptic plasticity, which support the pathogenesis of this group of diseases. More recently, immune system dysfunctions have been observed in ASD. In addition, high levels of reactive oxygen species (ROS), which cause oxidative stress, are present in ASD patients. In this review, we will describe the major alterations in the expression of genes coding for enzymes involved in the ROS scavenging system, in both ASD patients and ASD mouse models. In addition, we will discuss, in the context of the most recent literature, the possibility that oxidative stress, inflammation and immune system dysfunction may be connected to, and altogether support, the pathogenesis and/or severity of ASD. Finally, we will discuss the possibility of novel treatments aimed at counteracting the interplay between ROS and inflammation in people with ASD.

The impact of oxidative stress, inflammation, and senescence on the maintenance of immunological memory in the bone marrow in old age.
The bone marrow (BM) provides a preferential survival environment for the long-term maintenance of antigen-experienced adaptive immune cells. After the contact with antigens, effector/memory T cells and plasma cell precursors migrate to the BM, in which they can survive within survival niches in an antigen-independent manner. Despite this, the phenotype of adaptive immune cells changes with aging, and BM niches themselves are affected, leading to impaired long-term maintenance of immunological memory in the elderly as a result. Oxidative stress, age-related inflammation (inflammaging), and cellular senescence appear to play a major role in this process. This review will summarize the age-related changes in T and B cell phenotype, and in the BM niches, discussing the possibility that the accumulation of highly differentiated, senescent-like T cells in the BM during aging may cause inflammation in the BM and promote oxidative stress and senescence. In addition, senescent-like T cells may compete for space with other immune cells within the marrow, partially excluding effector/memory T cells and long-lived plasma cells from the niches.

Abnormal Whisker-Dependent Behaviors and Altered Cortico-Hippocampal Connectivity in Shank3b-/- Mice.
Abnormal tactile response is an integral feature of Autism Spectrum Disorders (ASDs), and hypo-responsiveness to tactile stimuli is often associated with the severity of ASDs core symptoms. Patients with Phelan-McDermid syndrome (PMS), caused by mutations in the SHANK3 gene, show ASD-like symptoms associated with aberrant tactile responses. The neural underpinnings of these abnormalities are still poorly understood. Here we investigated, in Shank3b-/- adult mice, the neural substrates of whisker-guided behaviors, a key component of rodents' interaction with the surrounding environment. We assessed whisker-dependent behaviors in Shank3b-/- adult mice and age-matched controls, using the textured novel object recognition (tNORT) and whisker nuisance (WN) test. Shank3b-/- mice showed deficits in whisker-dependent texture discrimination in tNORT and behavioral hypo-responsiveness to repetitive whisker stimulation in WN. Sensory hypo-responsiveness was accompanied by a significantly reduced activation of the primary somatosensory cortex (S1) and hippocampus, as measured by c-fos mRNA induction, a proxy of neuronal activity following whisker stimulation. Moreover, resting-state fMRI showed a significantly reduced S1-hippocampal connectivity in Shank3b mutants, in the absence of altered connectivity between S1 and other somatosensory areas. Impaired crosstalk between hippocampus and S1 might underlie Shank3b-/- hypo-reactivity to whisker-dependent cues, highlighting a potentially generalizable somatosensory dysfunction in ASD.

Fcμ receptor as a Costimulatory Molecule for T Cells.
Fc receptor for IgM (FcμR)-deficient mice display dysregulated function of neutrophils, dendritic cells, and B cells. The relevance of FcμR to human T cells is still unknown. We show that FcμR is mostly stored inside the cell and that surface expression is tightly regulated. Decreased surface expression on T cells from elderly individuals is associated with alterations in the methylation pattern of the FCMR gene. Binding and internalization of IgM stimulate transport of FcμR to the cell surface to ensure sustained IgM uptake. Concurrently, IgM accumulates within the cell, and the surface expression of other receptors increases, among them the T cell receptor (TCR) and costimulatory molecules. This leads to enhanced TCR signaling, proliferation, and cytokine release, in response to low, but not high, doses of antigen. Our findings indicate that FcμR is an

important regulator of T cell function and reveal an additional mode of interaction between B and T cells.

CD28 and CD57 define four populations with distinct phenotypic properties within human CD8 T cells.
After repeated antigen exposure, both memory and terminally differentiated cells can be generated within CD8 T cells. Although, during their differentiation, activated CD8 T cells may first lose CD28, and CD28 cells may eventually express CD57 as a subsequent step, a population of CD28 CD57 (DP) CD8 T cells can be identified in the peripheral blood. How this population is distinct from CD28 CD57 (DN) CD8 T cells, and from the better characterized non-activated/early-activated CD28 CD57 and senescent-like CD28 CD57 CD8 T cell subsets is currently unknown. Here, RNA expression of the four CD8 T cell subsets isolated from human PBMCs was analyzed using microarrays. DN cells were more similar to "early" highly differentiated cells, with decreased TNF and IFN-γ production, impaired DNA damage response and apoptosis. Conversely, increased apoptosis and expression of cytokines, co-inhibitory, and chemokine receptors were found in DP cells. Higher levels of DP CD8 T cells were observed 7 days after Hepatitis B vaccination, and decreased levels of DP cells were found in rheumatoid arthritis patients. More DP and DN CD8 T cells were present in the bone marrow, in comparison with PBMCs. In summary, our results indicate that DP and DN cells are distinct CD8 T cell subsets displaying defined properties.

The impact of body mass index on adaptive immune cells in the human bone marrow.
Obesity has been associated with chronic inflammation and oxidative stress. Both conditions play a determinant role in the pathogenesis of age-related diseases, such as immunosenescence. Adipose tissue can modulate the function of the immune system with the secretion of molecules influencing the phenotype of immune cells. The importance of the bone marrow (BM) in the maintenance of antigen-experienced adaptive immune cells has been documented in mice. Recently, some groups have investigated the survival of effector/memory T cells in the human BM. Despite this, whether high body mass index (BMI) may affect immune cells in the BM and the production of molecules supporting the maintenance of these cells it is unknown.

"Inflamm-aging" influences immune cell survival factors in human bone marrow.
The bone marrow (BM) plays a key role in the long-term maintenance of immunological memory. However, the impact of aging on the production of survival factors for effector/memory T cells and plasma cells in the human BM has not been studied. We now show that the expression of molecules involved in the maintenance of immunological memory in the human BM changes with age. While IL-15, which protects potentially harmful CD8 CD28 senescent T cells, increases, IL-7 decreases. IL-6, which may synergize with IL-15, is also overexpressed. In contrast, a proliferation-inducing ligand, a plasma cell survival factor, is reduced. IFN-y, TNF, and ROS accumulate in the BM in old age. IL-15 and IL-6 expression are stimulated by IFN-y and correlate with ROS levels in BM mononuclear cells. Both cytokines are reduced by incubation with the ROS scavengers N-acetylcysteine and vitamin C. IL-15 and IL-6 are also overexpressed in the BM of superoxide dismutase 1 knockout mice compared to their WT counterparts. In summary, our results demonstrate the role of inflammation and oxidative stress in age-related changes of immune cell survival factors in the BM, suggesting that antioxidants may be beneficial in counteracting immunosenescence by improving immunological memory in old age.

Prenatal exposure to infectious or inflammatory insults can increase the risk of developing neuropsychiatric disorder of neurodevelopmental etiology. A tight association between elevated IL-6 during pregnancy, IL6 elevation in the offspring and altered behavioral tasks has been widely reported. Taking advantage of a very well-established animal model of Maternal Immune Activation (MIA), we demonstrated that a single IL6 or Poly I:C administration in pregnant dams at gestational days (gd) 15 induces a significant excitation/inhibition (E/I) imbalance in the offspring, accompanied by an abnormal connectivity, as well as behavioral deficits. Furthermore, we found out that the long-lasting effects mediated by IL6 were causally linked to an early genetic signature involving the genes STAT3 and RGS4 (Mirabella et al., Immunity 2021). In the attempt to define putative prognostic biomarkers for altered neurodevelopmental disease as a consequence of MIA, we are analyzing in the Poly I:C treated dams and offspring, the profile of pro-inflammatory biomarkers, to be correlated with connectomic and behavioral alterations. Also, we are performing in humans a characterization of the inflammatory biomarkers generated during infection in pregnancy. The correlation between maternal and newborn inflammatory molecule levels is investigated by comparing the levels of biomarkers in the blood of each mother and her baby (funicular blood). Results from this study will allow to correlate the maternal clinical features and circulating immune biomarkers with neonatal brain signatures, in order to predict high risk of abnormal neurodevelopment in newborns. The maintenance of organelle and membrane compartment identity and function under stress conditions is essential for all complex organisms. Neurons are particularly well-suited for the investigation of stress responses as they represent one of the most complex cell types in animals and individual neurons must be maintained over the lifetime of an organism. Neurons have long axons separating soma and synapses with synaptic terminals showing one of the highest cellular rates of mitochondrial based energy consumption. Mitochondrial dysfunction is associated with multiple neurodegenerative diseases, however the precise molecular and cellular links between mitochondrial defects and neuronal degeneration remain largely elusive. To address the relationship between mitochondrial stress and synaptic integrity, we established a mitochondrial protein import (MPI)-stress model in Drosophila motoneurons. We used cellular, immunohistochemical, and transcriptomic approaches to identify the cellular mechanisms underlying the synaptic degeneration caused by impaired mitochondrial protein import. Here, we will present first insights into the transcriptional and cellular programs potentially contributing to progressive neurodegeneration in these conditions.

THE POST-DEVELOPMENTAL ROLES OF THE NETRIN RECEPTOR UNC-40/DCC IN HEALTH AND DISEASE

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Sapir Sela[1], Meital Oren-Suissa[2]
[1]Weizmann, Brain Science, Rehovot, Israel, [2]Weizmann Institute of Science, Brain Sciences, Rehovot, Israel

Synaptogenesis and maintenance are crucial for the formation of proper brain circuits, and for brain stability and health. The netrin-1 receptor DCC is involved not only in axon guidance and synapse formation in the developing brain, but also in synaptic maintenance, as it is expressed in certain types of cells in the adult mammalian brain. In recent years, polymorphisms in the DCC loci have been shown to associate with multiple neurodegenerative disorders, yet DCCs roles in the mature nervous system are still not completely understood. DCC is expressed in the Substentia nigra of the adult mammalian brain, in Dopamine neurons (DA) which are sensitive to degeneration in early onset of Parkinson's disease (PD). However, it is unclear whether and how DCC in involved in the disease. We utilize *C. elegans* to investigate the role of DCC in neurodegeneration. Surprisingly, we found that the expression of the worm homolog of DCC, UNC-40 in DA neurons is associated with a worse outcome for these neurons in a *C. elegans* model for Parkinson's disease (6-OHDA treatment). Conversely, in UNC-40-null animals, DA neurons survived more under 6-OHDA and showed almost no degeneration phenotype. Remarkably, UNC-40 stabilization using CRISPR was sufficient to significantly enhance DA cell degradation even without 6-OHDA treatment. We have also found that UNC-40 stabilization induces parthanatos, a novel cell-death pathway that has been implicated in the pathology of PD. Taken together, our results reveal new roles for UNC-40/DCC in the mature nervous system, and shed light on its involvement in neuronal health.

STUDY OF MECHANOTRANSDUCTION AND MIGRATION BEHAVIOR IN A KRABBE DISEASE CELL MODEL.

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Roberta Mezzena, Ilaria Tonazzini, Ambra Del Grosso, Marco Cecchini
Istituto Nanoscienze Consiglio Nazionale delle Ricerche (CNR) and Scuola Normale Superiore, National Enterprise For Nanoscience And Nanotechnology (nest), Pisa, Italy

Aims Krabbe disease (KD) is a genetic rare lysosomal storage pathology causing progressive neurodegeneration. The involved gene in KD codifies for the galactosylceramidase (GALC) enzyme. GALC loss causes the accumulation of toxic lipids, disruption of autophagy and degradation processes, and leads to devastating myelin loss: several molecular pathways are involved and a clear pathogenetic signalling picture is not present to date. Therefore, our research focuses on the identification of molecular linkers in the KD pathogenesis. **Methods** We study mechanotransduction and migration processes in primary fibroblasts collected from the twitcher (TWI) mouse, a KD murine model. By time-lapse microscopy, we investigate single-cell and collective migration. We evaluate the development and the expression of focal adhesions (FAs) components, by immunocytochemistry and western blot. We look at the crosstalk between the mechanotransduction and the autophagy process. We study the presence and localization of NBR1, the protein needed for FAs recycling and turnover, and we test TWI fibroblasts' response to rapamycin (i.e. autophagy activator) treatment. **Results** We discover an impairment in TWI fibroblasts' mechanotransduction. These cells show single cell and collective migration delay, increased FAs number per cell, reduced adhesion junction proteins, aggregated autophagy effector NBR1. We show that rapamycin administration rescues the migration behaviour and partially normalise FAs and NBR1 levels. **Conclusions** Overall, the mechanosensing impairment in TWI fibroblasts correlates with autophagy. We finally suggest that mechanotransduction impairment in TWI fibro may be linked to the lipid raft disorganization, induced by GALC-deficiency in cell membranes, and the consequent disruption of intracellular signal transduction.

Chitosan Micro-Grooved Membranes with Increased Asymmetry for the Improvement of the Schwann Cell Response in Nerve Regeneration.
Peripheral nerve injuries are a common condition in which a nerve is damaged, affecting more than one million people every year. There are still no efficient therapeutic treatments for these injuries. Artificial scaffolds can offer new opportunities for nerve regeneration applications; in this framework, chitosan is emerging as a promising biomaterial. Here, we set up a simple and effective method for the production of micro-structured chitosan films by solvent casting, with high fidelity in the micro-pattern reproducibility. Three types of chitosan directional micro-grooved patterns, presenting different levels of symmetricity, were developed for application in nerve regenerative medicine: gratings (GR), isosceles triangles (ISO) and scalene triangles (SCA). The directional patterns were tested with a Schwann cell line. The most asymmetric topography (SCA), although it polarized the cell shaping less efficiently, promoted higher cell proliferation and a faster cell migration, both individually and collectively, with a higher directional persistence of motion. Overall, the use of micro-structured asymmetrical directional topographies may be exploited to enhance the nerve regeneration process mediated by chitosan scaffolds.

Study of adhesion and migration dynamics in ubiquitin E3A ligase (UBE3A)-silenced SYSH5Y neuroblastoma cells by micro-structured surfaces.
During neuronal development, neuronal cells read extracellular stimuli from the micro/nano-environment within which they exist, retrieving essential directionality and wiring information. Here, focal adhesions (FAs-protein clusters anchoring integrins to cytoskeleton) act as sensors, by integrating signals from both the extracellular matrix environment and chemotactic factors, contributing to the final neuronal pathfinding and migration. In the processes that orchestrate neuronal development, the important function of ubiquitin E3A ligase (UBE3A) is emerging. UBE3A has crucial functions in the brain and changes in its expression levels lead to neurodevelopmental disorders: the lack of UBE3A leads to Angelman syndrome (AS, OMIN 105830), while its increase causes autisms (Dup15q-autism). By using nano/micro-structured anisotropic substrates we

previously showed that UBE3A-deficient neurons have deficits in contact guidance (Tonazzini et al, Mol Autism 2019). Here, we investigate the adhesion and migration dynamics of UBE3A-silenced SH-SY5Y neuroblastoma cells in vitro by exploiting nano/micro-grooved substrates. We analyze the molecular processes regulating the development of FAs by transfection with EGFP-vector encoding for paxillin, a protein of FA clusters, and by live-cell total-internal-reflection-fluorescence microscopy. We show that UBE3A-silenced SH-SY5Y cells have impaired FA morphological development and pathway activation, which lead to a delayed adhesion and also explain the defective contact guidance in response to directional topographical stimuli. However, UBE3A-silenced SH-SY5Y cells show an overall normal migration behavior, in terms of speed and ability to follow the GRs directional stimulus. Only the collective cell migration upon cell gaps was slightly delayed for UBE3Ash SHs. Overall, the deficits of UBE3Ash SHS-SY5Y cells in FA maturation/sensing and in collective migration may have patho-physiological implications, in AS condition, considering the much more complex stimuli that neurons find in vivo during the neurodevelopment.

NOCTURNIN'S ROLE IN OXIDATIVE STRESS MEDIATED NEURODEGENERATION

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Anne Ojo, Carla Green
UT Southwestern Medical Center, Department Of Neuroscience, Dallas, United States of America

Oxidative stress, an imbalance of reactive oxygen species (ROS) and antioxidants, has become a central focus in neurodegenerative disorders such as Parkinson's Disease (PD) due to its strong correlation with neuronal cell death. Our lab has identified Nocturnin, an NADPH phosphatase, as a putative regulator of oxidative stress. NADPH is a powerful reductant for regenerating antioxidants, such as glutathione (GSH), to lower ROS. Increases in Nocturnin expression results in a significant decrease in cellular viability following ROS challenge. In addition, Nocturnin is increased in Parkinson's patients and increases dyskinesia in L-DOPA treated patients. However, we do not understand how Nocturnin's role as an NADPH phosphatase is disrupting oxidative homeostasis and causing cell death, and whether this plays a role in development of PD. I hypothesize Nocturnin has a role in neurodegeneration in PD by lowering NADPH levels which exacerbates oxidative stress conditions and therefore a loss of Nocturnin will be protective. To characterize how changes in Nocturnin expression affect cellular health, I induced oxidative stress using H_2O_2, and measured cell viability in WT, Nocturnin knockdown, and Nocturnin overexpressed CAD neurons. Cell viability was significantly decreased in Nocturnin overexpressed cells while knockdown of Nocturnin reversed the phenotype. Interestingly, measurement of GSH in HEK293 cells showed a significant increase in GSH levels in Nocturnin knockout cells compared to WT cells at basal and oxidative stress conditions. This supports the hypothesis that a loss of Nocturnin protects the cell from cellular stress by indirectly increasing antioxidant levels.

LIGHT-INDUCED STRESS RESPONSE IS IMPAIRED IN THE RETINITIS PIGMENTOSA MOUSE MODEL CERKLKD/KO

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Rocío García-Arroyo[1,2,3], Elena Domènech[1,2,3], Carlos Herrera-Úbeda[3], Jordi Garcia-Fernàndez[3], Serena Mirra[2,3], Gemma Marfany[1,2,3]
[1]Centro de Investigación Biomédica en Red (CIBER), Rare Diseases (ciberer), Madrid, Spain, [2]Institut de Biomedicina-Institut de Recerca Sant Joan de Déu, Ibub, Barcelona, Spain, [3]University of Barcelona, Department Of Genetics, Microbiology And Statistics, Barcelona, Spain

The retina, the specialized region of the central nervous system that transduces light into neural signals, is endowed with an active metabolism. Therefore, the retina is particularly vulnerable to genetic and environmental alterations that generate reactive oxygen species (ROS), which eventually leads photoreceptors and retinal neurons to cell death. *CERKL* (*CERamide Kinase-Like*) mutations cause Retinitis Pigmentosa, a visual disorder characterized by photoreceptor degeneration and progressive vision loss. *CERKL* has been described as a resilience gene against oxidative stress, as its overexpression protects cells against oxidative stress-induced apoptosis. Moreover, preliminary evidence indicates that CERKL contributes to the formation of RNA stress granules in the retina. Using *Cerkl*$^{KD/KO}$ mouse models, we aimed to study the impact of *Cerkl* depletion on stress response and photoreceptor synaptic connectivity in response to luminic oxidative stress. To this end, we assessed the alteration of retinas from *Cerkl*$^{KD/KO}$ albino mice to acute light stress, as an immediate (early) or after two weeks (late) response using RNA-Seq and immunostaining. Our results show that the depletion of *Cerkl* causes an aberrant early response to stress and increased levels of ROS. In addition, as a late response, we found decreased photoreceptor synaptic connectivity in light exposed *Cerkl*$^{KD/KO}$ retinas. Overall, our studies indicate that *Cerkl* is a novel player in regulating light-challenged retinal homeostasis, by controlling multiple molecular pathways in neurons.

Overexpression of CERKL Protects Retinal Pigment Epithelium Mitochondria from Oxidative Stress Effects.
The precise function of , a Retinitis Pigmentosa (RP) causative gene, is not yet fully understood. There is evidence that is involved in the regulation of autophagy, stress granules, and mitochondrial metabolism, and it is considered a gene that is resilient against oxidative stress in the retina. Mutations in most RP genes affect photoreceptors, but retinal pigment epithelium (RPE) cells may be also altered. Here, we aimed to analyze the effect of overexpression and depletion in vivo and in vitro, focusing on the state of the mitochondrial network under oxidative stress conditions. Our work indicates that the depletion of increases the vulnerability of RPE mitochondria, which show a shorter size and altered shape, particularly upon sodium arsenite treatment. -depleted cells have dysfunctional mitochondrial respiration particularly upon oxidative stress conditions. The overexpression of two human CERKL isoforms (558 aa and 419 aa), which display different protein domains, shows that a pool of CERKL localizes at mitochondria in RPE cells and that CERKL protects the mitochondrial network-both in size and shape-against oxidative stress. Our results support being a resilient gene that regulates the mitochondrial network in RPE as in retinal neurons and suggest that RPE cell alteration contributes to particular phenotypic traits in patients carrying mutations.

34048907: Mirra S, García-Arroyo R, B Domènech E, Gavaldà-Navarro A, Herrera-Úbeda C, Oliva C, Garcia-Fernàndez J, Artuch R, Villarroya F, Marfany G
CERKL, a retinal dystrophy gene, regulates mitochondrial function and dynamics in the mammalian retina.
The retina is a highly active metabolic organ that displays a particular vulnerability to genetic and environmental factors causing stress and homeostatic imbalance. Mitochondria constitute a bioenergetic hub that coordinates stress response and cellular homeostasis, therefore structural and functional regulation of the mitochondrial dynamic network is essential for the mammalian retina. CERKL (ceramide kinase like) is a retinal degeneration gene whose mutations cause Retinitis Pigmentosa in humans, a visual disorder characterized by photoreceptors neurodegeneration and progressive vision loss. CERKL produces multiple isoforms with a dynamic subcellular localization. Here we show that a pool of CERKL isoforms localizes at mitochondria in mouse retinal ganglion cells. The depletion of CERKL levels in Cerkl(knockdown/knockout) mouse retinas

cause increase of autophagy, mitochondrial fragmentation, alteration of mitochondrial distribution, and dysfunction of mitochondrial-dependent bioenergetics and metabolism. Our results support CERKL as a regulator of autophagy and mitochondrial biology in the mammalian retina.
Neurobiol Dis, 2021; 156

33673358: Aísa-Marín I, García-Arroyo R, Mirra S, Marfany G
The Alter Retina: Alternative Splicing of Retinal Genes in Health and Disease.
Alternative splicing of mRNA is an essential mechanism to regulate and increase the diversity of the transcriptome and proteome. Alternative splicing frequently occurs in a tissue- or time-specific manner, contributing to differential gene expression between cell types during development. Neural tissues present extremely complex splicing programs and display the highest number of alternative splicing events. As an extension of the central nervous system, the retina constitutes an excellent system to illustrate the high diversity of neural transcripts. The retina expresses retinal specific splicing factors and produces a large number of alternative transcripts, including exclusive tissue-specific exons, which require an exquisite regulation. In fact, a current challenge in the genetic diagnosis of inherited retinal diseases stems from the lack of information regarding alternative splicing of retinal genes, as a considerable percentage of mutations alter splicing or the relative production of alternative transcripts. Modulation of alternative splicing in the retina is also instrumental in the design of novel therapeutic approaches for retinal dystrophies, since it enables precision medicine for specific mutations.

A New Cerkl Mouse Model Generated by CRISPR-Cas9 Shows Progressive Retinal Degeneration and Altered Morphological and Electrophysiological Phenotype.
Close to 100 genes cause retinitis pigmentosa, a Mendelian rare disease that affects 1 out of 4000 people worldwide. Mutations in the ceramide kinase-like gene (CERKL) are a prevalent cause of autosomal recessive cause retinitis pigmentosa and cone-rod dystrophy, but the functional role of this gene in the retina has yet to be fully determined. We aimed to generate a mouse model that resembles the phenotypic traits of patients carrying CERKL mutations to undertake functional studies and assay therapeutic approaches.

THE NMDA RECEPTOR TRIGGERS NEURONAL AUTOPHAGY DURING OXYGEN AND GLUCOSE DEPRIVATION

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Hortense Triniac, Cheun Pelleter, Charlotte Lechevallier, Denis Vivien, Benoît Roussel
Inserm U1237, Université De Caen, Blood And Brain @ Caen Normandie, Caen, France

Aims: Ischemic stroke induces multiple signaling pathways that contribute to neuronal death. Among them, we previously demonstrated the importance of neuronal autophagy in oxygen and glucose deprivation (OGD, an in vitro stroke model. Thiebaut et al Autophagy 2021). Here, we highlight the importance of the NMDA receptor in the induction of autophagy-mediated neuronal death. Methods: Pure mouse cortical neurons were subjected to OGD (in a hypoxic chamber) or to NMDA stimulations. Necrosis and apoptosis were evaluated by LDH release and caspase 3 cleavage + TUNEL; and autophagy was evaluated by both western blot and IHC. Results: OGD/R induces a rise in neuronal autophagic flux showed by an autophagosome accumulation (increased levels of LC3-II) and enhanced degradation of the autophagy receptor SQSTM1/p62. OGD/R also promotes a necrotic neuronal death as observed with elevated levels of LDH and the absence of cleaved caspase 3 or TUNEL staining. Interestingly, these effects are completely reversed by the NMDA receptor antagonist MK-801. Conclusions: These results indicate a strong link between the activation of the NMDA receptor and the induction of neuronal autophagy during hypoxia.

UNRAVELLING THE ROLE OF VPS13A IN NEURONS THROUGH ITS PROTEIN INTERACTING PARTNERS

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Esther García-García[1,2,3], Alba Ramón-Lainez[1,2,3], Daniel Del Toro[1,2,3], Jordi Alberch[1,2,3], Mercè Masana[1,2,3], Manuel José Rodríguez[1,2,3]

Chorea-acanthocytosis (ChAc) is caused by VPS13A gene mutations leading to marked reduction or absence of VPS13A protein. ChAc patients show progressive movement disorders such as chorea and dystonia. The main neuropathological feature in ChAc is a selective degeneration of the striatum. However, the study of the VPS13A function in neurons has been poorly addressed. In addition, there are no models available to study the molecular mechanism affected in neurons by the lack of VPS13A. The objective of this work is to understand the VPS13A function in neurons. First, we assessed the VPS13A interacting partners in wild-type mouse brain through a specific protein immunoprecipitation followed by mass spectrometry to dissect its possible functions in neurons. We found that VPS13A interacts predominantly with both Mre11a and Rad50, two proteins that play important roles in double-strand brake repair. Then, we aim to evaluate how the lack of VPS13A and its interacting partners are involved in ChAc pathology. For this, we first generated a cellular ChAc model by miR30-Based shRNA knockdown system. We found a significant reduction of the vps13a mRNA by qPCR, of the VPS13A protein by western blot and a tendency to decrease VPS13A staining intensity by immunocytochemistry in STHdh$^{Q7/Q7}$ cells. In the meeting, we will present our analysis of differences in Mre11a and Rad50 concentration and subcellular localization between wild-type and VPS13A knockdown neurons. The study of VPS13A protein interacting partners can provide novel insights toward VPS13A function in neurons that will contribute to further knowledge of ChAc pathophysiology.

Unraveling the Spatiotemporal Distribution of VPS13A in the Mouse Brain.
Loss-of-function mutations in the human vacuolar protein sorting the 13 homolog A (VPS13A) gene cause Chorea-acanthocytosis (ChAc), with selective degeneration of the striatum as the main neuropathologic feature. Very little is known about the VPS13A expression in the brain. The main objective of this work was to assess, for the first time, the spatiotemporal distribution of VPS13A in the mouse brain. We found VPS13A expression present in neurons already in the embryonic stage, with stable levels until adulthood. VPS13A mRNA and protein distributions were similar in the adult mouse brain. We found a widespread VPS13A distribution, with the strongest expression profiles in the pons, hippocampus, and cerebellum. Interestingly, expression was weak in the basal ganglia. VPS13A staining was positive in glutamatergic, GABAergic, and cholinergic neurons, but rarely in glial cells. At the cellular level, VPS13A was mainly located in the soma and neurites, co-localizing with both the endoplasmic reticulum and mitochondria. However, it was not enriched in dendritic spines or the synaptosomal fraction of cortical neurons. In vivo pharmacological modulation of the glutamatergic, dopaminergic or cholinergic systems did not modulate VPS13A concentration in the hippocampus, cerebral cortex, or striatum. These results indicate that VPS13A has remarkable stability in neuronal cells. Understanding the distinct expression pattern of VPS13A can provide relevant information to unravel pathophysiological hallmarks of ChAc.

RTP801 regulates motor cortex synaptic transmission and learning.
RTP801/REDD1 is a stress-regulated protein whose upregulation is necessary and sufficient to trigger neuronal death in in vitro and in vivo models of Parkinson's and Huntington's diseases and is up regulated in compromised neurons in human postmortem brains of both neurodegenerative disorders. Indeed, in both Parkinson's and Huntington's disease mouse

models, RTP801 knockdown alleviates motor-learning deficits.

Discovery and validation of an NMR-based metabolomic profile in urine as TB biomarker.
Despite efforts to improve tuberculosis (TB) detection, limitations in access, quality and timeliness of diagnostic services in low- and middle-income countries are challenging for current TB diagnostics. This study aimed to identify and characterise a metabolic profile of TB in urine by high-field nuclear magnetic resonance (NMR) spectrometry and assess whether the TB metabolic profile is also detected by a low-field benchtop NMR spectrometer. We included 189 patients with tuberculosis, 42 patients with pneumococcal pneumonia, 61 individuals infected with latent tuberculosis and 40 uninfected individuals. We acquired the urine spectra from high and low-field NMR. We characterised a TB metabolic fingerprint from the Principal Component Analysis. We developed a classification model from the Partial Least Squares-Discriminant Analysis and evaluated its performance. We identified a metabolic fingerprint of 31 chemical shift regions assigned to eight metabolites (aminoadipic acid, citrate, creatine, creatinine, glucose, mannitol, phenylalanine, and hippurate). The model developed using low-field NMR urine spectra correctly classified 87.32%, 85.21% and 100% of the TB patients compared to pneumococcal pneumonia patients, LTBI and uninfected individuals, respectively. The model validation correctly classified 84.10% of the TB patients. We have identified and characterised a metabolic profile of TB in urine from a high-field NMR spectrometer and have also detected it using a low-field benchtop NMR spectrometer. The models developed from the metabolic profile of TB identified by both NMR technologies were able to discriminate TB patients from the rest of the study groups and the results were not influenced by anti-TB treatment or TB location. This provides a new approach in the search for possible biomarkers for the diagnosis of TB.

M2 cortex-dorsolateral striatum stimulation reverses motor symptoms and synaptic deficits in Huntington's disease.
Huntington's disease (HD) is a neurological disorder characterized by motor disturbances. HD pathology is most prominent in the striatum, the central hub of the basal ganglia. The cerebral cortex is the main striatal afferent, and progressive cortico-striatal disconnection characterizes HD. We mapped striatal network dysfunction in HD mice to ultimately modulate the activity of a specific cortico-striatal circuit to ameliorate motor symptoms and recover synaptic plasticity. Multimodal MRI in vivo indicates cortico-striatal and thalamo-striatal functional network deficits and reduced glutamate/glutamine ratio in the striatum of HD mice. Moreover, optogenetically-induced glutamate release from M2 cortex terminals in the dorsolateral striatum (DLS) was undetectable in HD mice and striatal neurons show blunted electrophysiological responses. Remarkably, repeated M2-DLS optogenetic stimulation normalized motor behavior in HD mice and evoked a sustained increase of synaptic plasticity. Overall, these results reveal that selective stimulation of the M2-DLS pathway can become an effective therapeutic strategy in HD.

Diagnostic Accuracy of Interferon Gamma-Induced Protein 10 mRNA Release Assay for Tuberculosis.
Interferon gamma (IFN-γ) release assays (IGRAs) are increasingly used to test for latent tuberculosis (TB) infection. Although highly specific, IGRAs have a relatively high false-negative rate in active TB patients. A more sensitive assay is needed. IFN-γ-induced protein 10 (IP-10) is an alternative biomarker with a 100-fold-higher expression level than IFN-γ, allowing for different analysis platforms, including molecular detection. The PCR technique is already an integrated tool in most TB laboratories and, thus, an obvious platform to turn to. In this case-control study, we investigated the diagnostic sensitivity and specificity of a molecular assay detecting IP-10 mRNA expression following antigen stimulation of a blood sample. We included 89 TB patients and 99 healthy controls. Blood was drawn in QuantiFeron-TB gold in-tube (QFT) assay tubes. Eight hours poststimulation, IP-10 mRNA expression was analyzed, and 20 h poststimulation, IP-10 and IFN-γ protein plasma levels were analyzed using an in-house IP-10 enzyme-linked immunosorbent assay (ELISA) and the official QFT ELISA, respectively. The IP-10 mRNA assay provided high specificity (98%), sensitivity (80%), and area under the concentration-time curve (AUC) (0.97); however, the QFT assay provided a higher overall diagnostic potential, with specificity of 100%, sensitivity of 90%, and AUC of 0.99. The IP-10 protein assay performed on par with the QFT assay, with specificity of 98%, sensitivity of 87%, and AUC of 0.98. We have provided proof of high technical performance of a molecular assay detecting

IP-10 mRNA expression. As a diagnostic tool, this assay would gain from further optimization, especially on the kinetics of IP-10 mRNA expression.

Diagnostic benefits of adding EspC, EspF and Rv2348-B to the QuantiFERON Gold In-tube antigen combination.
Interferon (IFN)-γ release assays (IGRAs) are used to diagnose latent tuberculosis (TB) infection (LTBI). To improve the accuracy of these tests, different approaches, such as alternative cytokine detection and using different antigens, are considered. Following this purpose, this study aims to evaluate the addition of EspC, EspF and Rv2348-B to those present in the QuantiFERON-TB Gold In-Tube (QFN-G-IT). We included 115 subjects: 74 active TB patients, 17 LTBI individuals and 24 healthy controls. Whole blood samples were collected in QFN-G-IT and in-house tubes containing different combinations of EspC, EspF and Rv2348-B, together with ESAT-6, CFP-10, and TB7.7. After overnight incubation at 37 ºC, plasma was harvested and IFN-γ quantified. IFN-γ levels in the QFN-G-IT and in-house tubes correlated very good (Spearman Rho(r) > 0.86). In-house antigen combinations distinguished healthy individuals from those with active TB and LTBI (specificities and sensitivities higher than 87.5% and 96.3%, respectively [AUC > 0.938]). Adding EspC, EspF and Rv2348-B, increased the sensitivity of the test, being the addition of EspC and Rv2348-B the combination that yielded a higher sensitivity with no specificity loss. Addition of these antigens could improve diagnosis in patients with impaired or immature immune response who are at high risk of developing TB.

Reduced Fractalkine Levels Lead to Striatal Synaptic Plasticity Deficits in Huntington's Disease.
Huntington's disease (HD) is an inherited neurodegenerative disorder in which the striatum is the most affected brain region. Although a chronic inflammatory microglial reaction that amplifies disease progression has been described in HD patients, some murine models develop symptoms without inflammatory microglial activation. Thus, dysfunction of non-inflammatory microglial activity could also contribute to the early HD pathological process. Here, we show the involvement of microglia and particularly fractalkine signaling in the striatal synaptic dysfunction of R6/1 mice. We found reduced fractalkine gene expression and protein concentration in R6/1 striata from 8 to 20 weeks of age. Consistently, we also observed a down-regulation of fractalkine levels in the putamen of HD patients and in HD patient hiPSC-derived neurons. Automated cell morphology analysis showed a non-inflammatory ramified microglia in the striatum of R6/1 mice. However, we found increased PSD-95-positive puncta inside microglia, indicative of synaptic pruning, before HD motor symptoms start to manifest. Indeed, microglia appeared to be essential for striatal synaptic function, as the inhibition of microglial activity with minocycline impaired the induction of corticostriatal long-term depression (LTD) in wild-type mice. Notably, fractalkine administration restored impaired corticostriatal LTD in R6/1 mice. Our results unveil a role for fractalkine-dependent neuron-microglia interactions in the early striatal synaptic dysfunction characteristic of HD.

Novel intracellular antibiotic delivery system against : cloxacillin-loaded poly(d,l-lactide-co-glycolide) acid nanoparticles.
First, to compare minimum inhibitory concentrations (MIC) of free cloxacillin and cloxacillin-containing nanoparticles (NP) against methicillin-susceptible (MSSA) and resistant (MRSA) and second, to assess NP antimicrobial activity against intracellular . Poly(d,l-lactide-co-glycolide) acid (PLGA)-NP were loaded with cloxacillin and physico-chemically characterized. MICs were determined for reference strains Newman-(MSSA) and USA300-(MRSA). Murine alveolar macrophages were infected, and bacterial intracellular survival was assessed after incubating with free-cloxacillin or PLGA-cloxacillin-NP. For both isolates, MICs for antibiotic-loaded-NP were lower than those obtained with free cloxacillin, indicating that the drug encapsulation improves antimicrobial activity. A sustained antibiotic release was demonstrated when using the PLGA-cloxacillin-NP. When considering the lowest concentrations, the use of drug-loaded NP enabled a higher reduction of intracellular bacterial load.

Cell-Mediated Immune Responses to -Expressed and Stage-Specific Antigens in Latent and Active Tuberculosis Across Different Age Groups.
A quarter of the global human population is estimated to be latently infected by (), the causative agent of tuberculosis (TB).

TB remains the global leading cause of death by a single pathogen and ranks among the top-10 causes of overall global mortality. Current immunodiagnostic tests cannot discriminate between latent, active and past TB, nor predict progression of latent infection to active disease. The only registered TB vaccine, Bacillus Calmette-Guérin (BCG), does not adequately prevent pulmonary TB in adolescents and adults, thus permitting continued TB-transmission. Several proteins, mostly discovered through IFN-γ centered approaches, have been proposed as targets for new TB-diagnostic tests or -vaccines. Recently, however, we identified novel antigens capable of eliciting multiple cytokines, including antigens that did not induce IFN-γ but several other cytokines. These antigens had been selected based on high gene-expression in the lung , and have been termed expressed (IVE-TB) antigens. Here, we extend and validate our previous findings in an independent Southern European cohort, consisting of adults and adolescents with either LTBI or TB. Our results confirm that responses to IVE-TB antigens, and also DosR-regulon and Rpf stage-specific antigens are marked by multiple cytokines, including strong responses, such as for TNF-α, in the absence of detectable IFN-γ production. Except for TNF-α, the magnitude of those responses were significantly higher in LTBI subjects. Additional unbiased analyses of high dimensional flow-cytometry data revealed that TNF-α+ cells responding to antigens comprised 17 highly heterogeneous cell types. Among these 17 TNF-α+ cells clusters identified, those with CD8+TEMRA or CD8+CD4+ phenotypes, defined by the expression of multiple intracellular markers, were the most prominent in adult LTBI, while CD14+ TNF-α+ myeloid-like clusters were mostly abundant in adolescent LTBI. Our findings, although limited to a small cohort, stress the importance of assessing broader immune responses than IFN-γ alone in antigen discovery as well as the importance of screening individuals of different age groups. In addition, our results provide proof of concept showing how unbiased multidimensional multiparametric cell subset analysis can identify unanticipated blood cell subsets that could play a role in the immune response against .

Use of IP-10 detection in dried plasma spots for latent tuberculosis infection diagnosis in contacts via mail.
The aim of this study was to test the use of IP-10 detection in dried plasma from contact studies individuals (contacts of smear positive patients), by comparing it with IP-10 and IFN-γ detection in direct plasma, to establish IP-10 detection in DPS as a useful assay for LTBI diagnosis. Whole blood samples were collected from 80 subjects: 12 with active tuberculosis (TB), and 68 from contact studies. The amount of IFN-γ produced by sensitized T cells was determined in direct plasma by QuantiFERON Gold In-Tube test. IP-10 levels were determined in direct and dried plasma by an in-house ELISA. For dried plasma IP-10 determination, two 25 µl plasma drops were dried in Whatman903 filter paper and sent by mail to the laboratory. Regarding TB patients, 100.0%, 91.7% and 75.0% were positive for IFN-γ detection and IP-10 detection in direct and dried plasma, respectively. In contacts, 69.1%, 60.3% and 48.5% had positive results after IFN-γ and IP-10 in direct and dried plasma, respectively. The agreement among in vitro tests was substantial and IP-10 levels in direct and dried plasma were strongly correlated (r = 0.897). In conclusion, IP-10 detection in dried plasma is a simple and safe method that would help improve LTBI management.

Metabolomic profile of astrocytes exposed to pro-inflammatory conditions O.Alzahrani, H. Fiumelli and P.J. Magistretti King Abdullah University of Science and Technology (KAUST) Saudi Arabia Astrocytes are critical for neuronal function and survival. Astrocytes ensure metabolic support to the neurons, in particular by providing on-demand lactate derived from aerobic glycolysis, through a mechanism known as the Astrocyte Neuron Lactate Shuttle (ANLS). Previous results from our laboratory showed that exposure of astrocytes to the pathological form of amyloid-beta A-beta 25-35 induced marked changes in their metabolic phenotype rendering them less apt to ensure neuronal survival (Allaman et al, J. Neurosci, 2010). In the present study, we exposed cortical astrocyte cultures to pro-inflammatory cytokines such as IL1-beta and TNF-alpha. The cultures were then analyzed for their metabolomic profile in control and cytokine-induced inflammation. Several metabolic pathways were affected by the cytokine treatment, such as an increased glycolytic flux at the expense of mitochondrial oxidation associated with an increase in glutaminolysis. Markers of oxidative stress and nitric oxide synthase activation were also observed. Finally, amino acid oxidation to support the increased metabolic needs was also apparent. Work is now in progress to analyze the metabolomic profile in astrocytes exposed to a-beta 42 in various degrees of aggregation.

Background: Alzheimer's disease (AD) and age-related macular degeneration (AMD) present similarities, particularly with respect to oxidative stress, including production of 4-Hydroxy-2- nonenal (HNE). AMD has been named the AD in the eye. The Müller cells (MC) function as a principal glia of the retina and maintain water/potassium, glutamate homeostasis and redox status. Any MC dysfunction results in retinal neurodegeneration. **Objectives:** We investigated the effects of HNE in human MC. **Results:** HNE induced an increase of the reactive oxygen species associated with mitochondrial dysfunction and apoptosis. HNE induced endoplasmic reticulum (ER) stress (upregulation of GRP78/Bip, and the proapoptotic factor, CHOP). HNE also impaired expression of genes controlling potassium homeostasis (KCNJ10), glutamate detoxification (GS), and the visual cycle (RLBP1). MC adaptive response to HNE included upregulation of amyloid-β protein precursor (AβPP). To determine the role of AβPP, we overexpressed AβPP in MC. Overexpression of AβPP induced strong antioxidant and anti-ER stress (PERK downregulation and GADD34 upregulation) responses accompanied by activation of the prosurvival branch of the unfolded protein response. It was also associated with upregulation of major genes involved in MC-controlled retinal homeostasis (KCNJ10, GS, and RLBP1) and protection against HNE-induced apoptosis. Therefore, AβPP is an ER and oxidative stress responsive molecule, and is able to stimulate the transcription of major genes involved in MC functions impaired by HNE. **Conclusion:** Our study suggests that targeting oxidative and ER stress might be a potential therapeutic strategy against glia impairment in AMD and AD, in light of the common features between the two pathologies

In human neurodegenerative diseases, neurons undergo axonal degeneration months to years before they die. Here, we developed a system modelling early degenerative events in *Drosophila* adult photoreceptor cells. Thanks to the stereotypy of their axonal projections, this system delivers quantitative data on sporadic and progressive axonal degeneration of photoreceptor cells. Using this method, we show that exposure of adult flies to a constant light stimulation for several days overcomes the intrinsic resilience of R7 photoreceptors and leads to progressive axonal degeneration. This was not associated with apoptosis. We furthermore provide evidence that loss of synaptic integrity between R7 and a postsynaptic partner preceded axonal degeneration, thus recapitulating features of human neurodegenerative diseases. Finally, our experiments uncovered that neurotransmission to postsynaptic partners of R7 and their response are required to initiate degeneration, suggesting that postsynaptic cells signal back to the photoreceptor to maintain axonal structure. This model can be used to dissect cellular circuit mechanisms involved in the early events of axonal degeneration, allowing for a better understanding of how neurons cope with stress and lose their resilience capacities.

Whether organismal fitness is coordinated by the metabolism of neurons is unknown. In contrast to the predominantly glycolytic nature of astrocytes, neurons use very little glucose through glycolysis to obtain energy (1). This metabolic difference is dictated by the protein stability of the pro-glycolytic enzyme 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase-3 (PFKFB3), which is highly expressed in astrocytes, but continuously degraded in neurons by the E3-ubiquitin ligase anaphase-promoting complex/cyclosome-Cdh1 (2). However, the *in vivo* physiological significance of such a limited glycolytic activity of neurons is intriguing. To address this matter, we generated a genetically-engineered mouse that persistently expresses PFKFB3 in neurons *in vivo* (CaMKII-PFKFB3). We found that PFKFB3 enhancement in neurons shifted glucose metabolism towards glycolysis causing NAD depletion, dysfunctional mitochondria, redox stress and impairment of the autophagic flux in several brain regions, including the hippocampus and the medio-basal hypothalamus. Phenotypic characterization of these CaMKII-PFKFB3 mice revealed cognitive deterioration, motor discoordination, glucose intolerance and obesity. Interestingly, these biochemical and phenotypic alterations were rescued by abolishing redox stress *via* co-expression of a mitochondrially-tagged isoform of catalase (mCAT) in neurons. Mechanistically, the increase in glycolysis shifted down the pentose-phosphate pathway, causing redox stress that impaired mitochondrial respiration, triggering a signaling pathway leading to an aberrant positive loop of glycolytic activation. These data strongly suggest that the occurrence of a low glycolytic activity in neurons is a natural mechanism aimed to sustain organismal welfare. Abrogating mitochondrial ROS in neurons or astrocytes reveals cell-specific impact on mouse behaviour.
Cells naturally produce mitochondrial reactive oxygen species (mROS), but the in vivo pathophysiological significance has long remained controversial. Within the brain, astrocyte-derived mROS physiologically regulate behaviour and are produced at one order of magnitude faster than in neurons. However, whether neuronal mROS abundance differentially impacts on behaviour is unknown. To address this, we engineered genetically modified mice to down modulate mROS levels in neurons in vivo. Whilst no alterations in motor coordination were observed by down modulating mROS in neurons under healthy conditions, it prevented the motor discoordination caused by the pro-oxidant neurotoxin, 3-nitropropionic acid (3-NP). In contrast, abrogation of mROS in astrocytes showed no beneficial effect against the 3-NP insult. These data indicate that the impact of modifying mROS production on mouse behaviour critically depends on the specific cell-type where they are generated.

Glucose metabolism links astroglial mitochondria to cannabinoid effects.
Astrocytes take up glucose from the bloodstream to provide energy to the brain, thereby allowing neuronal activity and behavioural responses. By contrast, astrocytes are under neuronal control through specific neurotransmitter receptors. However, whether the activation of astroglial receptors can directly regulate cellular glucose metabolism to eventually

modulate behavioural responses is unclear. Here we show that activation of mouse astroglial type-1 cannabinoid receptors associated with mitochondrial membranes (mtCB) hampers the metabolism of glucose and the production of lactate in the brain, resulting in altered neuronal functions and, in turn, impaired behavioural responses in social interaction assays. Specifically, activation of astroglial mtCB receptors reduces the phosphorylation of the mitochondrial complex I subunit NDUFS4, which decreases the stability and activity of complex I. This leads to a reduction in the generation of reactive oxygen species by astrocytes and affects the glycolytic production of lactate through the hypoxia-inducible factor 1 pathway, eventually resulting in neuronal redox stress and impairment of behavioural responses in social interaction assays. Genetic and pharmacological correction of each of these effects abolishes the effect of cannabinoid treatment on the observed behaviour. These findings suggest that mtCB receptor signalling can directly regulate astroglial glucose metabolism to fine-tune neuronal activity and behaviour in mice.

Targeting PFKFB3 alleviates cerebral ischemia-reperfusion injury in mice.
The glycolytic rate in neurons is low in order to allow glucose to be metabolized through the pentose-phosphate pathway (PPP), which regenerates NADPH to preserve the glutathione redox status and survival. This is controlled by 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase-3 (PFKFB3), the pro-glycolytic enzyme that forms fructose-2,6-bisphosphate, a powerful allosteric activator of 6-phosphofructo-1-kinase. In neurons, PFKFB3 protein is physiologically inactive due to its proteasomal degradation. However, upon an excitotoxic stimuli, PFKFB3 becomes stabilized to activate glycolysis, thus hampering PPP mediated protection of redox status leading to neurodegeneration. Here, we show that selective inhibition of PFKFB3 activity by the small molecule AZ67 prevents the NADPH oxidation, redox stress and apoptotic cell death caused by the activation of glycolysis triggered upon excitotoxic and oxygen-glucose deprivation/reoxygenation models in mouse primary neurons. Furthermore, in vivo administration of AZ67 to mice significantly alleviated the motor discoordination and brain infarct injury in the middle carotid artery occlusion ischemia/reperfusion model. These results show that pharmacological inhibition of PFKFB3 is a suitable neuroprotective therapeutic strategy in excitotoxic-related disorders such as stroke.

Astrocytic mitochondrial ROS modulate brain metabolism and mouse behaviour.
To satisfy its high energetic demand, the brain depends on the metabolic cooperation of various cell types. For example, astrocytic-derived lactate sustains memory consolidation by serving both as an oxidizable energetic substrate for neurons and as a signalling molecule. Astrocytes and neurons also differ in the regulation of glycolytic enzymes and in the organization of their mitochondrial respiratory chain. Unlike neurons, astrocytes rely on glycolysis for energy generation and, as a consequence, have a loosely assembled mitochondrial respiratory chain that is associated with a higher generation of mitochondrial reactive oxygen species (ROS). However, whether this abundant natural source of mitochondrial ROS in astrocytes fulfils a specific physiological role is unknown. Here we show that astrocytic mitochondrial ROS are physiological regulators of brain metabolism and neuronal function. We generated mice that inducibly overexpress mitochondrial-tagged catalase in astrocytes and show that this overexpression decreases mitochondrial ROS production in these cells during adulthood. Transcriptomic, metabolomic, biochemical, immunohistochemical and behavioural analysis of these mice revealed alterations in brain redox, carbohydrate, lipid and amino acid metabolic pathways associated with altered neuronal function and mouse behaviour. We found that astrocytic mitochondrial ROS regulate glucose utilization via the pentose-phosphate pathway and glutathione metabolism, which modulates the redox status and potentially the survival of neurons. Our data provide further molecular insight into the metabolic cooperation between astrocytes and neurons and demonstrate that mitochondrial ROS are important regulators of organismal physiology in vivo.

Melatonin induces the expression of Nrf2-regulated antioxidant enzymes via PKC and Ca2+ influx activation in mouse pancreatic acinar cells.
The goal of this study was to evaluate the potential activation of the nuclear factor erythroid 2-related factor and the antioxidant-responsive element (Nrf2-ARE) signaling pathway in response to melatonin in isolated mouse pancreatic acinar cells. Changes in intracellular free Ca(2+) concentration were followed by fluorimetric analysis of fura-2-loaded cells. The activations of PKC and JNK were measured by Western blot analysis. Quantitative reverse transcription-polymerase chain reaction was employed to detect the expression of Nrf2-regulated antioxidant enzymes. Immunocytochemistry was employed

to determine nuclear location of phosphorylated Nrf2, and the cellular redox state was monitored following MitoSOX Red-derived fluorescence. Our results show that stimulation of fura-2-loaded cells with melatonin (1 µM to 1 mM), in the presence of Ca(2+) in the extracellular medium, induced a slow and progressive increase of [Ca(2+)](c) toward a stable level. Melatonin did not inhibit the typical Ca(2+) response induced by CCK-8 (1 nM). When the cells were challenged with indoleamine in the absence of Ca(2+) in the extracellular solution (medium containing 0.5 mM EGTA) or in the presence of 1 mM LaCl(3), to inhibit Ca(2+) entry, we could not detect any change in [Ca(2+)](c). Nevertheless, CCK-8 (1 nM) was able to induce the typical mobilization of Ca(2+). When the cells were incubated with the PKC activator PMA (1 µM) in the presence of Ca(2+) in the extracellular medium, we observed a response similar to that noted when the cells were challenged with melatonin 100 µM. However, in the presence of Ro31-8220 (3 µM), a PKC inhibitor, stimulation of cells with melatonin failed to evoke changes in [Ca(2+)]c. Immunoblots, using an antibody specific for phospho-PKC, revealed that melatonin induces PKCα activation, either in the presence or in the absence of external Ca(2+). Melatonin induced the phosphorylation and nuclear translocation of the transcription factor Nrf2, and evoked a concentration-dependent increase in the expression of the antioxidant enzymes NAD(P)H-quinone oxidoreductase 1, catalytic subunit of glutamate-cysteine ligase, and heme oxygenase-1. Incubation of MitoSOX Red-loaded pancreatic acinar cells in the presence of 1 nM CCK-8 induced a statistically significant increase in dye-derived fluorescence, reflecting an increase in oxidation, that was abolished by pretreatment of cells with melatonin (100 µM) or PMA (1 µM). On the contrary, pretreatment with Ro31-8220 (3 µM) blocked the effect of melatonin on CCK-8-induced increase in oxidation. Finally, phosphorylation of JNK in the presence of CCK-8 or melatonin was also observed. We conclude that melatonin, via modulation of PKC and Ca(2+) signaling, could potentially stimulate the Nrf2-mediated antioxidant response in mouse pancreatic acinar cells.

Aberrant upregulation of the glycolytic enzyme PFKFB3 in CLN7 neuronal ceroid lipofuscinosis.
CLN7 neuronal ceroid lipofuscinosis is an inherited lysosomal storage neurodegenerative disease highly prevalent in children. CLN7/MFSD8 gene encodes a lysosomal membrane glycoprotein, but the biochemical processes affected by CLN7-loss of function are unexplored thus preventing development of potential treatments. Here, we found, in the Cln7 mouse model of CLN7 disease, that failure in autophagy causes accumulation of structurally and bioenergetically impaired neuronal mitochondria. In vivo genetic approach reveals elevated mitochondrial reactive oxygen species (mROS) in Cln7 neurons that mediates glycolytic enzyme PFKFB3 activation and contributes to CLN7 pathogenesis. Mechanistically, mROS sustains a signaling cascade leading to protein stabilization of PFKFB3, normally unstable in healthy neurons. Administration of the highly selective PFKFB3 inhibitor AZ67 in Cln7 mouse brain in vivo and in CLN7 patients-derived cells rectifies key disease hallmarks. Thus, aberrant upregulation of the glycolytic enzyme PFKFB3 in neurons may contribute to CLN7 pathogenesis and targeting PFKFB3 could alleviate this and other lysosomal storage diseases.

Cell identity and nucleo-mitochondrial genetic context modulate OXPHOS performance and determine somatic heteroplasmy dynamics.
Heteroplasmy, multiple variants of mitochondrial DNA (mtDNA) in the same cytoplasm, may be naturally generated by mutations but is counteracted by a genetic mtDNA bottleneck during oocyte development. Engineered heteroplasmic mice with nonpathological mtDNA variants reveal a nonrandom tissue-specific mtDNA segregation pattern, with few tissues that do not show segregation. The driving force for this dynamic complex pattern has remained unexplained for decades, challenging our understanding of this fundamental biological problem and hindering clinical planning for inherited diseases. Here, we demonstrate that the nonrandom mtDNA segregation is an intracellular process based on organelle selection. This cell type-specific decision arises jointly from the impact of mtDNA haplotypes on the oxidative phosphorylation (OXPHOS) system and the cell metabolic requirements and is strongly sensitive to the nuclear context and to environmental cues.

Regulation of Bcl-xL-ATP Synthase Interaction by Mitochondrial Cyclin B1-Cyclin-Dependent Kinase-1 Determines Neuronal Survival.
The survival of postmitotic neurons needs continuous degradation of cyclin B1, a mitotic protein accumulated aberrantly in

the damaged brain areas of Alzheimer's disease and stroked patients. Degradation of cyclin B1 takes place in the proteasome after ubiquitylation by the anaphase-promoting complex/cyclosome (APC/C)-cadherin 1 (Cdh1), an E3 ubiquitin ligase that is highly active in neurons. However, during excitotoxic damage-a hallmark of neurological disorders-APC/C-Cdh1 is inactivated, causing cyclin B1 stabilization and neuronal death through an unknown mechanism. Here, we show that an excitotoxic stimulus in rat cortical neurons in primary culture promotes cyclin B1 accumulation in the mitochondria, in which it binds to, and activates, cyclin-dependent kinase-1 (Cdk1). The cyclin B1-Cdk1 complex in the mitochondria phosphorylates the anti-apoptotic protein B-cell lymphoma extra-large (Bcl-xL), leading to its dissociation from the β subunit of F1Fo-ATP synthase. The subsequent inhibition of ATP synthase activity causes complex I oxidative damage, mitochondrial inner membrane depolarization, and apoptotic neuronal death. These results unveil a previously unrecognized role for mitochondrial cyclin B1 in the oxidative damage associated with neurological disorders.

Astrocyte NMDA receptors' activity sustains neuronal survival through a Cdk5-Nrf2 pathway.
Neurotransmission unavoidably increases mitochondrial reactive oxygen species. However, the intrinsic antioxidant defense of neurons is weak and hence the mechanism whereby these cells are physiologically protected against oxidative damage is unknown. Here we found that the antioxidant defense of neurons is repressed owing to the continuous protein destabilization of the master antioxidant transcriptional activator, nuclear factor-erythroid 2-related factor-2 (Nrf2). By contrast, Nrf2 is highly stable in neighbor astrocytes explaining their robust antioxidant defense and resistance against oxidative stress. We also show that subtle and persistent stimulation of N-methyl-d-aspartate receptors (NMDAR) in astrocytes, through a mechanism not requiring extracellular Ca^{2+} influx, upregulates a signal transduction pathway involving phospholipase C-mediated endoplasmic reticulum release of Ca^{2+} and protein kinase Cδ activation. Active protein kinase Cδ promotes, by phosphorylation, the stabilization of p35, a cyclin-dependent kinase-5 (Cdk5) cofactor. Active p35/Cdk5 complex in the cytosol phosphorylates Nrf2 at Thr(395), Ser(433) and Thr(439) that is sufficient to promote Nrf2 translocation to the nucleus and induce the expression of antioxidant genes. Furthermore, this Cdk5-Nrf2 transduction pathway boosts glutathione metabolism in astrocytes efficiently protecting closely spaced neurons against oxidative damage. Thus, intercellular communication through NMDAR couples neurotransmission with neuronal survival.

Introduction: RTP801/REDD1 is a stress responsive protein overexpressed in neurons of patients with neurodegenerative disorders such as Parkinson's and Huntington's diseases. Its main function is to inhibit the mTOR pathway, but, if this inactivation is sustained in time, it has a pro-apoptotic effect in differentiated cells like neurons. Nevertheless, RTP801 might have other functions not yet elucidated. In preliminary proteomic studies from our laboratory, RTP801 was found to interact with HSPC117 and DDX1, two proteins that are part of the *tRNA splicing ligase complex*, which performs the ligation of the tRNA fragments generated during splicing. Aims: Since alterations in tRNA metabolism have recently been associated to the development of some neurodegenerative diseases, we aimed to deeper study the relationship between RTP801 and these tRNA-processing enzymes. Results: Here, we confirm by immunoprecipitation that endogenous RTP801 interacts with the *tRNA splicing ligase complex,* concretely with DDX1, HSPC117 and CGI-99. We also observe changes in the intensity and cellular distribution of these tRNA-processing enzymes when we modify the levels of RTP801. Additionally, the maturation of intron-containing tRNAs is altered in the cortex of 2-month-old RTP801 knockout mice compared to wild-type. Finally, we also observe related alterations in hippocampal and striatal postmortem samples from patients with Alzheimer's and Huntington's diseases, where RTP801 is involved in the pathogenesis. Conclusions: These results suggest a novel role of RTP801 in tRNA processing, which must be further studied, as RTP801 could be a potential target to prevent altered tRNA metabolism in neurodegenerative diseases.

RTP801/REDD1 contributes to neuroinflammation severity and memory impairments in Alzheimer's disease.
RTP801/REDD1 is a stress-regulated protein whose upregulation is necessary and sufficient to trigger neuronal death. Its downregulation in Parkinson's and Huntington's disease models ameliorates the pathological phenotypes. In the context of Alzheimer's disease (AD), the coding gene for RTP801, DDIT4, is responsive to Aβ and modulates its cytotoxicity in vitro. Also, RTP801 mRNA levels are increased in AD patients' lymphocytes. However, the involvement of RTP801 in the pathophysiology of AD has not been yet tested. Here, we demonstrate that RTP801 levels are increased in postmortem hippocampal samples from AD patients. Interestingly, RTP801 protein levels correlated with both Braak and Thal stages of the disease and with GFAP expression. RTP801 levels are also upregulated in hippocampal synaptosomal fractions obtained from murine 5xFAD and rTg4510 mice models of the disease. A local RTP801 knockdown in the 5xFAD hippocampal neurons with shRNA-containing AAV particles ameliorates cognitive deficits in 7-month-old animals. Upon RTP801 silencing in the 5xFAD mice, no major changes were detected in hippocampal synaptic markers or spine density. Importantly, we found an unanticipated recovery of several gliosis hallmarks and inflammasome key proteins upon neuronal RTP801 downregulation in the 5xFAD mice. Altogether our results suggest that RTP801 could be a potential future target for theranostic studies since it could be a biomarker of neuroinflammation and neurotoxicity severity of the disease and, at the same time, a promising therapeutic target in the treatment of AD.

RTP801 regulates motor cortex synaptic transmission and learning.
RTP801/REDD1 is a stress-regulated protein whose upregulation is necessary and sufficient to trigger neuronal death in in vitro and in vivo models of Parkinson's and Huntington's diseases and is up regulated in compromised neurons in human postmortem brains of both neurodegenerative disorders. Indeed, in both Parkinson's and Huntington's disease mouse models, RTP801 knockdown alleviates motor-learning deficits.
Exp Neurol, 2021; 342
35053183: Pérez-Sisqués L, Solana-Balaguer J, Campoy-Campos G, Martín-Flores N, Sancho-Balsells A, Vives-Isern M, Soler-Palazón F, Garcia-Forn M, Masana M, Alberch J, Pérez-Navarro E, Giralt A, Malagelada C
RTP801/REDD1 Is Involved in Neuroinflammation and Modulates Cognitive Dysfunction in Huntington's Disease.
RTP801/REDD1 is a stress-regulated protein whose levels are increased in several neurodegenerative diseases such as Parkinson's, Alzheimer's, and Huntington's diseases (HD). RTP801 downregulation ameliorates behavioral abnormalities in several mouse models of these disorders. In HD, RTP801 mediates mutant huntingtin (mhtt) toxicity in in vitro models and its levels are increased in human iPSCs, human postmortem putamen samples, and in striatal synaptosomes from mouse models of the disease. Here, we investigated the role of RTP801 in the hippocampal pathophysiology of HD. We found that RTP801 levels are increased in the hippocampus of HD patients in correlation with gliosis markers. Although RTP801 expression is not altered in the hippocampus of the R6/1 mouse model of HD, neuronal RTP801 silencing in the dorsal hippocampus with shRNA containing AAV particles ameliorates cognitive alterations. This recovery is associated with a partial rescue of synaptic markers and with a reduction in inflammatory events, especially microgliosis. Altogether, our results indicate that RTP801 could be a marker of hippocampal neuroinflammation in HD patients and a promising therapeutic target of the disease.

ER MORPHOLOGY AND CA2+ HANDLING: UNRAVELING THEIR ROLE IN NEURODEGENERATION IN DROSOPHILA MODELS OF HSP

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Sonia Sonda[1], Manuela Santalla[1,2], Nelly Redolfi[1], Nicola Vajente[2], Elisa Greotti[1,2], Diana Pendin[1,2]

Hereditary spastic paraplegias (HSPs) are axonopathies characterized by progressive lower limbs spasticity. Despite their genetic heterogeneity, morphological alterations of the Endoplasmic Reticulum (ER) appear as critical causative factors, as over 60% of patients carry mutations in genes encoding proteins influencing ER morphology (e.g., Atlastin-1, Reticulon-2, Spastin). Among ER functions, previous studies suggest that ER morphology alterations could affect Ca^{2+} homeostasis. Furthermore, there is increasing evidence of the involvement of ER-shaping proteins in axonal elongation. **Aims**. Our aim is to investigate the correlation between HSP-linked ER shaping defects and Ca^{2+} homeostasis, and to unravel its potential impact on neuronal development and degeneration. **Methods**. To elude genetic redundancy, we focused on *Drosophila* HSP orthologues. Noteworthy, the molecular Ca^{2+} toolkit is conserved in *Drosophila*, enabling imaging of Ca^{2+} dynamics in fly neurons. Previously generated fly lines were exploited to downregulate Rtnl1 (*Drosophila* orthologue of Reticulon-2) or atlastin (orthologue of Atlastin-1), and to express HSP-linked dominant-negative spastin mutation K467R selectively in neurons. **Results and Conclusions**. Confocal and EM analysis of larval brains confirmed characteristic alterations in ER morphology in the three models, i.e. an increase in long profiles ascribable to ER cisternae upon Rtnl1 downregulation or spastin (K467R) expression and ER fragmentation upon atlastin downregulation. Similarly, Ca^{2+} imaging experiments in dissociated larval neurons showed specific defects in ER Ca^{2+} handling. The results obtained suggest a defective pathway potentially relevant for HSP pathogenesis. Experiments aimed at assessing Ca^{2+} dynamics and neuronal morphology in live tissues/animals are ongoing.

Lighting Up Ca Dynamics in Animal Models.
Calcium (Ca) signaling coordinates are crucial processes in brain physiology. Particularly, fundamental aspects of neuronal function such as synaptic transmission and neuronal plasticity are regulated by Ca, and neuronal survival itself relies on Ca-dependent cascades. Indeed, impaired Ca homeostasis has been reported in aging as well as in the onset and progression of neurodegeneration. Understanding the physiology of brain function and the key processes leading to its derangement is a core challenge for neuroscience. In this context, Ca imaging represents a powerful tool, effectively fostered by the continuous amelioration of Ca sensors in parallel with the improvement of imaging instrumentation. In this review, we explore the potentiality of the most used animal models employed for Ca imaging, highlighting their application in brain research to explore the pathogenesis of neurodegenerative diseases.

ER Morphology in the Pathogenesis of Hereditary Spastic Paraplegia.
The endoplasmic reticulum (ER) is the most abundant and widespread organelle in cells. Its peculiar membrane architecture, formed by an intricate network of tubules and cisternae, is critical to its multifaceted function. Regulation of ER morphology is coordinated by a few ER-specific membrane proteins and is thought to be particularly important in neurons, where organized ER membranes are found even in the most distant neurite terminals. Mutation of ER-shaping proteins has been implicated in the neurodegenerative disease hereditary spastic paraplegia (HSP). In this review we discuss the involvement of these proteins in the pathogenesis of HSP, focusing on the experimental evidence linking their molecular function to disease onset. Although the precise biochemical activity of some ER-related HSP proteins has been elucidated, the pathological mechanism underlying ER-linked HSP is still undetermined and needs to be further investigated.

BEHIND SPORADIC ALS: A BIOPHYSICAL CHARACTERIZATION OF MOTOR NEURONS IN HEALTH AND DISEASE

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Martina Bonucci[1], Guney Akbalik[2], Hemali Phatnani[2], Yi-Shuan Tseng[1], Liam Holt[1]
[1]New York University Langone Health, Institute For Systems Genetics, New York, United States of America, [2]New York Genome Center, Center For Genomics Of Neurodegenerative Disease, New York, United States of America

Rationale. Sporadic amyotrophic lateral sclerosis (sALS) is characterized by death of motor neurons due to accumulation of aggregates and perturbation of intracellular transport. The underlying causes of these changes remain yet mysterious. Although a fraction of cases are caused by inherited mutations, the majority are sporadic, and the risk increases with age. The cell interior is extremely crowded with organelles and macromolecular complexes. This intracellular molecular crowding crucially impacts molecular assembly and transport. We hypothesized that age-associated changes could perturb macromolecular crowding and participate in the pathogenesis of sALS. *Methods*. For the first time, we leverage genetically encoded multimeric nanoparticles (GEMs) to quantify macromolecular crowding in human iPSC-derived motor neurons. The diffusivity of tracer particles like GEMs is generally decreased by molecular crowding and increased by active cellular processes. *Results*. GEMs' diffusivity was different depending on the subcellular localization. We observed that GEMs' diffusivity along neurites is regulated by active processes such as microtubules dynamics, while it seems to sensitively depend on the mechanical compression state of the cell in the somata. Microtubule dynamics and compression state are perturbed in ALS. Notably, motor neurons from ALS patients did not show modified basal molecular crowding, but might be more sensitive to perturbations. We are now studying how molecular crowding impacts aggregation and transport of TDP-43, a protein found in ALS aggregates. *Conclusion*. We are performing the first high-throughput characterization of the biophysical properties of motor neurons to decipher the relationship between intracellular biophysical changes and initiation of sALS.

mTOR and S6K1 drive polycystic kidney by the control of Afadin-dependent oriented cell division.
mTOR activation is essential and sufficient to cause polycystic kidneys in Tuberous Sclerosis Complex (TSC) and other genetic disorders. In disease models, a sharp increase of proliferation and cyst formation correlates with a dramatic loss of oriented cell division (OCD). We find that OCD distortion is intrinsically due to S6 kinase 1 (S6K1) activation. The concomitant loss of S6K1 in Tsc1-mutant mice restores OCD but does not decrease hyperproliferation, leading to non-cystic harmonious hyper growth of kidneys. Mass spectrometry-based phosphoproteomics for S6K1 substrates revealed Afadin, a known component of cell-cell junctions required to couple intercellular adhesions and cortical cues to spindle orientation. Afadin is directly phosphorylated by S6K1 and abnormally decorates the apical surface of Tsc1-mutant cells with E-cadherin and α-catenin. Our data reveal that S6K1 hyperactivity alters centrosome positioning in mitotic cells, affecting oriented cell division and promoting kidney cysts in conditions of mTOR hyperactivity.

Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease characterized by motor neurons (MNs) death in the spinal cord and brain, leading the loss of skeletal muscle mass. Previous data collected in my lab highlight an interesting aberrant crosstalk between the ALS-linked FUS protein and the RNA-binding protein HuD, leading to upregulation of HuD levels. As a consequence, some HuD targets such as the axonal proteins GAP43 and NRN1 are upregulated in FUS mutant MNs. Moreover, we have found NRN1-dependent aberrant increase in neurite branching and axonal outgrowth in these cells. The general aim of my PhD project is to assess whether such altered molecular circuitry, besides neurite alteration, can lead to neuromuscular junction (NMJ) disruption, with a particular focus on the involvement of HuD and GAP43. To recapitulate the NMJ circuit *in vitro* I am taking advantage of human induced pluripotent stem cells (hiPSCs) to obtain a neural-muscle model system by 2D co-cultures. We found that FUS-mutant MNs appear less able to establish NMJs with FUS-WT muscle despite the presence of a significant increase of the neurite network. Moreover, mutant MNs co-cultures show degeneration of both cellular components suggesting that this extensive neurite sprouting, as a part of a compensatory reinnervation process, could have a detrimental effect on neuromuscular endplate maturation, leading the axonal and motor unit degeneration. Interestingly, we observed similar phenotypes with FUS-WT, HuD overexpressing MNs, with implications for sporadic ALS.

Small heat-shock protein HSPB3 promotes myogenesis by regulating the lamin B receptor.
One of the critical events that regulates muscle cell differentiation is the replacement of the lamin B receptor (LBR)-tether with the lamin A/C (LMNA)-tether to remodel transcription and induce differentiation-specific genes. Here, we report that localization and activity of the LBR-tether are crucially dependent on the muscle-specific chaperone HSPB3 and that depletion of HSPB3 prevents muscle cell differentiation. We further show that HSPB3 binds to LBR in the nucleoplasm and maintains it in a dynamic state, thus promoting the transcription of myogenic genes, including the genes to remodel the extracellular matrix. Remarkably, HSPB3 overexpression alone is sufficient to induce the differentiation of two human muscle cell lines, LHCNM2 cells, and rhabdomyosarcoma cells. We also show that mutant R116P-HSPB3 from a myopathy patient with chromatin alterations and muscle fiber disorganization, forms nuclear aggregates that immobilize LBR. We find that R116P-HSPB3 is unable to induce myoblast differentiation and instead activates the unfolded protein response. We propose that HSPB3 is a specialized chaperone engaged in muscle cell differentiation and that dysfunctional HSPB3 causes neuromuscular disease by deregulating LBR.

A Computational Approach to Investigate TDP-43 RNA-Recognition Motif 2 C-Terminal Fragments Aggregation in Amyotrophic Lateral Sclerosis.
Many of the molecular mechanisms underlying the pathological aggregation of proteins observed in neurodegenerative diseases are still not fully understood. Among the aggregate-associated diseases, Amyotrophic Lateral Sclerosis (ALS) is of relevant importance. In fact, although understanding the processes that cause the disease is still an open challenge, its relationship with protein aggregation is widely known. In particular, human TDP-43, an RNA/DNA binding protein, is a major

component of the pathological cytoplasmic inclusions observed in ALS patients. Indeed, the deposition of the phosphorylated full-length TDP-43 in spinal cord cells has been widely studied. Moreover, it has also been shown that the brain cortex presents an accumulation of phosphorylated C-terminal fragments (CTFs). Even if it is debated whether the aggregation of CTFs represents a primary cause of ALS, it is a hallmark of TDP-43 related neurodegeneration in the brain. Here, we investigate the CTFs aggregation process, providing a computational model of interaction based on the evaluation of shape complementarity at the molecular interfaces. To this end, extensive Molecular Dynamics (MD) simulations were conducted for different types of protein fragments, with the aim of exploring the equilibrium conformations. Adopting a newly developed approach based on Zernike polynomials, able to find complementary regions in the molecular surface, we sampled a large set of solvent-exposed portions of CTFs structures as obtained from MD simulations. Our analysis proposes and assesses a set of possible association mechanisms between the CTFs, which could drive the aggregation process of the CTFs. To further evaluate the structural details of such associations, we perform molecular docking and additional MD simulations to propose possible complexes and assess their stability, focusing on complexes whose interacting regions are both characterized by a high shape complementarity and involve β3 and β5 strands at their interfaces.

Cannabinoids have been reported as orexigenic, i.e. as promoting food intake that, among others, is controlled by the so-called “hunger” hormone, ghrelin. The aim of this project focus in looking for functional and/or molecular interactions between ghrelin GHS-R1a and cannabinoid CB_2 receptors at the central nervous system (CNS) level. In a heterologous system we identified CB_2-GHS-R1a receptor complexes with a particular heteromer print consisting of impairment blockade of CB_2 receptor/Gi-mediated signaling. The blockade was due to allosteric interactions within the heteromeric complex as it was reverted by antagonists of the GHS-R1a receptor. On the other hand, cannabinoids acting on the CB_2 receptor did not affect cytosolic increases of calcium ion induced by ghrelin acting on the GHS-R1a receptor. Finally, in situ proximity ligation imaging assays confirmed the expression of CB_2-GHS-R1a receptor complexes in both heterologous cells and primary striatal neurons. Interestingly, there was a marked upregulation of those complexes in striatal neurons from siblings of pregnant female mice under a high-fat diet.

BRAIN DYSFUNCTION INDUCED BY CHRONIC KIDNEY DISEASE

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Veronica Buonincontri[1], Antonio De Donato[1], Pedro Imenez Silva[2], Carsten Wagner[2], Giovambattista Capasso[3], Davide Viggiano[4]
[1]Univ. Campania, Dept. Translational Medical Sciences, Naples, Italy, [2]Univ. Zurich, Inst. Physiology, Zurich, Switzerland, [3]BIOGEM, Lab. Intravital Microscopy, Ariano Irpino, Italy, [4]University of Campania, Department Translational Medical Sciences, Naples, Italy

Chronic kidney disease (CKD) is defined by a reduced filtration of the kidney. 20% of CKD patients develop a mild cognitive impairment (MCI) via unclear mechanisms that are investigated here. Brains of 5/6 nephrectomized mice (CKD model) and controls (n=8 per group) were stained for Nissl, Cytochrome Oxidase, Acetylcholine Esterase (AChE), Tyrosine-hydroxylase (TH), and DARPP32. The cerebral cortex, caudate-putamen, hippocampus, and cerebellum showed a normal cytoarchitecture and minimal changes in brain metabolic activity. The striatum demonstrated modified AChE activity and altered TH and DARPP32 expression. The extracellular spaces surrounding cortical interneurons (WFA staining) were reduced in CKD animals. To translate these data to patients, we analyzed retrospectively 313 patients (controls:139, CKD:79, kidney transplant (Tx):35, hemodialysis (HD):60). The Cognitive function (MoCA test) was reduced in CKD, Tx, and HD groups, inversely correlated with proteinuria, and directly correlated with uric acid levels and inflammatory scores in kidney biopsies. Sleepiness (ESS score) was increased in the HD group, whereas the chronotype was not significantly different among groups. The frequency spectrum of the hand tremor (accelerometer-measure) was altered in Tx and HD groups compared to controls and correlated with age and with BUN.
The extracellular space analyzed on MR-DTI sequences was reduced in patients with MCI compared to controls. In summary, reduced kidney function leads to functional and morphological changes in the brain of animals and patients. The altered water balance and the inflammatory state present in CKD are also relevant for brain dysfunction. This project was developed within the COST ACTION CA19127 "CONNECT".

THE IN VIVO ROLE OF M6A RNA MODIFICATION IN THE DROSOPHILA BRAIN DURING CELLULAR STRESS AND AGING

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Alexandra Perlegos[1], Nancy Bonini[2]
[1]University of Pennsylvania, Neuroscience Graduate Group, Philadelphia, United States of America, [2]University of Pennsylvania, Department Of Biology, Philadelphia, United States of America

Emerging evidence suggests that *N*^{6}-methyladenosine (m^{6}A), the most prevalent internal modification on eukaryotic mRNA, plays an essential role in various stress responses by regulating RNA processing. The brain is uniquely vulnerable to cellular stress, thus defining how m^{6}A sculpts the brain's stress susceptibility may provide insight into the vulnerability of the brain to age- and disease-related stress. The catalytic component of the methyltransferase complex that adds m^{6}A is *Mettl3*. Here we investigated the regulation and impact of *Mettl3*-dependent m^{6}A mRNA methylation in the adult *Drosophila* brain *in vivo* under normal conditions and stress, age, and in various situations of brain deterioration. Our data suggest a complex brain enriched response, and dynamic changes in m^{6}A levels, that are dependent on the methyltransferase complex component *Mettl3*. Through m^{6}A-immunoprecipitation sequencing, we show that 5'UTR *Mettl3*-dependent m^{6}A is enriched in transcripts of neuronal processes and dynamic signaling pathways, and marks a previously unrecognized class of genes that increase upon stress in the brain. *Mettl3* knockdown results in a brain-specific increase in protein and mRNA levels of *Mettl3*-dependent m^{6}A targets and, surprisingly, confers resilience to stress. We find that knockdown of the nuclear m^{6}A reader protein *Ythdc1* in the brain also results in increased resilience to stress. This work highlights that m^{6}A modification in the fly brain serves to dampen the acute stress response yet confers dynamic and brain-specific regulation on brain enriched genes, fine-tuning RNA levels and translation of critical transcripts involved in cell signaling, neuronal homeostasis, and the response to cellular stress.

Toxicity of pathogenic ataxin-2 in Drosophila shows dependence on a pure CAG repeat sequence.
Spinocerebellar ataxia type 2 is a polyglutamine (polyQ) disease associated with an expanded polyQ domain within the protein product of the ATXN2 gene. Interestingly, polyQ repeat expansions in ATXN2 are also associated with amyotrophic lateral sclerosis (ALS) and parkinsonism depending upon the length of the polyQ repeat expansion. The sequence encoding the polyQ repeat also varies with disease presentation: a pure CAG repeat is associated with SCA2, whereas the CAG repeat in ALS and parkinsonism is typically interrupted with the glutamine encoding CAA codon. Here, we asked if the purity of the CAG sequence encoding the polyQ repeat in ATXN2 could impact the toxicity of the ataxin-2 protein in vivo in Drosophila. We found that ataxin-2 encoded by a pure CAG repeat conferred toxicity in the retina and nervous system, whereas ataxin-2 encoded by a CAA-interrupted repeat or CAA-only repeat failed to confer toxicity, despite expression of the protein at similar levels. Furthermore, the CAG-encoded ataxin-2 protein aggregated in the fly eye, while ataxin-2 encoded by either a CAA/G or CAA repeat remained diffuse. The toxicity of the CAG-encoded ataxin-2 protein was also sensitive to the translation factor eIF4H, a known modifier of the toxic GGGGCC repeat in flies. These data indicate that ataxin-2 encoded by a pure CAG versus interrupted CAA/G polyQ repeat domain is associated with differential toxicity, indicating that mechanisms associated with the purity of the sequence of the polyQ domain contribute to disease.

UNEXPECTED LANDSCAPES OF MITOCHONDRIAL DESTRUCTION IN THE AGING BRAIN

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Anna Rappe, Fumi Suomi, Thomas Mcwilliams
University of Helsinki, FI, Faculty Of Medicine, Helsinki, Finland

Anna Rappe, Homa Ehsan, Fumi Suomi and Thomas G. McWilliams **Aims:** Mitochondrial damage is neutralised by mitophagy, thereby preventing cellular dysfunction and apoptosis. The selective autophagy of mitochondria (mitophagy) has long been linked to age-dependent neurodegenerative disorders such as Parkinson's and Alzheimer's disease. A prodigious body of work has studied mitophagy in cell-based systems and short-lived model organisms, yet how basal mitophagy proceeds in the aging mammalian brain remains unexplored. Our aim was to profile *in vivo* mitophagy in the aging mammalian brain. **Methods:** We analysed physiological mitophagy in neural tissues from distinct longitudinal cohorts of mitophagy reporter mice, using high-resolution confocal microscopy and quantitative cell biology. **Results:** We report widespread and surprising changes in mitophagy in the mammalian nervous system during progressive aging. Longitudinal quantitative profiling of mitophagy reporter mice cohorts from young (3 months) to geriatric (>26 months) revealed striking cell and tissue-specific alterations in mitochondrial turnover between distinct populations of neurons and non-neuronal cells. **Conclusions:** Our provocative findings establish a new and unexpected landscape of *in vivo* mitophagy through neural space and time. This comprehensive resource will refine therapeutic efforts to target age-mitochondrial dysfunction in the mammalian brain.

ENERGETIC FAILURE IS RESPONSIBLE FOR HEREDITARY NEURODEGENERATIVE DISORDERS DUE TO MUTATIONS IN THE HEME EXPORTER FLVCR1

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Eleonora Grasso[1], Francesca Bertino[1], Chiara Riganti[2], Andreas Roos[3], Boxun Zhao[4], Timothy Yu[4], Emanuela Tolosano[1], Deborah Chiabrando[1]
[1]University of Turin, Department Of Molecular Biotechnology And Health Sciences, Molecular Biotechnology Center, Turin, Italy, [2]University of Torino, Department Of Oncology, Torino, Italy, [3]University Hospital Essen University of Duisburg-Essen, Department Of Neuropediatrics/ Centre For Neuromuscular Disorders In Children, Essen, Germany, [4]Harvard Medical School, Division Of Genetics And Genomics, Boston, United States of America

Feline Leukemia Virus subgroup C Receptor 1 (FLVCR1) is a ubiquitously expressed heme exporter. FLVCR1 mutations cause Posterior Column Ataxia and Retinitis Pigmentosa (PCARP), non-syndromic retinitis pigmentosa (RP) and Hereditary Sensory and Autonomic Neuropathy (HSAN). These disorders are characterized by the progressive degeneration of photoreceptors and/or sensory neurons, resulting in progressive vision loss, sensory ataxia and/or pain insensitivity. The reason why photoreceptors and sensory neurons are particularly sensitive to the disruption of heme export is still unknown. We recently reported that heme export through FLVCR1 is required to sustain endogenous heme synthesis. Heme is a crucial cofactor of several proteins, Electron Transport Chain (ETC) complexes included. To investigate whether *FLVCR1* mutations affect energetic metabolism, we analyzed patient-derived primary fibroblasts. We showed that *FLVCR1* mutations result in impaired TCA cycle flux, ETC activity and ATP production resulting in oxidative stress and lipid peroxidation. The observed alterations were completely rescued by restoring the heme synthesis-export axis. Indeed, the treatment of patients' fibroblasts with ALA, to stimulate endogenous heme synthesis, and hemopexin, to promote heme export, completely restored energetic metabolism and lipid peroxidation in patients' fibroblasts. These data suggest that energetic failure is responsible for diseases due to *FLVCR1* mutations. Furthermore, these results also demonstrate the possibility to improve the function of the mutated transporter, at least *in vitro*. Further studies in animal models of the disease are required to fully understand the contribution of energetic metabolism to the progressive degeneration of the retina and sensory neurons.

The choroid plexus (ChP), a specialized vascular-epithelial structure located in the brain ventricular system, makes a selective interface between blood and cerebrospinal fluid (CSF), thus regulating brain homeostasis. It has been postulated that age-associated neurodegenerative diseases can be correlated with alterations of ChP function. Here we examined the ultrastructure of the ChP in adult (P60) and aging (P600) mice using electron microscopy. We identified different aging-related changes, including a reduction of epithelial cell height, a decrease in the area covered by apical microvilli, and a structural modification of tight junctions. We also found a redistribution of mitochondria along the basal-apical cell axis and a significant increase in the density of elongated mitochondria in old mouse ChP. Interestingly, 2-photon (2PM) imaging of whole ChP living explants and mitochondria tracking analysis revealed that mitochondria mainly show a wiggling movement, a feature that was rather constant throughout lifetime. Our data demonstrate that the choroid epithelium undergoes multiple structural alterations during aging. In particular, changes in the shape of mitochondria could correlate with increased vulnerability to metabolic stress.

SMALL MOLECULE FTO INHIBITOR AMELIORATES NEURONAL SENESCENCE

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Denise Greco[1], Barbora Černá[1], Petra Pohanová[1], Petra Tabáková[1], Zuzana Čočková[1], Karel Jezek[2], Jitka Kuncová[2], Jan Jedlička[2], Stephanie Proskauer-Peña[2], Annu Kala[2], Mark J. Olsen[3], Jiří Novotný[1], Petr Telenský[1,4]
[1]Charles University, Physiology Department, Prague, Czech Republic, [2]Charles University, Faculty Of Medicine In Pilsen, Pilsen, Czech Republic, [3]Midwestern University, Campus Glendale, Department Of Pharmaceutical Sciences, Glendale, United States of America, [4]International Clinical Research Center of St. Anne's University Hospital Brno,, Dementia Research Group, Brno, Czech Republic

Fat mass and obesity associated protein (FTO) is an epitranscriptomic eraser that demethylases N6-methyladenosine (m6A), the most abundant mRNA modification in eukaryotes. FTO is upregulated in brains of aged mice and aberrant m6A enrichment patterns can be present in senescence-associated transcripts. However, the role of FTO in neuronal senescence remains elusive. Here we used tert-butyl hydroperoxidase (TBHP) to induce senescence-like state in retinoic acid-differentiated SH-SY5Y neuronal cells. The role of FTO was studied using the novel small molecule inhibitor MO-I-500. We investigated cellular respiration (SeaHorse XF Mito Stress Test), ATP (ATP Bioluminescence Assay kit, Roche) and ROS (MitoSOX™ Red mitochondrial superoxide indicator) levels, β-galactosidase activity at pH 6 (Senescence Cells Histochemical Staining kit, Sigma-Aldrich) and markers of senescence-associated secretory phenotype (Western blotting). We show that FTO inhibition ameliorated the senescence-like phenotype induced by TBHP treatment. To assess whether FTO inhibition may ameliorate neural senescence in animal model, we administered 5 daily doses of 10 mg/kg MO-I-500 to 1 year old F344 rats. Treated rats displayed improved spatial memory acquisition in Active Allothetic Place Avoidance compared to aged-matched vehicle controls. High-resolution respirometry (OxyGraph, Oroboros) from ex vivo hippocampal samples demonstrated moderately increased rate of cellular respiration in the treated group. Overall, our data demonstrate that FTO inhibition might constitute a -novel therapy in the treatment of neuronal senescence in aging and age-related disease. This work was supported by Czech Science Foundation (GAČR) grant 16–12420Y, PRIMUS grant PRIMUS/SCI/33 and the European Regional Development Fund –Project ENOCH (No. CZ. 02. 1.01/0.0./0.0/16_019/0000868).

ALTERATIONS IN PACEMAKER CHANNEL'S MODULATIONS OF THALAMIC RELAY NEURONS BY DEMYELINATION DUE TO CPZ TREATMENT AND NEUROPROTECTIVE EFFECTS OF DRF

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Tengiz Oniani[1], Laura Vinnenberg[2], Anna Junker[3], Petra Hundehege[2], Thomas Budde[1]
[1]Westfälische Wilhelms-Universität, Institute Of Physiology I, Münster, Germany, [2]Institute of Translational Neurology, Department Of Neurology, Münster, Germany, [3]Westfälische Wilhelms-Universität, European Institute For Molecular Imaging, Münster, Germany

De- and remyelination processes caused by cuprizone (CPZ) treatment in animals mimic the relapsing forms of multiple sclerosis (MS) patients. In the CPZ model, progressive loss of oligodendrocytes and myelin in the brain is heavily associated with thalamic dysfunction – expressed by changes in burst activity in thalamic neurons. Since CPZ feeding alters both distribution and expression of different ion channels along the neuronal somata, we aimed to investigate the effects of CPZ treatment on the pacemaker of thalamic burst activity, the hyperpolarization-activated and cyclic nucleotide-gated (HCN) channels in acute brain slices both during de- and remyelination periods. In addition, we investigated whether the alterations in HCN channel properties may be reversed by diroximel fumarate (DRF), an approved oral drug for the treatment of relapsing forms of MS. C57BL/6 mice received 0.2% CPZ diet for 35 days, after which CPZ was substituted with standard rodent chow. Whole-cell patch clamp recording of thalamic relay neurons were performed after Day1, Day7 and Day25 starting from CPZ removal, corresponding to different states of axonal myelination. Measured I_h properties showed that the alterations of HCN channels depend on the state of the remyelination processes. In thalamic neurons, full demyelination on Day1 was associated with a decrease in I_h current density. On Day7, we found a transient maximum in current density before gradually reaching control values over the course of complete remyelination on Day25. Application of physiological relevant concentrations of DRF reversed alterations of I_h properties back to control values, indicating the neuroprotective effect of DRF.

ACTIVATION OF THE HEPCIDIN-FERROPORTIN1 PATHWAY IN THE BRAIN AND ASTROCYTIC-NEURONAL CROSSTALK TO COUNTERACT IRON DYSHOMEOSTASIS DURING AGING

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Serena Stanga[1], Mariarosa Mezzanotte[2], Giorgia Ammirata[2], Marina Boido[1], Antonella Roetto[2]
[1]University of Turin, Department Of Neuroscience Rita Levi Montalcini, Turin, Italy, [2]University of Turin, Department Of Clinical And Biological Sciences, Torino, Italy

Aims: During aging, iron accumulates in brain regions particularly vulnerable to neurodegeneration: the cerebral cortex and the hippocampus. However, knowledge on the mechanisms of iron regulation, together with its cellular distribution within neuronal tissue, remains scarce. Methods: We studied brain iron metabolism in C57BL/6 mice by Prussian blue Perl's staining for nonheme iron content, by Real-time quantitative PCR and Immunoblotting for genes and proteins related to iron storage and transport. Moreover, we performed Immunofluorescence in order to localize iron transporters and deposits within the nervous tissues and neuroinflammation. Results: We observed an age-dependent accumulation of iron in the cerebral cortex and hippocampus, that triggers neuroinflammation and oxidative stress measured by genes and markers of activated astrocytes and microglia. In old mice brain we found also alteration of the BBB integrity and we demonstrated the role of the Hepcidin/Ferroportin1 pathway during aging. Hepcidin, the major regulator of iron content and availability, interacts with the iron exporter Ferroportin1, causing its degradation and iron retention within the cell. Moreover, we observed NCOA4-dependent ferritinophagy of ferritin heavy-chain isoforms determining the increase of light-chain enriched ferritin heteropolymers that are more efficient as iron chelators. Furthermore, we demonstrated that both in the cerebral cortex and hippocampus Ferroportin1 colocalizes with astrocytes, while iron deposits with neurons. Conclusions: These data highlight the involvement of the Hepcidin/Ferroportin1 axis during mice aging as a response to a higher brain iron influx. This, represents the starting point to clarify iron metabolism in the brain, a typical feature of several neurodegenerative disorders.

Presenilin-Deficient Neurons and Astrocytes Display Normal Mitochondrial Phenotypes.
Presenilin 1 (PS1) and Presenilin 2 (PS2) are predominantly known as the catalytic subunits of the γ-secretase complex that generates the amyloid-β (Aβ) peptide, the major constituent of the senile plaques found in the brain of Alzheimer's disease (AD) patients. Apart from their role in γ-secretase activity, a growing number of cellular functions have been recently attributed to PSs. Notably, PSs were found to be enriched in mitochondria-associated membranes (MAMs) where mitochondria and endoplasmic reticulum (ER) interact. PS2 was more specifically reported to regulate calcium shuttling between these two organelles by controlling the formation of functional MAMs. We have previously demonstrated in mouse embryonic fibroblasts (MEF) an altered mitochondrial morphology along with reduced mitochondrial respiration and increased glycolysis in PS2-deficient cells (PS2KO). This phenotype was restored by the stable re-expression of human PS2. Still, all these results were obtained in immortalized cells, and one bottom-line question is to know whether these observations hold true in central nervous system (CNS) cells. To that end, we carried out primary cultures of PS1 knockdown (KD), PS2KO, and PS1KD/PS2KO (PSdKO) neurons and astrocytes. They were obtained from the same litter by crossing PS2 heterozygous; PS1 floxed (PS2; PS1) animals. Genetic downregulation of PS1 was achieved by lentiviral expression of the Cre recombinase in primary cultures. Strikingly, we did not observe any mitochondrial phenotype in PS1KD, PS2KO, or PSdKO primary cultures in basal conditions. Mitochondrial respiration and membrane potential were similar in all models, as were the glycolytic flux and NAD/NADH ratio. Likewise, mitochondrial morphology and content was unaltered by PS expression. We further investigated the differences between results we obtained here in primary nerve cells and those previously reported in MEF cell lines by analyzing PS2KO primary fibroblasts. We found no mitochondrial dysfunction in this model, in line with observations in PS2KO primary neurons and astrocytes. Together, our results indicate that the mitochondrial phenotype observed in immortalized PS2-deficient cell lines cannot be extrapolated to primary neurons, astrocytes, and even to primary fibroblasts. The PS-dependent mitochondrial phenotype reported so far might therefore be the consequence of a cell immortalization process and should be critically reconsidered regarding its relevance to AD.

How to Build and to Protect the Neuromuscular Junction: The Role of the Glial Cell Line-Derived Neurotrophic Factor.
The neuromuscular junction (NMJ) is at the crossroad between the nervous system (NS) and the muscle. Following neurotransmitter release from the motor neurons (MNs), muscle contraction occurs and movement is generated. Besides eliciting muscle contraction, the NMJ represents a site of chemical bidirectional interplay between nerve and muscle with the active participation of Schwann cells. Indeed, signals originating from the muscle play an important role in synapse formation, stabilization, maintenance and function, both in development and adulthood. We focus here on the contribution of the Glial cell line-Derived Neurotrophic Factor (GDNF) to these processes and to its potential role in the protection of the NMJ during neurodegeneration. Historically related to the maintenance and survival of dopaminergic neurons of the , GDNF also plays a fundamental role in the peripheral NS (PNS). At this level, it promotes muscle trophism and it participates to the functionality of synapses. Moreover, compared to the other neurotrophic factors, GDNF shows unique peculiarities, which make its contribution essential in neurodegenerative disorders. While describing the known structural and functional changes occurring at the NMJ during neurodegeneration, we highlight the role of GDNF in the NMJ-muscle cross-talk and we review its therapeutic potential in counteracting the degenerative process occurring in the PNS in progressive and severe diseases such as Alzheimer's disease (AD), Amyotrophic Lateral Sclerosis (ALS) and Spinal Muscular Atrophy (SMA). We also describe functional 3D neuromuscular co-culture systems that have been recently developed as a model for studying both NMJ formation in vitro and its involvement in neuromuscular disorders.

Mitochondrial Dysfunctions: A Red Thread across Neurodegenerative Diseases.
Mitochondria play a central role in a plethora of processes related to the maintenance of cellular homeostasis and genomic integrity. They contribute to preserving the optimal functioning of cells and protecting them from potential DNA damage which could result in mutations and disease. However, perturbations of the system due to senescence or environmental factors induce alterations of the physiological balance and lead to the impairment of mitochondrial functions. After the description of the crucial roles of mitochondria for cell survival and activity, the core of this review focuses on the "mitochondrial switch" which occurs at the onset of neuronal degeneration. We dissect the pathways related to mitochondrial dysfunctions which are shared among the most frequent or disabling neurodegenerative diseases such as Alzheimer's, Parkinson's, and Huntington's, Amyotrophic Lateral Sclerosis, and Spinal Muscular Atrophy. Can mitochondrial dysfunctions (affecting their morphology and activities) represent the early event eliciting the shift towards pathological neurobiological processes? Can mitochondria represent a common target against neurodegeneration? We also review here the drugs that target mitochondria in neurodegenerative diseases.

Amyloid Precursor Protein (APP) Controls the Expression of the Transcriptional Activator Neuronal PAS Domain Protein 4 (NPAS4) and Synaptic GABA Release.
The amyloid precursor protein (APP) has been extensively studied as the precursor of the β-amyloid (Aβ) peptide, the major component of the senile plaques found in the brain of Alzheimer's disease (AD) patients. However, the function of APP per se in neuronal physiology remains to be fully elucidated. APP is expressed at high levels in the brain. It resembles a cell adhesion molecule or a membrane receptor, suggesting that its function relies on cell-cell interaction and/or activation of intracellular signaling pathways. In this respect, the APP intracellular domain (AICD) was reported to act as a transcriptional regulator. Here, we used a transcriptome-based approach to identify the genes transcriptionally regulated by APP in the rodent embryonic cortex and on maturation of primary cortical neurons. Surprisingly, the overall transcriptional changes were subtle, but a more detailed analysis pointed to genes clustered in neuronal-activity dependent pathways. In particular, we observed a decreased transcription of neuronal PAS domain protein 4 (NPAS4) in APP-/- neurons. NPAS4 is an inducible transcription factor (ITF) regulated by neuronal depolarization. The downregulation of NPAS4 co-occurs with an increased production of the inhibitory neurotransmitter GABA and a reduced expression of the GABA receptors α1. CRISPR-Cas-mediated silencing of NPAS4 in neurons led to similar observations. Patch-clamp investigation did not reveal any functional decrease of GABA receptors activity, but long-term potentiation (LTP) measurement supported an increased GABA component in synaptic transmission of APP-/- mice. Together, NPAS4 appears to be a downstream target involved in APP-dependent regulation of inhibitory synaptic transmission.

A Role for GDNF and Soluble APP as Biomarkers of Amyotrophic Lateral Sclerosis Pathophysiology.
The current inability of clinical criteria to accurately identify the "at-risk group" for Amyotrophic Lateral Sclerosis (ALS)

development as well as its unknown etiology are fueling the interest in biomarkers aimed at completing clinical approaches for the diagnosis. The Glial cell line-derived neurotrophic factor (GDNF) is a diffusible peptide critically involved in neuronal differentiation and survival. GDNF is largely studied in various neurological and neuromuscular diseases, with a great interest in the peripheral nervous system (PNS). The recent discovery of Amyloid Precursor Protein (APP)-dependent GDNF regulation driving neuro-muscular junctions' formation in APP null transgenic mice, prompts to study whether neurodegeneration relies on loss or gain of APP function and suggests that it could affect peripheral processes. Here, we explored a brand-new aspect of the loss of trophic support in ALS by measuring GDNF, APP, soluble APP fragments and Aβ peptides levels in SOD1 or SOD1 transgenic mouse models of ALS and in human biological fluids [i.e. serum and cerebrospinal fluid (CSF)] from ALS patients and control subjects. Our results show that both GDNF and soluble APP fragments levels are altered at the onset of motor deficits in mice and that their levels are also modified in patient samples. This study indicates that both GDNF and soluble APPα represent possible biomarkers for ALS.

Presenilin 2-Dependent Maintenance of Mitochondrial Oxidative Capacity and Morphology.
Mitochondrial dysfunction plays a pivotal role in the progression of Alzheimer's disease (AD), and yet the mechanisms underlying the impairment of mitochondrial function in AD remain elusive. Recent evidence suggested a role for Presenilins (PS1 or PS2) in mitochondrial function. Mutations of PSs, the catalytic subunits of the γ-secretase complex, are responsible for the majority of inherited AD cases (FAD). PSs were shown to be present in mitochondria and particularly enriched in mitochondria-associated membranes (MAM), where PS2 is involved in the calcium shuttling between mitochondria and the endoplasmic reticulum (ER). We investigated the precise contribution of PS1 and PS2 to the bioenergetics of the cell and to mitochondrial morphology in cell lines derived from wild type (PS+/+), PS1/2 double knock-out (PSdKO), PS2KO and PS1KO embryos. Our results showed a significant impairment in the respiratory capacity of PSdKO and PS2KO cells with reduction of basal oxygen consumption, oxygen utilization dedicated to ATP production and spare respiratory capacity. In line with these functional defects, we found a decrease in the expression of subunits responsible for mitochondrial oxidative phosphorylation (OXPHOS) associated with an altered morphology of the mitochondrial cristae. This OXPHOS disruption was accompanied by a reduction of the NAD/NADH ratio. Still, neither ADP/ATP ratio nor mitochondrial membrane potential (ΔΨ) were affected, suggesting the existence of a compensatory mechanism for energetic balance. We observed indeed an increase in glycolytic flux in PSdKO and PS2KO cells. All these effects were truly dependent on PS2 since its stable re-expression in a PS2KO background led to a complete restoration of the parameters impaired in the absence of PS2. Our data clearly demonstrate here the crucial role of PS2 in mitochondrial function and cellular bioenergetics, pointing toward its peculiar role in the formation and integrity of the electron transport chain.

Specificity of presenilin-1- and presenilin-2-dependent γ-secretases towards substrate processing.
The two presenilin-1 (PS1) and presenilin-2 (PS2) homologs are the catalytic core of the γ-secretase complex, which has a major role in cell fate decision and Alzheimer's disease (AD) progression. Understanding the precise contribution of PS1- and PS2-dependent γ-secretases to the production of β-amyloid peptide (Aβ) from amyloid precursor protein (APP) remains an important challenge to design molecules efficiently modulating Aβ release without affecting the processing of other γ-secretase substrates. To that end, we studied PS1- and PS2-dependent substrate processing in murine cells lacking presenilins (PSs) (PS1KO, PS2KO or PS1-PS2 double-KO noted PSdKO) or stably re-expressing human PS1 or PS2 in an endogenous PS-null (PSdKO) background. We characterized the processing of APP and Notch on both endogenous and exogenous substrates, and we investigated the effect of pharmacological inhibitors targeting the PSs activity (DAPT and L-685,458). We found that murine PS1 γ-secretase plays a predominant role in APP and Notch processing when compared to murine PS2 γ-secretase. The inhibitors blocked more efficiently murine PS2- than murine PS1-dependent processing. Human PSs, especially human PS1, expression in a PS-null background efficiently restored APP and Notch processing. Strikingly, and contrary to the results obtained on murine PSs, pharmacological inhibitors appear to preferentially target human PS1- than human PS2-dependent γ-secretase activity.

APP-dependent glial cell line-derived neurotrophic factor gene expression drives neuromuscular junction formation.
Besides its crucial role in the pathogenesis of Alzheimer's disease, the knowledge of amyloid precursor protein (APP) physiologic functions remains surprisingly scarce. Here, we show that APP regulates the transcription of the glial cell line-derived neurotrophic factor (GDNF). APP-dependent regulation of GDNF expression affects muscle strength, muscular

trophy, and both neuronal and muscular differentiation fundamental for neuromuscular junction (NMJ) maturation in vivo In a nerve-muscle coculture model set up to modelize NMJ formation in vitro, silencing of muscular APP induces a 30% decrease in secreted GDNF levels and a 40% decrease in the total number of NMJs together with a significant reduction in the density of acetylcholine vesicles at the presynaptic site and in neuronal maturation. These defects are rescued by GDNF expression in muscle cells in the conditions where muscular APP has been previously silenced. Expression of GDNF in muscles of amyloid precursor protein null mice corrected the aberrant synaptic morphology of NMJs. Our findings highlight for the first time that APP-dependent GDNF expression drives the process of NMJ formation, providing new insights into the link between APP gene regulatory network and physiologic functions.-Stanga, S., Zanou, N., Audouard, E., Tasiaux, B., Contino, S., Vandermeulen, G., René, F., Loeffler, J.-P., Clotman, F., Gailly, P., Dewachter, I., Octave, J.-N., Kienlen-Campard, P. APP-dependent glial cell line-derived neurotrophic factor gene expression drives neuromuscular junction formation.

Searching for predictive blood biomarkers: misfolded p53 in mild cognitive impairment.
The identification and validation of biomarkers for preclinical patients with mild cognitive impairment (MCI) at-risk for Alzheimer's disease (AD) development is increasingly important. We used the cytofluorimetric analysis of unfolded p53 to determine the prognostic ability of the protein as predictive signature from MCI to AD in a longitudinal study of a population of presymptomatic patients with the clinical diagnosis of MCI. Venous blood samples from 24 healthy subjects, 28 MCI and 15 AD were analyzed with the cytofluorimetric method for unfolded p53 protein detection. Twenty-four MCI patients had clinical follow-up subsequent to the analysis for unfolded p53. Elevated levels of the conformationally altered protein were able to discriminate both MCI and AD patients comparing with healthy subjects. Longitudinal follow-up revealed that 7/24 MCI patients progressed to AD. All converters (100%) were predicted by elevated levels of unfolded p53, with a positive predictive value of 87.5%. These data support and extend our previous observation that the cytofluorimetric approach for unfolded p53 protein was able to discriminate AD patients from healthy subjects and to predict the progression from MCI to AD in presymptomatic patients before clinical diagnosis for AD was evident.

Unfolded p53 in the pathogenesis of Alzheimer's disease: is HIPK2 the link?
p53 transcriptional activity depends mainly on posttranslational modifications and protein/protein interaction. Another important mechanism that controls p53 function is its conformational stability since p53 is an intrinsically unstable protein. An altered conformational state of p53, independent from point mutations, has been reported in tissues from patients with Alzheimer's disease (AD), leading to an impaired and dysfunctional response to stressors. Recent evidence shows that one of the activators that induces p53 posttranslational modification and wild-type conformational stability is homeodomain interacting protein kinase 2 (HIPK2). Hence, conditions that induce HIPK2 deregulation would result in a dysfunctional response to stressors by affecting p53 activity. Discovering the mechanisms of HIPK2 activation/inhibition and the ways to manipulate HIPK2 activity are an interesting option to affect several biological pathways, including those underlying AD. Soluble beta-amyloid peptides have recently been involved in HIPK2 degradation, in turn regulating the p53 conformational state and vulnerability to a noxious stimulus, before triggering the amyloidogenic cascade. Here we discuss about these findings and the potential relevance of HIPK2 as a target for AD and highlight the existence of a novel amyloid-based mechanism in AD potentially leading to the survival of injured dysfunctional cells.

REGULATION OF NEURONAL AUTOPHAGY BY ENDOCYTIC KINASE AAK1

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Ebru Ozer Yildiz[1,2], Natalia Kononenko[1,2], Sujoy Bera[1]

Neuronal autophagy is regulated by a variety of cues, including the clathrin-mediated endocytosis (CME). Previously, we have shown that the CME adaptor protein complex 2 (AP-2) promotes autophagosome transport in neurons. How precisely AP-2 is recruited to autophagosomes is currently unknown. Association of AP-2 with membranes is regulated by the phosphorylation of its µ2 subunit by the Ser/Thr kinase adaptor-associated kinase-1 (AAK1). Here we identify AAK1 as a regulator of autophagic flux in neurons. By combining mouse genetics and biochemical approaches, we reveal that AAK1 is not essential for neuronal survival. Full-body AAK1 knockout mice are born normal but characterized by severe dwarfism and hyperactivity. Strikingly, the AAK1 is required to stabilize the AP-2 complex, since AAK1 deficient brains reveal significantly less of the AP-2 µ2 protein level when compared to the wildtype. Characterization of AAK1 binding partners in the brain reveals tectonin β-propeller containing protein 2 (TECPR2) as a novel AAK1 binding partner. TECPR2 is a hereditary spastic paraplegia–associated protein, required for autophagosome formation at the ER exit sites. We find that AAK1 interacts and co-traffics with TECPR2 in neurons, which raised a question if AP-2 is required for membrane trafficking at the ER exit sites and whether this function is regulated by the AAK1. Taken together, our data highlight AAK1 as a novel player of neuronal autophagy and propose that the function of AP-2 in autophagosome trafficking might be regulated by the AAK1.

A NEW INTRABODY BASED OPTOGENETIC TOOL TO DEGRADE THE AGGREGATION PRONE PROTEINS.

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Angela Bitonti, Simonetta Lisi, Ottavia Vitaloni, Antonino Cattaneo
Scuola Normale Superiore, Laboratorio Di Biologia, Pisa, Italy

Neurodegenerative diseases, such as Parkinson's disease, are characterized by the presence of misfolded protein that produce toxic aggregates. Since the mechanism of the aggregation remains unclear, one strategy could be to find a way to induce the degradation of the aggregates. The ability of intracellular antibodies to bind a pathological protein within the cell environment is not enough to reduce the toxic phenotype. The degradation of the complex, composed by intrabody and toxic target, can only be achieved by introducing a degron domain which is able to activate the ubiquitin proteasome system. The selection of an appropriate degron is a key aspect to develop a tool for the modulation of the proteasome activity, but it may not be sufficient to control the timing of the degradation pathway. In this work, we create a target specific photosensitive degron domain fused to a camelid intrabody directed against alpha-Synuclein protein to modulate the degradation of alpha synuclein protein by using a blue light stimulation protocol on yeast cell cultures. Yeast cells are widely used as eukaryotic model organism to study protein aggregation. Our data show that the photosensitive degron, made by photoreceptor light oxygen voltage (LOV) domain and ornithine decarboxylase enzyme fused with a nanobody directed against alpha synuclein protein, is a powerful tool to detect and reduce the protein level. We provide the proof of concept for the optimization of the illumination protocol in a yeast cellular model using alpha synuclein as target for degradation.

INVOLVEMENT OF OLIGODENDROCYTES IN AMYOTROPHIC LATERAL SCLEROSIS (ALS) LINKED TO FUSED IN SARCOMA PROTEIN

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Marguerite Jamet[1], Luc Dupuis[2]
[1]INSERM UMR-S 1118, Department Of Neurology, Strasbourg, France, [2]Inserm UMR-S 1118, Department Of Neurology, Strasbourg, France

Aims : ALS is a neurodegenerative disorder leading to death after 3 to 5 years**.** A mutation in the nuclear localisation signal (NLS) of the Fused in Sarcoma protein (FUS) leads to FUS cytoplasmic mislocalisation and early-onset ALS. FUS is a DNA/RNA binding protein which regulates gene expression and mRNA splicing. Increasing evidence suggests that not only motor neurons but also glial cells are affected in the disease. The aim of my PhD is to understand the contribution of oligodendrocytes in *FUS*-ALS. **Methods :** To conduct my project, we first used a murine model of *FUS*-ALS carrying a truncation of the NLS signal in the FUS protein to characterize the oligodendrocytes deficiencies. Then, we developed two new mice models in which we can either induce the FUS mutation only in oligodendrocytes, or rescue the mutation only in oligodendrocytes using a Cre-Lox recombination technology under the control of an oligodendrocyte promoter. We are currently investigating the pathological hallmarks and behavioural outcomes in those two models to determine whether this *Fus* mutation in oligodendrocytes is sufficient and/or necessary to induce ALS symptoms. **Results and discussion:** The ultrastructure of myelin sheath is altered in *FUS*-ALS mouse model, as well as myelin production. This could be explained by the fact that the FUS protein binds to several myelin mRNAs. Also, cuprizone-induced demyelination leads to increased motor impairements in *FUS*-ALS mice compared to their control.

MERCURY CONTAMINATION EFFECTS ON RATS SENSORY GANGLION

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Liudmyla Sokurenko[1], Oleksandr Maievskyi[2], Vladyslav Lasavutz[1]
[1]Bogomolets National Medical University, Histology And Embriology, Kyiv, Ukraine, [2]Educational and Scientific Center "Institute of Biology and Medicine" of Taras Shevchenko National University, Clinical Medicine, Kyiv, Ukraine

The effects of xenobiotics, such as mercury, primarily affect the nervous system functions. Therefore, the aim was to study the mercury chloride small doses effect on the sensory ganglions structure at different exposures time: 4 and 12 weeks. The morphological study examined the rats sensory ganglion microscopic and electron microscopic features with using a solution of mercuric chloride (II). During examination after 4 weeks of daily exposure, sensory ganglion structural changes in neurons and neuroglia are observed. The cytoplasm of some neurons in the perinuclear zone is enlightened, the granular endoplasmic reticulum and mitochondria are structurally altered. The nuclei of such neurons are swollen, the number of nuclear pores is reduced. Swollen mitochondria and their cristae reduction is also found in some glial cells; as well as widening and swelling of the Golgi complex and endoplasmic reticulum, ribosomes loss; the number of lysosomes increase. Some of the nerve fibers that are part of the sensory ganglion have a myelin structure destruction and swollen mitochondria with partial cristae reduction. Endotheliocytes are functionally active, have cytoplasmic outgrowths on the lumenal surface and vacuoles in the cytoplasm. After 12 weeks of daily exposure, the number of structurally altered neurons and gliocytes increased and endothelial cells were less functionally active. Thus, changes in neurons, neuroglia, and endothelial cells indicate a nerve tissue response according to the mercuric chloride action duration.

COENZYME Q10 MODULATES Aβ-INDUCED DISRUPTION OF CELLULAR PROTEOSTASIS AND MITOCHONDRIAL DAMAGE IN NEURO2A CELLS

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Yoana Rabanal-Ruiz, Emilio Llanos-González, Javier Frontiñán-Rubio, Cristina Pedrero-Prieto, Juan Ramon Peinado, Francisco Javier Alcaín, Mario Durán-Prado
GEON, Faculty of Medicine of Ciudad Real, University of Castilla-La Mancha, Cellular Biology, Ciudad Real, Spain

Oxidative stress (OS) appears as a major component of the pathophysiologic process in Alzheimer´s disease (AD) and contributes to endoplasmic reticulum (ER) stress, mitochondrial dysfunction and ultimately, leads to proteostasis imbalance. Our previous results have demonstrated that the natural antioxidant coenzyme Q10 (CoQ10) protects human endothelial cells against Aβ-induced oxidative injury and cell death. Therefore, we hypothesize that early regulation of OS in AD could prevent ER stress, mitochondrial damage and normalize cellular proteostasis, which would delay the progression of the disease. Methodology: To explore the impact of CoQ10 on Aβ internalization and incorporation to endoplasmic reticulum (ER), mitochondria and lysosomes, Neuro2A cells were incubated with CoQ10 or vehicle for 24 h, stained with Mitotracker and ERtracker or Lysotracker, and then exposed to $A\beta_{25-35}$ conjugated with green HiLyte Fluor. To evaluate autophagy, cells were transfected with the expression vector GFP-LC3. Image acquisition was performed for 24 h using a confocal microscope. Results: CoQ10 reduced both, Aβ uptake and its trafficking/accumulation into mitochondria and ER, whilst enhanced its incorporation into lysosomes. CoQ10 was also efficacious in protecting against Aβ-induced mitochondrial dysfunction and impaired autophagy. Conclusions: CoQ10 could prevent Aβ-associated mitochondrial damage and proteostasis imbalance, thereby delaying the progression of the pathophysiology associated to this disease.

Macroautophagy is a highly conserved cellular recycling pathway that sequesters cellular constituents in autophagic vesicles (AVs) and delivers them to the lysosome for degradation. Previous studies demonstrated that ablation of core autophagy genes, such as *atg5* or *atg7*, in pallial progenitors compromises the survival of their glutamatergic neuron progeny, suggesting that autophagy may be required for neuronal survival. Here, we examine the effects of *atg5* conditional ablation in neurons expressing parvalbumin (PV-*atg5*KO), which in the forebrain mainly represent fast-spiking inhibitory neurons that provide peri-somatic inhibition onto the principal pyramidal cells. Contrary to the prevailing view, we show that autophagy-deficient PV neurons survive throughout the brain, with the exception of Purkinje neurons in the cerebellum, which rapidly degenerate. However, proteomic analysis of forebrain PV neurons indicated that autophagy deficiency leads to aberrant proteostasis of synaptic and other proteins. Consistently, in the hippocampus, PV-interneurons show altered synaptic properties and the PV-*atg5*KO animals exhibit memory deficits. Our findings reveal a neuronal type-specific vulnerability to autophagy deficiency while indicating a role of autophagy for the proper function of PV interneurons.

We have here assessed, using Δ9 -tetrahydrocannabinol (Δ9 -THC) for comparison, the effect of Δ9 -tetrahydrocannabinolic acid (Δ9 -THCA) and of Δ9 -tetrahydrocannabivarin (Δ9-THCV) that is mediated by human versions of CB1, CB2, and CB1-CB2 receptor functional units, expressed in a heterologous system. CB1 is the most abundant receptor in SNC and CB2 has an important roll as a neuroprotector component in neuroimflamation conditions. Binding to the CB1 and CB2 receptors was addressed in living cells by means of a homogeneous assay. Signaling studies included cAMP level determination, activation of the mitogen-activated protein kinase pathway and ß-arrestin recruitment were performed. The signaling triggered by Δ9 -THCA and Δ9 -THCV via individual receptors or receptor heteromers disclosed differential bias, i.e. the bias observed using a given phytocannabinoid depended on the receptor and on the compound used as reference to calculate the bias factor. These results are consistent with different binding modes leading to differential functional selectivity depending on the agonist structure, and the state (monomeric or heteromeric) of the cannabinoid receptor. In addition, on studying Gi-coupling we showed that Δ9 -THCV and Δ9-THCA and Δ9-THCV were able to revert the effect of a selective CB2 receptor agonist, but only Δ9-THCV, and not Δ9-THCA, reverted the effect of arachidonyl-2′ -chloroethylamide (ACEA 100 nM) a selective agonist of the CB1 receptor. Overall, these results indicate that cannabinoids may have a variety of binding modes that results in qualitatively different effects depending on the signaling pathway that is engaged upon cannabinoid receptor activation.

Similarities and differences upon binding of naturally occurring Δ-tetrahydrocannabinol-derivatives to cannabinoid CB and CB receptors.
We have here assessed, using Δ-tetrahydrocannabinol (Δ-THC) for comparison, the effect of Δ-tetrahydrocannabinolic acid (Δ-THCA) and of Δ-tetrahydrocannabivarin (Δ9-THCV) that is mediated by human versions of CB, CB, and CB-CB receptor functional units, expressed in a heterologous system. Binding to the CB and CB receptors was addressed in living cells by means of a homogeneous assay. A biphasic competition curve for the binding to the CB receptor, was obtained for Δ-THCV in cells expressing the two receptors. Signaling studies included cAMP level determination, activation of the mitogen-activated protein kinase pathway and ß-arrestin recruitment were performed. The signaling triggered by Δ-THCA and Δ-THCV via individual receptors or receptor heteromers disclosed differential bias, i.e. the bias observed using a given phytocannabinoid depended on the receptor (CB, CB or CB-CB) and on the compound used as reference to calculate the bias factor (Δ-THC, a selective agonist or a non-selective agonist). These results are consistent with different binding modes leading to differential functional selectivity depending on the agonist structure, and the state (monomeric or heteromeric) of the cannabinoid receptor. In addition, on studying Gi-coupling we showed that Δ-THCV and Δ-THCA and Δ-THCV were able to revert the effect of a selective CB receptor agonist, but only Δ9-THCV, and not Δ9-THCA, reverted the effect of arachidonyl-2'-chloroethylamide (ACEA 100 nM) a selective agonist of the CB receptor. Overall, these results indicate that cannabinoids may have a variety of binding modes that results in qualitatively different effects depending on the signaling pathway that is engaged upon cannabinoid receptor activation.

Potentiation of cannabinoid signaling in microglia by adenosine A receptor antagonists.
Neuroprotective M2-skewed microglia appear as promising to alter the course of neurodegenerative diseases and G protein-coupled receptors (GPCRs) are potential targets to achieve such microglial polarization. A common feature of adenosine A (A

R) and cannabinoid CB (CB R) GPCRs in microglia is that their expression is upregulated in Alzheimer's disease (AD). On the one hand, CB R seems a target for neuroprotection, delaying neurodegenerative processes like those associated to AD or Parkinson's diseases. A R antagonists reduce amyloid burden and improve cognitive performance and memory in AD animal models. We here show a close interrelationship between these two receptors in microglia; they are able to physically interact and affect the signaling of each other, likely due to conformational changes within the A -CB receptor heteromer (A -CB Het). Particularly relevant is the upregulation of A -CB Het expression in samples from the APP , AD transgenic mice model. The most relevant finding, confirmed in both heterologous cells and in primary cultures of microglia, was that blockade of A receptors results in increased CB R-mediated signaling. This heteromer-specific feature suggests that A R antagonists would potentiate, via microglia, the neuroprotective action of endocannabinoids with implications for AD therapy.

Expression of the Adenosine A-A Receptor Heteromer in Different Brain Regions and Marked Upregulation in the Microglia of the Transgenic APP Alzheimer's Disease Model.
Adenosine (Ado) receptors have been instrumental in the detection of heteromers and other higher-order receptor structures, mainly via interactions with other cell surface G-protein-coupled receptors. Apart from the first report of the A Ado receptor interacting with the A Ado receptor, there has been more recent data on the possibility that every Ado receptor type, A, A, A, and A, may interact with each other. The aim of this paper was to look for the expression and function of the A/A receptor heteromer (AAHet) in neurons and microglia. In situ proximity ligation assays (PLA), performed in primary cells, showed that AAHet expression was markedly higher in striatal than in cortical and hippocampal neurons, whereas it was similar in resting and activated microglia. Signaling assays demonstrated that the effect of the AR agonist, PSB 777, was reduced in the presence of the AR agonist, 2-Cl-IB-MECA, whereas the effect of the AR agonist was potentiated by the AR antagonist, SCH 58261. Interestingly, the expression of the heteromer was markedly enhanced in microglia from the APP model of Alzheimer's disease. The functionality of the heteromer in primary microglia from APP mice was more similar to that found in resting microglia from control mice.

Ghrelin and Cannabinoid Functional Interactions Mediated by Ghrelin/CB Receptor Heteromers That Are Upregulated in the Striatum From Offspring of Mice Under a High-Fat Diet.
There is evidence of ghrelinergic-cannabinoidergic interactions in the central nervous system (CNS) that may impact on the plasticity of reward circuits. The aim of this article was to look for molecular and/or functional interactions between cannabinoid CB and ghrelin GHS-R1a receptors. In a heterologous system and using the bioluminescence resonance energy transfer technique we show that human versions of cannabinoid CB and ghrelin GHS-R1a receptors may form macromolecular complexes. Such receptor heteromers have particular properties in terms of CB/G-mediated signaling and in terms of GHS-R1a-G-mediated signaling. On the one hand, just co-expression of CBR and GHS-R1a led to impairment of cannabinoid signaling. On the other hand, cannabinoids led to an increase in ghrelin-derived calcium mobilization that was stronger at low concentrations of the CB receptor agonist, arachidonyl-2'-chloroethylamide (ACEA). The expression of CB-GHS-R1a receptor complexes in striatal neurons was confirmed by proximity ligation imaging assays. Upregulation of CB-GHS-R1a- receptor complexes was found in striatal neurons from siblings of pregnant female mice on a high-fat diet. Surprisingly, the expression was upregulated after treatment of neurons with ghrelin (200 nM) or with ACEA (100 nM). These results help to better understand the complexities underlying the functional interactions of neuromodulators in the reward areas of the brain.

Pharmacological data of cannabidiol- and cannabigerol-type phytocannabinoids acting on cannabinoid CB, CB and CB/CB heteromer receptors.
Recent approved medicines whose active principles are ΔTetrahidrocannabinol (Δ-THC) and/or cannabidiol (CBD) open novel perspectives for other phytocannabinoids also present in Cannabis sativa L. varieties. Furthermore, solid data on the potential benefits of acidic and varinic phytocannabinoids in a variety of diseases are already available. Mode of action of cannabigerol (CBG), cannabidiolic acid (CBDA), cannabigerolic acid (CBGA), cannabidivarin (CBDV) and cannabigerivarin (CBGV) is, to the very least, partial.

The Heteromeric Complex Formed by Dopamine Receptor D and CCR9 Leads the Gut Homing of CD4 T Cells Upon

Inflammation.
CD4 T cells constitute central players in inflammatory bowel diseases (IBDs), driving inflammation in the gut mucosa. Current evidence indicates that CCR9 and the integrin α4β7 are necessary and sufficient to imprint colonic homing on CD4 T cells upon inflammation. Interestingly, dopaminergic signaling has been previously involved in leukocyte homing. Despite dopamine levels are strongly reduced in the inflamed gut mucosa, the role of dopamine in the gut homing of T cells remains unknown. Here, we study how dopaminergic signaling affects T cells upon gut inflammation.

DECIPHERING MINIMAL REGIONS IN THE TAU REPEAT DOMAIN THAT ACTS AS THE LOCI FOR AGGREGATION, SEEDING AND PROPAGATION

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Narendran Annadurai[1], Lukáš Malina[2], Marián Hajdúch[1], Viswanath Das[1]
[1]Palacky University Olomouc, Institute Of Molecular And Translational Medicine, Olomouc, Czech Republic, [2]Palacký University in Olomouc, Department Of Medical Biophysics, Olomouc, Czech Republic

Background: Neurofibrillary tangles are pathological hallmarks of Alzheimer's disease (AD), but the prion-like propagation of tau may underlie disease progression. Our study aimed to identify the minimal regions in the tau repeat domain that define seeding and its impact on intracellular tau phosphorylation and aggregation. **Methods:** Peptides of repeat 2 (R2) and repeat 3 (R3) of the tau repeat domain were used to generate different seed types. The effect of seeds on intracellular seeding was examined in cells expressing P301S and P301L tau. **Results:** R2, like R3, forms seed-competent fibrils (seeds) when assembled in the presence of heparin. However, R3, but not R2, forms seed-competent seeds when assembled without heparin, even though both R2 and R3 have identical N-terminal hexapeptide and cysteine residue sequences. Cysteine to alanine substitution in R3 abrogates its self-aggregation and seeding potency. R2 and R3 seeds induce tau phosphorylation at pathological sites and oligomerisation of native tau in tau expressing cells (seeded cells). When introduced in a fresh set of cells, protein fractions of seeded cells reseed endogenous tau aggregation. **Conclusion:** We show that R3 in tau is the minimal region for pathological seed generation under physiological conditions, whereas R2 might need polyanionic cofactors to generate pathogenic seeds. **Acknowledgement**: European Regional Development Fund - Project ENOCH (No. CZ.02.1.01/0.0/0.0/16_019/0000868).

ALTERED POLYUNSATURATED SPHINGOLIPIDS CORRELATE WITH α-SYNUCLEIN IN MULTIPLE SYSTEM ATROPHY CEREBELLAR SUBTYPE

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Finula Isik[1], Ying He[1], Russell Pickford[2], Glenda Halliday[1], Woojin Kim[1]
[1]Halliday Laboratory, Brain and Mind Centre, Faculty Of Medicine And Health, University Of Sydney, Sydney, Australia, [2]Bioanalytical Mass Spectrometry Facility, University Of New South Wales, Sydney, Australia

Background & Aims: Multiple System Atrophy (MSA) is a rapidly progressive neurodegenerative disease that is classified into two subtypes - MSA-Cerebellar (MSA-C) and MSA-Parkinsonian (MSA-P). Both subtypes are pathologically characterised by oligodendroglial α-synuclein inclusions and demyelination. Lipids constitute a large component of myelin and are diminished in disease-affected brain regions. Furthermore, polyunsaturated fatty acids are susceptible to peroxidation and are associated with α-synuclein aggregation. Despite the clear importance of lipids in MSA pathology, little is known about the lipid oxidative state of MSA brain. The aim of this study was to determine the relationship between unsaturated lipids and α-synuclein in MSA brain. **Methods:** Total lipids were extracted from tissue samples collected from MSA-C (n = 5), MSA-P (n = 6) and control (n = 13) putamen, motor cortex white matter, cerebellum and occipital cortex, and analysed by mass spectrometry. The abundance of unsaturated lipids was analysed by multivariate analysis covarying for age and sex. α-Synuclein protein in the same tissue samples was measured by western blotting. **Results:** Abundance of several unsaturated sphingolipids was significantly altered in MSA compared to controls across all four regions. Specifically, in MSA-C cerebellum, polyunsaturated hexosylceramide was reduced ($p = 0.01$), whilst polyunsaturated sphingosine was increased ($p = 0.01$). Polyunsaturated hexosylceramide ($r = -0.421$, $p = 0.04$) and sphingosine ($r = 0.419$, $p = 0.04$) correlated with α-synuclein levels. **Conclusion**: These results indicate that specific unsaturated lipids are altered in disease-affected regions of MSA brain, and this could relate to a regional vulnerability to synucleinopathy.

IRON CHELATION AND RYANODINE RECEPTOR INHIBITION PROTECT PRIMARY HIPPOCAMPAL NEURONS AGAINST FERROPTOSIS

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Silvia Gleitze[1], Pedro Lobos[1], Andrea Paula-Lima[1,2,3], Cecilia Hidalgo[1,2,4]
[1]Biomedical Neuroscience Institute, Faculty Of Medicine, Universidad De Chile, Santiago, Chile, [2]Department of Neurosciences, Faculty Of Medicine, Universidad De Chile, Santiago, Chile, [3]Institute for Research in Dental Sciences, Faculty Of Dentistry, Universidad De Chile, Santiago, Chile, [4]Physiology and Biophysics Program, Institute of Biomedical Sciences and Center for Exercise, Metabolism and Cancer Studies, Faculty Of Medicine, Universidad De Chile, Santiago, Chile

Introduction: Ferroptosis, a recently described cell death pathway, is characterized by iron-mediated lipid peroxidation, altered mitochondrial morphology and decreased levels of the intracellular antioxidant glutathione. Inhibition of glutathione peroxidase 4 (Gpx4), a key antioxidant regulator, promotes ferroptosis in different cell types. However, scant information is available on Gpx4-induced ferroptosis in primary hippocampal neurons. Moreover, the role of Ca^{2+}, a universal second messenger, in Gpx4-induced ferroptosis in neuronal cells remains elusive. **Hypothesis:** We propose that Gpx4 inhibition induces ferroptosis in primary hippocampal neurons, and that the ensuing dysregulation of the cellular redox state dysregulates Ca^{2+} signaling through excessive activation of ryanodine receptor (RyR) channels. **Material and Methods:** Primary hippocampal neurons were treated with RSL3, a selective Gpx4 inhibitor, and ferroptosis was characterized by analyzing cell viability, cell morphology and lipid peroxidation. The effects of iron chelation by deferoxamine (DFO), and RyR inhibition by 20 uM ryanodine were evaluated. **Results:** Incubation of cultures with RSL3 (15 µM) for 24 hours induced 50% cell death, dendritic damage, and lipid peroxidation, which was reduced by previous incubation with DFO. Suppression of RyR activity offered partial protection in RSL3-treated hippocampal neurons. **Conclusion:** Gpx4 inhibition induced ferroptosis in primary hippocampal cultures, as evidenced by the protection offered by the iron chelator DFO. Suppression of RyR activity mitigated the effects of Gpx4 inhibition, indicating that Ca^{2+} contributes to ferroptosis in hippocampal neuronal cells, a result with possible implications for neurodegenerative diseases. **Acknowledgements**: CONICYT-PFCHA/Doctorado Nacional/2020-21200346, BNI ICM09_015, BMBF 180051.

ROLES OF GROWTH FACTORS ON USP14 MEDIATED CONTROL OF NEURONAL PROTEOSTASIS

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Vignesh Srinivasan
University of Helsinki, Department Of Biochemistry And Developmental Biology, Biomedicum 1, Helsinki, Finland

Ubiquitin specific protease-14 (USP14) is a deubiquitinating enzyme reversibly associated with the proteasome 19S regulatory particle (RP), regulating its degradation activity. Proteasome independent pool of USP14 could also influence other pathways like autophagy and endoplasmic reticulum (ER) signaling. We have identified that proteasome inhibition or USP14 mutant (W58A-USP14) disrupted the association of USP14 with PSMD2, a component of the proteasome 19S RP. Furthermore, we identified a dynamic interaction of USP14 with molecular chaperone, HSC70 coordinating the crosstalk between proteasome, autophagy and ER signaling. By employing the W58A-USP14 mutant, we showed an increase in the formation of GABARAP positive autophagosomes and their clearance via lysosomal degradation in mutant huntingtin (Htt) expressing striatal neurons. We have also identified potential post-translational modifications in USP14, which could play a role in its underlying regulatory mechanisms. In this respect, we show here that stimulation with the growth factor, IGF1 can inhibit autophagy and induce accumulation of K48-linked Polyubiquitin chains indicating proteasomal inhibition. IGF1 further increases the catalytic activity of USP14 in SH-SY5Y neuroblastoma cells and in primary neurons. The upstream mechanisms regulating these dynamics of USP14 warrants further studies.

IMPAIRMENT OF BACH-1/NRF-2 AXIS IN DOWN SYNDROME

POSTER SESSION 01 - SECTION: CELLULAR AND MOLECULAR MECHANISMS OF NEURODEGENERATION

Marzia Perluigi, Eugenio Barone, Sara Pagnotta, Antonella Tramutola, Fabio Di Domenico
sapienza university of Rome, Biochemicals Sciences, rome, Italy

Oxidative Stress (OS) is a chronic condition that contributes to phenotypical alterations of Down Syndrome (DS) individuals, representing a strong risk factor for neurodegeneration. A number of triplicated genes are involved in the over-production of ROS as well as in defects of the antioxidant response in DS individuals and animal models. Among candidate genes, BACH-1 levels have been found to be elevated in DS and we hypothesize that dysregulation of Keap-1-Nrf-2-ARE/BACH-1 axis may be involved in the alteration of redox homeostasis in DS tissues. Protein oxidation (total HNE adduct), gene expression and protein levels of BACH-1, Nrf-2 and its targets (HO-1 and NQO1) were evaluated in different models of DS: (i) hippocampus of Ts2cje mice, Tg mouse model of DS and primary neurons/astrocytes, and (ii) human DS lymphoblastoid cell lines (LCLs) from pediatric patients. Further, we tested the ability of Caffeic Acid Phenethyl Ester and its synthetic analogue VP961 to modulate Nrf-2 activity. Ts2cje mice and DS LCLs showed the impairment of BACH-1/Nrf-2 pathway: increased protein oxidation; increased gene expression and protein levels iii) reduced Nrf-2 nuclear translocation and subsequently decreased Nrf-2-mediated anti-oxidant response were observed. Both compounds, at different concentrations, 10 mM and 5 mM respectively, were administered to DS LCLs and were able to promote Nrf-2 nuclear translocation, which resulted in the improvement of the antioxidant response. Collected results demonstrated the impairment of BACH-1/Nrf-2 axis as a pathological feature of DS that negatively modulate the anti-oxidant response. The treatment restored BACH1/Nrf-2 axis and rescued OS-phenotype in DS LCLs.

AIMS: Rett syndrome (RTT) is a neurodevelopmental disorder, representing the most common genetic cause of severe intellectual disability in females. RTT is caused by mutations in the X-linked *MECP2* gene. Given its role as a master regulator of gene expression, transcriptional maturation is affected in null neurons, as well as the ability to respond to external *stimuli*. Neuronal activity plays a key role during brain development, thus any variation from physiological ranges lead to severe consequences. We tested the possible causative link between immaturity and reduced neuronal activity by pharmacologically stimulating *in vitro* and *in vivo Mecp2* null neurons within different time windows of differentiation. **METHODS:** To enhance activity and rescue maturation *in vitro,* we used Ampakine CX546, a positive AMPA receptor modulator. The efficacy of an early treatment with CX546 *in vivo* was tested by evaluating the general well-being of mice, and by performing motor and cognitive behavioral tests. **RESULTS:** By treating cortical neurons with CX546 we ameliorated null neurons transcription and activity, highlighting the contribution of defective mechanisms of development to typical RTT phenotypes. Although the early time window of treatment *in vivo* suggested a prolonged benefic effect on knock-out mice, it was devoid of translational value. We thus tested later timepoints and different Ampakines. **CONCLUSIONS:** Our results support the value of an early therapeutic approach acting on neuronal activity as a strategy for Rett syndrome therapy. More studies are needed to pinpoint the correct time window and to identify the molecular pathways involved in any observed benefits.

HIPPOCAMPAL GABAERGIC DYSFUNCTION IN MECP2 -/Y MICE

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Azam Asgarihafshejani, Melissa Serranilla, Jessica C. Pressey, Melanie A. Woodin
University of Toronto, Department Of Cell And Systems Biology, Ramsay Wright Biological Laboratories, Toronto, Canada

Rett syndrome (RTT) is a neurodevelopmental disorder caused by a mutation in the gene that encodes for the transcriptional regulator, MeCP2. In RTT, patients exhibit severe synaptic dysfunction in neurons found in layers II and III of the entorhinal cortex (EC), resulting in severely impaired memory and learning. The temporoammonic (TA) pathway provides input directly from layer III of the EC to distal dendrites of CA1 neurons in the stratum lacunosum-moleculare (SLM). Despite the importance of the TA pathway on the firing of the CA1 neurons, spatial navigation, learning, and memory, this pathway has not been fully characterized in the context of Rett syndrome. To characterize the effect of the MeCP2 mutation on synaptic and network connectivity of TA-CA1 and Schaffer collateral (SC)-CA1 pathways, we performed in vitro whole-cell recordings, local field potential recordings, and behavioral assays in a MeCP2-mouse model of RTT. Our results show that the eEPSCs amplitude were significantly larger in MeCP2 -/Y relative to wild-type mice following10 Hz stimulation trains with no change in eIPSCs amplitude. We also found both LTP induction and paired-pulse ratio were unaffected. Additionally, training did not improve rotarod performance in MeCP2-/Y mice, unlike wild-types. Furthermore, GABA reversal potential was depolarized in both SLM and CA1 neurons measured using a high chloride concentration (30 mM) internal solution and KCC2 expression was reduced, suggesting impairments in GABAergic inhibition. Taken together, this data demonstrates that altered GABAergic signaling may underlie synaptic dysfunction in MeCP2 deficient mice and may contribute to disease progression in RTT.

Effect of low frequency stimulation on impaired spontaneous alternation behavior of kindled rats in Y-maze test.
Epileptic seizures are characterized with cognitive disorders. In this study we investigated the effect of electrical low frequency stimulation (LFS), as a potential anticonvulsant agent, on kindled seizure-induced cognitive impairments. Animals were kindled through electrical stimulation of hippocampal CA1 area in a semi-rapid manner (12 stimulations/day). One group of animals received LFS 4 times at 0.5, 6.5, 24 and 30h following the last kindling stimulation. Applied LFS was consisted of 4 packages at 5min intervals. Each package contained 200 monophasic square wave pulses of 0.1ms duration at 1Hz. The Y-maze test was performed in all animals to measure the spontaneous alternation behavior. Kindled animals showed significant impairment in spontaneous alternation behavior compared to the control group. Application of LFS improved the observed impairment in spontaneous alternation behavior in kindled animals, so that there was no significant difference between kindled+LFS and control group. The observed improving effect of LFS was accompanied with a significant increase in calcineurin gene expression within the hippocampal area. Therefore, it may be postulated that application of LFS in kindled animals, which resulted in increment of calcineurin gene expression, can improve the seizure-induced impairment in spontaneous alternation behavior in Y-maze test.
Epilepsy Res, 2016; 126

Low-frequency electrical stimulation enhances the effectiveness of phenobarbital on GABAergic currents in hippocampal slices of kindled rats.
Low frequency stimulation (LFS) has been proposed as a new approach in the treatment of epilepsy. The anticonvulsant mechanism of LFS may be through its effect on GABAA receptors, which are the main target of phenobarbital anticonvulsant

action. We supposed that co-application of LFS and phenobarbital may increase the efficacy of phenobarbital. Therefore, the interaction of LFS and phenobarbital on GABAergic inhibitory post-synaptic currents (IPSCs) in kindled and control rats was investigated. Animals were kindled by electrical stimulation of basolateral amygdala in a semi rapid manner (12 stimulations/day). The effect of phenobarbital, LFS and phenobarbital+LFS was investigated on GABAA-mediated evoked and miniature IPSCs in the hippocampal brain slices in control and fully kindled animals. Phenobarbital and LFS had positive interaction on GABAergic currents. In vitro co-application of an ineffective pattern of LFS (100 pulses at afterdischarge threshold intensity) and a sub-threshold dose of phenobarbital (100μM) which had no significant effect on GABAergic currents alone, increased the amplitude and area under curve of GABAergic currents in CA1 pyramidal neurons of hippocampal slices significantly. Interestingly, the sub-threshold dose of phenobarbital potentiated the GABAergic currents when applied on the hippocampal slices of kindled animals which received LFS in vivo. Post-synaptic mechanisms may be involved in observed interactions. Obtained results implied a positive interaction between LFS and phenobarbital through GABAA currents. It may be suggested that a combined therapy of phenobarbital and LFS may be a useful manner for reinforcing the anticonvulsant action of phenobarbital.
Neuroscience, 2016; 330

Combined sub-threshold dosages of phenobarbital and low-frequency stimulation effectively reduce seizures in amygdala-kindled rats.
Low-frequency stimulation (LFS) is a potential therapy utilized in patients who do not achieve satisfactory control of seizures with pharmacological treatments. Here, we investigated the interaction between anticonvulsant effects of LFS and phenobarbital (a commonly used medicine) on amygdala-kindled seizures in rats. Animals were kindled by electrical stimulation of basolateral amygdala in a rapid manner (12 stimulations/day). Fully kindled animals randomly received one of the three treatment choices: phenobarbital (1, 2, 3, 4 and 8 mg/kg; i.p.; 30 min before kindling stimulation), LFS (one or 4 packages contained 100 or 200 monophasic square wave pulses, 0.1-ms pulse duration at 1 Hz, immediately before kindling stimulation) or a combination of both (phenobarbital at 3 mg/kg and LFS). Phenobarbital alone at the doses of 1, 2 and 3 mg/kg had no significant effect on the main seizure parameters. LFS application always produced anticonvulsant effects unless applied with the pattern of one package of 100 pulses, which is considered as non-effective. All the seizure parameters were significantly reduced when phenobarbital (3 mg/kg) was administered prior to the application of the non-effective pattern of LFS. Phenobarbital (3 mg/kg) also increased the anticonvulsant actions of the effective LFS pattern. Our results provide an evidence of a positive cumulative anticonvulsant effect of LFS and phenobarbital, suggesting a potential combination therapy at sub-threshold dosages of phenobarbital and LFS to achieve a satisfactory clinical effect.

eIF2α controls memory consolidation via excitatory and somatostatin neurons.
An important tenet of learning and memory is the notion of a molecular switch that promotes the formation of long-term memory. The regulation of proteostasis is a critical and rate-limiting step in the consolidation of new memories. One of the most effective and prevalent ways to enhance memory is by regulating the synthesis of proteins controlled by the translation initiation factor eIF2. Phosphorylation of the α-subunit of eIF2 (p-eIF2α), the central component of the integrated stress response (ISR), impairs long-term memory formation in rodents and birds. By contrast, inhibiting the ISR by mutating the eIF2α phosphorylation site, genetically and pharmacologically inhibiting the ISR kinases, or mimicking reduced p-eIF2α with the ISR inhibitor ISRIB, enhances long-term memory in health and disease. Here we used molecular genetics to dissect the neuronal circuits by which the ISR gates cognitive processing. We found that learning reduces eIF2α phosphorylation in hippocampal excitatory neurons and a subset of hippocampal inhibitory neurons (those that express somatostatin, but not parvalbumin). Moreover, ablation of p-eIF2α in either excitatory or somatostatin-expressing (but not parvalbumin-expressing) inhibitory neurons increased general mRNA translation, bolstered synaptic plasticity and enhanced long-term memory. Thus,

eIF2α-dependent mRNA translation controls memory consolidation via autonomous mechanisms in excitatory and somatostatin-expressing inhibitory neurons.

Cell-Genotype Specific Effects of Mecp2 Mutation on Spontaneous and Nicotinic Acetylcholine Receptor-Evoked Currents in Medial Prefrontal Cortical Pyramidal Neurons in Female Rett Model Mice.
Rett syndrome (RTT) is a neurodevelopmental disorder caused by mutation in the X-linked MECP2 gene. Random X-inactivation produces a mosaic of mutant (MT) and wild-type (WT) neurons in female Mecp2+/- (het) mice. Many RTT symptoms are alleviated by increasing activity in medial prefrontal cortex (mPFC) in RTT model mice (Howell et al., 2017). Using a GFP-MeCP2 fusion protein to distinguish WT from MT pyramidal neurons in mPFC we found cell autonomous (cell genotype specific) and non-autonomous effects of MeCP2 deficiency on spontaneous excitatory/inhibitory balance, nicotinic acetylcholine receptor (nAChR) currents and evoked activity. MT Layer 5 and 6 (L5, L6) neurons of male nulls, and MT L6 of het mice had reduced spontaneous excitatory synaptic input compared to WT in wild-type male (WTm), female (WTf) and het mice. Inhibitory synaptic charge in MT L6 equaled WT in 2-4-month hets. At 6-7 months inhibitory charge in WT in het slices was increased compared to both MT in het and WT in WTf; however, in hets the excitatory/inhibitory charge ratio was still greater in WT compared to MT. nAChR currents were reduced in L6 of nulls and MT L6 in het slices compared to WT neurons of het, WTm and WTf. At 2-4 months, ACh perfusion increased frequency of inhibitory currents to L6 neurons equally in all genotypes but increased excitatory inputs to MT and WT in hets less than WT in WTfs. Unexpectedly ACh perfusion evoked greater sustained IPSC and EPSC input to L5 neurons of nulls compared to WTm.

MITOCHONDRIAL DYSFUNCTION IN RETT SYNDROME MICE MODELS: STUDYING A NEUROLOGICAL DISORDER FROM SYNAPTIC METABOLISM PERSPECTIVE TO FIND NEW TREATMENT OPTIONS

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Uliana Musokhranova[1], Alfonso Oyarzábal[1], Pilar Pizcueta[2], Àngels García-Cazorla[1]
[1]Institut de Recerca Sant Joan de Déu, Department Of Neurology, Esplugues de Llobregat, Spain, [2]Minoryx Therapeutics, Department Of Biology, Mataró, Spain

Rett syndrome is a neurodevelopmental disease affecting 1:10,000 girls, usually due to *MECP2* mutations. It is characterized by a regression in the neuronal development, resulting in the loss of acquired capabilities and arousal of epileptic crisis. While it is a neurotransmission and neuronal maturation disorder, attention towards bioenergetics has been brought, and can be explored to find therapeutic options. AIMS | We have focused our research on the analysis of mitochondrial homeostasis in different brain areas of Rett mice models and whether it can be modulated in a therapeutic purpose. RESULTS | Resembling the patients, MeCP2 female mice go through an asymptomatic phase to later develop the symptomatology. We observed mitochondrial dysfunction already in pre-symptomatic mice (altered dynamics and antioxidant protein expression), suggesting that the mitochondrial malfunction plays a role in the phenotype development and progression. Treatment of symptomatic mice with a PPARγ agonist resulted in behavioral improvement (in terms of explorative activity and motor coordination) through mitochondrial dysfunction amelioration (especially regarding ATP production in cerebellum, closely related with motor coordination improvement). Neuronal maturation and activation markers were also altered and corrected by the treatment. CONCLUSION | Our results reaffirm mitochondria as an effective target for the treatment of an archetypical neurodevelopment disease as Rett syndrome, and endorse a clinical trial with the mentioned PPARγ agonist. Moreover, we highlight the mitochondrial dysfunction even before the symptoms' onset, setting mitochondria as a highly relevant target to modify the natural history of Rett syndrome, and reassuring the necessity of early diagnosis.

It has been proposed that altered processing of social rewards contributes to defective sociability in Autism Spectrum Disorder (ASD). Exposure to the anticonvulsant drug valproic acid (VPA) during gestation is a recognized environmental risk factor for ASD in humans and is used experimentally to induce ASD features in rodents. We previously described a neurophysiological endophenotype of Nucleus Accumbens (NAc) medium spiny neurons (MSNs) from VPA-exposed rats, consisting of profound alterations in basic electrical properties, likely attributable to inward rectifying potassium currents, which lead to abnormal intrinsic excitability. It was recently reported that the mTOR pathway inhibitor rapamycin (RAPA), administered acutely during adolescence, improves ASD-like behavioral defects induced by prenatal VPA exposure. We decided to study the somatic excitability, synaptic function and neuronal morphology of accumbal MSNs in brain slices obtained from rats exposed to prenatal VPA, postnatal RAPA, or both. On NAc tissue homogenates, we also measured the levels of pre- and post-synaptic markers of excitatory and inhibitory synapses and changes in gene expression pattern. We report that postnatal acute administration of RAPA normalizes the VPA-induced increase of intrinsic excitability in accumbal MSNs, although not affecting inward rectifying potassium currents. No significant differences were found in excitatory or inhibitory synaptic drive across treatments. Accordingly, no major alterations in the expression level and molecular composition of main pre- and post-synaptic proteins were detected. Finally, gene expression analysis revealed that postnatal mTOR inhibition interacts with VPA-induced disruption of neurodevelopmental pathways at multiple levels, an in a complex manner.

NRG1 SIGNALING PROMOTES AXONAL DEVELOPMENT OF CORTICAL NEURONS

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Angela Rodriguez-Prieto[1], Yaiza Domínguez Canterla[1], Isabel Mateos White[2], Cristina Gil Sanz[2], Mar Anibal-Martinez[3], Guillermina López-Bendito[3], Ana González Manteiga[1], Tomás Armenteros Barron[1], Pietro Fazzari[1]
[1]Centro de Investigación Príncipe Felipe, Lab Of Cortical Circuits In Health And Disease, Valencia, Spain, [2]University of Valencia, Cell Biology / Biotecmed, Burjassot, Spain, [3]Instituto De Neurociencia de Alicante, Developmental Neurobiology, Alicante, Spain

Schizophrenia is a developmental disorder characterized by atrophy of neuronal processes and alterations in connections between cortical neurons. Neuregulin 1 (NRG1) was identified as a major schizophrenia risk gene and we and others showed that NRG1 intracellular signaling is required for dendritic elongation, excitatory transmission and synaptic plasticity. Here, we studied the role of NRG1 intracellular signaling in the axonal development *in vitro* and *in vivo* taking advantage of multiple approaches, including culture of primary cortical neurons, *in utero* electroporation and neuronal tracing with DiI in newborn NRG1 *knockout* mice. Our study suggests that NRG1 expression in cortical neurons regulates de neurites growth *in vitro* and *in vivo*, being necessary and sufficient for the formation of the axonal projections. From a molecular point of view, we are currently studying the NRG1 signaling pathways underlying the neurites growth that characterizes our phenotype. These results expand the knowledge about NRG1 signaling, hopefully contributing to the understanding of its molecular role in schizophrenia.

A Scalable Method to Study Neuronal Survival in Primary Neuronal Culture with Single-cell and Real-Time Resolution.
Neuronal loss is at the core of many neuropathologies, including stroke, Alzheimer's disease, and Parkinson's disease. Different methods were developed to study the process of neuronal survival upon cytotoxic stress. Most methods are based on biochemical approaches that do not allow single-cell resolution or involve complex and costly methodologies. Presented here is a versatile, inexpensive, and effective experimental paradigm to study neuronal survival. This method takes advantage of sparse fluorescent labeling of the neurons followed by live imaging and automated quantification. To this aim, the neurons are electroporated to express fluorescent markers and co-cultured with non-electroporated neurons to easily regulate cell density and increase survival. Sparse labeling by electroporation allows a simple and robust automated quantification. In addition, fluorescent labeling can be combined with the co-expression of a gene of interest to study specific molecular pathways. Here, we present a model of stroke as a neurotoxic model, namely, the oxygen-glucose deprivation (OGD) assay, which was performed in an affordable and robust homemade hypoxic chamber. Finally, two different workflows are described using IN Cell Analyzer 2200 or the open-source ImageJ for image analysis for semi-automatic data processing. This workflow can be easily adapted to different experimental models of toxicity and scaled up for high-throughput screening. In conclusion, the described protocol provides an approachable, affordable, and effective in vitro model of neurotoxicity, which can be suitable for testing the roles of specific genes and pathways in live imaging and for high-throughput drug screening.

Nrg1 haploinsufficiency alters inhibitory cortical circuits.
Neuregulin 1 (NRG1) and its receptor ERBB4 are schizophrenia (SZ) risk genes that control the development of both excitatory and inhibitory cortical circuits. Most studies focused on the characterization ErbB4 deficient mice. However, ErbB4 deletion concurrently perturbs the signaling of Nrg1 and Neuregulin 3 (Nrg3), another ligand expressed in the cortex. In addition, NRG1 polymorphisms linked to SZ locate mainly in non-coding regions and they may partially reduce Nrg1 expression. Here, to study the relevance of Nrg1 partial loss-of-function in cortical circuits we characterized a recently developed haploinsufficient mouse model of Nrg1 (Nrg1). These mice display SZ-like behavioral deficits. The cellular and molecular underpinnings of the behavioral deficits in Nrg1 mice remain to be established. With multiple approaches including

Magnetic Resonance Spectroscopy (MRS), electrophysiology, quantitative imaging and molecular analysis we found that Nrg1 haploinsufficiency impairs the inhibitory cortical circuits. We observed changes in the expression of molecules involved in GABAergic neurotransmission, decreased density of Vglut1 excitatory buttons onto Parvalbumin interneurons and decreased frequency of spontaneous inhibitory postsynaptic currents. Moreover, we found a decreased number of Parvalbumin positive interneurons in the cortex and altered expression of Calretinin. Interestingly, we failed to detect other alterations in excitatory neurons that were previously reported in ErbB4 null mice suggesting that the Nrg1 haploinsufficiency does not entirely phenocopies ErbB4 deletions. Altogether, this study suggests that Nrg1 haploinsufficiency primarily affects the cortical inhibitory circuits in the cortex and provides new insights into the structural and molecular synaptic impairment caused by NRG1 hypofunction in a preclinical model of SZ.

ROLE OF USP9X IN REGULATING PREFRONTAL CORTEX EXCITABILITY AND ITS POTENTIAL IMPLICATIONS FOR ANGELMAN SYNDROME

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Unai Alduntzin[1,2], Nagore Elu[2], Ugo Mayor[2], Andreas Frick[1]
[1]Neurocentre Magendie, Inserm U1215, Bordeaux, France, [2]UPV/EHU, Department Of Biochemistry And Molecular Biology, Faculty Of Science And Technology, Leioa, Spain

Aims: The lack of functional ubiquitin E3 ligase UBE3A in the brain leads to the rare neurodevelopmental disorder Angelman Syndrome (AS), associated with alterations in prefrontal cortex (PFC) function and cognitive impairment. Protein ubiquitination, however, is not only modulated by E3 ligases, but also by deubiquitinating (DUB) enzymes. Identifying and characterizing DUBs responsible of counteracting UBE3A could lead to therapeutic targets that could ameliorate AS symptoms. A previous study from our lab demonstrated that USP9X –a DUB associated with X-linked intellectual disability– counteracts UBE3A mediated ubiquitination. We aim to characterize the role of USP9X in regulating cortical excitability, found to be altered in AS mouse models, and shed light on the potential therapeutic value of USP9X inhibitors. **Methods**: We performed *in vitro* patch clamp recordings in cortical slices of C57BL/6 mice focusing on pyramidal cells of layer V in the medial PFC (mPFC), one of the main output neuron types of the PFC. USP9X activity was blocked using the two specific inhibitors. **Results**: Blocking USP9X led to changes in several parameters of neuronal excitability, the most prominent being an increase in the sag ratio and in the medium after hyperpolarization (mAHP) of mPFC layer V pyramidal neurons. **Conclusions**: Our results suggest that UPS9X regulates the activity or expression of different ion channels that contribute to intrinsic properties regulating basic membrane properties and synaptic integration. Following these results, we will examine whether blocking USP9X activity ameliorates changes observed in AS mouse models, to further investigate the therapeutic potential of USP9X inhibitors.

DEVELOPMENT OF A NEW DRUG SCREENING SYSTEM FOR RETT SYNDROME THERAPY

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Irene Sormonta[1], Concetta De Quattro[2], Giuseppina De Rocco[3], Marzia Rossato[2], Ugo Borello[4], Nicoletta Landsberger[5]
[1]Università Vita-Salute San Raffaele, Neuroscience, Milan, Italy, [2]University of Verona, Department Of Biotechnology, Verona, Italy, [3]Università degli studi di Milano, Medical Biotechnology And Translational Medicine, Milan, Italy, [4]Univeristy of Pisa, Department Of Biology, Pisa, Italy, [5]San Raffaele Hospital, Department Of Neuroscience, Milan, Italy

AIMS: Rett syndrome is a severe neurodevelopmental disorder caused by mutations in the X-linked *MECP2* gene, primarily acting as transcriptional repressor. Although Rett proved to be reversible in mice, no cure is available. Animal-based drug screenings are widely used to evaluate drug efficacy, though requiring a large number of animals and elevated costs. New drug screening approaches have emerged *in vitro*, based on the analysis of neuronal defective morphology. However, we demonstrated that the amelioration of the transcriptional profile in *Mecp2* null neurons appears as a better indicator of functional rescue compared to morphological restoration. For this reason, we aim at developing a cell-based drug screening system for Rett syndrome therapy, based on customized high-throughput 96x96 qRT-PCR Arrays. **METHODS**: To identify a Rett-neuronal transcriptional profile, a longitudinal RNASeq was performed in *Mecp2* null neurons differentiated from neuronal precursor cells (NPCs) at three timepoints along maturation (DIV7-14-18). Differentially expressed genes (DEGs) were validated using 96x96 qRT-PCR Microfluidic Cards (Fluidigm). **RESULTS**: Bioinformatics analysis identified 1469 DEGs (p-adj<0,1) and gene ontology well-recapitulated previous results *in vivo*. By using different prioritization criteria and testing selected neuronal DEGs on 96x96 microfluidic cards, we identified 80 reproducible DEGs which we are validating on primary cortical neurons either treated or untreated with specific drugs. **CONCLUSIONS**: Obtained data suggest that our transcriptional platform could represent a new drug screening system to pre-select drugs with a higher chance of success in pre-clinical studies. In this communication we will discuss *pro* and *cons* of the proposed approach for drug screening.

DECIPHERING THE ROLE OF THE KINASE CK2 IN A NOVEL MOUSE MODEL OF THE OKUR-CHUNG AUTISM-LIKE DISORDER

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Jose Manuel Cruz Gamero[1], David Boulet[1], Demetra Ballardin[1,2], Heike Rebholz[1,2,3]
[1]Université de Paris, Institut De Psychiatrie Et Neurosciences De Paris, Paris, France, [2]GHU-Paris Psychiatrie et Neurosciences, Hôpital Sainte Anne, Paris, France, [3]Danube private university, Center Of Neurodegeneration, Faculty Of Medicine, Krems, Austria

In 2016, WES analysis led to the identification of mutations in the gene coding for the catalytic subunit of the kinase CK2 in the Okur-Chung neurodevelopmental syndrome (OCNDS). It is a rare condition within autism spectrum disorders (ASD), characterised by developmental delay, intellectual disability, behavioral problems, hypotonia, epilepsy and verbalization deficits. CK2 is ubiquitously expressed and consists of 2 α catalytic and 2 β regulatory subunits. CK2 is highly expressed in the brain and has multitude of substrates that regulate homeostasis and neurons signalling. Several different missense variants are known to be linked to OCNDS, however the K198R variant is the most common comprising approximately 30% of the cases. Aim: Our aim is to characterize these mice at behavioral, cellular and proteomic levels in order to understand how and through which mechanisms mutant CK2 can mediate OCNDS symptoms. Methods: We evaluated the behavioral phenotype and analysed the changes in activity and in the phospho-proteome by Western Blotting and Mass Spectrometry. Results: We found differences in learning and memory paradigms (Barnes test and Y-maze) in heterozygote mice compared to wildtype littermates. We show that K198R$^{+/-}$ mice exhibit reduced expression levels of CK2α compared to wild type, and that CK2 activity is reduced in striatal tissue. Total and phospho-proteome pointed towards involvement of pre and postsynaptic proteins. These findings help us to start elucidating CK2α mechanisms underlying OCNDS phenotype and to establish the K198R mice line as a model for the disease and also delivering valid information on ASD in general.

NO LOSS OF GLUTAMATERGIC NEURONS OR INTERNEURONS IN MICE LACKING THE AUTISM-ASSOCIATED GENE GLRA2 ENCODING THE GLYCINE RECEPTOR ALPHA-2 SUBUNIT

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Laura Upton, Franck Louis, Vincent Vialou, Catalina Betancur
Sorbonne Université, INSERM, CNRS, Neuroscience Paris Seine, Institut De Biologie Paris Seine, Paris, France

Autism spectrum disorder (ASD) is a neurodevelopmental disorder with a heterogeneous genetic aetiology. Mutations of the *GLRA2* gene, which encodes the glycine receptor alpha-2 subunit, were implicated in ASD, unveiling a previously undescribed mechanism for the physiopathology of autism. Our group showed that *Glra2*-deficient male (*Glra2*$^{Y/-}$) mice present with cognitive deficits and reduced synaptic plasticity (Pilorge et al. 2016). Developmental studies in mice expressing the same *Glra2* mutation in a different genetic background reported deficits in cortical migration and a global loss of cortical neurons with microcephaly (Avila et al. 2013; Morelli et al. 2017). Since our *Glra2*$^{Y/-}$ mice bred on a C57BL/6JRj background are not microcephalic, we decided to quantify projection neurons and interneurons in the prefrontal and somatosensory cortices of adult and postnatal day 14 *Glra2*$^{Y/-}$ mice using fluorescent *in situ* hybridization and immunofluorescence. No loss of glutamatergic neurons or interneurons (parvalbumin, calretinin and cholecystokinin) was observed at either age with either technique. There was however a significant increase in somatostatin-positive cells in *Glra2*$^{Y/-}$ mice. These findings contrast with those reported by other groups, suggesting a possible interaction of the *Glra2* mutation with genetic background. Our results obtained in the C57BL/6 background suggest *Glra2* plays a more subtle role in neocortical development and assembly, whilst implicating *Glra2* in the development of somatostatin-expressing interneurons. Funded by an EU Horizon 2020 Marie Sklodowska-Curie grant.

Background: Higher frequency of Mthfr's polymorphism, 677C>T, was found among ASD patients and their mothers. In mice, maternal and offspring Mthfr+/- genotypes lead to ASD like-behavior and alternation in the GABA pathway. Here, we investigate the developmental origin of interneurons deficiency in Mthfr deficient mice. **Experimental design:** Mthfr+/+(WT) and Mthfr+/-(HT) female mice were mated with WT male to generate 3 groups of offspring representing maternal:offspring genotype: 1. WT:WT 2.HT:WT 3.HT:HT. Parental mice carried the GAD65-tdTomato for interneurons identification. Immunofluorescent was used to examine cerebral cortex of postnatal-day 7 pups. **Results:** An interaction between offspring Mthfr+/- genotype and the anterior-posterior axis altered cortical laminar distribution of interneurons: In layer 1 (L1), HT:HT presented higher interneurons density in the anterior cortex (p=0.01), while decreased density was observed in the sub-ventricular zone (p=0.001). Similar results were obtained in the medial and lateral regions in L1. Evaluation of the chloride transporter NKCC1 density has presented a strong interaction between offspring Mthfr+/- genotype and the anterior-posterior axis; while NKCC1 density in L1 was suppressed in the anterior cortex, elevation in the posterior cortex was observed (p=0.001). **Conclusions**: These findings suggest that Mthfr changes in the early postnatal stage, perhaps induced in the in-utero environment, were sufficient to induce de-synchronization of interneuron's development, and may be a part of the mechanisms leading to behavioral changes in a parallel age. Our results point to an essential role of folate-cycle in the normal course of interneurons cortical localization and the transition of GABAergic potential nature to fully inhibitory.

Inhibitory interneurons (INs) play a critical role in shaping the activity of excitatory neurons in the mature brain. Although recent studies have begun to shed light onto the origin of different IN subclasses and how they functionally integrate into circuits, less is known about how INs modulate excitatory neurons in the developing brain. This is a critical question because INs have been implicated in the pathophysiology of various neurodevelopmental disorders (NDDs). A reduced density and/or activity of parvalbumin (PV) INs has been reported in the adult brain of various mouse models of autism and intellectual disability, including Fragile X Syndrome (FXS), which is the leading inherited cause of autism and intellectual disability. Here, we sought to identify when IN hypofunction is first apparent in the developing neocortex of Fmr1 knockout (*Fmr1*$^{-/-}$) mice, the best studied animal model of FXS. We find that PV-INs in *Fmr1*$^{-/-}$ mice are already hypoactive in the primary somatosensory cortex (S1) in the first postnatal week and are decoupled from neighboring excitatory neurons. This results in excessive IN apoptosis during a critical early postnatal cell death period which explains the reduced density of PV-INs in *Fmr1*$^{-/-}$ mice, and in humans with FXS. Importantly, boosting the activity of PV-INs after this critical period ameliorates both circuit and behavioral sensory phenotypes of *Fmr1*$^{-/-}$ mice. These findings suggest that circuit changes and sensory symptoms in FXS and other NDDs could be ameliorated with interventions that target PV-INs.

Neurodevelopmental disorders (NDDs) affect over 3% of children worldwide. Recent evidence associates chromatin-related gene mutations in NDDs with neuronal primary cilia dysfunction. These include MBD5, the causal locus for 2q23.1 microdeletion syndrome and MECP2, responsible for Rett Syndrome. Despite evidence linking these mutations to primary cilia, little is known on the mechanisms that lead to NDDs. Our goal is to generate 3D brain organoids, derived non-invasively from patients' dental stem cells, to explore the impact of gene mutations such as MBD5 on ciliary function during neurodevelopment. We established the first biobank of dental stem cells in Portugal, and our dental stem cell-derived brain organoids were characterized at specific timepoints for synaptic and neuronal network activity, using electrophysiology and calcium imaging. We are assessing primary cilia distribution and colocalization with specialized neurons and glia and using CRISPR/Cas9 to correct patient mutations to effectively pinpoint the contribution of those mutations in NDDs. Transcriptional consequences of MBD5 disruption in mouse brain and CRISPR-derived neurons.
MBD5, encoding the methyl-CpG-binding domain 5 protein, has been proposed as a necessary and sufficient driver of the 2q23.1 microdeletion syndrome. De novo missense and protein-truncating variants from exome sequencing studies have directly implicated MBD5 in the etiology of autism spectrum disorder (ASD) and related neurodevelopmental disorders (NDDs). However, little is known concerning the specific function(s) of MBD5.

A novel microduplication of ARID1B: Clinical, genetic, and proteomic findings.
Genetic alterations of ARID1B have been recently recognized as one of the most common mendelian causes of intellectual disability and are associated with both syndromic and non-syndromic phenotypes. The ARID1B protein, a subunit of the chromatin remodeling complex SWI/SNF-A, is involved in the regulation of transcription and multiple downstream cellular

processes. We report here the clinical, genetic, and proteomic phenotypes of an individual with a unique apparent de novo mutation of ARID1B due to an intragenic duplication. His neurodevelopmental phenotype includes a severe speech/language disorder with full scale IQ scores 78-98 and scattered academic skill levels, expanding the phenotypic spectrum of ARID1B mutations. Haploinsufficiency of ARID1B was determined both by RNA sequencing and quantitative RT-PCR. Fluorescence in situ hybridization analysis supported an intragenic localization of the ARID1B copy number gain. Principal component analysis revealed marked differentiation of the subject's lymphoblast proteome from that of controls. Of 3426 proteins quantified, 1014 were significantly up- or down-regulated compared to controls ($q < 0.01$). Pathway analysis revealed highly significant enrichment for canonical pathways of EIF2 and EIF4 signaling, protein ubiquitination, tRNA charging and chromosomal replication, among others. Network analyses revealed down-regulation of: (1) intracellular components involved in organization of membranes, organelles, and vesicles; (2) aspects of cell cycle control, signal transduction, and nuclear protein export; (3) ubiquitination and proteosomal function; and (4) aspects of mRNA synthesis/splicing. Further studies are needed to determine the detailed molecular and cellular mechanisms by which constitutional haploinsufficiency of ARID1B causes syndromic and non-syndromic developmental disabilities.

SMCHD1 mutations associated with a rare muscular dystrophy can also cause isolated arhinia and Bosma arhinia microphthalmia syndrome.
Arhinia, or absence of the nose, is a rare malformation of unknown etiology that is often accompanied by ocular and reproductive defects. Sequencing of 40 people with arhinia revealed that 84% of probands harbor a missense mutation localized to a constrained region of SMCHD1 encompassing the ATPase domain. SMCHD1 mutations cause facioscapulohumeral muscular dystrophy type 2 (FSHD2) via a trans-acting loss-of-function epigenetic mechanism. We discovered shared mutations and comparable DNA hypomethylation patterning between these distinct disorders. CRISPR/Cas9-mediated alteration of smchd1 in zebrafish yielded arhinia-relevant phenotypes. Transcriptome and protein analyses in arhinia probands and controls showed no differences in SMCHD1 mRNA or protein abundance but revealed regulatory changes in genes and pathways associated with craniofacial patterning. Mutations in SMCHD1 thus contribute to distinct phenotypic spectra, from craniofacial malformation and reproductive disorders to muscular dystrophy, which we speculate to be consistent with oligogenic mechanisms resulting in pleiotropic outcomes.

The genomic landscape of balanced cytogenetic abnormalities associated with human congenital anomalies.
Despite the clinical significance of balanced chromosomal abnormalities (BCAs), their characterization has largely been restricted to cytogenetic resolution. We explored the landscape of BCAs at nucleotide resolution in 273 subjects with a spectrum of congenital anomalies. Whole-genome sequencing revised 93% of karyotypes and demonstrated complexity that was cryptic to karyotyping in 21% of BCAs, highlighting the limitations of conventional cytogenetic approaches. At least 33.9% of BCAs resulted in gene disruption that likely contributed to the developmental phenotype, 5.2% were associated with pathogenic genomic imbalances, and 7.3% disrupted topologically associated domains (TADs) encompassing known syndromic loci. Remarkably, BCA breakpoints in eight subjects altered a single TAD encompassing MEF2C, a known driver of 5q14.3 microdeletion syndrome, resulting in decreased MEF2C expression. We propose that sequence-level resolution dramatically improves prediction of clinical outcomes for balanced rearrangements and provides insight into new pathogenic mechanisms, such as altered regulation due to changes in chromosome topology.

Engineering microdeletions and microduplications by targeting segmental duplications with CRISPR.
Recurrent, reciprocal genomic disorders resulting from non-allelic homologous recombination (NAHR) between near-identical segmental duplications (SDs) are a major cause of human disease, often producing phenotypically distinct syndromes. The genomic architecture of flanking SDs presents a challenge for modeling these syndromes; however, the capability to efficiently generate reciprocal copy number variants (CNVs) that mimic NAHR would represent a valuable modeling tool. We describe here a CRISPR/Cas9 genome engineering method, single-guide CRISPR/Cas targeting of repetitive elements (SCORE), to model reciprocal genomic disorders and demonstrate its capabilities by generating reciprocal CNVs of 16p11.2 and 15q13.3, including alteration of one copy-equivalent of the SDs that mediate NAHR in vivo. The method is reproducible, and RNA sequencing reliably clusters transcriptional signatures from human subjects with in vivo CNVs and their corresponding in vitro models. This new approach will provide broad applicability for the study of genomic disorders and, with further development, may also permit efficient correction of these defects.

The mutational spectrum of WT1 in male infertility.
We evaluated the impact of WT1 mutations in isolated severe spermatogenic impairment in a population of European ancestry. WT1 was first identified as the gene responsible for Wilms tumor. It was later associated with a plethora of clinical phenotypes often accompanied by urogenital defects and male infertility. The recent finding of WT1 missense mutations in Chinese azoospermic males without major gonadal malformations broadened the phenotypic spectrum of WT1 defects and motivated this study.

A novel Alu-mediated microdeletion at 11p13 removes WT1 in a patient with cryptorchidism and azoospermia.
This article describes a patient with cryptorchidism and nonobstructive azoospermia presenting a novel microdeletion of approximately 1 Mb at 11p13. It was confirmed by multiplex ligation-dependent probe amplification that this heterozygous deletion spanned nine genes (WT1, EIF3M, CCDC73, PRRG4, QSER1, DEPDC7, TCP11L1, CSTF3 and HIPK3) and positioned the breakpoints within highly homologous repetitive elements. As far as is known, this is the smallest deletion as-yet described encompassing the WT1 gene and was detected only once in a total of 32 Portuguese patients with isolated uni- or bilateral cryptorchidism. These findings suggest that molecular analysis in patients with genitourinary features suggestive of WT1 impairment, namely cryptorchidism and renal abnormalities, may reveal cryptic genetic defects.

LEDA-1/PIANP INFLUENCES CEREBELLAR HISTOARCHITECTURE AND CELLULAR COMPOSITION

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Moritz Küchler[1], Manuel Winkler[2], Cyrill Géraud[2], Oliver Von Bohlen Und Halbach[1]
[1]University of Greifswald, Institute Of Anatomy And Cell Biology, Greifswald, Germany, [2]University Medical Center and Medical Faculty Mannheim, Heidelberg University, and Center of Excellence in Dermatology, Mannheim, Germany, Department Of Dermatology, Venereology, And Allergology, Mannheim, Germany

PIANP is a primarily neuronally localised protein which binds to the N-terminal domain of GABA-B receptors as well as the inhibitory immunoglobuline-like type 2 receptor PILRa [1]. In humans, a homozygous loss-of-function mutation of PIANP is associated with features of intellectual disability and global development delay whilst PIANP knockout mice display autism spectrum disorder (ASD)-like behaviour as well as heightened anxiety [2]. As we previously reported, PIANP knockout mice present with a different composition of telencephalic cell layers and markedly altered hippocampal neurogenesis [2, 3]. To shed further light on the specific cellular processes behind the PIANP-associated ASD-like phenotype, we analysed male homozygous knockout mice (PIANPcre) and compared them to both mutant mice floxed at the PIANP locus (PIANPflp) and wildtype C57Bl6/N mice. PIANP knockouts showed altered gross cerebellar morphology compared to wildtype mice, which seems to be influenced by both structural and cellular alterations. Interestingly enough, we observed changes in all layers of the cerebellum with specific alterations for each individual layer present. These results unveil additional factors which seem to be involved in the observed ASD-like phenotype of PIANP knockout mice. Further research is necessary to map the precise influences of these individual changes and their interplay in effecting the above-mentioned behaviour observed in both humans and mice. Pianp deficiency links GABA receptor signaling and hippocampal and cerebellar neuronal cell composition to autism-like behavior.
Pianp (also known as Leda-1) is a type I transmembrane protein with preferential expression in the mammalian CNS. Its processing is characterized by proteolytic cleavage by a range of proteases including Adam10, Adam17, MMPs, and the γ-secretase complex. Pianp can interact with Pilrα and the GB1a subunit of the GABA receptor (GBR) complex. A recent case description of a boy with global developmental delay and homozygous nonsense variant in PIANP supports the hypothesis that PIANP is involved in the control of behavioral traits in mammals. To investigate the physiological functions of Pianp, constitutive, global knockout mice were generated and comprehensively analyzed. Broad assessment did not indicate malformation or malfunction of internal organs. In the brain, however, decreased sizes and altered cellular compositions of the dentate gyrus as well as the cerebellum, including a lower number of cerebellar Purkinje cells, were identified. Functionally, loss of Pianp led to impaired presynaptic GBR-mediated inhibition of glutamate release and altered gene expression in the cortex, hippocampus, amygdala, and hypothalamus including downregulation of Erdr1, a gene linked to autism-like behavior. Behavioral phenotyping revealed that Pianp deficiency leads to context-dependent enhanced anxiety and spatial learning deficits, an altered stress response, severely impaired social interaction, and enhanced repetitive behavior, which all represent characteristic features of an autism spectrum disorder-like phenotype. Altogether, Pianp represents a novel candidate gene involved in autism-like behavior, cerebellar and hippocampal pathology, and GBR signaling.

ALTERED ULTRASTRUCTURE OF SYNAPTIC MITOCHONDRIA IN A NOVEL MOUSE MODEL OF AUTISM-ASSOCIATED NEURODEVELOPMENTAL DISORDER, TRAP-1 MUTANT MICE

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Marta Magnowska[1], Bozena Kuzniewska[1], Ewelina Knapska[2], Andrzej Dziembowski[3], Magdalena Dziembowska[1]
[1]University of Warsaw, Centre Of New Technologies, Warsaw, Poland, [2]Nencki Institute of Experimental Biology, Centre Of Excellence For Neural Plasticity And Brain Disorders (braincity), Warsaw, Poland, [3]International Institute of Molecular and Cell Biology, Laboratory Of Rna Biology, Warsaw, Poland

Neurons critically depend on mitochondrial function to establish membrane excitability and to execute the complex processes of neurotransmission and plasticity. Recently it was shown, that synapses are the regions of the neuron with the highest energy consumption, thus they have the highest demand for mitochondrial ATP production. Additionally, dysregulated synthesis of mitochondrial proteins may contribute to the pathomechanism of neurodevelopmental disorders. We created a new mouse model of autism-associated neurodevelopmental disorder, based on the human mutation in TRAP-1 gene. TRAP-1 mutant mice display behaviors characteristic for ASD such as social behavior deficits. TRAP1 is a mitochondrial chaperone from HSP-90 family engaged in the regulation of mitochondrial stress response. Mitochondrial functions are intrinsically linked to their morphology and membrane ultrastructure. For a detailed analysis of mitochondria morphology and organization in the hippocampi of TRAP1 mutant mice, heterozygous and wild-types, we used Serial Block Face-Scanning Electron Microscopy (SBF-SEM). Mitochondria shape and volume reconstruction was performed in RECONSTRUCT software. We compared the morphology and number of synaptic mitochondria in TRAP-1 mutant, heterozygous and wt mice and found significant changes between the analyzed genotypes.

The cell adhesion protein dystroglycan affects the structural remodeling of dendritic spines.
Dystroglycan (DG) is a cell membrane protein that binds to the extracellular matrix in various mammalian tissues. The function of DG has been well defined in embryonic development as well as in the proper migration of differentiated neuroblasts in the central nervous system (CNS). Although DG is known to be a target for matrix metalloproteinase-9 (MMP-9), cleaved in response to enhanced synaptic activity, the role of DG in the structural remodeling of dendritic spines is still unknown. Here, we report for the first time that the deletion of DG in rat hippocampal cell cultures causes pronounced changes in the density and morphology of dendritic spines. Furthermore, we noted a decrease in laminin, one of the major extracellular partners of DG. We have also observed that the lack of DG evokes alterations in the morphological complexity of astrocytes accompanied by a decrease in the level of aquaporin 4 (AQP4), a protein located within astrocyte endfeet surrounding neuronal dendrites and synapses. Regardless of all of these changes, we did not observe any effect of DG silencing on either excitatory or inhibitory synaptic transmission. Likewise, the knockdown of DG had no effect on Psd-95 protein expression. Our results indicate that DG is involved in dendritic spine remodeling that is not functionally reflected. This may suggest the existence of unknown mechanisms that maintain proper synaptic signaling despite impaired structure of dendritic spines. Presumably, astrocytes are involved in these processes.

Three-Dimensional Segmentation and Reconstruction of Neuronal Nuclei in Confocal Microscopic Images.
The detailed architectural examination of the neuronal nuclei in any brain region, using confocal microscopy, requires quantification of fluorescent signals in three-dimensional stacks of confocal images. An essential prerequisite to any quantification is the segmentation of the nuclei which are typically tightly packed in the tissue, the extreme being the hippocampal dentate gyrus (DG), in which nuclei frequently appear to overlap due to limitations in microscope resolution. Segmentation in DG is a challenging task due to the presence of a significant amount of image artifacts and densely packed nuclei. Accordingly, we established an algorithm based on continuous boundary tracing criterion aiming to reconstruct the nucleus surface and to separate the adjacent nuclei. The presented algorithm neither uses a pre-built nucleus model, nor

performs image thresholding, which makes it robust against variations in image intensity and poor contrast. Further, the reconstructed surface is used to study morphology and spatial arrangement of the nuclear interior. The presented method is generally dedicated to segmentation of crowded, overlapping objects in 3D space. In particular, it allows us to study quantitatively the architecture of the neuronal nucleus using confocal-microscopic approach.

Prophylactic Ketamine Treatment Promotes Resilience to Chronic Stress and Accelerates Recovery: Correlation with Changes in Synaptic Plasticity in the CA3 Subregion of the Hippocampus.
Ketamine is an -methyl-d-aspartate receptor antagonist that has gained wide attention as a potent antidepressant. It has also been recently reported to have prophylactic effects in animal models of depression and anxiety. Alterations of neuroplasticity in different brain regions; such as the hippocampus; prefrontal cortex; and amygdala; are a hallmark of stress-related disorders; and such changes may endure beyond the treatment of symptoms. The present study investigated whether a prophylactic injection of ketamine has effects on structural plasticity in the brain in mice that are subjected to chronic unpredictable stress followed by an 8-day recovery period. Ketamine administration (3 mg/kg body weight) 1 h before stress exposure increased the number of resilient animals immediately after the cessation of stress exposure and positively influenced the recovery of susceptible animals to hedonic deficits. At the end of the recovery period; ketamine-treated animals exhibited significant differences in dendritic spine density and dendritic spine morphology in brain regions associated with depression compared with saline-treated animals. These results confirm previous findings of the prophylactic effects of ketamine and provide further evidence of an association between the antidepressant-like effect of ketamine and alterations of structural plasticity in the brain.

Quantitative 3-D morphometric analysis of individual dendritic spines.
The observation and analysis of dendritic spines morphological changes poses a major challenge in neuroscience studies. The alterations of their density and/or morphology are indicators of the cellular processes involved in neural plasticity underlying learning and memory, and are symptomatic in neuropsychiatric disorders. Despite ongoing intense investigations in imaging approaches, the relationship between changes in spine morphology and synaptic function is still unknown. The existing quantitative analyses are difficult to perform and require extensive user intervention. Here, we propose a new method for (1) the three-dimensional (3-D) segmentation of dendritic spines using a multi-scale opening approach and (2) define 3-D morphological attributes of individual spines for the effective assessment of their structural plasticity. The method was validated using confocal light microscopy images of dendritic spines from dissociated hippocampal cultures and brain slices (1) to evaluate accuracy relative to manually labeled ground-truth annotations and relative to the state-of-the-art Imaris tool, (2) to analyze reproducibility of user-independence of the segmentation method, and (3) to quantitatively analyze morphological changes in individual spines before and after chemically induced long-term potentiation. The method was monitored and used to precisely describe the morphology of individual spines in real-time using consecutive images of the same dendritic fragment.

Computational Approach to Dendritic Spine Taxonomy and Shape Transition Analysis.
The common approach in morphological analysis of dendritic spines of mammalian neuronal cells is to categorize spines into subpopulations based on whether they are stubby, mushroom, thin, or filopodia shaped. The corresponding cellular models of synaptic plasticity, long-term potentiation, and long-term depression associate the synaptic strength with either spine enlargement or spine shrinkage. Although a variety of automatic spine segmentation and feature extraction methods were developed recently, no approaches allowing for an automatic and unbiased distinction between dendritic spine subpopulations and detailed computational models of spine behavior exist. We propose an automatic and statistically based method for the unsupervised construction of spine shape taxonomy based on arbitrary features. The taxonomy is then utilized in the newly introduced computational model of behavior, which relies on transitions between shapes. Models of different populations are compared using supplied bootstrap-based statistical tests. We compared two populations of spines at two time points. The first population was stimulated with long-term potentiation, and the other in the resting state was used as a

control. The comparison of shape transition characteristics allowed us to identify the differences between population behaviors. Although some extreme changes were observed in the stimulated population, statistically significant differences were found only when whole models were compared. The source code of our software is freely available for non-commercial use.

Transient ECM protease activity promotes synaptic plasticity.
Activity-dependent proteolysis at a synapse has been recognized as a pivotal factor in controlling dynamic changes in dendritic spine shape and function; however, excessive proteolytic activity is detrimental to the cells. The exact mechanism of control of these seemingly contradictory outcomes of protease activity remains unknown. Here, we reveal that dendritic spine maturation is strictly controlled by the proteolytic activity, and its inhibition by the endogenous inhibitor (Tissue inhibitor of matrix metalloproteinases-1 - TIMP-1). Excessive proteolytic activity impairs long-term potentiation of the synaptic efficacy (LTP), and this impairment could be rescued by inhibition of protease activity. Moreover LTP is altered persistently when the ability of TIMP-1 to inhibit protease activity is abrogated, further demonstrating the role of such inhibition in the promotion of synaptic plasticity under well-defined conditions. We also show that dendritic spine maturation involves an intermediate formation of elongated spines, followed by their conversion into mushroom shape. The formation of mushroom-shaped spines is accompanied by increase in AMPA/NMDA ratio of glutamate receptors. Altogether, our results identify inhibition of protease activity as a critical regulatory mechanism for dendritic spines maturation.

2dSpAn: semiautomated 2-d segmentation, classification and analysis of hippocampal dendritic spine plasticity.
Accurate and effective dendritic spine segmentation from the dendrites remains as a challenge for current neuroimaging research community. In this article, we present a new method (2dSpAn) for 2-d segmentation, classification and analysis of structural/plastic changes of hippocampal dendritic spines. A user interactive segmentation method with convolution kernels is designed to segment the spines from the dendrites. Formal morphological definitions are presented to describe key attributes related to the shape of segmented spines. Spines are automatically classified into one of four classes: Stubby, Filopodia, Mushroom and Spine-head Protrusions.

Synaptically released matrix metalloproteinase activity in control of structural plasticity and the cell surface distribution of GluA1-AMPA receptors.
Synapses are particularly prone to dynamic alterations and thus play a major role in neuronal plasticity. Dynamic excitatory synapses are located at the membranous neuronal protrusions called dendritic spines. The ability to change synaptic connections involves both alterations at the morphological level and changes in postsynaptic receptor composition. We report that endogenous matrix metalloproteinase (MMP) activity promotes the structural and functional plasticity of local synapses by its effect on glutamate receptor mobility and content. We used live imaging of cultured hippocampal neurons and quantitative morphological analysis to show that chemical long-term potentiation (cLTP) induces the permanent enlargement of a subset of small dendritic spines in an MMP-dependent manner. We also used a superresolution microscopy approach and found that spine expansion induced by cLTP was accompanied by MMP-dependent immobilization and synaptic accumulation as well as the clustering of GluA1-containing AMPA receptors. Altogether, our results reveal novel molecular and cellular mechanisms of synaptic plasticity.

Novel higher-order epigenetic regulation of the Bdnf gene upon seizures.
Studies in cultured cells have demonstrated the existence of higher-order epigenetic mechanisms, determining the relationship between expression of the gene and its position within the cell nucleus. It is unknown, whether such mechanisms operate in postmitotic, highly differentiated cell types, such as neurons in vivo. Accordingly, we examined whether the intranuclear positions of Bdnf and Trkb genes, encoding the major neurotrophin and its receptor respectively, change as a result of neuronal activity, and what functional consequences such movements may have. In a rat model of massive neuronal activation upon kainate-induced seizures we found that elevated neuronal expression of Bdnf is associated with its detachment from the nuclear lamina, and translocation toward the nucleus center. In contrast, the position of stably expressed Trkb remains unchanged after seizures. Our study demonstrates that activation-dependent architectural

remodeling of the neuronal cell nucleus in vivo contributes to activity-dependent changes in gene expression in the brain. J Neurosci, 2013; 33

DEXAMETHASONE IMPROVES CELL SURFACE TRAFFICKING OF R451C NEUROLIGIN3, AN AUTISM GENE RISK

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Tamara Diamanti[1], Federica Serafini[1], Camilla Perfetto[1], Lorenza Mautone[2], Clotilde Lauro[2], Tommaso Seri[1], Andrea Setini[1], Laura Trobiani[3], Davide Comoletti[3], Arianna Rinaldi[1], Silvia Di Angelantonio[2], Emanuele Cacci[1], Antonella De Jaco[1]
[1]La Sapienza University of Rome, Biology And Biotechnologies C. Darwin, Rome, Italy, [2]La sapienza University of Rome, Department Of Physiology And Pharmacology "v. Erspamer", Rome, Italy, [3]Victoria University of Wellington, School Of Biological Sciences, Wellington, New Zealand

Aims Autism spectrum disorders (ASDs) are neurodevelopmental syndromes also characterized by alterations in neurotransmission. Among the risk genes are synaptic molecules such as the Neuroligins (NLGNs). The autism-linked substitution, R451C in NLGN3, induces a local misfolding of the extracellular domain, causing defective trafficking and partial retention of the mutant protein in the Endoplasmic Reticulum (ER) and the activation of the Unfolded Protein Response. The knock-in (KI) R451C mouse model presents reduced NLGN3 levels in the brain and autistic-like behaviors. Compounds belonging to the family of glucocorticoids, such as dexamethasone (DEX), were selected for increasing the secretion of a soluble form of R451C NLGN3, expressed in HEK293 cells. **Methods** The effect of DEX was studied in HEK-293 cells stably expressing full-length NLGN3, either WT or R451C, and in adult neural progenitor cells from the hippocampus of either WT or R451C NLGN3 KI mice, endogenously expressing mutant NLGN3. **Results** DEX treatment rescues R451C NLGN3 mutant protein levels, promotes its trafficking to the cell surface from the ER and mitigates ER stress, both in over-expression and in physiological conditions. The formation of artificial synapses from co-cultured hippocampal neurons and HEK-293 cells expressing R451C NLGN3 will be evaluated in the presence or absence of DEX. **Conclusions** Our data show a strategy to rescue, *in vitro,* NLGN3 R451C trafficking. The effect of the DEX in R451C NLGN3 mouse model will be tested to ascertain whether improving trafficking of mutant NLGN3 R451C, *in vivo*, could rescue behavioral and functional defects of the R451C NLGN3 KI model.

The neuroligins and the synaptic pathway in Autism Spectrum Disorder.
The genetics underlying autism spectrum disorder (ASD) is complex and heterogeneous, and de novo variants are found in genes converging in functional biological processes. Neuronal communication, including trans-synaptic signaling involving two families of cell-adhesion proteins, the presynaptic neurexins and the postsynaptic neuroligins, is one of the most recurrently affected pathways in ASD. Given the role of these proteins in determining synaptic function, abnormal synaptic plasticity and failure to establish proper synaptic contacts might represent mechanisms underlying risk of ASD. More than 30 mutations have been found in the neuroligin genes. Most of the resulting residue substitutions map in the extracellular, cholinesterase-like domain of the protein, and impair protein folding and trafficking. Conversely, the stalk and intracellular domains are less affected. Accordingly, several genetic animal models of ASD have been generated, showing behavioral and synaptic alterations. The aim of this review is to discuss the current knowledge on ASD-linked mutations in the neuroligin proteins and their effect on synaptic function, in various brain areas and circuits.

Aims: Copy-number variants of the CYFIP1 gene in humans have been associated to Autism and Schizophrenia, two neuropsychiatric disorders characterized by defects in brain connectivity. CYFIP1 has a dual role regulating protein synthesis and actin remodeling, both molecular events being crucial for correct post-synaptic functions. Consistent with this, *Cyfip1* deficient mice present an immature spine morphology and synaptic plasticity defects. However, a possible role of CYFIP1 in brain connectivity and presynaptic function was largely unknown. *Methods:* Here we use state of the art imaging, cellular and molecular biology techniques to investigate the role of CYFIP1 in axonal development. *Results:* Here, we show that CYFIP1 plays an important role in brain functional connectivity, callosal axonal development and function. We find that adult *Cyfip1* heterozygous (*Cyfip1*$^{+/-}$) mice have reduced bilateral functional connectivity and defects in white matter architecture, deficits in the callosal axons, namely reduced myelination. Reduced CYFIP1 levels during development result in a delayed growth and arborization of callosal axons. We have identified a series of molecular targets of CYFIP1 that might explain the axonal phenotype observed in the adult and provide a therapeutical approach to ameliorate those observed deficits. *Conclusions:* Altogether, our results show that *Cyfip1* haploinsufficiency compromises callosal axons and connectivity in various ways, which not only might explain the genetic association of this gene to neuropsychiatric disorders but also provide further insights into its function as key molecular player in the development of callosal projections.

Aims. Rett Syndrome (RTT) is a neurodevelopment disorder mainly caused by Methyl CpG binding protein 2 (*MeCP2*) gene mutations causing neuronal atrophy which is substantially rescued in adult MeCP2-null mice by chronic treatment with the antidepressant mirtazapine (MTZ). However, the mechanisms of action of mirtazapine in RTT remain unclear. **Methods**. MeCP2-null mice were daily-treated with 50 mg/kg MTZ treatment from postnatal-day 28 for 15 days and soma and dendritic size of hippocampal neurons were measured. Cultured hippocampal neurons were treated with 10 µM MTZ for 9 or 3 days. Time course of BDNF mRNA and protein expression and of TrkB phosphorylation were investigated MTZ treatment. Molecular docking of mirtazapine was performed on crystal structure of LPAR1 and homology models of LPAR2 and LPAR3 with AutoDock Vina. **Results**. MTZ treatment in vivo and in vitro completely restored dendritic arborization and soma size of hippocampal neurons. Although BDNF levels in vivo and in vitro were unaffected by MTZ treatment, the TrkB signaling was activated by MTZ by transactivation through the lysophosphaditic acid receptor and src-fyn kinases. Molecular docking revealed that MTZ may bind to LPAR1/3 and weakly to LPAR2. **Conclusions.** Mirtazapine is able to elicit trophic effects through TrkB receptor transactivation leading to the complete rescue of dendritic atrophy in RTT. These results reveal a novel mechanism of action of MTZ and support its use as a novel treatment for Rett syndrome.

In vitro modeling of dendritic atrophy in Rett syndrome: determinants for phenotypic drug screening in neurodevelopmental disorders.
Dendritic atrophy, defined as the reduction in complexity of the neuronal arborization, is a hallmark of several neurodevelopmental disorders, including Rett Syndrome (RTT). RTT, affecting 1:10,000 girls worldwide, is mainly caused by mutations in the MECP2 gene and has no cure. We describe here an in vitro model of dendritic atrophy in Mecp2 mouse hippocampal primary cultures, suitable for phenotypic drug-screening. Using High-Content Imaging techniques, we systematically investigated the impact of culturing determinants on several parameters such as neuronal survival, total dendritic length, dendritic endpoints, soma size, cell clusterization, spontaneous activity. Determinants included cell-seeding density, glass or polystyrene substrates, coating with poly-Ornithine with/without Matrigel and miniaturization from 24 to 96-half surface multiwell plates. We show that in all plate-sizes at densities below 320 cells/mm, morphological parameters remained constant while spontaneous network activity decreased according to the cell-density. Mecp2 neurons cultured at

160 cells/mm density in 96 multiwell plates, displayed significant dendritic atrophy and showed a marked increase in dendritic length following treatment with Brain-derived neurotrophic factor (BDNF) or Mirtazapine. In conclusion, we have established a phenotypic assay suitable for fast screening of hundreds of compounds, which may be extended to other neurodevelopmental diseases with dendritic atrophy.

THE AUTISM RISK GENE DDX3X IN SHAPING NEURONAL MORPHOGENESIS AND SYNAPTOGENESIS IN A SEX-SPECIFIC MANNER

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Adele Mossa[1], Yeaji Park[1], Devina Ung[1], Zeynep Akpinar[1], Alice Romagnoli[2], Daniele Di Marino[2], Silvia De Rubeis[1]
[1]Icahn School of Medicine at Mount Sinai, Psychiatry, New York, United States of America, [2]Università Politecnica delle Marche, Ny-masbic, Ancona, Italy

This project aims at unraveling the cellular and molecular functions of the autism risk gene *DDX3X* during neuronal development. *DDX3X* is X-linked but escapes X chromosome inactivation in human and mice, resulting in higher expression of DDX3X in female brains when compared with male brains. Mutations in *DDX3X* affect primarily females. DDX3X regulates mRNA translation, but the mechanisms of action in neurons, the impact of clinical mutations and the influence of sex have not been studied yet. Understanding the role of DDX3X in the regulation of local mRNA translation in female and male neurons might offer a new key to decipher ASD. We generated a mouse with loxP sites around exon 2 of *Ddx3x* (*Ddx3x*^{flox} mice). Using this model, we can generate *Ddx3x*-haploinsufficient female neurons or *Ddx3x*-null male neurons, upon transfection of male (*Ddx3x*$^{flox/y}$) and female (*Ddx3x*$^{flox/+}$) cortical neurons with a mCherry-Cre construct. We also introduced sex-specific mutations in female and male neurons, after manipulating *Ddx3x* dosage. We then examined morphogenesis, synaptogenesis, and mRNA translation. DDX3X contributes to sex differences in neuronal morphogenesis and synaptogenesis. Female-pathogenic mutations completely disrupt neuronal morphology, while male pathogenic mutations cause a milder phenotype. These findings support a sex-specific role for DDX3X in regulating neuronal development. Our data lay the bases to understand the sex biases in the prevalence and severity of DDX3X syndrome. A deeper insight on the molecular mechanisms underlying this sex difference will also shed the light for more personalized treatment for girls and boys.

Developmental impaired Akt signaling in the Shank1 and Shank3 double knock-out mice.
Human mutations and haploinsufficiency of the SHANK family genes are associated with autism spectrum disorders (ASD) and intellectual disability (ID). Complex phenotypes have been also described in all mouse models of Shank mutations and deletions, consistent with the heterogeneity of the human phenotypes. However, the specific role of Shank proteins in synapse and neuronal functions remain to be elucidated. Here, we generated a new mouse model to investigate how simultaneously deletion of Shank1 and Shank3 affects brain development and behavior in mice. Shank1-Shank3 DKO mice showed a low survival rate, a developmental strong reduction in the activation of intracellular signaling pathways involving Akt, S6, ERK1/2, and eEF2 during development and a severe behavioral impairments. Our study suggests that Shank1 and Shank3 proteins are essential to developmentally regulate the activation of Akt and correlated intracellular pathways crucial for mammalian postnatal brain development and synaptic plasticity. Therefore, Akt function might represent a new therapeutic target for enhancing cognitive abilities of syndromic ASD patients.

Molecular causes of sex-specific deficits in rodent models of neurodevelopmental disorders.
Neurodevelopmental disorders (NDDs) such as intellectual disability and autism spectrum disorder consistently show a male bias in prevalence, but it remains unclear why males and females are affected with different frequency. While many behavioral studies of transgenic NDD models have focused only on males, the requirement by the National Institutes of Health to consider sex as a biological variable has promoted the comparison of male and female performance in wild-type and mutant animals. Here, we review examples of rodent models of NDDs in which sex-specific deficits were identified in molecular, physiological, and/or behavioral responses, showing sex differences in susceptibility to disruption of genes mutated in NDDs. Haploinsufficiency in genes involved in mechanisms such as synaptic function (GABRB3 and NRXN1), chromatin remodeling (CHD8, EMHT1, and ADNP), and intracellular signaling (CC2D1A and ERK1) lead to more severe

behavioral outcomes in males. However, in the absence of behavioral deficits, females can still present with cellular and electrophysiological changes that could be due to compensatory mechanisms or differential allocation of molecular and cellular functions in the two sexes. By contrasting these findings with mouse models where females are more severely affected (MTHFR and AMBRA1), we propose a framework to approach the study of sex-specific deficits possibly leading to sex bias in NDDs.

Male-Specific cAMP Signaling in the Hippocampus Controls Spatial Memory Deficits in a Mouse Model of Autism and Intellectual Disability.
The prevalence of neurodevelopmental disorders is biased toward male individuals, with male-to-female ratios of 2:1 in intellectual disability and 4:1 in autism spectrum disorder. However, the molecular mechanisms of such bias remain unknown. While characterizing a mouse model for loss of the signaling scaffold coiled-coil and C2 domain-containing protein 1A (CC2D1A), which is mutated in intellectual disability and autism spectrum disorder, we identified biochemical and behavioral differences between male and female mice, and explored whether CC2D1A controls male-specific intracellular signaling.

eEF2K/eEF2 Pathway Controls the Excitation/Inhibition Balance and Susceptibility to Epileptic Seizures.
Alterations in the balance of inhibitory and excitatory synaptic transmission have been implicated in the pathogenesis of neurological disorders such as epilepsy. Eukaryotic elongation factor 2 kinase (eEF2K) is a highly regulated, ubiquitous kinase involved in the control of protein translation. Here, we show that eEF2K activity negatively regulates GABAergic synaptic transmission. Indeed, loss of eEF2K increases GABAergic synaptic transmission by upregulating the presynaptic protein Synapsin 2b and α5-containing GABAA receptors and thus interferes with the excitation/inhibition balance. This cellular phenotype is accompanied by an increased resistance to epilepsy and an impairment of only a specific hippocampal-dependent fear conditioning. From a clinical perspective, our results identify eEF2K as a potential novel target for antiepileptic drugs, since pharmacological and genetic inhibition of eEF2K can revert the epileptic phenotype in a mouse model of human epilepsy.

Shank synaptic scaffold proteins: keys to understanding the pathogenesis of autism and other synaptic disorders.
Shank/ProSAP proteins are essential to synaptic formation, development, and function. Mutations in the family of SHANK genes are strongly associated with autism spectrum disorders (ASD) and other neurodevelopmental and neuropsychiatric disorders, such as intellectual disability (ID), and schizophrenia. Thus, the term 'Shankopathies' identifies a number of neuronal diseases caused by alteration of Shank protein expression leading to abnormal synaptic development. With this review we want to summarize the major genetic, molecular, behavior and electrophysiological studies that provide new clues into the function of Shanks and pave the way for the discovery of new therapeutic drugs targeted to treat patients with SHANK mutations and also patients affected by other neurodevelopmental and neuropsychiatric disorders. Circulating T regulatory cells migration and phenotype in glioblastoma patients: an in vitro study.
Glioblastoma multiforme (GBM) is the most aggressive primary human brain tumor. The relatively high amount of T regulatory lymphocytes present in the tumor, contributes to the establishment of an immunosuppressive microenvironment. Samples of peripheral blood were collected from GBM patients and healthy controls and a purified population of Treg (CD4(+)/CD25(bright)) was isolated using flow cytometric cell sorting. Treg migrating capacities toward human glioma cell line conditioned medium were evaluated through an in vitro migration test. Our data show that supernatants collected from GBM cell lines were more attractant to Treg when compared to complete standard medium. The addition of an anti-CCL2 antibody

to conditioned medium decreased conditioned medium-depending Treg migration, suggesting that CCL2 (also known as Monocyte Chemoattractant Protein, MCP-1) is implicated in the process. The number of circulating CD4(+)/µL or Treg/µL was similar in GBM patients and controls. Specific Treg markers (FOXP3; CD127; Helios; GITR; CTLA4; CD95; CCR2, CCR4; CCR7) were screened in peripheral blood and no differences could be detected between the two populations. These data confirm that the tumor microenvironment is attractive to Treg, which tend to migrate toward the tumor region changing the immunological response. Though we provide evidence that CCL2 is implicated in Treg migration, other factors are needed as well to provide such effect.

Autism spectrum disorder (ASD) is characterised by impaired social interaction, language delay and repetitive or restrictive behaviours. Despite increasing in prevalence, its aetiology remains elusive. *JAKMIP1* was identified as an ASD candidate gene due to its dysregulation in both syndromic and idiopathic ASD. *JAKMIP1* is highly expressed in developing neurons and interacts with a wide array of binding partners. The N-terminus stabilises microtubules, promoting neuronal migration and neurite extension. Conversely, the C-terminus interacts with JAK1, a receptor-associated tyrosine kinase that initiates Signal Transducer and Activator of Transcription (STAT) signalling downstream of cytokine receptors. We demonstrate that JAKMIP1 forms a component of the Interleukin-6 Receptor (IL-6R) complex in neurons, co-localising with IL-6R subunits and associated JAK1 in neuronal cells. This suggests that JAKMIP1 may regulate JAK1/STAT3 signalling downstream of the IL-6R. To investigate this potential role in cytokine signalling, we generated a *JAKMIP1*-knockout human neuroblastoma SH-SY5Y cell line using CRISPR-Cas9 genome-editing. JAKMIP1-deficiency was observed to reduce *STAT3* expression and impair IL-6-induced STAT3 activity, which was validated through measuring the expression of STAT3-target genes. Importantly, IL-6 is reported to promote neuronal differentiation and neuritogenesis. To determine whether JAKMIP1-modulated STAT3 activity may play a role in IL-6-induced neuritogenesis, we assessed the morphology of differentiated SH-SY5Y cells through immunofluorescent staining. Agreeing with previous studies, JAKMIP1-deficiency results in reduced neurite extension and neuritogenesis. Interestingly though, JAKMIP1 deficiency also impairs IL-6-induced neuritogenesis in SH-SY5Y cells. Altogether, these findings suggest that JAKMIP1 may regulate neuronal responses to IL-6 during nervous system development via modulating STAT3 activity.

NEUROANATOMICAL MAPPING OF THE LIGAND BINDING PROFILE IN VARIOUS AUTISM SPECTRUM DISORDER (ASD) MODELS AT ADULTHOOD

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Aims. ASD comprises multifactorial neurodevelopmental disorders characterized by impaired social interaction and communication and repetitive behavior, whose molecular underpinnings are not fully understood. Several lines of evidence highlighted the crucial balance between excitatory and inhibitory transmission in ASD pathogenesis. Aim of the study was to determine the binding densities of NMDA, AMPA and GABA-A receptors in main regions implicated in ASD such as dorsal hippocampus (DH) and prefrontal cortex (PFC) of adult BTBR (idiopathic ASD model) and FMR1 knockout (genetic ASD model) animals. We hypothesize that brain region-specific imbalances between excitatory and inhibitory inputs might account for at least some of the alterations typical of ASD. **Methods.** *In vitro* receptor autoradiography was performed by incubating brain slices containing the regions of interest with tritium-labeled ligands specific for AMPA, NMDA and GABA-A receptors. Hematoxylin-eosin staining supported us in localizing and analyzing the regions of interest on the autoradiograms. The ratio between ligand binding to excitatory and inhibitory receptors (ligand binding E/I ratio) was also calculated. **Results.** Both in BTBR and FMR1 mice, GABA binding density was higher in the DH, also leading to a reduced ligand binding E/I ratio. Interestingly, the ligand binding E/I ratio in the PFC of the FMR1 mice was higher than in controls, while in the BTBR it was reduced. **Conclusions.** Our preliminary results confirm a major involvement of excitatory and inhibitory ligand binding to main ionotropic membrane receptors and clearly outline brain region-specific effects. We are running quantitative western blots and electrophysiology to strengthen our findings.

Carl Toldt Centennial, Surgeon and Anatomist.
Carl Florian Toldt was an Austrian anatomist who made meaningful contributions worldwide and defined what is one of the most important surgical landmarks in abdominal surgery. Through his research studies, the embryologic dissection plane known as the "White Line of Toldt" represents an important anatomical landmark that helps to mobilize either the ascending or descending colon. His career spanned over 45 years, beginning in Verona and continuing to Prague and Vienna. He was an author of several innovative books and scientific articles regarding micro- and macroscopic anatomy. In addition, he received numerous recognitions and prizes for his work, making him an essential figure in the medical scientific community. Even a street in Vienna, Karl-Toldt-Weg, is named in his honor. The purpose of this historical article is to celebrate and honor Toldt 100 years following his death, remembering his scientific contributions to the medical and surgical fields and giving thanks for his numerous accomplishments. This article brings light to the man behind the eponym.

Criss-crossing autism spectrum disorder and adult neurogenesis.
Autism spectrum disorder (ASD) comprises a group of multifactorial neurodevelopmental disorders primarily characterized by deficits in social interaction and repetitive behavior. Although the onset is typically in early childhood, ASD poses a lifelong challenge for both patients and caretakers. Adult neurogenesis (AN) is the process by which new functional neurons are created from neural stem cells existing in the post-natal brain. The entire event is based on a sequence of cellular processes, such as proliferation, specification of cell fate, maturation, and ultimately, synaptic integration into the existing neural circuits. Hence, AN is implicated in structural and functional brain plasticity throughout life. Accumulating evidence shows that impaired AN may underlie some of the abnormal behavioral phenotypes seen in ASD. In this review, we approach the interconnections between the molecular pathways related to AN and ASD. We also discuss existing therapeutic approaches targeting such pathways both in preclinical and clinical studies. A deeper understanding of how ASD and AN reciprocally

affect one another could reveal important converging pathways leading to the emergence of psychiatric disorders.

Abnormalities of synaptic mitochondria in autism spectrum disorder and related neurodevelopmental disorders.
Autism spectrum disorder (ASD) is a neurodevelopmental condition primarily characterized by an impairment of social interaction combined with the occurrence of repetitive behaviors. ASD starts in childhood and prevails across the lifespan. The variability of its clinical presentation renders early diagnosis difficult. Mutations in synaptic genes and alterations of mitochondrial functions are considered important underlying pathogenic factors, but it is obvious that we are far from a comprehensive understanding of ASD pathophysiology. At the synapse, mitochondria perform diverse functions, which are clearly not limited to their classical role as energy providers. Here, we review the current knowledge about mitochondria at the synapse and summarize the mitochondrial disturbances found in mouse models of ASD and other ASD-related neurodevelopmental disorders, like DiGeorge syndrome, Rett syndrome, Tuberous sclerosis complex, and Down syndrome.

SPECIFIC ANATOMICAL MAPPING OF RECEPTOR DENSITY ALTERATIONS IN VARIOUS MOUSE MODELS OF AUTISM USING QUANTITATIVE IN-VITRO RECEPTOR AUTORADIOGRAPHY

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Stuti Chhabra
Universitätsmedizin der Johannes-Gutenberg Universität Mainz, Institute For Microscopic Anatomy And Neurobiology, Mainz, Germany

Aims: Tight balance between excitatory and inhibitory synaptic transmission mainly at neural circuits is crucial for normal brain development and function. Accordingly, shifts in balances, particularly glutamatergic and GABAergic synapses are undertaken as one of the key underlying mechanisms in understanding the pathophysiology of ASD. To this axis, we decided to undertake a comparative study to demonstrate the alteration of receptor densities of ionotropic glutamate (iGluRs) and GABAA receptors in two typical mouse lines, Fmr1 (genetic) and BTBR (idiopathic) characterised to study the ASD features in an age and region dependent fashion. **Methods:** *In vitro* receptor autoradiography was performed by incubating brain slices containing the regions of interest with tritium-labeled ligands specific for AMPA, NMDA and GABA-A receptors. Hematoxylin-eosin staining supported us in localizing and analyzing the regions of interest on the autoradiograms. The ratio between ligand binding to excitatory and inhibitory receptors (ligand binding E/I ratio) was also calculated. **Results:** In BTBR mice it is observed that $GABA_A$ receptor density is significantly upregulated in dorsal hippocampus and prefrontal cortex. Interestingly, changes in AMPA receptor densities are particularly seen in striatum as compared to the other regions. Furthermore, in Fmr1 KO mice changes in AMPA and NMDA receptor densities were more profound in dorsal hippocampus of as compared to GABAA receptor density. Significant changes in GABAA receptor density in cerebellum are also highlighted. **Conclusion:** The aforementioned changes thus designate the regional variations of different receptor densities at an early stage, 4week, of postnatal brain development in BTBR and Fmr1 mice.

MITOCHONDRIAL MORPHOLOGY AND DYNAMIC ABNORMALITIES IN AN IN VITRO MODEL OF RETT SYNDROME

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Michela Sgubin, Agnes Thalhammer, Enrico Tongiorgi, Gabriele Baj
University of Trieste, Life Sciences, Trieste, Italy

Rett syndrome (RTT) is a rare neurodevelopmental disorder that affects predominantly females, with a prevalence of 1 in every 10,000 female births. The disorder manifests early in life and to this date there is no cure. It has been reported that oxidative stress in mitochondria contributes to RTT pathogenesis. **Aims**: We aimed to characterize mitochondria morphologies and dynamics to identify new therapeutical targets for RTT. **Methods:** We used a well-established *in vitro* model of dendritic atrophy of Mecp2$^{-/y}$ mouse hippocampal primary neurons to evaluate mitochondria morphology, membrane potential, aging and dynamics. We used specific mitochondrial markers (Mito-Dendra2 and Mito-Timer constructs and JC-1 dye) to label the organelles and evaluate which parameters were affected in RTT using confocal and super-resolution lattice SIM microscopy. **Results:** We detected significant abnormalities in area, perimeter, circularity and maximum Feret diameter of the mitochondria localized in neuronal dendrites. We detect early aging mitochondria in RTT neurons and a significant redox unbalance thanks to JC-1 imaging analysis. Mitochondria in the apical dendrites of Mecp2$^{-/y}$ hippocampal neurons displayed a range of dynamic alterations as we recorded speed, direction, fission/fusion activities. **Conclusions:** In this study we show that mitochondria of Mecp2$^{-/y}$ mouse hippocampal primary neurons are smaller and round-shaped compared with healthy ones. Moreover, we detect an early aging and the impairment of the oxidative/activity status. In addition, we determined a set of measures of mitochondria dynamics. Taken together these analyses could be a powerful tool to investigate RTT syndrome dysfunctions and to identify new possible therapeutic targets.

CRISPR-MEDIATED ACTIVATION OF AUTISM GENE ITGB3 RESTORES CORTICAL NETWORK EXCITABILITY VIA MGLUR5 SIGNALING

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Fanny Jaudon[1,2], Agnes Thalhammer[1,3], Lorena Zentilin[4], Lorenzo Cingolani[1,2]
[1]Istituto Italiano di Tecnologia (IIT), Center For Synaptic Neuroscience And Technology (nsyn), GENOVA, Italy, [2]Università degli Studi di Trieste, Dipartimento Di Scienze Della Vita, TRIESTE, Italy, [3]IRCCS, Ospedale Policlinico San Martino, GENOVA, Italy, [4]International Centre for Genetic Engineering and Biotechnology (ICGEB), Aav Vector Unit, TRIESTE, Italy

Many mutations in autism spectrum disorder (ASD) affect a single allele, indicating a key role for gene dosage in ASD susceptibility. Recently, haplo-insufficiency of *ITGB3*, the gene encoding the extracellular matrix receptor β3 integrin, was associated with ASD. Accordingly, *Itgb3* KO mice exhibit autism-*like phenotypes. T*he pathophysiological mechanisms of *Itgb3* remain however unknown, and the potential of targeting this gene for developing ASD therapies uninvestigated. By combining molecular, biochemical, imaging and pharmacological analyses, we establish that *Itgb3* haplo-insufficiency impairs cortical network excitability by promoting extra-synaptic over synaptic signaling of the metabotropic glutamate receptor mGluR5, which is similarly dysregulated in fragile X syndrome, the most frequent monogenic form of ASD. To assess the therapeutic potential of regulating *Itgb3* gene dosage, we implemented CRISPR activation and compared its efficacy with that of a pharmacological rescue strategy for fragile X syndrome. Correction of neuronal *Itgb3* haplo-insufficiency by CRISPR activation rebalanced network excitability as effectively as blockade of mGluR5 with the selective antagonist MPEP. Our findings reveal an unexpected functional interaction between two ASD genes, thereby validating the pathogenicity of *ITGB3* haplo-insufficiency. Further, they pave the way for exploiting CRISPR activation as gene therapy for normalizing gene dosage and network excitability in ASD.

MNK1/2 KINASES REGULATE MEMORY AND AUTISM-RELATED BEHAVIOURS VIA SYNGAP1

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Kleanthi Chalkiadaki[1], Gilliard Lach[1], Mehdi Hooshmandi[2], Elpida Statoulla[1], Seyed Jafarnejad[3], Arkady Khoutorsky[2], Christos Gkogkas[1]
[1]Foundation for Research and Technology (FORTH), Biomedical Research Institute (bri), Ioannina, Greece, [2]McGill University, Department Of Anesthesia And Alan Edwards Centre For Research On Pain, Montreal, Canada, [3]The Queen's University of Belfast,, Pathrick G. Johnston Centre For Cancer Research,, Belfast, Ireland

MAPK (mitogen-activated protein kinase) interacting protein kinases 1 and 2 (Mnk1/2) regulate a plethora of functions, presumably via phosphorylation of their best characterised substrate, eukaryotic translation initiation factor 4E (eIF4E) on Ser209. Here, we show that whereas deletion of Mnk1/2 (Mnk DKO) impairs synaptic plasticity and memory in mice, ablation of phopsho-eIF4E (Ser209) does not affect these processes, suggesting that Mnk1/2 possess additional downstream effectors in the brain. Translational profiling revealed only a small overlap between Mnk1/2- and phospho-eIF4E(Ser209)-regulated translatome. We identified the synaptic Ras GTPase activating protein 1 (Syngap1), encoded by a syndromic autism gene, as a downstream target of Mnk1 since Syngap1 immunoprecipitated with Mnk1 and showed reduced phosphorylation (S788) in Mnk DKO mice. Knock-down of Syngap1 reversed memory deficits in Mnk DKO mice, and pharmacological inhibition of Mnks rescued autism-related phenotypes in Syngap1 +/- mice. Thus, Syngap1 is a downstream effector of Mnk1, and the Mnks-Syngap1 axis regulates memory formation and autism-related behaviours.

Translational control in neurovascular brain development.
The human brain carries out complex tasks and higher functions and is crucial for organismal survival, as it senses both intrinsic and extrinsic environments. Proper brain development relies on the orchestrated development of different precursor cells, which will give rise to the plethora of mature brain cell-types. Within this process, neuronal cells develop closely to and in coordination with vascular cells (endothelial cells (ECs), pericytes) in a bilateral communication process that relies on neuronal activity, attractive or repulsive guidance cues for both cell types and on tight-regulation of gene expression. Translational control is a master regulator of the gene-expression pathway and in particular for neuronal and ECs, it can be localized in developmentally relevant (axon growth cone, endothelial tip cell) and mature compartments (synapses, axons). Herein, we will review mechanisms of translational control relevant to brain development in neurons and ECs in health and disease.

Regulation of mRNA translation in stem cells; links to brain disorders.
Translational control of gene expression is emerging as a cardinal step in the regulation of protein abundance. Especially for embryonic (ESC) and neuronal stem cells (NSC), regulation of mRNA translation is involved in the maintenance of pluripotency but also differentiation. For neuronal stem cells this regulation is linked to the various neuronal subtypes that arise in the developing brain and is linked to numerous brain disorders. Herein, we review translational control mechanisms in ESCs and NSCs during development and differentiation, and briefly discuss their link to brain disorders.

COMPARATIVE ANALYSIS OF THE αV AND β3 INTEGRIN KO MOUSE MODELS OF EPILEPSY AND AUTISM

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Lucia Celora[1], Caterina Michetti[2], Riccardo Ruggeri[1], Agnes Thalhammer[1,2], Carmela Vitale[2], Eduardo Morais[2], Fanny Jaudon[1,2], Lorenzo Cingolani[1,2]
[1]Università di Trieste, Dipartimento Di Scienze Della Vita, Trieste, Italy, [2]Italian Institute of Technology (IIT), Center Of Synaptic Neuroscience And Technology (nysn), Genova, Italy

Integrins are biomechanical receptors for extracellular matrix proteins and counter-receptors on adjacent cells. Loss of αV and β3 integrin subunits have been implicated in the onset of epilepsy and autism, respectively, two comorbid brain disorders. Whether this is because of deficits in αvβ3 integrin receptor signaling at synapses is not known. Here, we performed comparative behavioral and electrophysiological analyses on two mouse models: a conditional KO for αV integrin and a constitutive KO for β3 integrin. We find that both mouse models exhibit increased seizure susceptibility and defects in social interactions. To investigate synaptic defects triggered by loss of αVβ3 integrin, we analyzed dendritic spines and excitatory synaptic currents in cortical neurons. We find selective alterations in dendritic spine morphology and synaptic plasticity in cortical pyramidal neurons of the medial prefrontal cortex. We concluded that αvβ3 integrin is important for regulating cortical excitability.

The prolyl-isomerase PIN1 is essential for nuclear Lamin-B structure and function and protects heterochromatin under mechanical stress.
Chromatin organization plays a crucial role in tissue homeostasis. Heterochromatin relaxation and consequent unscheduled mobilization of transposable elements (TEs) are emerging as key contributors of aging and aging-related pathologies, including Alzheimer's disease (AD) and cancer. However, the mechanisms governing heterochromatin maintenance or its relaxation in pathological conditions remain poorly understood. Here we show that PIN1, the only phosphorylation-specific cis/trans prolyl isomerase, whose loss is associated with premature aging and AD, is essential to preserve heterochromatin. We demonstrate that this PIN1 function is conserved from Drosophila to humans and prevents TE mobilization-dependent neurodegeneration and cognitive defects. Mechanistically, PIN1 maintains nuclear type-B Lamin structure and anchoring function for heterochromatin protein 1α (HP1α). This mechanism prevents nuclear envelope alterations and heterochromatin relaxation under mechanical stress, which is a key contributor to aging-related pathologies.

IPSC-DERIVED CORTICAL NEURONS AND PATTERNED CORTICAL ORGANOIDS TO DISSECT THE NEURODEVELOPMENTAL ROOTS OF FRAGILE X SYNDROME.

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Chiara D'Antoni[1,2], Federica Cordella[1], Alessandro Soloperto[2], Silvia Di Angelantonio[1]
[1]Sapienza, Department Of Physiology And Pharmacology, Rome, Italy, [2]Istituto Italiano Di Tecnologia, Cln2s, Roma, Italy

Fragile X syndrome (FXS) is a human form of mental retardation, caused by expansion of CGG repeat in the *FMR1* gene. The resulting epigenetic silencing causes the loss of the fragile X mental retardation protein with defects in dendritic spine morphology and synaptogenesis. Growing evidence demonstrates how human development and disease can be modeled *in vitro* using human induced pluripotent stem cells (hiPSCs). In this regard, using hiPSC-derived 2D and 3D cultures could give an improvement to better understand this neurodevelopmental disorder. We generated human cortical organoids (hCOs) using both wild type (WT) and FXS-patient derived iPSC. Preliminary data show that day 30 FMR1-WT hCOs, in contrast to FXS hCOs, revealed areas resembling the ventricular zone and the subventricular zone where N-CADHERIN and PAX6 positive neural progenitors were able to form neuroepithelial regions and start cortical neurogenesis. Day 100 FMR1-WT hCOs show a cortical stratification containing the first deep-layer cortical neurons. Moreover, an increased gene expression of *GFAP*, a radial glia and astrocytes marker, in FXS organoids was present at day 50. This evidence is consistence with our previous study where an aberrant presence of astrocytes is detected in FXS whole brain organoids (Brighi et al., 2021). In addition, 2D cultures allows us to investigate the impact of FXS on spine formation and synaptic transmission. In conclusion, combining both model systems, we could investigate dysregulation at cellular and synapses level and analyze the effect of the mutation, in a more physiological context, looking at cytoarchitecture and networking level.

Novel fragile X syndrome 2D and 3D brain models based on human isogenic FMRP-KO iPSCs.
Fragile X syndrome (FXS) is a neurodevelopmental disorder, characterized by intellectual disability and sensory deficits, caused by epigenetic silencing of the FMR1 gene and subsequent loss of its protein product, fragile X mental retardation protein (FMRP). Delays in synaptic and neuronal development in the cortex have been reported in FXS mouse models; however, the main goal of translating lab research into pharmacological treatments in clinical trials has been so far largely unsuccessful, leaving FXS a still incurable disease. Here, we generated 2D and 3D in vitro human FXS model systems based on isogenic FMR1 knock-out mutant and wild-type human induced pluripotent stem cell (hiPSC) lines. Phenotypical and functional characterization of cortical neurons derived from FMRP-deficient hiPSCs display altered gene expression and impaired differentiation when compared with the healthy counterpart. FXS cortical cultures show an increased number of GFAP positive cells, likely astrocytes, increased spontaneous network activity, and depolarizing GABAergic transmission. Cortical brain organoid models show an increased number of glial cells, and bigger organoid size. Our findings demonstrate that FMRP is required to correctly support neuronal and glial cell proliferation, and to set the correct excitation/inhibition ratio in human brain development.

THE CAV1.3 CHANNEL MUTATION A749G DETECTED IN AN AUTISTIC PATIENT AFFECTS DENDRITIC SPINE MORPHOLOGY

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Yuliia Nikonishyna[1], Cornelia Ablinger[2], Sabrin Haddad[2], Nadja Hofer[1], Marta Campiglio[2], Joerg Striessnig[1], Nadine Ortner[1], Stefanie Geisler[1], Gerald Obermair[2,3]

Background: Voltage-gated L-type calcium Cav1.3 channels compose an important calcium entry pathway involved in synapse formation, dendritic refinement, and specifically in the regulation of spine morphology. We and others showed that de novo missense mutations in the Cav1.3 channel α1-subunit (*CACNA1D*) induce a gain-of-function phenotype compatible with increased calcium influx and therefore confer a high risk for neurological disorders. Nonetheless, the influence of these pathogenic mutations on synapse structure is not known.
Aims: Here we studied the effect of the A749G gain-of-function mutation in Cav1.3, associated with autism spectrum disorder and intellectual disability, on the dendritic spine morphology and density.
Methods: We analyzed spine morphology and channel surface expression in cultured hippocampal neurons transfected with untagged and HA-tagged wild-type and mutant Cav1.3 channels. Additionally, by employing a knock-in mouse model carrying the A749G mutation, we currently test the effect of the mutation on spine morphology in Golgi-Cox-stained brain sections.
Results: Expression of the HA-tagged and untagged A749G α1-subunits resulted in a significant increase in dendritic spine length but had no effect on spine density. Furthermore, the spine shape factor was reduced in A749G transfected neurons indicating an overall elongation of spines. Compared to wild-type Cav1.3, the abundance of filopodia-like and thin spines was higher in A749G transfected neurons.
Conclusions: Our results demonstrate an aberrant spine morphology caused by the autism-linked Cav1.3 mutation A749G. We hypothesize that altered local calcium signaling of Cav1.3 gain-of-function mutations can lead to changes in spine stability ultimately triggering neurodevelopmental deficits.

Stabilization of negative activation voltages of Cav1.3 L-Type Ca-channels by alternative splicing.
-->Low voltage-activated Cav1.3 L-type Ca-channels are key regulators of neuronal excitability controlling neuronal development and different types of learning and memory. Their physiological functions are enabled by their negative activation voltage-range, which allows Cav1.3 to be active at subthreshold voltages. Alternative splicing in the C-terminus of their pore-forming α1-subunits gives rise to C-terminal long (Cav1.3) and short (Cav1.3) splice variants allowing Cav1.3 to activate at even more negative voltages than Cav1.3. We discovered that inclusion of exons 8b, 11, and 32 in Cav1.3 further shifts activation (-3 to -4 mV) and inactivation (-4 to -6 mV) to more negative voltages as revealed by functional characterization in tsA-201 cells. We found transcripts of these exons in mouse chromaffin cells, the cochlea, and the brain. Our data further suggest that Cav1.3-containing exons 11 and 32 constitute a significant part of native channels in the brain. We therefore investigated the effect of these splice variants on human disease variants. Splicing did not prevent the gating defects of the previously reported human pathogenic variant S652L, which further shifted the voltage-dependence of activation of exon 11-containing channels by more than -12 mV. In contrast, we found no evidence for gating changes of the missense variant R498L, located in exon 11, which has recently been identified in a patient with an epileptic syndrome. Our

data demonstrate that alternative splicing outside the C-terminus involving exons 11 and 32 contributes to channel fine-tuning by stabilizing negative activation and inactivation gating properties of wild-type and mutant Cav1.3 channels.

Biophysical classification of a de novo mutation as a high-risk mutation for a severe neurodevelopmental disorder.
There is increasing evidence that de novo missense mutations inducing increased Cav1.3 L-type Ca-channel-function confer a high risk for neurodevelopmental disorders (autism spectrum disorder with and without neurological and endocrine symptoms). Electrophysiological studies demonstrating the presence or absence of typical gain-of-function gating changes could therefore serve as a tool to distinguish likely disease-causing from non-pathogenic de novo variants in affected individuals. We tested this hypothesis for mutation S652L, which has previously been reported in twins with a severe neurodevelopmental disorder in the Deciphering Developmental Disorder Study, but has not been classified as a novel disease mutation.

INTEGRATIVE MULTI-OMICS ANALYSES REVEAL MULTI-MODAL FOXG1 FUNCTIONS ACTING ON EPIGENETIC PROCESSES AND IN CONCERT WITH NEUROD1 TO REGULATE SYNAPTOGENESIS IN THE MOUSE HIPPOCAMPUS

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Tanja Vogel[1], Ipek Akol[1], Thomas Manke[2]
[1]Albert-Ludwigs-University Freiburg, Anatomy And Cell Biology, Molecular Embryology, Freiburg, Germany, [2]Max Planck Institute of Immunobiology and Epigenetics, Bioinformatics Core, Freiburg, Germany

Development of the central nervous system (CNS) depends on spatiotemporal control of signalling pathways and transcription programs. Forkhead Box G1 (FOXG1) is one of the master regulators that plays fundamental roles in forebrain development, from timing of neurogenesis to patterning of the cerebral cortex. Mutations in *FOXG1* cause a neurodevelopmental disorder, FOXG1 syndrome, and patients manifest a spectrum of phenotypes ranging from severe cognitive dysfunction and microcephaly to social withdrawal with varying severities. Despite steady progress towards understanding the role of FOXG1 its multifaceted functions and changes at the molecular level underlying functional abnormalities upon *FOXG1* haploinsufficiency remain largely unexplored. Using multi-omics data (RNA-, ChIP-, and ATAC-seq), we explored the influence of FOXG1 on neuronal maturation at the chromatin level in the adult mouse hippocampus. We revealed that FOXG1 both repressed and activated transcription, binding mainly to enhancer regions, and affecting the epigenetic landscape bidirectionally as displayed by the levels of H3K27ac, H3K4me3 and chromatin accessibility. Alterations in the chromatin affected synaptogenesis and axonogenesis, signifying the role of FOXG1 in the regulation of genes required for proper neuronal function. Notably, FOXG1 interacted with histone deacetylases (HDACs) and inhibition of HDACs partially rescued transcriptional alterations observed upon FOXG1 reduction. We have also identified NEUROD1 as a novel interaction partner of FOXG1, which acted in coordination with FOXG1 to control neuronal differentiation. Together, our integrative approach uncovered that FOXG1 acts through different epigenetic mechanisms and in concert with other TFs, one of which is NEUROD1, emphasising the multimodality of FOXG1 at the chromatin level.

SCN2A, encoding voltage gated sodium channel 1.2 ($Na_V1.2$), is one of the most significant single-gene contributors to neurodevelopmental disorders. Genetic variants resulting in autism spectrum disorder (ASD) typically confer a severe loss-of-function (LOF) of $Na_V1.2$, however the pathomechanisms of disease, such as associated intellectual disability and developmental delay, are unknown, mostly due to the lack of impressive or consistent behavioural and electrophysiological phenotypes in mouse models of *SCN2A* LOF. We recruited one candidate patient with a novel *SCN2A* ASD genetic variant (S1758R) for phenotypic characterisation and induced-pluripotent stem cell (iPSC) generation. We investigated the pathomechanisms of *SCN2A* in ASD using neurons differentiated from patient iPSCs, in the first phenotypic characterisation of an *SCN2A* ASD variant in a neuron model derived from a patient's own cells. We find that the S1758R variant has no effect on the electrophysiological properties of neurons differentiated by the Ngn2 rapid neuronal differentiation protocol when compared to the isogenic control, suggesting mechanisms of redundancy or homeostatic plasticity in the model that are able to compensate for *SCN2A* LOF. To investigate these processes, we performed RNA-sequencing analysis of neuron cultures and discovered dysregulated potassium channel genes as a possible mechanism for compensation. The findings from this study have motivated the design of a 3D organoid project, investigating *SCN2A* LOF in the context of a more native and complex model of the developing human brain.

Sodium channel expression and transcript variation in the developing brain of human, Rhesus monkey, and mouse.
Genetic variation in voltage-gated sodium (Na) channels is a significant contributor to neurodevelopmental disorders. Na channel alpha subunits are encoded by the SCNxA family and four are predominately expressed in the brain: SCN1A, SCN2A, SCN3A, and SCN8A. Gene expression is developmentally regulated, and they are known to express functionally distinct transcript variants. Precision therapies targeting these genes and their transcript variants are currently in preclinical development, yet the developmental expression of these transcripts in the human brain is yet to be fully understood. Additionally, the functional consequences of some mutations differ depending on the studied channel isoform, suggesting differential transcript variant expression can affect disease prognoses. We characterise the expression of the four SCNxAs and their transcript variants in human, Rhesus monkey and mouse brain using publicly available RNA-sequencing data and analysis tools, demonstrating that this approach can be used to answer important biological questions of gene and transcript developmental regulation. We find that gene expression and transcript variant regulation are conserved across species at similar developmental stages and determine the developmental milestones for transcript variant expression. Our study provides a guide to researchers testing therapies and clinicians advising prognoses based on the expression of channel isoforms.

Novel venom-derived inhibitors of the human EAG channel, a putative antiepileptic drug target.
Recently, we and other groups revealed that gain-of-function mutations in the human ether à go-go voltage-gated potassium channel hEAG1 (K10.1) lead to developmental disorders with associated infantile-onset epilepsy. However, the physiological role of hEAG1 in the central nervous system remains elusive. Potent and selective antagonists of hEAG1 are therefore much sought after, both as pharmacological tools for studying the (patho)physiological functions of this enigmatic channel and as potential leads for development of anti-epileptic drugs. Since animal venoms are a rich source of potent ion channel modifiers

that have been finely tuned by millions of year of evolution, we screened 108 arachnid venoms for hEAG1 inhibitors using electrophysiology. Two hit peptides (Aa1a and Ap1a) were isolated, sequenced, and chemically synthesised for structure-function studies. Both of these hEAG1 inhibitors are C-terminally amidated peptides containing an inhibitor cystine knot motif, which provides them with exceptional stability in both plasma and cerebrospinal fluid. Aa1a and Ap1a are the most potent peptidic inhibitors of hEAG1 reported to date, and they present a novel mode of action by targeting both the activation and inactivation gating of the channel. These peptides should be useful pharmacological tools for probing hEAG1 function as well as informative leads for the development of novel anti-epileptic drugs.

Antisense oligonucleotide therapy reduces seizures and extends life span in an SCN2A gain-of-function epilepsy model.
De novo variation in SCN2A can give rise to severe childhood disorders. Biophysical gain of function in SCN2A is seen in some patients with early seizure onset developmental and epileptic encephalopathy (DEE). In these cases, targeted reduction in SCN2A expression could substantially improve clinical outcomes. We tested this theory by central administration of a gapmer antisense oligonucleotide (ASO) targeting Scn2a mRNA in a mouse model of Scn2a early seizure onset DEE (Q/+ mice). Untreated Q/+ mice presented with spontaneous seizures at P1 and did not survive beyond P30. Administration of the ASO to Q/+ mice reduced spontaneous seizures and significantly extended life span. Across a range of behavioral tests, Scn2a ASO-treated Q/+ mice were largely indistinguishable from WT mice, suggesting treatment is well tolerated. A human SCN2A gapmer ASO could likewise impact the lives of patients with SCN2A gain-of-function DEE.

Aims: Fragile X syndrome (FXS) is the most common monogenic cause of inherited intellectual disability and autism caused by the silencing of the *FMR1* gene and the subsequent loss of the fragile X mental retardation protein (FMRP). The fragile X mental retardation 1 (*Fmr1*) knockout mouse shows cognitive impairment and some of the synaptic alterations observed in subjects with FXS. These alterations in *Fmr1* KO were significantly prevented by blocking the cannabinoid type-1 receptor (CB1R) with low doses of the systemic antagonist/inverse agonist rimonabant. The molecular hallmarks underlying the neurological and behavioural improvements of CB1R blockade in *Fmr1* KO mice are not yet understood. **Methods**: We performed high-throughput RNA sequencing focused on synaptic relevant transcripts to analyse differential expression patterns between *Fmr1* KO mice and WT after rimonabant (0.1 mg/kg, i.p., 7 days) or vehicle administration. **Results**: Differential expression analysis in *Fmr1* KO samples revealed the up-regulation of transcripts related with synapse structure and the down regulation of transcripts involved in synapse organization and mRNA processing. Notably, rimonabant treatment in *Fmr1* KO samples induced a marked up-regulation of transcripts related with mRNA splicing. Furthermore, alternative splicing analysis identified a relevant number of splicing events in *Fmr1* KO mice that were reverted after rimonabant treatment in terms of Percent Splice In measurements. **Conclusions**: Together, we identified a synaptic transcriptomic signature that may contribute to central deficits in the FXS mouse model, a signature that was sensitive to CB1R inhibition under conditions that improve neurological and behavioural traits.

Rett syndrome (RTT) is a severe neurodevelopmental disorder that afflicts mostly females and is mainly caused by mutations in the *MECP2* gene. Unfortunately, a cure is still lacking. Neural Precursor/Stem Cells (NPCs) transplantation was proved safe and beneficial in many neurological disorders, including autism. We thus decided to investigate the therapeutic potential of NPCs in the *Mecp2* null mouse modeling RTT. NPCs exert their beneficial effect mainly through the “bystander” mechanism: by sensing the pathological environment, they secrete neurotrophic and immunomodulatory factors that promote neuroprotection and brain plasticity. Using an *in vitro* transwell-based co-culture system, we demonstrated that NPCs promote morphological and synaptic rescues in *Mecp2* null neurons by paracrine secreted factors. I*n vivo*, we collected several data demonstrating that NPCs can prolong lifespan and restore memory and motor functions of *Mecp2* null mice. To identify the molecular mechanisms set in motion by NPCs transplantation, we performed bulk RNA sequencing analyses of wild-type and knock out cerebral tissues transplanted or not with NPCs. Obtained results revealed many transcriptional alterations directly or indirectly caused by the lack of *Mecp2* and by NPCs treatment. Among all the deregulated pathways we focused on Interferon gamma (IFNγ) one, which is upregulated in *Mecp2 null* + NPCs mice vs *Mecp2* null control mice. Assuming that this cytokine could be one of the candidate factors responsible for the benefic effects exerted by NPCs transplant, we collected *in vivo* and *in vitro* evidence in favor of its therapeutic potential for *Mecp2* null models.

EPIGENETIC MECHANISMS OF HOMEOSTATIC PLASTICITY IN A HUMAN NEURONAL MODEL SYSTEM

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Xiuming Yuan[1], Barbara Franke[2], Nael Nadif Kasri[2]
[1]Donders Institute for Brain, Cognition and Behavior, Radboud University Medical Center, Human Genetics, NIJMEGEN, Netherlands, [2]Donders Institute for Brain, Cognition and Behavior, Radboud University Medical Center, Human Genetics, Nijmegen, Netherlands

Neurodevelopmental disorders (NDDs) are conditions of impaired cognitive, behavioral, and/or motor functions stemming from an atypical development of the central nervous system. Impairments found in NDDs have been associated with disrupted homeostatic plasticity, a process known to stabilize neuronal network activity by balancing neuronal excitation and inhibition. Several studies have shown that homeostatic plasticity is regulated by epigenetic mechanisms, such as DNA-methylation. However, the epigenetic profile involved in homeostatic plasticity in NDDs is currently insufficiently defined. This study aims to explore the role of epigenetics in altered homeostatic plasticity relevant to NDDs. As a first step, we established a model of homeostatic plasticity in human induced pluripotent stem cell (hiPSC)-derived neurons, grown on micro-electrode arrays (MEAs). In hiPSC-derived excitatory neurons, we demonstrate that chronic deprivation of neuronal activity through the inhibition of sodium channels with tetrodotoxin (TTX) elicits a time-dependent increase in neuronal network activity after TTX removal, and this increase is restored to baseline after 48 hours. In accordance with previous reports, we show that the early stage of TTX-induced homeostatic plasticity is mediated by GluA2-lacking AMPA receptors. We further show that the changes in network properties are caused by an upregulation of postsynaptic AMPA receptors expression and changes in intrinsic properties. Having validated this model as described above, it is now being used to test whether hiPSC-derived neurons with mutations in genes linked to NDD through epigenetic mechanisms display altered homeostatic plasticity.

ARID1B-HAPLOINSUFFICIENCY LEADS TO DELAYED NEURONAL NETWORK DEVELOPMENT OF IPSC-DERIVED EXCITATORY NEURONS

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Ummi Ciptasari[1], Marina Hommersom[1], Chantal Schoenmaker[1], Femke Bakker[1], Brooke Latour[1], Dirk Schubert[2], Hans Van Bokhoven[1], Nael Nadif Kasri[1]
[1]Donders Institute for Brain, Cognition and Behavior, Radboud University Medical Center, Human Genetics, Nijmegen, Netherlands, [2]Donders Institute for Brain, Cognition and Behavior, Department Of Cognitive Neuroscience, Nijmegen, Netherlands

ARID1B is one of the most commonly mutated genes in patients with intellectual disabilities (ID) ranging from Coffin-Siris syndrome (CSS) to syndromic forms of autism spectrum disorders (ASD). The mechanism by which deficiency of ARID1B leads to the disease phenotypes seen in patients remains unclear. We generated excitatory glutamatergic neurons from induced pluripotent stem cells (iPSCs) derived from fibroblasts of CSS patients with loss-of-function mutations in *ARID1B*, as well as *ARID1B*$^{+/-}$ CRISPR line originated from healthy control iPSCs. Using Micro-Electrode Arrays (MEAs) to investigate the spontaneous neuronal network activity of the neurons, we found that *ARID1B*$^{+/-}$ neurons showed delayed developmental trajectory in comparison to control neurons. In support of this phenotype, mature network activity of ARID1B-deficient neurons showed increased response to blockage of GluA2-lacking AMPA receptors, reminiscent of the response of immature control neuronal network. Single-cell electrophysiological recording and immunofluorescence data suggest altered GluA2-expression in *ARID1B*$^{+/-}$ neuronal synapses. These results give insight into the molecular mechanism by which haploinsufficiency of ARID1B leads to phenotypes seen in CSS, ID , and ASD patients carrying *ARID1B* mutations.

Defective metabolic programming impairs early neuronal morphogenesis in neural cultures and an organoid model of Leigh syndrome.
Leigh syndrome (LS) is a severe manifestation of mitochondrial disease in children and is currently incurable. The lack of effective models hampers our understanding of the mechanisms underlying the neuronal pathology of LS. Using patient-derived induced pluripotent stem cells and CRISPR/Cas9 engineering, we developed a human model of LS caused by mutations in the complex IV assembly gene SURF1. Single-cell RNA-sequencing and multi-omics analysis revealed compromised neuronal morphogenesis in mutant neural cultures and brain organoids. The defects emerged at the level of neural progenitor cells (NPCs), which retained a glycolytic proliferative state that failed to instruct neuronal morphogenesis. LS NPCs carrying mutations in the complex I gene NDUFS4 recapitulated morphogenesis defects. SURF1 gene augmentation and PGC1A induction via bezafibrate treatment supported the metabolic programming of LS NPCs, leading to restored neuronal morphogenesis. Our findings provide mechanistic insights and suggest potential interventional strategies for a rare mitochondrial disease.

The phenomenal epigenome in neurodevelopmental disorders.
Disruption of chromatin structure due to epimutations is a leading genetic etiology of neurodevelopmental disorders, collectively known as chromatinopathies. We show that there is an increasing level of convergence from the high diversity of genes that are affected by mutations to the molecular networks and pathways involving the respective proteins, the disrupted cellular and subcellular processes, and their consequence for higher order cellular network function. This convergence is ultimately reflected by specific phenotypic features shared across the various chromatinopathies. Based on these observations, we propose that the commonly disrupted molecular and cellular anomalies might provide a rational target for the development of symptomatic interventions for defined groups of genetically distinct neurodevelopmental disorders.

Antigenotoxic Properties of against Hydrogen Peroxide in Human Peripheral Blood Cells.
The ability of mushroom in its dried and powdered mycelial form was evaluated for its antigenotoxic properties for the first time. Antigenotoxic effects in human peripheral blood cells against HO-induced DNA damage were examined in pretreatment and posttreatment protocol by comet assay. The results showed better antigenotoxic properties of on the interventional level, respectively, after treatment. in concentration of 250 g/mL after treatment was most efficient in regard to its action against DNA damage. The evaluation of repair kinetics showed decrease in HO induced DNA damage 15 min after the application of , reaching the maximum potency after 30 min. Analysis of antioxidant properties of revealed strong OH scavenging properties and moderate reducing power, while its DPPH scavenging ability was weak. In regard to our findings, we can conclude that our preliminary results demonstrated antigenotoxic properties of and its strong OH scavenging ability. Mechanisms underlying its properties should be further evaluated in in vivo studies.

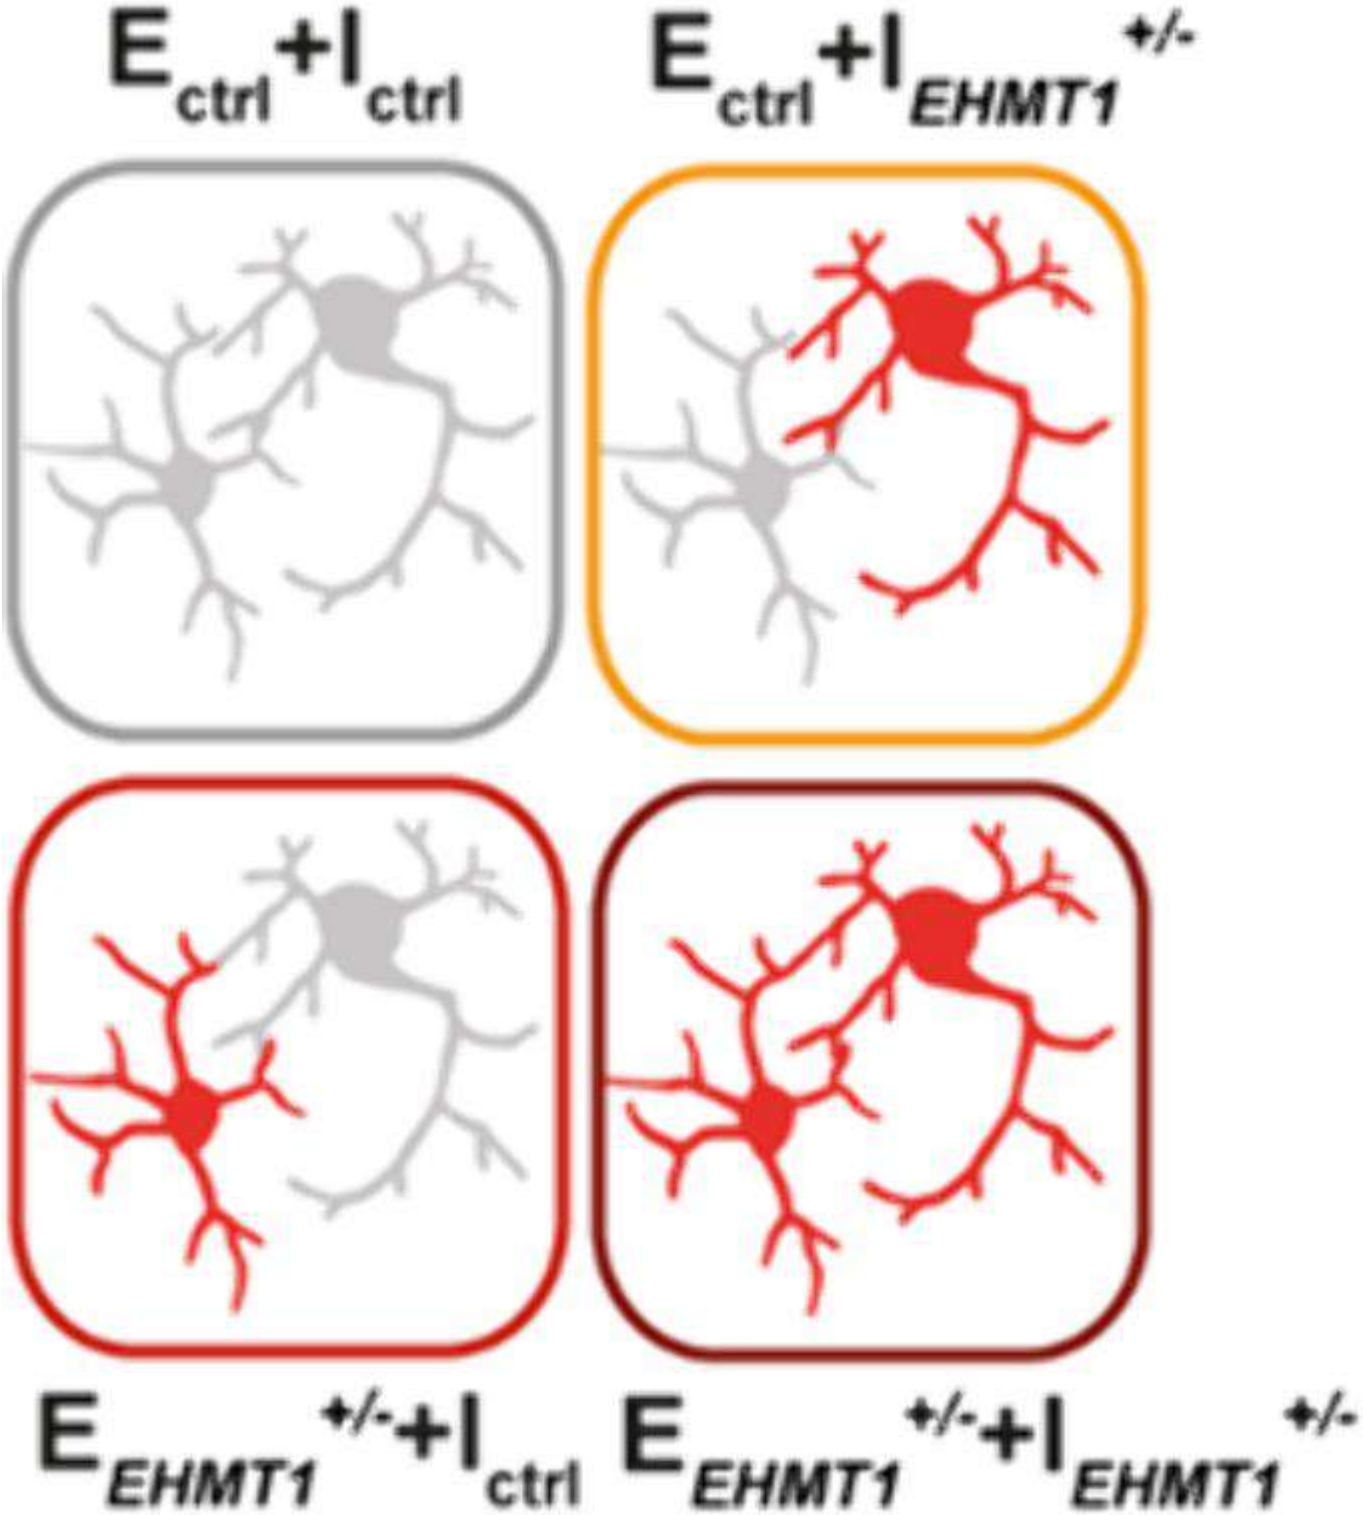
Kleefstra syndrome is a neurodevelopmental disorder caused by mutations in the histone methyltransferase EHMT1. EHMT1 has recently been identified to be a key player in the maintenance of excitatory/inhibitory (E/I) balance. However, little is known about its function in human GABAergic neurons, as well as how EHMT1 controls the function of glutamatergic or GABAergic neurons in maintaining E/I balance. To disentangle the cell-type specific contribution of EHMT1 to E/I balance, we generated four network compositions containing human induced pluripotent stem-cell (hiPSC) derived glutamatergic- and GABAergic neurons from either control or EHMT1-deficient hiPSCs and recorded their electrophysiological network activity on a multi-electrode array (MEA). We found that selective EHMT1-deficieny in glutamatergic or GABAergic neurons results in cell-type specific alterations in neuronal network activity. The largest contribution to the affected network phenotype is attributed to EHMT1-deficient glutamatergic neuron, of which some affected neuronal network parameters are exacerbated when also in the presence of EHMT1-deficient GABAergic neurons. A discriminant analysis of all MEA parameters resulted in four clusters, with the large majority of MEA recordings correctly classified within their own culture composition cluster. Taken together, our results suggest that EHMT1 controls both glutamatergic and GABAergic neuron function during the

maintenance of E/I



balance.

EHMT1 regulates Parvalbumin-positive interneuron development and GABAergic input in sensory cortical areas.

FENS Forum 2022
9-13 July 2022 | Paris, France

Mutations in the Euchromatic Histone Methyltransferase 1 (EHMT1) gene cause Kleefstra syndrome, a rare form of intellectual disability (ID) with strong autistic traits and sensory processing deficits. Proper development of inhibitory interneurons is crucial for sensory function. Here we report a timeline of Parvalbumin-positive (PV) interneuron development in the three most important sensory cortical areas in the Ehmt1 mouse. We find a hitherto unreported delay of PV neuron maturation early in sensory development, with layer- and region-specific variability later in development. The delayed PV maturation is also reflected in a delayed maturation of GABAergic transmission in Ehmt1 auditory cortex, where we find a reduced GABA release probability specifically in putative PV synapses. Together with earlier reports of excitatory impairments in Ehmt1 neurons, we propose a shift in excitatory-inhibitory balance towards overexcitability in Ehmt1 sensory cortices as a consequence of early deficits in inhibitory maturation.

UNDERSTANDING THE ROLE OF SYNGAP1 IN PARVALBUMIN-EXPRESSING GABAERGIC CIRCUIT DEVELOPMENT AND FUNCTION.

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Vidya Jadhav[1,2], Bidisha Chattopadhyaya[1], Maria Carreño-Muñoz[1,2], Jacques Michaud[1,2,3], Graziella Di Cristo[1,2]

Haploinsufficiency of *Syngap1* gene encoding the Synaptic Ras-GTPase Activating protein is associated with intellectual disability, autism spectrum disorder and epilepsy. Mouse models of *Syngap1* haploinsufficiency show alterations in synaptic plasticity, behavioural abnormalities and cognitive deficits. Several studies have shown that *Syngap1* regulates the developmental trajectory and function of excitatory neurons; in contrast, the role of *Syngap1* in inhibitory GABAergic neurons is less well understood. GABAergic neurons are a diverse class of neurons with different morphology, connectivity and physiological properties. Parvalbumin (PV)-expressing interneurons, one of the major classes of cortical GABAergic interneurons, form synapses onto the soma and proximal dendrites of pyramidal cells and play an important role in neural circuit development and plasticity. We aim to understand the role of *Syngap1* expressed by PV cells in sensory processing and cognition. We used both a) Nkx2.1 Cre conditional mice to specifically delete *Syngap1* embryonically in interneurons derived from the medial ganglionic eminence (where PV and somatostatin-expressing interneurons originate), and b) PV Cre conditional mice to specifically delete *Syngap1* postnatally in PV cells, respectively. Our results suggest altered social behavior and fear extinction, specifically in *Nkx2.1Cre:Syngap1^{lox}* but not in *PVCre:Syngap1^{lox}* mutant mice. Further we found that *Nkx2.1Cre:Syngap1^{lox}* mice show specific alterations in auditory processing. Haploinsufficiency of *Syngap1* in interneurons can thus contribute to cognitive alterations caused by *Syngap1* mutations during development.

Sensitive period for rescuing parvalbumin interneurons connectivity and social behavior deficits caused by TSC1 loss.
The Mechanistic Target Of Rapamycin Complex 1 (mTORC1) pathway controls several aspects of neuronal development. Mutations in regulators of mTORC1, such as Tsc1 and Tsc2, lead to neurodevelopmental disorders associated with autism, intellectual disabilities and epilepsy. The correct development of inhibitory interneurons is crucial for functional circuits. In particular, the axonal arborisation and synapse density of parvalbumin (PV)-positive GABAergic interneurons change in the postnatal brain. How and whether mTORC1 signaling affects PV cell development is unknown. Here, we show that Tsc1 haploinsufficiency causes a premature increase in terminal axonal branching and bouton density formed by mutant PV cells, followed by a loss of perisomatic innervation in adult mice. PV cell-restricted Tsc1 haploinsufficient and knockout mice show deficits in social behavior. Finally, we identify a sensitive period during the third postnatal week during which treatment with the mTOR inhibitor Rapamycin rescues deficits in both PV cell innervation and social behavior in adult conditional haploinsufficient mice. Our findings reveal a role of mTORC1 signaling in the regulation of the developmental time course and maintenance of cortical PV cell connectivity and support a mechanistic basis for the targeted rescue of autism-related behaviors in disorders associated with deregulated mTORC1 signaling.

Restriction of intracellular replication by restoring TFEB-mediated xenophagy.
Macroautophagy/autophagy functions as a part of the innate immune system in clearing intracellular pathogens. Although this process is well known, the mechanisms that control antibacterial autophagy are not clear. In this study we show that during intracellular infection, the activity of TFEB (transcription factor EB), a master regulator of autophagy and lysosome biogenesis, is suppressed by maintaining it in a phosphorylated state on the lysosomes. Furthermore, we have identified a novel, antibacterial small molecule autophagy (xenophagy) modulator, acacetin. The xenophagy effect exerted by acacetin occurs in an MTOR (mechanistic target of rapamycin kinase)-independent, TFEB-dependent manner. Acacetin treatment results in persistently maintaining active TFEB in the nucleus and also in TFEB mediated induction of functional lysosomes

that target -containing vacuoles (SCVs). The enhanced proteolytic activity due to deployment of lysosomes results in clamping down replication in SCVs. Acacetin is effective as a xenophagy compound in an mouse model of infection and reduces intracellular burden.

In the mammalian cerebral cortex, up to 90% of neurons are ciliated, yet at present, little is known about the role of the primary cilium in postmitotic neurons. Recent work indicates that there is a role of ciliary proteins with the intrinsic excitability of single cells but the role the cilium plays in network dynamics at present is poorly characterised. In addition, findings in mouse models of seizure suggest hippocampal neurons display shortened cilium following excitotoxic events. We sought to discern the effect of pharmacological manipulation of the network on neuronal cilia morphology in human induced pluripotent stem cell derived neuronal networks. We present evidence that the primary cilium dynamically changes (bidirectionally, shortened and longer) when network function is altered . In this system, the cilium shows responsiveness to an array of molecules, including tetrodotoxin and potassium chloride, that alter the excitable state of the neurons. To our knowledge, this work is the first finding in human induced neuronal model that shows that the neuronal primary cilium is reactive to neuromodulation in vitro, and adds novel insight into the role that primary cilia, and ciliary proteins, play in excitable transmission.

CTIP2-Regulated Reduction in PKA-Dependent DARPP32 Phosphorylation in Human Medium Spiny Neurons: Implications for Huntington Disease.
The mechanisms underlying the selective degeneration of medium spiny neurons (MSNs) in Huntington disease (HD) remain largely unknown. CTIP2, a transcription factor expressed by all MSNs, is implicated in HD pathogenesis because of its interactions with mutant huntingtin. Here, we report a key role for CTIP2 in protein phosphorylation via governing protein kinase A (PKA) signaling in human striatal neurons. Transcriptomic analysis of CTIP2-deficient MSNs implicates CTIP2 target genes at the heart of cAMP-Ca signal integration in the PKA pathway. These findings are further supported by experimental evidence of a substantial reduction in phosphorylation of DARPP32 and GLUR1, two PKA targets in CTIP2-deficient MSNs. Moreover, we show that CTIP2-dependent dysregulation of protein phosphorylation is shared by HD hPSC-derived MSNs and striatal tissues of two HD mouse models. This study therefore establishes an essential role for CTIP2 in human MSN homeostasis and provides mechanistic and potential therapeutic insight into striatal neurodegeneration.

Background: Drinking during pregnancy can lead to physical, learning and behavioral disorders in newborns, a pathological condition referred as Fetal Alcohol Spectrum Disorder (FASD). Unfortunately, there is no cure for FASD and the molecular mechanisms underlying this pathology are still unknown. We have recently demonstrated that chronic EtOH exposure followed by withdrawal induced a significant decrease in AMPA receptor (AMPAR) expression and function and an incorrect formation of neuronal circuits in developing hippocampus *in vitro* [Gerace et al., 2016]. Here, we hypothesized a role for microRNA (137 and 501-3p) in the regulation of AMPAR-mediated neurotransmission, by translational repression of AMPAR subunit GluA1 via metabotropic glutamate receptor 5 (mGlu5) at CA1 hippocampal synapse. **Methods:** Organotypic hippocampal slices (2 days in cultures) were exposed to EtOH (150 mM) for 7 days followed by 24 h EtOH withdrawal. Then, slices were analyzed by RT-PCR for miRNA content, by western blotting for expression of AMPA related-synaptic proteins in postsynaptic compartment (PSD) and by electrophysiology to record electrical properties from CA1 pyramidal neurons. **Results:** We found that EtOH induces miRNA 137 and 501-3p upregulation that is prevented by application of the selective mGlu5 antagonist MPEP during EtOH withdrawal. Simultaneously, we observed a significant downregulation of postsynaptic AMPA subunits and relative scaffold proteins expression and accordingly, a decrease of AMPA-mediated neurotransmission. **Conclusions:** Our data indicate miRNA137 and 501-3p as key factors in the regulation of AMPAergic neurotransmission, contributing to the pathogenesis of FASD.

Moderate ethanol drinking is sufficient to alter Ventral Tegmental Area dopamine neurons activity via functional and structural remodeling of GABAergic transmission.
Earlier studies have shown a major involvement of Ventral Tegmental Area (VTA) dopamine (DA) neurons in mediating the rewarding effects of ethanol (EtOH). Much less is known on the role of this system in mediating the transition from moderate to excessive drinking and abuse. Here we sought to explore the hypothesis that early stage drinking in rodents, resembling recreational EtOH use in humans, is sufficient to dysregulate VTA DA transmission thus increasing the propensity to use over time. To this purpose, midbrain slice recordings in mice previously exposed to an escalating (3, 6 and 12%) 18-day voluntary EtOH drinking paradigm was used. By recording from DA and γ-aminobutyric acid (GABA) VTA neurons in midbrain slices, we found that moderate EtOH drinking leads to a significant suppression of the spontaneous activity of VTA DA neurons, while increasing their response to acute EtOH application. We also found that chronic EtOH leads to the enhancement of GABA input frequency onto a subset of DA neurons. Structurally, chronic EtOH induced a significant increase in the number of GABA axonal boutons contacting DA neurons, suggesting deep rewiring of the GABA network. This scenario is consistent with a downmodulation of the reward DA system induced by moderate EtOH drinking, a neurochemical state defined as "hypodopaminergic" and previously associated with advanced stages of drug use in humans. In this context, increased sensitivity of DA neurons towards acute EtOH may represent the neurophysiological correlate of increased unitary rewarding value, possibly driving progression to addiction.

REVERSAL OF NEUROLOGICAL DEFICITS BY PAINLESS NERVE GROWTH FACTOR IN A MOUSE MODEL OF RETT SYNDROME

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Alexia Tiberi[1], Giulia Borgonovo[2], Paola Pacifico[2], Maria Antonietta Calvello[2], Simona Capsoni[2], Antonino Cattaneo[2]

Rett syndrome is a rare genetic neurodevelopmental disease, affecting 1 over 10,000 females born worldwide, caused by sporadic mutations in the X-chromosome-located methyl-CpG-binding protein 2 (MeCP2) gene. Despite the great effort put forth by the scientific community, a therapy for this devastating disease is still needed. Here, we tested the therapeutic potential of a painless mutein of the Nerve Growth Factor, called human NGF painless (hNGFp), via a non-invasive intranasal delivery in female MeCP2+/- mice. We report that treatment with hNGFp (1) increased the chance of survival while (2) greatly improving behavioral parameters in MeCP2+/- mice. Furthermore, we observed (3) the rescue of a known target population of NGF, cholinergic neurons in the medial septum. We also reveal (4) a deficit in microglial morphology in MeCP2+/- mice, completely reversed in treated animals. To understand the immunomodulatory activity of hNGFp, we analyzed (5) the cytokine profile after hNGFp treatment in MeCP2+/- mice, to discover that our treatment rescued the expression of key neuroimmune-communication molecules such as Fractalkine and C-C Motif Chemokine Ligand 1 (CCL1). The overall conclusion is that hNGFp delivered intranasally can ameliorate symptoms in the MeCP2+/- model of Rett syndrome via its pleiotropic activity on both neurons and glia.

Targeting Neuroinflammation to Treat Alzheimer's Disease.
Over the past few decades, research on Alzheimer's disease (AD) has focused on pathomechanisms linked to two of the major pathological hallmarks of extracellular deposition of beta-amyloid peptides and intra-neuronal formation of neurofibrils. Recently, a third disease component, the neuroinflammatory reaction mediated by cerebral innate immune cells, has entered the spotlight, prompted by findings from genetic, pre-clinical, and clinical studies. Various proteins that arise during neurodegeneration, including beta-amyloid, tau, heat shock proteins, and chromogranin, among others, act as danger-associated molecular patterns, that-upon engagement of pattern recognition receptors-induce inflammatory signaling pathways and ultimately lead to the production and release of immune mediators. These may have beneficial effects but ultimately compromise neuronal function and cause cell death. The current review, assembled by participants of the Chiclana Summer School on Neuroinflammation 2016, provides an overview of our current understanding of AD-related immune processes. We describe the principal cellular and molecular players in inflammation as they pertain to AD, examine modifying factors, and discuss potential future therapeutic targets.

NGF steers microglia toward a neuroprotective phenotype.
Microglia are the sentinels of the brain but a clear understanding of the factors that modulate their activation in physiological and pathological conditions is still lacking. Here we demonstrate that Nerve Growth Factor (NGF) acts on microglia by steering them toward a neuroprotective and anti-inflammatory phenotype. We show that microglial cells express functional NGF receptors in vitro and ex vivo. Our transcriptomic analysis reveals how, in primary microglia, NGF treatment leads to a modulation of motility, phagocytosis and degradation pathways. At the functional level, NGF induces an increase in membrane dynamics and macropinocytosis and, in vivo, it activates an outward rectifying current that appears to modulate glutamatergic neurotransmission in nearby neurons. Since microglia are supposed to be a major player in Aβ peptide

clearance in the brain, we tested the effects of NGF on its phagocytosis. NGF was shown to promote TrkA-mediated engulfment of Aβ by microglia, and to enhance its degradation. Additionally, the proinflammatory activation induced by Aβ treatment is counteracted by the concomitant administration of NGF. Moreover, by acting specifically on microglia, NGF protects neurons from the Aβ-induced loss of dendritic spines and inhibition of long term potentiation. Finally, in an ex-vivo setup of acute brain slices, we observed a similar increase in Aβ engulfment by microglial cells under the influence of NGF. Our work substantiates a role for NGF in the regulation of microglial homeostatic activities and points toward this neurotrophin as a neuroprotective agent in Aβ accumulation pathologies, via its anti-inflammatory activity on microglia.

Regulation of BACE1 expression after injury is linked to the p75 neurotrophin receptor.
BACE1 is a transmembrane aspartic protease that cleaves various substrates and it is required for normal brain function. BACE1 expression is high during early development, but it is reduced in adulthood. Under conditions of stress and injury, BACE1 levels are increased; however, the underlying mechanisms that drive BACE1 elevation are not well understood. One mechanism associated with brain injury is the activation of injurious p75 neurotrophin receptor (p75), which can trigger pathological signals. Here we report that within 72 h after controlled cortical impact (CCI) or laser injury, BACE1 and p75 are increased and tightly co-expressed in cortical neurons of mouse brain. Additionally, BACE1 is not up-regulated in p75 null mice in response to focal cortical injury, while p75 over-expression results in BACE1 augmentation in HEK-293 and SY5Y cell lines. A luciferase assay conducted in SY5Y cell line revealed that BACE1 expression is regulated at the transcriptional level in response to p75 transfection. Interestingly, this effect does not appear to be dependent upon p75 ligands including mature and pro-neurotrophins. In addition, BACE1 activity on amyloid precursor protein (APP) is enhanced in SY5Y-APP cells transfected with a p75 construct. Lastly, we found that the activation of c-jun n-terminal kinase (JNK) by p75 contributes to BACE1 up-regulation. This study explores how two injury-induced molecules are intimately connected and suggests a potential link between p75 signaling and the expression of BACE1 after brain injury.

KDM1A ENABLES POLYCOMB-MEDIATED SILENCING OF NON-NEURONAL GENES INTO NEURONAL EUCHROMATIN

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Ana Martín González[1], Sergio Niñerola[1], Juan Paraíso Luna[1], Minji Kim[2], Rafael Muñoz Viana[1], Román Olivares[1], Yijun Ruan[2], Ángel Barco[1], Beatriz Del Blanco[1]
[1]Instituto de Neurociencias (CSIC-UMH), Molecular Neurobiology And Neuropathology, San Juan de Alicante, Spain, [2]The Jackson laboratory for Genomic Medicine, Computational Biology, 3d Genome Organization, Farmington, United States of America

Although Kdm1a is the most expressed histone demethylases in adult neuronal cells, its molecular function is unknown. Here, we generated inducible and forebrain-restricted knockout (ifKO) mice in which Kdm1a is specifically eliminated in forebrain excitatory neurons during adulthood. The mice showed a prominent transcriptional and epigenomic dysregulation signature characterized by the expression of non-neuronal genes in excitatory neurons. By combining RNA-seq, ChIP-seq, ChIA-PET, Hi-C and Super-resolution microscopy experiments in adult excitatory neuronal we show that Kdm1a exerts its repressive function in the euchromatin compartment in CTCF-encapsulated micro-domains enriched in H3K27me3. Specifically, Kdm1a loss led to the destabilization of CTCF-encapsulated H3K27me3-microdomains, and weakened the boundaries between active and silent chromatin. These results underscore the role of Kdm1a safeguarding chromatin organization and silencing non neuronal genes in adult neurons.

IMPACT OF ALTERED UBE3A DOSAGE ON SYNAPSE DEVELOPMENT: THE CASE OF THE ANGELMAN SYNDROME

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Martina Biagioni[1], Alessandra Folci[2], Marco Erreni[3], Matteo Fossati[4]
[1]Humanitas Clinical and Research Center-IRCCS, Neuroscience, Rozzano (MI), Italy, [2]National Research Council- CNR, Neuroscience Institute, Vedano al Lambro, Italy, [3]Humanitas Clinical and Research Center - IRCCS, Unit Of Advanced Optical Microscopy, Rozzano (MI), Italy, [4]Humanitas Clinical and Research Center, Institute Of Neuroscience - Cnr, Rozzano (MI), Italy

The UBE3A gene codes for an E3 ubiquitin ligase and is critical to ensure a proper brain function. Indeed, perturbations of UBE3A dosage or function result in pathological phenotypes. Loss of UBE3A causes the Angelman Syndrome, a severe neurodevelopmental disorder characterized by intellectual disability, motor delay and seizures, while increased UBE3A copy number or activity are strongly associated with Autism. Importantly, the molecular underpinnings of UBE3A-associated pathogenic mechanisms of neurodevelopmental disorders are still poorly understood. In this project, we study the effects of UBE3A loss (mimicking the genetic alterations of the Angelman syndrome) on the regulation of synaptic development at single cell level in vivo. To this aim, we combine cortex-directed in utero electroporation to inactivate UBE3A in sparse layer 2/3 pyramidal neurons with confocal and super-resolution Stimulated Emission Depletion (STED) microscopy to investigate the consequences of UBE3A loss on the functional organization of excitatory and inhibitory postsynaptic compartments at synaptic and sub-synaptic resolution. As already suggested by other groups, our results indicate that UBE3A critically regulates the formation of excitatory synapses. Strikingly, our data also suggests that UBE3A controls the assembly and the maturation of specific subtypes of inhibitory synapses, namely those located in the perisomatic region and in the axon initial segment. Together, our preliminary results suggest for the first time that the UBE3A gene may be critical to set the number of excitatory and inhibitory synaptic connections at the single-cell level, thus contributing to regulate the ratio between excitation and inhibition through cell-autonomous mechanisms.

Myriocin Effect on Tvrm4 Retina, an Autosomal Dominant Pattern of Retinitis Pigmentosa.
Tvrm4 mice, a model of autosomal dominant retinitis pigmentosa (RP), carry a mutation of Rhodopsin gene that can be activated by brief exposure to very intense light. Here, we test the possibility of an anatomical, metabolic, and functional recovery by delivering to degenerating Tvrm4 animals, Myriocin, an inhibitor of ceramide synthesis previously shown to effectively slow down retinal degeneration in rd10 mutants (Strettoi et al., 2010; Piano et al., 2013). Different routes and durations of Myriocin administration were attempted by using either single intravitreal (i.v.) or long-term, repeated intraperitoneal (i.p.) injections. The retinal function of treated and control animals was tested by ERG recordings. Retinas from ERG-recorded animals were studied histologically to reveal the extent of photoreceptor death. A correlation was observed between Myriocin administration, lowering of retinal ceramides, and preservation of ERG responses in i.v. injected cases. Noticeably, the i.p. treatment with Myriocin decreased the extension of the retinal-degenerating area, preserved the ERG response, and correlated with decreased levels of biochemical indicators of retinal oxidative damage. The results obtained in this study confirm the efficacy of Myriocin in slowing down retinal degeneration in genetic models of RP independently of the underlying mutation responsible for the disease, likely targeting ceramide-dependent, downstream pathways. Alleviation of retinal oxidative stress upon Myriocin treatment suggests that this molecule, or yet unidentified metabolites, act on cellular detoxification systems supporting cell survival. Altogether, the pharmacological approach chosen here meets the necessary pre-requisites for translation into human therapy to slow down RP.

Retinal Phenotype in the rd9 Mutant Mouse, a Model of X-Linked RP.

Retinal degeneration 9 (rd9) mice carry a mutation in the retina specific "Retinitis Pigmentosa GTPase Regulator (RPGR)" Open Reading Frame (ORF) 15 gene, located on the X chromosome and represent a rare model of X-linked Retinitis Pigmentosa (XLRP), a common and severe form of retinal degeneration (Wright et al., 2010; Tsang and Sharma, 2018). The rd9 RPGR-ORF15 mutation in mice causes lack of the protein in photoreceptors and a slow degeneration of these cells with consequent decrease in Outer Nuclear Layer (ONL) thickness and amplitude of ERG responses, as previously described (Thompson et al., 2012). However, relative rates of rod and cone photoreceptor loss, as well as secondary alterations occurring in neuronal and non-neuronal retinal cell types of rd9 mutants remain to be assessed. Aim of this study is to extend phenotype analysis of the rd9 mouse retina focusing on changes occurring in cells directly interacting with photoreceptors. To this purpose, first we estimated rod and cone survival and its degree of intraretinal variation over time; then, we studied the morphology of horizontal and bipolar cells and of the retinal pigment epithelium (RPE), extending our observations to glial cell reactivity. We found that in rd9 retinas rod (but not cone) death is the main cause of decrease in ONL thickness and that degeneration shows a high degree of intraretinal variation. Rod loss drives remodeling in the outer retina, with sprouting of second-order neurons of the rod-pathway and relative sparing of cone pathway elements. Remarkably, despite cone survival, functional defects can be clearly detected in ERG recordings in both scotopic and photopic conditions. Moderate levels of Muller cells and microglial reactivity are sided by striking attenuation of staining for RPE tight junctions, suggesting altered integrity of the outer Blood Retina Barrier (BRB). Because of many features resembling slowly progressing photoreceptor degeneration paradigms or early stages of more aggressive forms of RP, the rd9 mouse model can be considered a rare and useful tool to investigate retinal changes associated to a process of photoreceptor death sustained throughout life and to reveal disease biomarkers (e.g., BRB alterations) of human XLRP.

Rescuing cones and daylight vision in retinitis pigmentosa mice.
Hallmark of retinitis pigmentosa (RP) is the primary, genetic degeneration of rods followed by secondary loss of cones, caused by still elusive biologic mechanisms. We previously shown that exposure of rd10 mutant mice, modeling autosomal recessive RP, to environmental enrichment (EE), with enhanced motor, sensorial and social stimuli, results into a sensible delay of retinal degeneration and vision loss. Searching for effectors of EE-mediated retinal protection, we performed transcriptome analysis of the retina of rd10 enriched and control mice and found that gene expression at the peaks of rod and cone degeneration is characterized by a strong inflammatory/immune response, which is however measurably lower in enrichment conditions. Treating rd10 mice with dexamethasone during the period of maximum photoreceptors death lowered retinal inflammation and caused a preservation of cones and cone-mediated vision. Our findings indicate a link between retinal inflammation and bystander cone degeneration, reinforcing the notion that cone vision in RP can be preserved using anti-inflammatory approaches.-Guadagni, V., Biagioni, M., Novelli, E., Aretini, P., Mazzanti, C. M., Strettoi, E. Rescuing cones and daylight vision in retinitis pigmentosa mice.

Pattern of retinal morphological and functional decay in a light-inducible, rhodopsin mutant mouse.
Hallmarks of Retinitis Pigmentosa (RP), a family of genetic diseases, are a typical rod-cone-degeneration with initial night blindness and loss of peripheral vision, followed by decreased daylight sight and progressive visual acuity loss up to legal blindness. Great heterogeneity in nature and function of mutated genes, variety of mutations for each of them, variability in phenotypic appearance and transmission modality contribute to make RP a still incurable disease. Translational research relies on appropriate animal models mimicking the genetic and phenotypic diversity of the human pathology. Here, we provide a systematic, morphological and functional analysis of Rho/Rho rhodopsin mutant mice, originally described in 2010 and portraying several features of common forms of autosomal dominant RP caused by gain-of-function mutations. These mice undergo photoreceptor degeneration only when exposed briefly to strong, white light and allow controlled timing of induction of rod and cone death, which therefore can be elicited in adult animals, as observed in human RP. The option to control severity and retinal extent of the phenotype by regulating intensity and duration of the inducing light opens possibilities to exploit this model for multiple experimental purposes. Altogether, the unique features of this mutant make it an excellent resource for retinal degeneration research.

Visual impairment in FOXG1-mutated individuals and mice.
The Forkead Box G1 (FOXG1 in humans, Foxg1 in mice) gene encodes for a DNA-binding transcription factor, essential for the development of the telencephalon in mammalian forebrain. Mutations in FOXG1 have been reported to be involved in the onset of Rett Syndrome, for which sequence alterations of MECP2 and CDKL5 are known. While visual alterations are not

classical hallmarks of Rett syndrome, an increasing body of evidence shows visual impairment in patients and in MeCP2 and CDKL5 animal models. Herein we focused on the functional role of FOXG1 in the visual system of animal models (Foxg1(+/Cre) mice) and of a cohort of subjects carrying FOXG1 mutations or deletions. Visual physiology of Foxg1(+/Cre) mice was assessed by visually evoked potentials, which revealed a significant reduction in response amplitude and visual acuity with respect to wild-type littermates. Morphological investigation showed abnormalities in the organization of excitatory/inhibitory circuits in the visual cortex. No alterations were observed in retinal structure. By examining a cohort of FOXG1-mutated individuals with a panel of neuro-ophthalmological assessments, we found that all of them exhibited visual alterations compatible with high-level visual dysfunctions. In conclusion our data show that Foxg1 haploinsufficiency results in an impairment of mouse and human visual cortical function.

EXCESSIVE DENDRITIC INHIBITION IN THE PREFRONTAL CORTEX OF A MOUSE MODEL OF DOWN SYNDROME PERSISTS THROUGHOUT DEVELOPMENT INTO ADULTHOOD

POSTER SESSION 01 - SECTION: PRECLINICAL MODELS OF AUTISM AND NEURODEVELOPMENTAL DISORDERS

Javier Zorrilla De San Martin, Andrea Aguirre, Marie-Claude Potier, Alberto Bacci

Down syndrome (DS) is a condition characterized by various physical and neurological features including mild to severe intellectual disability. Individuals with DS present important deficits in cognitive tasks known to depend on the anatomical and functional integrity of the prefrontal cortex (PFC). Recovery of behavioral and neurophysiological deficits using $GABA_AR$ antagonists in DS mouse models led to hypothesize an excessive activity of inhibitory cortical circuits in this condition. Nonetheless, the rich diversity of inhibitory neurons prompts the question of potential GABAergic circuit-specific alterations in DS. We previously reported that dendritic inhibition, mediated by α5-containing $GABA_ARs$, is enhanced in juvenile (P18-25) Ts65Dn mice, and that parvalbumin-expressing interneurons (PV-INs) exhibit abnormalities of intrinsic excitability leading to the loss of typical fast spiking behavior and precocious firing. Here we show that in adult Ts65Dn mice, PV-INs recovered their excitability deficits. In contrast, α5-mediated dendritic inhibition remains enhanced in adult mice suggesting that over-inhibition of principal neurons' dendrites is a major pathophysiological mechanism in DS that persists throughout development. In order to assess the impact of dendritic over-inhibition on PFC network activity, we implemented *in vivo* electrophysiological recordings using fully integrated, high density Neuropixels probes. Preliminary results suggest that acute treatment with specific α5 negative allosteric modulator (α5IA) drastically enhances neuronal population activity patterns of PFC deep layers, likely enhancing cortical output. Our data indicate dendritic inhibition as a prominent mechanism underlying over-inhibition of cortical circuits in DS mice, and support potential therapeutic strategies based on the modulation of α5-containing $GABA_ARs$.

Mutations in genes coding for synaptic proteins are among the most well-characterized disease-associated elements in individuals with autism spectrum disorders (ASDs). The postsynaptic scaffolding protein SHANK3 is a critical orchestrator of the signaling complex at glutamatergic synapses. Hemi-deletion of SHANK3 occurs in neurodevelopmental disorders characterized by ASD-like behaviors, including intellectual disability. Furthermore, epidemiological studies suggest that pesticides may represent an add-on risk factor for ASD. Here, we examined whether dietary exposure to non-observed adverse effect levels of glyphosate exacerbates the neurological phenotype driven by SHANK3 deletions, revealing the interaction between genome and exposome. We used wild-type, heterozygous or homozygous mice for SHANK3 deleted after exon 21 and compared functional sequel of glyphosate dietary exposure from weaning to adulthood. We analyzed cognitive performances, molecular and cellular modifications related to neurological adaptations. Results showed an increased neuro-inflammation signature with no significant impact on cognition. To further mimic developmental exposure, mice of the three genotypes were continuously exposed to glyphosate, first mothers during gestation and lactation, then pups from weaning until adulthood. We found increased mortality of embryos during the gestation period of WT and heterozygous mice fed with glyphosate. The mortality analysis at the weaning reveals an increase in the mortality rate in heterozygous SHANK3 mice exposed to glyphosate. We are now assessing cognitive performance and neuro-inflammation biomarkers. Our results outline links between environmental risks and genetic factors of ASD, depending on the exposure period.

NMDA receptor (NMDAR) and GABA neuronal dysfunctions are observed in animal models of autism spectrum disorders, but how these dysfunctions impair social cognition and behavior remains unclear. We report here that NMDARs in cortical parvalbumin (Pv)-positive interneurons cooperate with gap junctions to promote high-frequency (>80 Hz) Pv neuronal burst firing and social cognition. *Shank2*$^{-/-}$ mice, displaying improved sociability upon NMDAR activation, show impaired cortical social representation and inhibitory neuronal burst firing. Cortical *Shank2*$^{-/-}$ Pv neurons show decreased NMDAR activity, which suppresses the cooperation between NMDARs and gap junctions (GJs) for normal burst firing. *Shank2*$^{-/-}$ Pv neurons show compensatory increases in GJ activity that are not sufficient for social rescue. However, optogenetic boosting of Pv neuronal bursts, requiring GJs, rescues cortical social cognition in *Shank2*$^{-/-}$ mice, similar to the NMDAR-dependent social rescue. Therefore, NMDARs and gap junctions cooperate to promote cortical Pv neuronal bursts and social cognition.

THE ROLE OF HIPPOCAMPAL VIP-EXPRESSING INTERNEURONS IN THE PATHOPHYSIOLOGY OF TEMPORAL LOBE EPILEPSY

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Sadegh Rahimi, Meinrad Drexel
Medical University of Innsbruck, Department Of Pharmacology, Innsbruck, Austria

In the hippocampus, two groups of VIP-expressing interneurons, containing CCK-expressing basket cells and/or interneuron-selective interneurons (ISIs) control GABAergic transmission and pyramidal cell activity. The aim of the current study is to assess the possible role of VIP-expressing interneurons in the pathophysiology of epilepsy. We permanently inhibited GABA release selectively from VIP interneurons of the ventral subiculum by injecting a viral vector expressing tetanus toxin light chain (TeLC) in male epileptic as well as nonepileptic VIP-cre mice. Mice were then subjected to telemetric EEG recording for 4 weeks. In addition, spontaneous alternation Y-maze and novel location recognition tests were conducted to evaluate spatial memory and learning, respectively. In non-epileptic mice, injection of TeLC and GFP did not cause development of seizures in both groups. In addition, behavioral tests addressing anxiety, memory, and navigation showed no differences between groups. In epileptic animals, the average number of spontaneous seizures per day as well as the average time spent in seizure per day showed a significant reduction in TeLC in comparison to GFP group. Surprisingly, we observed a clear connection between gender and the severity of status epilepticus and the animal's response to vector injection. ISIs mainly target other interneurons; therefore, silencing them would increase inhibition in pyramidal cells. However, the outcome of the silencing of VIP-interneurons in epileptic mice is highly dependent on the status of the network before silencing. To prove, we need further assessment by triple immunohistochemistry labeling for GFP, CCK, and VIP, which is currently ongoing in our lab.

Silencing of Hippocampal Somatostatin Interneurons Induces Recurrent Spontaneous Limbic Seizures in Mice.
The hippocampus proper and the subiculum contain two major populations of somatostatin (SST)-containing interneurons, oriens-lacunosum moleculare (O-LM) cells projecting from the stratum oriens to the stratum lacunosum moleculare and bistratified cells with their cell bodies close to the pyramidal cell layer and axons terminating in the strata radiatum and oriens. Both types of interneurons innervate pyramidal cell dendrites and exert prominent feedback inhibition. We now investigated whether impairing this type of feed-back inhibition by selectively inhibiting GABA release from SST expressing interneurons in hippocampal sector CA1 and subiculum may be sufficient to induce spontaneous recurrent seizures. We injected transgenic mice expressing Cre-recombinase on the SST promoter unilaterally into the ventral CA1 sector and subiculum with an adeno-associated viral (AAV) vector expressing tetanus toxin light chain (TeLC) with its reading frame inverted in a flip-excision (FLEX) cassette. This treatment resulted in specific expression of TeLC and silencing of SST-containing interneurons. We continuously monitored the EEG and behavior of the mice for six weeks. Nine out of eleven mice within 10 days developed series of pre- or interictal spikes (IS, 21.4 ± 6.83 per week) and four mice exposed recurrent spontaneous seizures (SRS, 1.5 ± 0.29 per week). All 23 SRS observed were preceded by IS series. Our data demonstrate a critical role of feed-forward inhibition mediated by SST-containing interneurons suggesting that their sustained malfunctioning can be causatively involved in the development of TLE.

The effect of GABAergic neurotransmission on the seizure-related activity of the laterodorsal thalamic nuclei and the somatosensory cortex in a genetic model of absence epilepsy.
The present study aimed to investigate the alterations of the GABAergic system in the laterodorsal nucleus (LDN) of the thalamus and the somatosensory cortex (SC) in an experimental model of absence seizure. The effects of pharmacological manipulation of both GABA and GABA receptor subunits in the LDN on the generation of spike-wave discharges (SWD) were evaluated. The experiments were carried out in four groups of both WAG/Rij and Wistar rats with 2 and 6 months of age. The expressions of various GABA receptor subunits were studied in the LDN and SC. Furthermore, recordings of unit activity from

the LDN and electrocorticography were simultaneously monitored before, during, and after the application of GABA and GABA antagonists in the LDN. The generation of SWD in the older WAG/Rij rats was associated with significant alterations in the expression of GABARα1, GABARβ3, and GABAR2 subunits in the LDN as well as GABARα1, GABARβ3, GABARγ2, and GABAR2 subunits in the SC. Furthermore, the occurrence of SWD was associated with a significant reduction of gene expression of GABAARα1 and increase of GABAARβ3 in the LDN as well as reduction of GABAARα1, GABAARβ3, GABAARγ2, and GABABR2 in the SC. The microionthophoretic application of the GABA antagonist bicuculline resulted in a significant increase in the population firing rate of LDN neurons as well as the mean number and duration of SWD. The application of the GABA antagonist CGP35348 significantly increased the population firing rate of LDN neurons but decreased the mean number of SWD. Our data indicate the regulatory effect of the GABAergic system of the LDN and SC in absence seizures.

Alteration of the neurogenesis and long term potential of olfactory bulb in an animal model of PTSD.
Failure of extinction of fear-conditioned traumatic memory is the main pathology behind post-traumatic stress disorder (PTSD). Functional and structural dysfunctions in the olfactory system are implicated by studies in PTSD patients. However, little is known regarding the neurobiological networks of trauma-related odor sensitivity in PTSD. Male Wistar rats were exposed with a female cat for 10 min and long-term stress was evaluated by behavioral tests, containing open field (OF) and elevated plus maze (EPM). To prove the PTSD model, the serum level of cortisol was evaluated and compared with the control group. Local field potential (LFP) was applied to compare the electrophysiology of the OB in two groups. To assess neurogenesis, the expression of nestin, and doublecortin were evaluated. Data from EPM revealed a significant increase in spent time in the closed arms in PTSD group. We observed a significant reduction in OF parameters in terms of the total distance traveled, the time spent in the central zone, and the number of crossing the central zone in PTSD group compared to the control group. The mean serum cortisol level was significantly higher in the PTSD group than the control group. In LFP recording, the slope and the amplitude of field excitatory postsynaptic potential (fEPSP) in the PTSD group were significantly higher than that of the control group. Our results also showed that the mRNA expression level of nestin as a neural progenitor marker and doublecortin, as an immature neuron marker, significantly decreased in the PTSD group compared to the control group. This study has shown that PTSD can disrupt the OB function through decreasing neurogenesis. More information on PTSD and OB would help us to establish a greater degree of accuracy on this matter.

The effect of repetitive spreading depression on neuronal damage in juvenile rat brain.
Spreading depression (SD) is pronounced depolarization of neurons and glia that travels slowly across brain tissue followed by massive redistribution of ions between intra- and extracellular compartments. There is a relationship between SD and some neurological disorders. In the present study the effects of repetitive SD on neuronal damage in cortical and subcortical regions of juvenile rat brain were investigated. The animals were anesthetized and the electrodes as well as cannula were implanted over the brain. SD-like event was induced by KCl injection. The brains were removed after 2 or 4 weeks after induction of 2 or 4 SD-like waves (with interval of 1 week), respectively. Normal saline was injected instead of KCl in sham group. For stereological study, paraffin-embedded brains were cut in 5 microm sections. The sections were stained with Toluidine Blue to measure the volume-weighted mean volume of normal neurons and the numerical density of dark neurons. The volume-weighted mean volume of normal neurons in the granular layer of the dentate gyrus and layer V of the temporal cortex in SD group were significantly decreased after four repetitive SD. Furthermore, densities of dark neurons in the granular layer of the dentate gyrus (after 2 weeks), the caudate-putamen, and layer V of the temporal cortex (after 4 weeks) were significantly increased in SD group. Repetitive cortical SD in juvenile rats may cause neuronal damage in cortical and subcortical areas of the brain. This may important in pathophysiology of SD-related neurological disorders.

ROLE OF HIPPOCAMPAL FOCAL RHYTHMIC DISCHARGES (FRDS) IN IMPAIRED SPATIAL WORKING MEMORY IN EPILEPTIC MICE.

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Maryam Pasdarnavab[1], Laura Kück[1], Gergely Tarcsay[2], Fetullah Gerin[1], Laura Ewell[2]
[1]Institute of Experimental Epileptology and Cognition Research, University Of Bonn Medical Center, Bonn, Germany, [2]University of California – Irvine, Department Of Anatomy & Neurobiology, Irvine, United States of America

Memory impairment is a common cognitive deficit in temporal lobe epilepsy (TLE). The hippocampus is severely altered in TLE exhibiting multiple anatomical changes that lead to a hyperexcitable network capable of generating frequent epileptic discharges and seizures. In this study we investigated whether hippocampal involvement in epileptic activity drives working memory deficits. We employed the supra-hippocampal kainic acid (KA) mouse model of TLE. Furthermore, mice experienced frequent focal seizures and less frequent behavioural seizures (stage IV, Racine scale). We observed a working memory deficit in epileptic mice in a delayed-alternation spatial working memory task (Ctrl, 73.54% correct; n = 11; KA ,62.07 % correct, n =13). We further investigated the neural mechanisms of the working memory deficit using bilateral LFP recordings from CA1 during task performance and during long sleep sessions pre and post memory task. We discovered that epileptic mice experienced focal rhythmic discharges (FRDs) while they performed the spatial working memory task (n=1686 on the maze, n=7 mice). Spatial correlation analysis revealed that FRDs were often spatially stable on the maze (7/8 mice and 55/124 sessions) – and were most common around reward zones (25 %) and delay zones (50 %). Preliminary results showed that FRDs shifted to the new reward zones following the change of the reward locations – suggesting that reward-related dynamics such as sharp wave ripple, may drive FRDs. Memory performance was correlated with stability of FRDs ($p \leq .001$, $R=0.56$), suggesting that spatially unstable FRDs interfere with working memory codes in real time.

Epileptogenesis is the neurobiological process by which epilepsy develops. It most often affects a healthy brain and occurs following severe brain damage. One of the key mechanisms underlying this pathological conversion is the subsequent neuroinflammation, mainly supported by microglial cell activation and extravasation of circulating monocytes. Agonists of the cannabinoid receptor type 2 (CB2), massively expressed in vivo by monocytes and presumably by microglia, are known to have potent anti-inflammatory and neuroprotective effects. Here, we evaluated whether GP1a, a CB2-specific ligand administered following pilocarpine-induced *status epilepticus* (Pilo-SE) in 21-old-day male rat pups, counteracted epileptogenesis and underlying inflammatory processes and reduced the severity of cognitive impairments. GP1a was administered at the dose of 3 mg/kg i.p. every other day for 2 weeks, starting 2 hours after SE onset. We provide evidence that the establishment of memory impairments and their underlying cellular mechanisms can be thwarted by GP1a given during the early phase of epileptogenesis. We also show that the development of handling-induced seizures can be delayed and their number lessened by GP1a. Interestingly, these beneficial effects do not appear to be underpinned by a decrease in the inflammatory peak following Pilo-SE. Contrary to what has been previously described in other neuroinflammatory situations, GP1a did not inhibit but rather potentiated the extravasation of monocytes into the brain. Ongoing investigations at the cellular level using flow cytometry will help to determine the phenotype of CB2-expressing cells and their polarization. Overall, our study highlights the promising therapeutic potential of drugs targeting CB2 during epileptogenesis.

EVALUATION OF DENDRITE MORPHOLOGY IN WISTAR AND GENETIC ABSENCE EPILEPTIC (GAERS) RATS

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Sevdenur Yazi[1], Umit S. Sehirli[1], Rezzan Gulhan[2], Filiz Onat[3], Ozlem Kirazli[1]
[1]Marmara University, Department Of Anatomy, School Of Medicine, Istanbul, Turkey, [2]Marmara University, Department Of Medical Pharmacology, School Of Medicine, Istanbul, Turkey, [3]Acıbadem Mehmet Ali Aydınlar University, Department Of Medical Pharmacology, School Of Medicine, Istanbul, Turkey

Aims The aim of the study is to examine the morphological features of dendrites and dendritic spines of pyramidal neurons in somatosensory cortex and hippocampus of Wistar and GAERS (Genetic Absence Epilepsy Rat from Strasbourg) rats. **Methods** GAERS (n=5) and Wistar (n=5) rats were sacrificed by transcardial perfusion method. Brain tissues were stained using the FD Rapid GolgiStain Kit. Coronal sections of 200 µm thickness were obtained with cryostat. Pyramidal neurons in deep layers of the somatosensory cortex and CA1 region of the hippocampus were examined using light microscope and Neurolucida 360 software. Branching and length of apical dendrite and basal dendrites, and types and densities of dendritic spines were analyzed. **Results** Statistically the total number of dendrite nodes (p=0.0053, p=0,0047), the total number of dendrite segments (dendritic arborization) (p=0.0036, p=0,0036), the total number of dendrite terminations (p=0.0033, p=0,0029), the total dendrite length (µm) (p=0.0002, p=0,0007) and the dendritic spine density (1/µm) (p=0.0168, p=0,0120) of the somatosensory cortex and the hippocampus were significantly higher in GAERS rats, respectively. When dendritic spine types were evaluated separately, stubby type dendritic spines in the hippocampus were found to be significantly higher in GAERS rats compared to Wistar rats (p=0.0204). **Conclusions** It was concluded that intense synaptic activation seen in postsynaptic cells in the somatosensory cortex and hippocampus in GAERS causes changes in the dendrite morphology of pyramidal neurons. This study was supported by Marmara University Scientifical Research Projects Commission (TYL-2021-10244). **Keywords** Absence epilepsy, GAERS, dendrite, dendritic spine

Aims: Our aim is to describe the spatio-temporal dynamics of extracellular neuronal activities during the transition to an ictal-like event (ILE), by assessing multiscale electrophysiological data including field potentials (FP), multiunit activity (MUA) and high frequency oscillations (HFO), in human postoperative neocortical slices. **Methods:** Fourty four peritumoral neocortical slices from 27 glioma patients were included in this study. *Ex vivo* extracellular recordings were performed using a 120 contacts MultiElectrode Array, both at a basal state during which spontaneous interictal discharges (IIDs) are generated and during the transition to ILE, induced by bathing slices with a proexcitatory milieu. **Results:** The transition from the interictal basal state to the ILE was characterized by the emergence of PIDs presenting larger and progressively increasing amplitudes, time to peak, rising slopes, decay and frequency, compared to spontaneous IIDs that remained stable. PIDs then presented a temporal evolution with another increase in amplitude, time to peak, rising slope, decay and frequency just before ILE onset. HFO also presented a progressive increase in their power, duration and a temporal shift in their phase coupling with FP. A spatial recruitment was observed, with larger territories recruited over time. **Conclusion**: During the transition to an ILE, neuronal synchronized activities evolve in their temporal and spatial dynamics, suggesting an increased and wider neuronal synchronization. This pattern peaks during the seconds before the ILE, suggesting a maximal network recruitment. Further, HFO's phase-coupling to FP also evolves, reinforcing such dynamical pattern of recruitment and stressing neuronal interaction complexity in seizure generation.

THE UNTOLD IMPLICATION OF MICROGLIA ON THE PROTECTIVE EFFECT OF CANNABIDIOL IN EPILEPSY

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Elisa Landucci, Costanza Mazzantini, Domenico Pellegrini-Giampietro
University of Florence, Department Of Health Sciences, Section Of Clinical Pharmacology And Oncology, Florence, Italy

Cannabinoids (CBs) are implicated in a number of physiological and pathological mechanisms in the central nervous system. Over the past ten years the number of scientific studies demonstrating the efficacy of some of the most abundant non-psychoactive compounds present in Cannabis sativa has massively increased. In particular, cannabidiol (CBD) has been shown to be effective in the treatment of several types of neurological disorders and neurodegenerative diseases. Aims: The present study aimed at exploring the mechanism by which cannabidiol reduces neuronal damage induces by kainite in organotypic hippocampal slices, an *in vitro* model of epilepsy. Methods: Rat organotypic hippocampal slices were exposed to 5 µM kainic acid for 24 hours in presence or absence of cannabinoids. The cell death in the CA3 subregion of slices was quantified by propidium iodide fluorescence. Microglia activation and polarization was evaluated using Flow Cytometry and Morphology Analysis. Results: When present in the incubation medium, cannabidiol and natural compounds reduced CA3 injury induced by kainic acid. Conversely, incubation with Delta-9-tetrahydrocannabinol (Delta-9-THC) exacerbated hippocampal damage. The neuroprotective effects of cannabidiol was blocked by TRPV1, TRPV2, 5-HT1A, and PPARγ antagonists. Cannabidiol incubation significantly reverse microglia activation and transition from the M2 to M1 phenotype observed in epileptic model. Conclusions: Our study suggests that cannabidiol mitigate neuronal death by inhibiting microglial activation and promoting transformation from an M1 to an M2 phenotype.

New treatments of epilepsy are required since almost 30% of the millions of epileptic patients suffer from a drug-resistant form of it. One possible approach is the local heating of brain tissue, as it has been shown to influence the general network excitability and influence the frequency of neural oscillations. This project aims to reveal the influence of local temperature increase on generalized tonic-clonic epileptic seizures. We used a recently developed optogenetic epilepsy model, in which we can reliably induce tonic-clonic seizures by rhythmic stimulation of channelrhodopsin expressing layer 6 corticothalamic cells of NTSR1 double transgenic mice. Generalized tonic-clonic seizures were provoked by 447 nm blue light stimulation of corticothalamic pathway, under freely moving conditions. The local field potential of epileptiform activity was recorded from the cortex and from the hippocampus. Local heating was induced by 1550 nm infrared stimulation applied at the site of epileptogenesis. Each day only one seizure was evoked from each animal, alternating the heating and non-heating epochs. Local heating of the site of epileptogenesis was unable to inhibit the development of the epileptiform activity, however, it was able to change the pattern of seizure events. A significant decrease in the duration and so far, a non-significant decrease in the prevalence of seizures were found in the heated sessions of seizure induction. The power of spectral components also showed a prominent rearrangement due to the rise of local temperature, but there was no change in spreading patterns or latencies of synchronized activity among distant cortical regions.

GENETIC SUSCEPTIBILITY TO ACQUIRED EPILEPSY AFFECTS SEIZURE PROGRESSION AFTER AMYGDALA KINDLING: VALIDATION OF THE FAST AND SLOW RAT MODELS

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Wai Lam Leung[1], Crystal Li[1], Piero Perucca[1,2,3,4,5], Terence O'Brien[1,2,5,6], Bridgette Semple[1,2,6], Pablo Casillas-Espinosa[1,2,6]

Introduction: Animal models are valuable tools to study how genetic predisposition influences acquired epileptogenesis. Previously, Racine and colleagues (1999) have developed selectively-bred rat strains with different susceptibility to evoked seizures using the amygdala kindling model, designated as FAST (seizure-prone) or SLOW (seizure-resistant). **Aims:** To validate the phenotypes of our current FAST & SLOW rat colony to experimental amygdala kindling, and to evaluate the seizure susceptibility of their F2 generation progeny. **Methods:** A stimulating bipolar electrode was inserted into the left amygdala of 11-week-old male rats—FAST (n= 10), SLOW (n= 14) and their F2 generation (n= 68). One week post-surgery, the after-discharge threshold to generate an electrographic seizure of >5 sec was determined. Rats then either received a maximum of 30 kindling stimulations (2/day, 5 days/week) or until 5 class V seizures were observed (i.e., fully kindled). **Results:** FAST rats required fewer stimulations to fully kindle compared to SLOW rats ($p < 0.001$), with all animals fully kindled within 30 stimulations. The F2 generation required fewer stimulations to fully kindle compared to SLOW rats ($p < 0.01$) but were comparable to FAST rats. Total seizure duration was also significantly shorter for SLOW rats compared to FAST and F2 rats for the first 12-15 stimulations. **Conclusion:** Differences in kindling profiles between FAST, SLOW rats and their F2 generation suggest that differences in susceptibility to acquired epileptogenesis are genetically inherited. This finding supports further investigation of candidate genes and proteins in this model which may explain inherent susceptibility to acquired epilepsy in humans.

An animal model of genetic predisposition to develop acquired epileptogenesis: The FAST and SLOW rats.
Epidemiological data and gene association studies suggest a genetic predisposition to developing epilepsy after an acquired brain insult, such as traumatic brain injury. An improved understanding of genetic determinants of vulnerability is imperative for early disease diagnosis and prognosis prediction, with flow-on benefits for the development of targeted antiepileptogenic treatments as well as optimal clinical trial design. In the laboratory, one approach to investigate why some individuals are more vulnerable to acquired epilepsy than others is to examine unique rodent models exhibiting either vulnerability or resistance to epileptogenesis. This review focuses on the most well-characterized of these models, the FAST (seizure-prone) and SLOW (seizure-resistant) rat strains, which were derived by selective breeding for differential amygdala electrical kindling rates. We describe how these strains differ in their seizure profiles, neuroanatomy, and neurobehavioral phenotypes, both at baseline and after a brain insult, with this knowledge proving fruitful to identify common pathological abnormalities associated with seizure susceptibility and psychiatric comorbidities. It is important to note that accruing data on strain differences in multiple biological processes provides insight into why some individuals may be more vulnerable to epileptogenesis, although future studies are evidently needed to identify the precise molecular and genetic risk factors. Together, the FAST and SLOW rat strains, and other similar experimental models, are invaluable neurobiological tools to investigate the effect of genetic background on acquired epilepsy risk, as well as the poorly understood relationship between epilepsy development and associated comorbidities.

Neuroinflammation in Post-Traumatic Epilepsy: Pathophysiology and Tractable Therapeutic Targets.
Epilepsy is a common chronic consequence of traumatic brain injury (TBI), contributing to increased morbidity and mortality for survivors. As post-traumatic epilepsy (PTE) is drug-resistant in at least one-third of patients, there is a clear need for novel

therapeutic strategies to prevent epilepsy from developing after TBI, or to mitigate its severity. It has long been recognized that seizure activity is associated with a local immune response, characterized by the activation of microglia and astrocytes and the release of a plethora of pro-inflammatory cytokines and chemokines. More recently, increasing evidence also supports a causal role for neuroinflammation in seizure induction and propagation, acting both directly and indirectly on neurons to promote regional hyperexcitability. In this narrative review, we focus on key aspects of the neuroinflammatory response that have been implicated in epilepsy, with a particular focus on PTE. The contributions of glial cells, blood-derived leukocytes, and the blood-brain barrier will be explored, as well as pro- and anti-inflammatory mediators. While the neuroinflammatory response to TBI appears to be largely pro-epileptogenic, further research is needed to clearly demonstrate causal relationships. This research has the potential to unveil new drug targets for PTE, and identify immune-based biomarkers for improved epilepsy prediction.

CHARACTERIZATION OF THE ANTIAPOPTOTIC AND NEUROPROTECTIVE EFFECT OF DAPSONE IN A MODEL OF STATUS EPILEPTICUS INDUCED WITH KAINIC ACID IN RATS

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Amairani Ruiz-Díaz[1], Araceli Diaz-Ruiz[2], Marcela Islas-Cortez[3], Camilo Ríos[4]
[1]Universidad Autónoma Metropolitana, Doctorado En Ciencias Biológicas Y De La Salud, Ciudad de México, Mexico, [2]Instituto Nacional de Neurología y Neurocirugía, Neuroquímica, Ciudad de México, Mexico, [3]Instituto Politécnico Nacional, Fisiología, Ciudad de México, Mexico, [4]Universidad Autonoma Metropolitana-Xochimilco, Sistemas Biologicos Laboratorio De Neurofarmacologia Molecular, Ciudad de México, Mexico

Status epilepticus (SE) is a serious condition with long-term consequences, including neuronal death. The main pathophysiological mechanism of damage is excitotoxicity, a mechanism characterized by an increased excitatory neurotransmission by glutamate causing neuronal damage. Dapsone (DDS), is a drug currently in use for leprosy, however, its anticonvulsant effects have been reported, both in models and human patients. The objective of this study was to characterize the anticonvulsant, antiapoptotic and neuroprotective effects of dapsone (DDS) treatment in a model of SE induced by kainic acid (KA). Methods: SE was induced in Wistar male rats (250 to 280 g), using KA (5 mg/kg, ip). If a rat approached the SE, half doses (2.5 mg/Kg) were administered at intervals of 1 h, until behavioral SE. 25 h after KA administration, caspases 8 and 3 activities were measured, while degenerated neurons in the hippocampus were counted, using Fluoro Jade-B staining. Results: Activities of caspases 8 and 3 were increased by KA, as compared to the control group. This effect was decreased by DDS doses of 12.5 and 25 mg/kg, showing its ability to inhibit apoptosis markers. (*$p<0.05$). A lower number of degenerated neurons in the hippocampus was also observed, by effect of DDS at both doses employed. Conclusions: The results demonstrate a relevant therapeutic potential of DDS since, currently, most of the drugs prescribed in patients with epilepsy are anticonvulsants, but not neuroprotective. Given its safety, therapeutic success, antiapoptotic and neuroprotective actions, DDS is an excellent candidate for the treatment of patients with SE.

Expression of nuclear factor-erythroid 2-related factor 2 in rat brain following the administration of kainic acid and pentylenetetrazole.
Epilepsy is a neurological disorder of the central nervous system characterized by hypersynchronized neuronal activity and has been associated with oxidative stress. Oxidative stress interferes with the expression of genes as well as transcriptional factors such as nuclear factor-erythroid 2-related factor 2 (Nrf2). We evaluated the expression of Nrf2 in the rat brain in treated with kainic acid (KA) and pentylenetetrazole (PTZ). Nrf2 immunoreactivity was observed in astrocytes of the hippocampal region in rats exposed at KA. Nrf2 expression was increased significantly in rats with KA and PTZ. These results provide evidence that the increased expression of Nrf2 is part of the mechanism against KA and PTZ toxicity.

Immunohistochemical Study of Antioxidant Enzymes Regulated by Nrf2 in the Models of Epileptic Seizures (KA and PTZ).
Epilepsy is a neurological disorder characterized by recurrent spontaneous seizures due to an imbalance between cerebral excitability and inhibition, with a tendency towards uncontrolled excitability. Epilepsy has been associated with oxidative and nitrosative stress due to prolonged neuronal hyperexcitation and loss neurons during seizures. The experimental animal models report level of ATP diminished and increase in lipid peroxidation, catalase, and glutathione altered activity in the brain. We studied the immunohistochemical expression and localization of antioxidant enzymes GPx, SOD, and CAT in the rat brains treated with KA and PTZ. A significant decrease was observed in the number of immunoreactive cells to GPx, without significant changes for SOD and CAT in KA-treated rats, and decrease in the number of immunoreactive cells to SOD, without significant changes for GPx and only CAT in PTZ-treated rats. Evident immunoreactivity of GPx, SOD, and CAT was observed mainly in astrocytes and neurons of the hippocampal brain region in rats exposed at KA; similar results were observed in rats treated with PTZ at the first hours. These results provide evidence supporting the role of activation of the

Nrf2 antioxidant system pathway against oxidative stress effects in the experimental models of epileptic seizures.

Efficacy of dapsone administered alone or in combination with diazepam to inhibit status epilepticus in rats.
Status epilepticus (SE) is a serious medical condition, as it may trigger epileptogenesis. SE produces continuous generalized seizures resulting in irreversible brain damage. Therefore, the use of neuroprotective agents to prevent cell damage, may reduce the impact of SE. The use of diazepam (DZP), has shown limited neuroprotective effect in SE patients. According to previous reports, dapsone (DDS) is able to reduce both cell damage and seizures, when administered 30 min before the onset of seizures. This study is aimed to evaluate the ability of DDS, alone or in combination with DZP starting their administration once the SE is onset to evaluate the control of seizures in rats. Results showed a reduced convulsive electrical activity after 30 min, 1 and 2 h after SE induced by kainic acid (KA) administration, in the animals treated with DZP alone or in combination with DDS. At 24 h, we observed electrical activity similar to baseline in all groups receiving treatment. The animals treated with DDS and DZP alone or in combination showed an increase in the number of viable pyramidal cells but only the combination showed a lower number of damaged pyramidal neurons of hippocampal CA3. In conclusion, DDS plus DZP was able to control SE and to prevent SE-induced damage, when administered in combination with DZP. As DDS is already in use for patients with leprosy, that combination may be a safe, good option for human cases of SE.

THE ROLE OF ENKEPHALIN IN HYPOXIC PRECONDITIONING

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Lisa Bergmeister[1], Christoph Schwarzer[1], Carolina Doerrier[2], Erich Gnaiger[2,3]
[1]Medical University of Innsbruck, Department Of Pharmacology, Innsbruck, Austria, [2]Oroboros, Instruments, Innsbruck, Austria, [3]Medical University of Innsbruck, D. Swarovski Research Laboratory, Department Of Visceral, Transplant And Thoracic Surgery, Innsbruck, Austria

Background: Hypoxic preconditioning (HPC) is the application of mild transient hypoxia which protects the brain against a following more severe hypoxic insult as it occurs during epileptic seizures. HPC decreases seizure susceptibility and severity as well as neuronal damage in the hippocampus. The delta opioid receptor (DOR) and its primary endogenous ligands, the neuropeptides met- and leu-enkephalin (Enk), are thought to be involved in the neuroprotective actions of HPC. Recently, we showed that Enk influences mitochondrial respiration that may contribute to the neuroprotective effects of the Enk/DOR system. The present study aims at investigating the effects of the Enk/DOR system on structural and functional alterations of mitochondria in HPC. Methods: Wild type (WT) and met-Enk-knockout (met-Enk-KO) mice were exposed to hypoxia. Subsequently, we determined the seizure threshold, analyzed mitochondrial function and dynamics. Results: In WT mice after HPC we observed an elevated seizure threshold, improved mitochondrial reserve capacity and increased mitochondrial fusion. In addition, our results suggest mitochondrial biogenesis after HPC in WT mice. Naïve met-Enk-KO mice had an increased seizure threshold and increased mitochondrial fusion but no changes upon HPC. Conclusion: The observed mitochondrial alterations after HPC in WT mice could explain improved neuronal survival and increased seizure threshold. Enhanced mitochondrial reserve capacity improves energy supply in stress situations and increased mitochondrial fusion is associated with neuronal survival and elevated Ca^{2+} storage capacities. However, the precise role of met-Enk in HPC is unclear but we observed adaptive mechanisms in WT mice upon hypoxia which are absent in met-Enk-KO mice.

Background and aims: Thermal-based neuromodulation of neural activity could be achieved depending on thermal-induced changes in the transmembrane capacitance and non-uniform changes in the functionality of the ionic channels. Infrared neuromodulation (INM) is a promising neuromodulation tool relying on the use of pulsed or continuous-wave near-infrared (NIR) laser light (of wavelength range between 1400 and 2100 nm) to induce heat within the neural tissue and modulate the neuronal activity. This research aims to study the impact of infrared-based heat irradiation on the morphological shape and propagation of interictal spikes using penicillin-induced epileptic rat model. **Methods**: This study consists of recording the ECoG signals, pre-processing, inter-ictal spikes detection and classification, and finally, studying the relation between interictal spikes types and features during different frequencies of infrared light. Optrode device is used to induce heat irradiation within the neocortex and multi-modal micro-probe is used to record the cerebral cortex activities of anesthetized rats. The detected interictal spikes are classified into two main categories: (1) Blunt, Double, and Triple (2) Biphasic and Sharp spikes. On other hand, the extracted features of those spikes are tracked in real-time to investigate more the real impact of thermal-based neuromodulation on the morphological shape and inducing rate of interictal spikes. **Results and conclusions**: The results show legible mitigation in the induced interictal spikes during neuromodulation phases compared with baseline (pure epilepsy case), and lower synchrony of firing neuronal networks in the focal epilepsy area. The results provide also a comprehensive insight into the neocortex activities during neuromodulation.

GABAERGIC MODULATION OF CORTICAL EXCITABILITY AND RESILIENCE TO SEIZURES

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Gregory Lepeu, Kristina Slabeva, Antoine Adamantidis, Maxime Baud
University of Bern, Center For Experimental Neurology, Dept Of Neurology, Bern, Switzerland

Background: The limbic circuit is particularly prone to seizures, even in non-epileptic brains. Short stimulation of the entorhinal cortex can evoke self-terminating responses of varying magnitude in the hippocampus. Beyond the circuit's resilience (its capacity to absorb perturbation), more sustained stimulation can result in self-sustained seizures. How the limbic circuit transitions between these regimes is unknown. **Aim:** To quantify GABAergic modulation of excitability and resilience in the limbic system in healthy mice. **Methods:** We compared states of relatively low and high cortical excitability in freely-moving mice by administering a control vehicle (NaCl) intraperitoneally or low doses of GABAergic agonist (Diazepam (DZ)) or antagonist (Pentylenetetrazol (PTZ) or Picrotoxin (PTX)), respectively. To probe excitability, we stimulated pyramidal cells in the entorhinal cortex, using optogenetics single-pulses and measured evoked responses in the hippocampus. To probe resilience of this circuit, we administered trains of stimulation of increasing duration until a seizure was triggered. **Results:** We found that the magnitude of evoked hippocampal responses was reduced by 29.3% [95%CI, 27.6-31.2] with DZ and increased with PTZ (5.1% [3.0-7.1]) or PTX (9.3% [7.1-11.3]). Additionally, the amount of stimulation needed to induce seizures increased by 78.1% [54.5-113.0] with DZ and decreased by 19.6% [3.0-10.8] and 10.6% [-4.0-18.5] with PTZ or PTX, respectively, corroborating the changes observed in cortical excitability. **Conclusion:** We provide experimental evidence *in vivo* for a direct relevance of using minute perturbations of ongoing activity as markers of cortical excitability and show their correlation with resilience to epileptic seizures.

Alterations in brain-derived neurotrophic factor (BDNF) and its TrkB- FL receptor have been suggested to contribute to epilepsy. Under excitotoxic conditions, TrkB-FL receptor is cleaved, forming an intracellular fragment (TrkB-ICD). In an *in vitro* model of *status epilepticus* (SE) a putative TrkB-FL cleavage was also suggested. Therefore, we studied whether the TrkB-FL cleavage occurs in an *in vivo* model of SE and chronic epilepsy and if it is related with seizure severity, neurogenesis and memory. A rat model of epilepsy was induced with kainate (KA, intraperitoneal) and two groups were obtained: SE group; and chronic group. Seizure severity was classified using the modified Racine's Scale. In the SE group, animals with the highest seizure score showed a significant decrease of TrkB-FL protein levels and increased levels in TrkB-ICD/TrkB-FL ratio. Moreover, a positive significant effect of TrkB-ICD levels on the number of seizures was observed, suggesting that animals with more seizures have higher levels of TrkB-ICD. Nevertheless, no differences were found in $Ki67^+$ proliferative cells comparing with saline-treated animals. Regarding the chronic group, although no evidence of TrkB-FL cleavage was observed, a positive significant effect of proliferative $Ki67^+$ cells in the number of spontaneous seizures per hour was found. Also, a preliminary novel object location test revealed a loss of preference for the displaced object in the epileptic animals, indicating memory impairment. Taken together, our results suggest that TrkB-FL is cleaved in an *in vivo* KA-induced epilepsy model, a mechanism that appears to occur during *SE*, affecting later neurogenesis and memory.

Neural Stem Cells and Cannabinoids in the Spotlight as Potential Therapy for Epilepsy.
Epilepsy is one of the most common brain diseases worldwide, having a huge burden in society. The main hallmark of epilepsy is the occurrence of spontaneous recurrent seizures, having a tremendous impact on the lives of the patients and of their relatives. Currently, the therapeutic strategies are mostly based on the use of antiepileptic drugs, and because several types of epilepsies are of unknown origin, a high percentage of patients are resistant to the available pharmacotherapy, continuing to experience seizures overtime. Therefore, the search for new drugs and therapeutic targets is highly important. One key aspect to be targeted is the aberrant adult hippocampal neurogenesis (AHN) derived from Neural Stem Cells (NSCs). Indeed, targeting seizure-induced AHN may reduce recurrent seizures and shed some light on the mechanisms of disease. The endocannabinoid system is a known modulator of AHN, and due to the known endogenous antiepileptic properties, it is an interesting candidate for the generation of new antiepileptic drugs. However, further studies and clinical trials are required to investigate the putative mechanisms by which cannabinoids can be used to treat epilepsy. In this manuscript, we will review how cannabinoid-induced modulation of NSCs may promote neural plasticity and whether these drugs can be used as putative antiepileptic treatment.

Challenges of BDNF-based therapies: From common to rare diseases.
Neurotrophins are a well-known family of neurotrophic factors that play an important role both in the central and peripheral nervous systems, where they modulate neuronal survival, development, function and plasticity. Brain-derived neurotrophic factor (BDNF) possesses diverse biological functions which are mediated by the activation of two main classes of receptors, the tropomyosin-related kinase (Trk) B and the p75 neurotrophin receptor (p75). The therapeutic potential of BDNF has

drawn attention since dysregulation of its signalling cascades has been suggested to underlie the pathogenesis of both common and rare diseases. Multiple strategies targeting this neurotrophin have been tested; most have found obstacles that ultimately hampered their effectiveness. This review focuses on the involvement of BDNF and its receptors in the pathophysiology of Alzheimer's disease (AD), Amyotrophic Lateral Sclerosis (ALS) and Rett Syndrome (RTT). We describe the known mechanisms leading to the impairment of BDNF/TrkB signalling in these disorders. Such mechanistic insight highlights how BDNF signalling compromise can take various shapes, nearly disease-specific. Therefore, BDNF-based therapeutic strategies must be specifically tailored and are more likely to succeed if a combination of resources is employed.

INFLUENCE OF ADRENOAGONIST CLONIDINE AND ADRENOBLOCKER PROPRANOLOL ON NEOCORTICAL AND HIPPOCAMPAL EPILEPTIFORM DISCHARGES

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Eteri Saralidze[1], Irma Diasamidze[1], Lia Khuchua[2]
[1]Batumi Shota Rustaveli State University, Biology, Batumi, Georgia, [2]Ivane javakhishvili State university, Biology, tbilisi, Georgia

The goal of the work was investigation of clonidine and propranolol influences on the neocortical and hipocampal epileptiform discharges.
Materials and Methods.
In vivo experiments were carried out on chronic Wistar rats. Under ketalar anesthesia Stimulating (bipolar) and recording (unipolar) electrodes were implanted in the neocortex and dorsal hippocampus (DH) according to stereotaxic coordinates by Paxinos and Watson atlas.epileptiform discharges (EDs) were evoked with electrical stimulation (30Hz) either of neocortex or dorsal hippocampus. Intraperitoneal injection of clonidine, β-adrenoreceptor stimulant (1mg/kg) and propranolol β-adrenoblocker (0,5mg/kg) was performed after establishing a minimal threshold stimulation sufficient for elicitation stable epileptiform discharges either in neocortex or in hippocampus. The brain electrical activity was recorded with electroencephalograph.
Results.
Propranolol injection decreased epileptiform discharges elicited by cortical stimulation, while hippocampally-induced discharges, after propranolol injection – increased. propranolol injection deacreased epileptogenic threshold of hippocampus and increased of neocortex.This result may be due to suppressed inhibitory capacity of β-adrenoreceptors. Influence of clonidine injection was just an opposite to that of clonidine – cortically-induced Epileptiform discharges increased, while the hippocampally-induced ones- decreased.clonidine injection decreased epileptogenic threshold of neocortex and increased epileptogenic threshold of hippocampus.

CIRCADIAN TIMING OF LIMBIC SEIZURES IN THE EPILEPTIC MOUSE

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Kristina Slabeva, Antoine Adamantidis, Maxime Baud
University of Bern, Center For Experimental Neurology, Dept Of Neurology, Bern, Switzerland

Aims: In epilepsy, seizures often display circadian clustering. This clustering may result from recent active-rest states (so-called process S) and/or from the circadian rhythm (so-called process C). The aim of this study is to disentangle the individual contributions of process S and C to seizure timing in the Kainic Acid mouse model of temporal lobe epilepsy. **Methods:** We recorded spontaneous seizures in epileptic mice (n=9) over months. These animals were kept in a 12:12 light-dark cycling environment (LD), before subjecting them to different experimental schedules: 1) constant dim red light (DD), 2) constant light (LL), 3) 10:10 light-dark cycling (T20). We identified the underlying circadian and active-rest cycle based on core body temperature (CBT) and actimetry, respectively, and extracted the preferred phase at which seizures occurred. **Results:** We observed a circadian clustering of seizures between the peak and the falling phase of 24-hour activity in LD (PLV= 0.29+/-0.18). While the circadian clustering persisted at the same phase during DD (PLV= 0.27+/-0.01) it was attenuated in LL (PLV= 0.16+/-0.07), when the strength of the underlying circadian cycle was also weakened. Under T20, we observed a periodic uncoupling of the active rest cycle and CBT cycle (about every third day). The clustering of seizures was higher during the period when both cycles were aligned (PLV= 0.54+/-0.14) and lower when they were misaligned (PLV= 0.32+/-0.13). **Conclusions:** The temporal clustering of seizures depends on the strength and alignment of Process S and Process C, which may help guide chronotherapeutic interventions in the future.

HARNESSING NEUROGLIAFORM INTERNEURONS TO CONTROL CORTICAL SEIZURES IN AWAKE MICE

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Marion Mercier, Amy Richardson, Yoshiteru Shimoda, Andreas Lieb, Dimitri Kullmann, Vincent Magloire
University College London, Ucl Queen Square Institute Of Neurology, London, United Kingdom

Focal seizures are widely considered to arise from a disturbance of the excitation/inhibition balance, and in particular a failure of the GABAergic inhibitory system. Recent work focusing on parvalbumin-positive and somatostatin-positive interneurons has shown that inhibition mediated by these populations is too weak to suppress seizures effectively. In contrast, neurogliaform (NGF) cells, if appropriately recruited, could be much more effective, due to their high density of GABA release sites and signalling via “volume transmission”. *Here, we therefore investigate the role of NGF cells in seizure generation and maintenance*. For this, we use a mouse line (Ndnf-Cre) that enables targeting of NGF cells and a combination of calcium imaging, electrocorticography and closed-loop optogenetic stimulation in models of acute, focal cortical epilepsy. *In vivo* calcium imaging revealed that Ndnf+ NGF cells are recruited during interictal activity. We also observed a delayed activation of these cells after the onset of ictal discharges. These findings suggests that Ndnf+ NGF neurons are involved in seizure activity but whether they promote or prevent the spread of overexcitation remains unknown. To answer this question, we are using optogenetic activation of NGF cells together with local chemoconvulsant application. Our preliminary data indicate a 30% reduction in interictal spikes during Ndnf+ cell photo-activation and indicate a ~50% reduction in seizure duration during light stimulation. Together, this is the first evidence that Ndnf+ cell photo-activation can have strong anti-epileptic effects. We are currently testing whether a general increase of Ndnf+ NGF neuron excitability using chemogenetics can prevent seizure initiation.

ROLE OF CA++-PERMEABLE AMPA RECEPTORS IN INTERNEURONS AND PYRAMIDAL CELLS IN SEIZURE ONSET AND PROPAGATION IN HUMAN NEOCORTEX.

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Alice Podestà[1], Martin Holtkamp[1], Jörg Geiger[2], Pawel Fidzinski[1]
[1]Charité - Universitätsmedizin Berlin, Experimental Neurology, Berlin, Germany, [2]Charité - Universitätsmedizin Berlin, Institute Of Neurophysiology, Berlin, Germany

AMPA receptors play a major role in excitatory signalling in neocortex. Within the plethora of AMPA receptor compositions, GluR2 subunit lacking receptors are of particular importance as they mediate calcium ion permeability. GluR2 lacking AMPA receptors are expressed both in pyramidal cells and interneurons. Their role in the synchronization of neuronal activity in neocortex, specifically their contribution to inhibition/excitation balance and imbalance during seizures is not known. By using human brain slices derived from surgical resections, we aimed to investigate the role of calcium permeable AMPA receptors in the onset, maintenance and propagation of seizure like events using specific blockers such as 1-naphthyl acetyl spermine (NASPM) and IEM-1460. We found that in an acute in vitro seizure model using 0 Mg and bicuculline (10 µM), the application of NASPM (100 µM) leads to the complete block of ictal activity, while IEM-1460 (100-150 µM) changes the shape and duration of seizure like events but does completely block ictal activity. Since in the 0 Mg/bicuculline model the activity of interneurons is blocked, we hypothesize that the block of calcium permeable AMPA receptors in pyramidal cells is sufficient to block ictal activity in this specific model. Next, we aim to apply other models in which interneurons are not blocked and to engage single cell recordings to investigate the interplay between inhibitory and excitatory signalling during ictal activity and the involvement of calcium permeable AMPA receptors in human tissue in more detail

Hydrogenated Graphene Improves Neuronal Network Maturation and Excitatory Transmission.
Graphene is regarded as a viable bio-interface for neuroscience due to its biocompatibility and electrical conductivity, which would contribute to efficient neuronal network signaling. Here, monolayer graphene grown via chemical vapor deposition is treated with remote hydrogen plasma to demonstrate that hydrogenated graphene (HGr) fosters improved cell-to-cell communication with respect to pristine graphene in primary cortical neurons. When transferred to polyethylene terephthalate, HGr exhibits higher wettability than graphene (water contact angle of 83.7° vs 40.7°), while preserving electrical conductivity (≈3 kΩ □). A rich and mature network is observed to develop onto HGr. The intrinsic excitability and firing properties of neurons plated onto HGr appears unaltered, while the basic passive and active membrane properties are fully preserved. The formation of excitatory synaptic connections increases in HGr with respect to pristine graphene, leading to a doubled miniature excitatory postsynaptic current frequency. This study supports the use of hydrogenation for tailoring graphene into an improved neuronal interface, indicating that wettability, more than electrical conductivity, is the key parameter to be controlled. The use of HGr can bring about a deeper understanding of neuronal behavior on artificial bio-interfaces and provide new insight for graphene-based biomedical applications.

DAPSONE PREVENTS HYPERMETABOLIC EFFECT OF KAINIC ACID IN RATS: AN 18FDG-PET STUDY

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Camilo Ríos[1], Araceli Diaz-Ruiz[2], Arturo Avendaño-Estrada[3], Miguel Angel Avila-Rodriguez[3], Joaquin Manjarrez-Marmolejo[4], Javier Franco-Perez[4], Iñigo Aguirre-Aranda[2], Veronica Baron-Flores[1]
[1]Universidad Autonoma Metropolitana-Xochimilco, Sistemas Biologicos Laboratorio De Neurofarmacologia Molecular, Ciudad de México, Mexico, [2]Instituto Nacional de Neurologia y Neurocirugia, Neuroquimica, Mexico City, Mexico, [3]Facultad de Medicina, Universidad Nacional Autónoma de Mexico, Unidad Radiofarmacia-ciclotron, Mexico City, Mexico, [4]Instituto Nacional de Neurologia y Neurocirugia, Formacion Reticular, Mexico City, Mexico

It is known that approximately 30% of epilepsy cases are drug-resistant, thus, there is a need to develop safe and effective therapies. On the other hand, dapsone (DDS) is a drug used to treat leprosy, with anticonvulsant effects. The aim of this work is to employ a ^{18}FDG-PET study to characterize its anticonvulsant effect in rats. Methods: Male Wistar rats (250 to 280 g) were used. They received a single dose of 10 mg/Kg of kainic acid (KA), as a model of temporal lobe epilepsy. Prior to KA administration, ^{18}FDG-PET studies were performed as basal activity. Electroencephalography (EEG) was also recorded. DDS or vehicle were administered 30 min before KA, while ^{18}FDG uptake and brain EEG activity were evaluated at 2 and 25 h. Results: The PET study showed increased ^{18}FDG uptake in the KA plus vehicle group during the ictal stage, which was decreased by DDS treatment at 2 h. At 25 h after KA, a decreased ^{18}FDG uptake was observed as compared to KA group. ^{18}FDG uptake values increased to basal levels by DDS. EEG study showed an increased activity 2 h after KA administration, which is reversed by effect of DDS, that correlates with changes in ^{18}FDG-PET uptake. (* $p<0.05$). The results of this study demonstrate the therapeutic potential of DDS since, currently, most of the drugs prescribed in patients with epilepsy are anticonvulsants, but not neuroprotective. Given its safety, therapeutic success and neuroprotective effect, DDS may be an excellent candidate to treat epilepsy patients.

IMPAIRED DENTATE GYRUS PATTERN SEPARATION AND MNEMONIC DISCRIMINATION IN TEMPORAL LOBE EPILEPSY

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Antoine Madar[1], Jesse Pfammatter[2], Jessica Bordenave[3], Erin Plumley[3], Swetha Ravi[2], Michael Cowie[2], Eli Wallace[2], Bruce Hermann[3], Rama Maganti[3], Mathew Jones[2]
[1]University of Chicago, Neurobiology, Chicago, United States of America, [2]University of Wisconsin-Madison, Neuroscience, Madison, United States of America, [3]University of Wisconsin-Madison, Neurology, Madison, United States of America

In temporal lobe epilepsy (TLE), the ability of the dentate gyrus (DG) to limit excitatory cortical input to the hippocampus breaks down, leading to seizures. DG is also thought to help discriminate between similar memories by performing pattern separation, but whether epilepsy leads to a breakdown in this neural computation, and thus to mnemonic discrimination impairments, remains unclear[1]. First, using the DG-dependent Mnemonic Similarity Task, we found that mnemonic discrimination is specifically impaired in patients with TLE. In mice too, TLE (low-dose systemic kainate model) leads to discrimination impairments on an object-location novelty-preference task. Using our patch-clamp assay in brain slices of the same mice, we measured different forms of pattern separation (PS): On average, the epileptogenic treatment caused a PS deficit. Interestingly, only a subset of granule cells from TLE mice had pathologically low levels of PS, with normal and abnormal neurons coexisting. Low PS was explained by high firing rates and abnormal bursting, likely due to decreased inhibition. Finally, cross-referencing EEG, behavior and patch-clamp records of the same mice revealed that PS levels correlate with individual mnemonic discrimination abilities, thus supporting a long-hypothesized tenet of episodic memory theories. This analysis also suggests that memory deficits and abnormal PS can develop before traditional EEG signs of epilepsy. Overall, our results could help design new diagnostic tests and point to a biological mechanism of early memory problems in people later diagnosed with TLE. [1]Madar et al. Deficits in behavioral and neuronal pattern separation in temporal lobe epilepsy. J. Neurosci. (2021)41:9669-9686

BEHAVIORAL, CANNABINOID CB1 RECEPTOR AND ASTROCYTIC CHANGES IN A KAINIC ACID MODEL OF TEMPORAL LOBE EPILEPSY

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Ilazki Anaut-Lusar[1,2], Amaia Mimenza[1,2], Maitane Serrano[1,2], Leire Lekumberri[1,2], Jon Egaña-Huguet[1,2], Edgar Soria-Gomez[1,2,3], Almudena Ramos-Uriarte[1,2], Nagore Puente[1,2], Irantzu Rico-Barrio[1,2], Izaskun Elezgarai[1,2], Pedro Grandes[1,2]

People with temporal lobe epilepsy (TLE) often endure memory impairments and they are more likely to suffer from psychiatric comorbidities such as anxiety and depression. On top of that, TLE frequently fails to be controlled by antiseizure drugs. Thus, it is crucial to better understand all mechanisms underlying its pathophysiology. The endocannabinoid system has been in the spotlight of pharmacological interest in epilepsy as the cannabinoid CB1 receptor regulates neuronal excitability. Nonetheless, the existence of a long-term correlation between disturbed hippocampal-related behaviors, CB1 receptor expression and glial cells in TLE is still unclear. To investigate this, kainic acid (KA, 25mg/kg) was intraperitoneally administered in 8-week-old C57BL/6J male mice. Controls, mice with mild (Racine scale: RS ≤ 3) and severe seizures (RS > 3) were compared. Then, spatial memory (Barnes-maze), nesting ability and anxiety were assessed. Furthermore, 4 weeks after KA injection, immunohistochemistry was carried out to study hippocampal CB1 expression and astrocytic morphology for light and electron microscopy. RS > 3 mice exhibited impaired spatial memory, harmed nesting ability and anxiolysis. They also showed a drastic reduction in CB1 optical density, especially in the CA1 hippocampus. Moreover, the astrocytic processes were bigger, covered a larger area and displayed an increased number of CB1 immunoparticles. Altogether, these findings suggest that severe epileptic seizures impair long-term hippocampal-dependent behaviors, and cause reactive astrogliosis associated with the increase in astroglial CB1 receptor in the hippocampus.

INSIGHTS INTO THE ROLE OF THE CANNABINOID CB2 RECEPTOR IN A MOUSE MODEL OF TEMPORAL LOBE EPILEPSY

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Amaia Mimenza[1,2], Ilazki Anaut-Lusar[1,2], Leire Lekumberri[1,2], Maitane Serrano[1,2], Jon Egaña-Huguet[1,2], Edgar Soria-Gomez[1,2,3], Itziar Bonilla Del Río[1,2], Julián Romero[4], María Grande[4], Samuel Ruiz De Martín Esteban[4], Cecilia J. Hillard[5], Nagore Puente[1,2], Izaskun Elezgarai[1,2], Pedro Grandes[1,2]
[1]Achucarro Basque Centre of Neuroscience, Achucarro Basque Centre Of Neuroscience, Leioa, Spain, [2]University of the Basque Country (UPV/EHU), Neuroscience, Leioa, Spain, [3]Basque Foundation for Science, Ikerbasque, Bilbao, Spain, [4]Universidad Francisco de Vitoria, Faculty Of Experimental Sciences, Pozuelo de Alarcón, Spain, [5]Medical College of Wisconsin, Neuroscience Research Center And Department Of Pharmacology And Toxicology, Milwaukee, United States of America

The cannabinoid receptor type 2 (CB2) is expressed primarily in peripheral tissues. Nevertheless, it is also present in microglia where it is rapidly upregulated during inflammation. Numerous studies have evidenced the correlation between inflammation and epileptic susceptibility in temporal lobe epilepsy (TLE). However, the role of CB2 receptor in TLE is still unknown. To address this, status epilepticus was induced in CB2-EGFP (CB2-Enhanced Green Fluorescent Protein) and CB2-KO mice by intraperitoneal kainic acid administration (KA, 25 mg/kg). Seizures' severity was assessed by a modified Racine's scale. Afterwards, overall well-being and memory were analyzed by several tests: marble burying, nest building behavior and novel object recognition. During the first 1.5h of the Racine's assessment, CB2-KO mice exhibited higher susceptibility to KA insults, but recovered faster than CB2-EGFP. Moreover, the absence of CB2 together with KA injection seems to impact on marble burying and nesting ability, but not on recognition memory. In order to elucidate whether synaptic dysfunction may be underlying these behavioral changes, in the future, electrophysiological recordings will be performed in this KA model mice. Nevertheless, as the role of CB2 is not fully characterized yet, it has been first performed extracellular field recordings on the hippocampal dentate medial perforant path (MPP) in untreated CB2-KO mice. Preliminary results indicate that in CB2-KO mice low frequency stimulation elicits MPP-LTP instead of the endocannabinoid-dependent LTD reported by our laboratory in WT mice.

Acute Δ9-tetrahydrocannabinol prompts rapid changes in cannabinoid CB receptor immunolabeling and subcellular structure in CA1 hippocampus of young adult male mice.
The use and abuse of cannabis can be associated with significant pathophysiology, however, it remains unclear whether (1) acute administration of Δ-9-tetrahydrocannabinol (THC) during early adulthood alters the cannabinoid type 1 (CB) receptor localization and expression in cells of the brain, and (2) THC produces structural brain changes. Here we use electron microscopy and a highly sensitive pre-embedding immunogold method to examine CB receptors in the hippocampus cornu ammonis subfield 1 (CA1) 30 min after male mice were exposed to a single THC injection (5 mg/kg). The findings show that acute exposure to THC can significantly decrease the percentage of CB receptor immunopositive terminals making symmetric synapses, mitochondria, and astrocytes. The percentage of CB receptor-labeled terminals forming asymmetric synapses was unaffected. Lastly, CB receptor expression was significantly lower at terminals of symmetric and asymmetric synapses as well as in mitochondria. Structurally, CA1 dendrites were significantly larger, and contained more spines and mitochondria following acute THC administration. The area of the dendritic spines, synaptic terminals, mitochondria, and astrocytes decreased significantly following acute THC exposure. Altogether, these results indicate that even a single THC exposure can have a significant impact on CB receptor expression, and can alter CA1 ultrastructure, within 30 min of drug exposure. These changes may contribute to the behavioral alterations experienced by young individuals shortly after cannabis intoxication.

Environmental Enrichment Rescues Endocannabinoid-Dependent Synaptic Plasticity Lost in Young Adult Male Mice after Ethanol Exposure during Adolescence.
Binge drinking (BD) is a serious health concern in adolescents as high ethanol (EtOH) consumption can have cognitive sequelae later in life. Remarkably, an enriched environment (EE) in adulthood significantly recovers memory in mice after adolescent BD, and the endocannabinoid, 2-arachydonoyl-glycerol (2-AG), rescues synaptic plasticity and memory impaired in adult rodents upon adolescent EtOH intake. However, the mechanisms by which EE improves memory are unknown. We investigated this in adolescent male C57BL/6J mice exposed to a drinking in the dark (DID) procedure four days per week for a duration of 4 weeks. After DID, the mice were nurtured under an EE for 2 weeks and were subjected to the Barnes Maze Test performed the last 5 days of withdrawal. The EE rescued memory and restored the EtOH-disrupted endocannabinoid (eCB)-dependent excitatory long-term depression at the dentate medial perforant path synapses (MPP-LTD). This recovery was dependent on both the cannabinoid CB1 receptor and group I metabotropic glutamate receptors (mGluRs) and required 2-AG. Also, the EE had a positive effect on mice exposed to water through the transient receptor potential vanilloid 1 (TRPV1) and anandamide (AEA)-dependent MPP long-term potentiation (MPP-LTP). Taken together, EE positively impacts different forms of excitatory synaptic plasticity in water- and EtOH-exposed brains.

The Absence of the Transient Receptor Potential Vanilloid 1 Directly Impacts on the Expression and Localization of the Endocannabinoid System in the Mouse Hippocampus.
The transient receptor potential vanilloid 1 (TRPV1) is a non-selective ligand-gated cation channel involved in synaptic transmission, plasticity, and brain pathology. In the hippocampal dentate gyrus, TRPV1 localizes to dendritic spines and dendrites postsynaptic to excitatory synapses in the molecular layer (ML). At these same synapses, the cannabinoid CB receptor (CBR) activated by exogenous and endogenous cannabinoids localizes to the presynaptic terminals. Hence, as both receptors are activated by endogenous anandamide, co-localize, and mediate long-term depression of the excitatory synaptic transmission at the medial perforant path (MPP) excitatory synapses though by different mechanisms, it is plausible that they might be exerting a reciprocal influence from their opposite synaptic sites. In this anatomical scenario, we tested whether the absence of TRPV1 affects the endocannabinoid system. The results obtained using biochemical techniques and immunoelectron microscopy in a mouse with the genetic deletion of TRPV1 show that the expression and localization of components of the endocannabinoid system, included CBR, change upon the constitutive absence of TRPV1. Thus, the expression of fatty acid amide hydrolase (FAAH) and monoacylglycerol lipase (MAGL) drastically increased in TRPV1 whole homogenates. Furthermore, CBR and MAGL decreased and the cannabinoid receptor interacting protein 1a (CRIP1a) increased in TRPV1 synaptosomes. Also, CBR positive excitatory terminals increased, the number of excitatory terminals decreased, and CBR particles dropped significantly in inhibitory terminals in the dentate ML of TRPV1 mice. In the outer 2/3 ML of the TRPV1 mutants, the proportion of CBR particles decreased in dendrites, and increased in excitatory terminals and astrocytes. In the inner 1/3 ML, the proportion of labeling increased in excitatory terminals, neuronal mitochondria, and dendrites. Altogether, these observations indicate the existence of compensatory changes in the endocannabinoid system upon TRPV1 removal, and endorse the importance of the potential functional adaptations derived from the lack of TRPV1 in the mouse brain.

ANTIEPILEPTOGENIC EFFECTS OF TRILOSTANE IN THE KAINIC ACID MODEL OF TEMPORAL LOBE EPILEPSY

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Mohammad Gol, Giuseppe Biagini, Anna Maria Costa, Davide Ibatici
University of Modena and Reggio Emilia, Department Of Biomedical, Metabolic And Neural Sciences, Modena, Italy

Background Trilostane selectively inhibits the enzyme 3β-hydroxysteroid dehydrogenase in the adrenal cortex and leads to an increase in neurosteroid levels in the brain. Previously, it was found that epileptogenesis could be anticipated by reducing the synthesis of allopregnanolone in a model of temporal lobe epilepsy. Thus, we hypothesized that epileptogenesis could instead be delayed by increasing the brain availability of neurosteroids with trilostane. **Methods** We designed an experiment in which trilostane (50 mg/kg) was administered once daily for six consecutive days, starting 10 minutes after intraperitoneal administration of kainic acid (15 mg/kg) to induce status epilepticus (SE). Rats were euthanized 1 or 10 weeks after SE induction. **Results** In comparison to the control group, the total duration of convulsive seizures during SE was not significantly reduced in trilostane-treated rats. The latency to develop the first convulsive and nonconvulsive seizures of the SE was unchanged. Additionally, the treatment with trilostane did not affect the neuronal cell density and the area of lesion in the hippocampus. However, the mean duration of convulsive seizures during SE was markedly decreased by trilostane. Notably, the repeated administration of trilostane significantly increased the latency to develop both the first electrocorticographic and convulsive tonic-clonic spontaneous seizures. In subiculum, a significant change was observed in activated microglia morphology by comparing rats repeatedly treated with trilostane with those treated with the vehicle. **Conclusion** Overall, our results indicate that the repeated administration of trilostane delays the onset of epileptogenesis, an effect related to enhanced availability of neurosteroids in the brain.

Houtt Extract Attenuates Neuronal Loss and Glial Activation in Pentylenetetrazol-Induced Kindling Model.
Inflammatory reactions are closely associated with the development and progression of epilepsy. It has been shown that inhibition of pro-inflammatory cytokines, which are released from activated astrocytes and microglia, are considered to be an effective therapeutic approach for the treatment of epileptic disorders. Regarding the anti-inflammatory effects of nutmeg (Houtt), the present study was designed to investigate whether the nutmeg ethanolic extract could exert anticonvulsant and inhibitory effects on glial activation in pentylenetetrazol (PTZ)-induced mice model of kindling. Ethanolic extract of nutmeg was administrated intraperitoneally (i.p.) 1 hour before PTZ injection or one week before PTZ as a separate group, to become fully-kindled. The chemical components of nutmeg extract were analyzed by gas chromatography mass spectrometry (GC-MS). Immunostaining against neuronal and glial markers was performed on hippocampus sections. GC-MS data indicated that the main components of nutmeg extract are myristic acid (39.93%), elemicin (22.16%) and myristicin (11.17%). Behavioral studies showed that pre-treatment of nutmeg extract effectively reduced seizures behavior, decreased cell death, and ameliorated glial activation that is followed by PTZ administration. In conclusion, nutmeg extract might be regarded as a useful supplementary agent in epilepsy treatment through its attenuation of neuronal loss and glial activation.

Arbutin reduces cognitive deficit and oxidative stress in animal model of Alzheimer's disease.
Recent evidences have shown the beneficial effects of natural products for treating of Alzheimer's disease (AD). Arbutin is derived from and exerts a wide range of pharmacological activities including anti-inflammatory and anti-oxidant effects. The present study was designed to examine the protective effects of arbutin on streptozotocin (STZ)-induced neurotoxicity in rats. The spatial memory impairment was induced by intracerebroventricular (i.c.v) microinjection of STZ (3 mg/kg, 10 µL). Animals received the pretreatment of arbutin (50 mg/kg) for 21 days before STZ injection. The Morris Water maze (MWM) task was used to study the spatial learning and memory. The levels of oxidative stress markers including malondialdehyde (MDA), nitrite and carbonyl were measured in serum and hippocampus samples. In addition, antioxidant level was assessed by ferric

reducing antioxidant power (FRAP) test. The obtained result indicated that administration of STZ is led to memory impairment and increases the levels of oxidative stress markers in the hippocampus tissues. Conversely, arbutin improves spatial memory and reduces oxidative and nitrosative stress, as evidenced by a significant decrease in the amount of MDA and nitrite in the serum and hippocampus. In addition, an increase in FRAP levels of hippocampus was observed in arbutin receiving animals. The protein carbonyl content was not reduced in arbutin receiving animals. It could be concluded that arbutin protects the brain against STZ-induced memory impairment and oxidative damage in the hippocampus. The neuroprotective effect of arbutin might be mediated through its antioxidant and free radical scavenging effects.

miR-302/367-induced neurons reduce behavioral impairment in an experimental model of Alzheimer's disease.
In vivo reprogramming of reactive glial cells to neurons has opened a new horizon in regenerative medicine. Our previous study showed that astrocytes could be converted to neurons by the microRNA-302/367 (miR-302/367) cluster in adult brains. In this study, we investigated the possible contribution of miR-302/367-induced neurons in behavioral improvement and neural repair in an Alzheimer's disease (AD) animal model. The AD model was induced by an intracerebroventricular (i.c.v) injection of streptozotocin (STZ). GFP-only or miR-302/367+GFP expressing lentiviral particles were injected into the dentate gyrus of the hippocampus along with intraperitoneal (i.p) valproate (VPA) injection, 3weeks after the STZ administration. We assessed short-term and spatial memories by the Y-maze and Morris water maze (MWM) tasks, respectively. Electrophysiological activities of induced neuron-like cells were investigated using a whole-cell patch clamp technique, 6months after injection of miR-302/367. Behavioral analysis showed that the STZ injection significantly impaired short-term memory and increased escape latency parameter in the MWM task. Compared to STZ and STZ+VPA groups, miR-302/367 combined with VPA significantly improved the spontaneous alternation and spatial memory. Immunostaining against NeuN, as a mature neuronal marker, and its quantification indicated that co-labeled GFP and NeuN significantly increased in the miR-302/367+VPA group. Induced neurons were detected 6months after the miR-302/367 injection. The patch-clamp recording suggested that induced neurons could fire repetitive action potential like endogenous neurons. In conclusion, our results indicated that in vivo reprogramming of reactive astrocytes to neurons by the miR-302/367 cluster might be considered as a novel strategy to restore learning and memory in AD patients.

Piperine restores streptozotocin-induced cognitive impairments: Insights into oxidative balance in cerebrospinal fluid and hippocampus.
Piperine has been shown to have antioxidant activity and a cognitive-enhancing effect following long-term oral administration. In a comparative study of memantine, the current investigation threw light on the cognitive benefits of piperine. Lipid peroxidation and the ferric reducing antioxidant power (FRAP) of cerebrospinal fluid (CSF) and hippocampus in streptozotocin (STZ)-induced experimental dementia of the Alzheimer's type was measured. After reaching a criterion in a memory test, STZ-induced rats received piperine [2.5, 5, and 10mg/kg, intraperitoneally (i.p.)], vehicle, and memantine (10mg/kg, i.p.) for two weeks after the first STZ administration, or two weeks before and one week after, as a preventive approach. After the behavioral studies, samples were taken for biochemical and histological assays. An appropriate concentration of piperine (2.5mg/kg), on a daily basis, effectively increased the number of correct (non-repeated) arm entries and repressed reentry to a previously visited arm, in terms of reference errors as well as memantine (10mg/kg, i.p.), irrespective of the dose administered. The cognitive-enhancing effect induced by piperine at a relevant dose was simultaneous with CSF and hippocampal malonaldehyde decrement, and the redox balance was established to some extent by maintaining the FRAP levels of CSF near to those of the control. Similarly, the neuroprotective properties of piperine are in accordance with histopathological outcomes, which have shown an increased number of live cresyl violet (CV)-positive neurons in a dentate gyrus (DG) subregion. Therefore, the effects of piperine on the redox balance of CSF and hippocampal neurons may certainly contribute to the cognitive-enhancing activity of the drug.

Inhibition of GABA A receptor improved spatial memory impairment in the local model of demyelination in rat hippocampus.
Cognitive impairment and memory deficit are common features in multiple Sclerosis patients. The mechanism of memory

impairment in MS is unknown, but neuroimaging studies suggest that hippocampal demyelination is involved. Here, we investigate the role of GABA A receptor on spatial memory in the local model of hippocampal demyelination. Demyelination was induced in male Wistar rats by bilaterally injection of lysophosphatidylcholine (LPC) 1% into the CA1 region of the hippocampus. The treatment groups were received daily intraventricular injection of bicuculline (0.025, 0.05µg/2µl/animal) or muscimol (0.1, 0.2µg/2µl/animal) 5days after LPC injection. Morris Water Maze was used to evaluate learning and memory in rats. We used Luxol fast blue staining and qPCR to assess demyelination extention and MBP expression level respectively. Immunohistochemistry (IHC) for CD45 and H&E staining were performed to assess inflammatory cells infiltration. Behavioral study revealed that LPC injection in the hippocampus impaired learning and memory function. Animals treated with both doses of bicuculline improved spatial learning and memory function; however, muscimol treatment had no effect. Histological and MBP expression studies confirmed that demylination in LPC group was maximal. Bicuculline treatment significantly reduced demyelination extension and increased the level of MBP expression. H&E and IHC results showed that bicuculline reduced inflammatory cell infiltration in the lesion site. Bicuculline improved learning and memory and decreased demyelination extention in the LPC-induced hippocampal demyelination model. We conclude that disruption of GABAergic homeostasis in hippocampal demyelination context may be involved in memory impairment with the implications for both pathophysiology and therapy.

Protective effect of raisin (currant) against spatial memory impairment and oxidative stress in Alzheimer disease model.
Alzheimer's disease (AD) is a neurodegenerative disorder characterized by progressive pathological changes of the brain. A number of studies demonstrated compelling evidence of the importance of oxidative processes in AD pathogenesis. Raisin contains polyphenol, phenolic acid, and tannin compounds, which have antioxidant and anti-inflammatory properties. The present study was aimed to evaluate the protective effect of raisin on neurobehavioral and histological changes in rats with Alzheimer. Animal model of AD was induced by intraperitoneal injection of aluminium chloride for 60 days (100 mg/kg body weight). During these 60 days both Alzheimer's and control rats were given 6 g of raisin per rat. At the end of the treatment, blood was collected for biochemical assessment. We used a Morris water task and passive avoidance test to assess spatial memory. Our results showed that aluminium exposure significantly decreased the memory in the MWT and passive avoidance test, but in the raisin + AlCl group, it significantly increased spatial memory in both tests. Also, Aluminium exposure significantly increased malondialdehyde (MDA) and decreased ferric reducing ability of plasma (ferric reducing/antioxidant power (FRAP)), while treatment with raisin significantly decreased MDA and increased FRAP in plasma of blood. Our findings showed that raisin has a neuroprotective effect and improves the spatial memory in AD animal models.

Fingolimod enhances myelin repair of hippocampus in pentylenetetrazol-induced kindling model.
Recent evidence indicates that demyelination occurs in epilepsy patients and kindling animal models. Regarding the well-known literature on anti-inflammatory and myelin protective effects of fingolimod (FTY720) in multiple sclerosis patients and animal models, we hypostatized whether FTY720 administration could exert myelin protective effects in pentylenetetrazol (PTZ)-induced kindling model. To end this, animals received 0.3 or 1mg/kg dosage of FTY720, 1h before PTZ injections. In another approach, after achieving fully kindling stage, FTY720 was administrated i.p. once daily for 7 consecutive days. Treatment with FTY720 (especially lower dose) reduced the frequency of seizures and epileptiform discharges in both approaches. We found that FTY720 administration decreases cell death and glial activation in CA1 and CA3 regions of hippocampus. Myelin protection effect was shown by increasing myelin levels. Furthermore, post-treatment of FTY720 enhanced endogenous remyelination and the number of oligodendrocyte precursor cells in fully kindled animals. Together, these results demonstrate that FTY720 behind the anti-inflammatory and neuroprotection effects has beneficial role in myelin protection and remyelination enhancement in PTZ kindling model of seizure and it may be provide a new therapeutic option for demyelination associated with epilepsy.

INTRACEREBRAL LONGITUDINAL CHARACTERIZATION OF LARGE-SCALE EPILEPTOGENESIS IN THE KAINATE MOUSE MODEL OF FOCAL TEMPORAL LOBE EPILEPSY

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Fabien Friscourt[1,2], Laurent Sheybani[1,3], Guru Padmasola[1], Maëlle Hernot[1], Karl Schaller[3], Christoph Michel[1,3], Charles Quairiaux[1]
[1]Functional Brain Mapping Laboratory, Department Of Fundamental Neurosciences, Geneva, Switzerland, [2]Department of Fundamental Neurosciences, Faculty Of Medicine, Geneva, Switzerland, [3]Neurology Clinic, Department Of Clinical Neurosciences, Geneva, Switzerland

Temporal lobe epilepsy (TLE) is the most common type of focal epilepsies. While TLE is characterized by the presence of an epileptic focus (EF) that is held to be responsible for triggering seizures and driving interictal activities, recent studies show that epileptogenic networks (EN) and brain alterations are widely distributed. In this context, a fundamental question is yet to be answered: is the EN responsible for the emergence of epileptic activities, with the EF as one of its major outputs, or is the EF upstream in the cascade that leads to the formation of the EN? Using multisite chronic mSEEG recordings and chemogenetic tools in the status epilepticus (SE) induced intra hippocampal kainate mouse model of TLE, we propose to characterize in detail the emergence of epileptic activities in the EF and in remote regions and evaluate the role of the primary epileptogenic region for the development of the large-scale EN. We found that different epileptiform signatures, with ictal, ictal-like and interictal patterns, appear in the very early stage of the latent phase (LP) (as early as 72h after SE) in both the EF and distant regions and then evolve along the LP to become typical epileptic events characterizing the chronic phase. We investigate these network dynamics with high spatial and temporal precision using systematic unbiased detection of pathological activities. Our work aims at identifying key mechanisms involved in the development of epileptic neuronal networks and clarify the pathogenic stream of events at play between the EF and the EN.

SYNAPTIC NETWORK DYSFUNCTION AND INCREASED INTRINSIC NEURONAL EXCITABILITY IN GLUA2 AUTOIMMUNE ENCEPHALITIS

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Yang Yuan, Christian Geis, Holger Haselmann
University Hospital Of Jena, Section Translational Neuroimmunology, Jena, Germany

Title of the Poster: Synaptic network dysfunction and increased intrinsic neuronal excitability in GluA2 autoimmune encephalitis Authors: Yang Yuan, Christian Geis, Holger Haselmann Abstract Aims Autoimmune encephalitis (AE) is a new group of neurological disorders induced by autoantibodies (aAB) against distinct neuronal surface antigens such as α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPAR). As epilepsy is a characteristic feature of AMPA receptor encephalitis, we aim to investigate the effect of anti-GluA2 (AMPAR subunit) aABs on the neuronal network and the balance of excitation and inhibition as a prerequisite for increased susceptibility to seizures. Methods We performed intra-parenchymal injections of a-GluA2 aABs into the hippocampus area of mice and prepared acute brain slices after 24 hours incubation. We hypothesized a dysbalance of the excitatory to inhibitory ratio (I/E ratio) and performed stimulation of Schaffer-collateral pathway to evaluate glutamatergic and bi-synaptic GABAergic signaling on the single-cell level in CA1 pyramidal neurons. Moreover, we investigated the influence of anti-GluA2 aABs on intrinsic neuronal excitability. Results The I/E ratio of evoked postsynaptic currents was changed. The intrinsic excitability of neurons was increased due to anti-GluA2 autoantibodies. In addition, anti-GluA2 antibodies increased significantly the action potentials firing rate after Schaffer-collateral stimulation. Conclusions Anti-GluA2 autoantibodies affect hippocampal networks and the intrinsic excitability of neurons. They may increase synaptic transmission. Our results contribute to the understanding of the epileptogenic potential of anti-GluA2 aABs and may help to identify optimized treatment strategies in controlling epilepsy in AMPAR AE.

CHLORIDE DYNAMICS IN SPECIFIC NEURONAL SUBTYPES DURING EPILEPTIFORM ACTIVITY IN VITRO

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Alexandru Călin[1], Tatiana Waseem[1], Joseph Raimondo[2], Sarah Newey[1], Colin Akerman[1]
[1]University of Oxford, Department Of Pharmacology, Oxford, United Kingdom, [2]University of Cape Town, Cell Biology, Cape Town, South Africa

Aims: We set out to investigate the intracellular chloride resting levels and activity-dependent chloride dynamics in specific neuronal subtypes of the mouse hippocampus during epileptiform activity. Methods: We developed a floxed version of the genetically-encoded chloride indicator, ClopHensorN, to perform fluorescence chloride imaging in defined neuronal populations. Floxed ClophensorN was successfully delivered to mice expressing Cre recombinase in specific cell types. This enabled us to measure the resting state absolute intracellular chloride concentration in pyramidal neurons, and parvalbumin (PV), somatostatin (SST) and vasoactive intestinal polypeptide (VIP) expressing interneurons. Simultaneous confocal microscopy and electrophysiological recordings were used to quantify the relationship between the dynamics of intracellular chloride and epileptiform activity in organotypic hippocampal brain slices. Results: Intracellular chloride steady states varied significantly across cell types. Average resting somatic chloride was 5.8±2.9 mM in pyramidal neurons, 32.5±6.6 mM in PV interneurons, 12.9±2.3 mM in SST interneurons, and 22.6±4 mM in VIP interneurons. Interestingly, epileptiform activity resulted in a convergence in intracellular chloride concentrations across neuronal subtypes, with PV interneurons maintaining relatively stable somatic chloride levels, and other neuronal subtypes exhibiting activity-dependent increases in intracellular chloride. Conclusions: Using novel optical methods, we reveal distinct chloride steady states and activity-dependent dynamics in defined GABAergic interneuron subtypes. Since intracellular chloride determines the ionic driving force for fast synaptic inhibition, these findings advance our understanding of the interplay between excitatory and inhibitory signalling during epileptic seizures.

TYPICAL ABSENCE EPILEPSY SIMULATED IN A FULL HUMAN VIRTUAL BRAIN MODEL SUGGEST THAT SEIZURES ARE NOT GENERALIZED AND INDUCE A HYPER-INHIBITION OF THE ASSOCIATIVE CORTEX

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Conscious perception results from an interplay between two processes interacting with each other: *awareness* and *wakefulness* supported respectively by large-scale cortico-cortical functional connectivity whereas *wakefulness* depends critically on thalamocortical connectivity[1].
We have developed a full virtual human brain named COALIA able to simulate realistic EEG, as compared to real EEG recorded in humans at two levels of consciousness[2]. We used COALIA to understand the neurobiological mechanisms of typical absence seizures. Accounting for brain characteristics present in the immature brain and the human structural connectivity, we were able to generate realistic absence seizures activity patterns in simulated high-density EEG with our human computational full brain model. Results suggest that a focal initiation in the frontal cortex triggers a switch in the firing mode of the cognitive/associative nuclei of the thalamus from tonic to “UP and down” discharge mode due to and excessive feed-forward cortico-thalamic inhibition. This thalamic bursting mode initiates 3Hz spike-wave discharge onto the associative area of the cortex through an exaggerated thalamo-cortical feed-forward inhibition (hyperexcitation of cortical SST GABAergic subtype onto pyramidal cells) that explain the large wave of the SWD. This large cortical inhibition transiently disrupts the cortico-cortical connectivity by suppression of the PV-PC loop. Simulated TMS-evoked potential confirmed a dramatic drop of the consciousness index during absence seizures. Finally, high-density EEG-based source location during typical absence seizure recorded in child confirm that SWD are not generalized but mainly affect the associative part of the cortex. 1: PMID: 32537530 2:PMID: 31798421 ***Grants****: INCR predilepsy project, ERC Syn Galvani*

SELECTIVE LOSS OF INTERNEURONS IN THE SUBICULUM IN A MOUSE MODEL FOR MESIAL TEMPORAL LOBE EPILEPSY

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Nicole Barheier[1,2], Julia Franz[1], Susanne Tulke[1], Carola Haas[1,3,4], Ute Häussler[1,4]
[1]Medical Center - University of Freiburg, Experimental Epilepsy Research, Dept. Of Neurosurgery, Freiburg, Germany, [2]University of Freiburg, Faculty Of Biology, Freiburg, Germany, [3]University of Freiburg, Center For Basics In Neuromodulation, Faculty Of Medicine, Freiburg, Germany, [4]University of Freiburg, Brainlinks-braintools, Freiburg, Germany

Mesial temporal lobe epilepsy (MTLE) is characterized by a loss of principal cells in the hilus, CA1 and CA3, as well as interneurons throughout the hippocampus. Whereas the hippocampus has been intensely investigated, data on structural changes in the subiculum, which is the main output region of the hippocampal formation, are rare. Yet, its connectivity and cellular characteristics render the subiculum an important part of the epileptic network. Based on our previous work showing differential vulnerability of interneurons in the hippocampus, we now performed a detailed study of epilepsy-related changes in the subiculum. Using the intrahippocampal kainate (KA) mouse model for MTLE we analyzed neuronal loss after *status epilepticus*. Furthermore, we performed quantitative immunocytochemistry for different interneuron populations [parvalbumin, calbindin, calretinin and Neuropeptide Y (NPY)] across all layers along the dorsoventral axis of the subiculum and determined GAD67 expression with fluorescent *in situ* hybridization in the chronic stage of MTLE (21 days after KA). Finally, we confirmed the occurrence of epileptic activity by local field potential recordings in the subiculum. We found prominent cell loss in the subiculum and a consistent reduction of parvalbumin-expressing interneurons along its entire dorsoventral axis. The density of CB-positive cells was increased, whereas CR-expressing neurons remained unaltered. Interestingly, the number of NPY-expressing cells was increased, yet NPY- and GAD67-doublelabeled cells were reduced, indicating interneuron loss but NPY upregulation in principal cells. In summary, our results indicate that a selective loss of parvalbumin- and NPY-positive interneurons contributes to epileptogenicity in the subiculum after KA injection.

THE CONSTITUTIVE ACTIVITY OF THE HISTAMINE H1 RECEPTOR, INTERACTION WITH THE NMDA RECEPTOR: CONSEQUENCES IN EPILEPSY

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Vincent Armand[1], Jean Michel Arrang[1], Nicolas Josset[2]
[1]Université Paris Descartes, Saints Pères Paris Institute For Neurosciences, Paris, France, [2]Baylor college of Medicine, Baylor College Of Medicine, houston, United States of America

We have explored the epileptogenic effects of several drugs specific to the antihistaminic H1 receptor on NMDA and GABA responses. With patch-clamp whole-cell recordings of hippocampal neurons of rats, we observe the effects of several histaminergic agonists and antagonists on the NMDA and GABA currents. During the NMDA rundown and GABA rundown, we applied the drugs and observe the effect on the responses, and compare them to control conditions. **Results** Mepyramine with nanomolar concentrations increases significantly the NMDA responses about 35 %, this effect is mimicked by another Anti H1 drug Triprolidine. Histamine alone has no effect on NMDA rundown but 100 µM Histamine can reduce partially the effect of Mepyramine. An H1 receptor agonist 2,3 Bromophenyl Histamine also shows the same properties as Histamine. The H1 receptor of Histamine seems to be crucial during these experiments, blockade of its constitutive activity by Mepyramine induces a significant increase of the NMDA responses. On the GABA response, the same nanomolar dose of Mepyramine has no effect on the rundown and we also observed no effect of Histamine on the GABA rundown. An interaction between Histamine H1 receptor and the NMDA is revelated by using Mepyramine in nanomolar concentration, Histamine has no effect on these responses also in these experiments Mepyramine acts as an inverse agonist blocking the constitutive activity of the H1 receptor. The constitutive activity of the H1 receptor seems to be crucial in the regulation of NMDA receptor activities.

ROLE OF THE HYDROXYCARBOXYLIC ACID RECEPTOR 1 (HCAR1) IN HIPPOCAMPAL NETWORK REGULATION DURING EPILEPTIC SEIZURES

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Maxime Alessandri[1], Romain Cardis[1], Alejandro Osorio-Forero[2], Anita Lüthi[2], Jean-Yves Chatton[2]
[1]University of Lausanne, Department Of Fundamental Neurosciences, Lausanne, Switzerland, [2]University of Lausanne, Department Of Fundamental Neuroscience, Lausanne, Switzerland

The goal of this research is to investigate the role of the lactate receptor hydroxycarboxylic acid receptor 1 (HCAR1) in the regulation of the hippocampal network in the pathology of epilepsy and its ability to modulate seizures. HCAR1 is especially enriched in the hippocampal glutamatergic neurons in the CA fields and in the dentate gyrus. Investigations first using mouse primary neuronal cultures then acute brain slices led us to unravel the mechanisms of action of HCAR1 as a modulator of neuronal activity and its interactions with other G_i-protein coupled receptors involving $G_{\beta\gamma}$ subunits. By its ability to reduce neuronal activity and its expression by glutamatergic hippocampal neurons, HCAR1 appears as a potential target for the modulation of seizures. In this study, we focused on the pathophysiology of acute seizures. We elicited seizures on freely behaving mice using the intrahippocampal kainate injection model in the presence or absence of the non-metabolized HCAR1 agonist 3-chloro-5-hydroxybenzoic acid (3Cl-HBA) and investigated the potential modulatory effect of HCAR1 activation on seizures using electroencephalography (EEG). We quantified the frequency bands power of delta, theta, alpha, beta and gamma waves. Contrasting to ex vivo observation by us and other groups, activating HCAR1 during seizures had no significant effect on the recorded signals. We are currently using *in vitro* models of epilepsy to determine if and under which conditions HCAR1 activation can modulate seizures, with particular attention to potential interference with other Gi-coupled receptors.

TRANSCRIPTOMIC ANALYSIS OF HIPPOCAMPAL SUBREGIONS AFTER INDUCTION OF ACUTE SEIZURES BY ELECTRIC STIMULATION OF THE PERFORANT PATHWAY IN RATS

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Preconditioning is a mechanism in which injuries induced by non-lethal hypoxia or seizures trigger cellular resistance to subsequent events. Norwood et al., in a 2010 study, showed that an 8-hour-long period of electrical stimulation of the perforant pathway in rats is required for the induction of hippocampal sclerosis. However, in order to avoid generalized seizures, status epilepticus (SE), and death, a state of resistance to seizures must be induced in the hippocampus by a preconditioning paradigm consisting of 2 daily 30-minute stimulation periods. The present study aims to investigate differential gene expression patterns in different hippocampal subregions using RNA-sequencing, after induction of a preconditioning protocol by electrical stimulation of the perforant pathway. The dorsal and ventral dentate gyrus (dDG, vDG), CA3 (dCA3, vCA3) and subiculum (dSub, vSub) regions were collected by laser-microdissection 24 hours after preconditioning protocol induction in rats. RNA sequencing was performed in a Hiseq 4000 platform, reads were aligned using the STAR and DESEq2 statistics package was used to estimate gene expression. When comparing control to preconditioned samples, we found the differential expression of 1436 genes in dDG, 987 in vDG, 744 in dCA3, 662 genes in vCA3, 204 in dSub and 972 in vSub. Our results indicate that preconditioning by perforant pathway electrical stimulation may induce a coordinated increase in GABAergic inhibition in both DG regions but not in CA3. Furthermore, we observed changes in synaptic reorganization, increased cholesterol metabolism, and astrogliosis in the subiculum.

ELEVATED CO2 IS A MAJOR BRAIN-SPARING MECHANISM IN BIRTH ASPHYXIA

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Alexey Pospelov[1,2], Tommi Ala-Kurikka[1,2], Juha Voipio[2], Kai Kaila[1,2]
[1]University of Helsinki, Neuroscience Center (hilife), Helsinki, Finland, [2]University of Helsinki, Biological And Environmental Sciences, Molecular And Integrative Biosciences, Helsinki, Finland

Aims: Birth asphyxia (BA) is a period of severe systemic O_2 deprivation (hypoxia) and build-up of CO_2 (hypercapnia). Most animal models of BA neglect the fundamental hypercapnia component. Here, we have studied the multiple protective roles of CO_2 during oxygen deprivation. Methods: 11-day-old rat pups were exposed to pure hypoxia, pure hypercapnia, or their combination (i.e. asphyxia) by altering the O_2 (from 21% to 5-9%) and CO_2 (up to 20%) concentrations of the inhaled gas. Brain and body pH and PO_2 levels were measured using microsensors. Results: An increase in ambient PCO_2 strongly suppressed the fall in brain PO_2 during asphyxia, obviously reflecting a brain-sparing vasomotor response. Moreover, extending the hypercarbia exposure beyond the asphyxia strongly suppressed post-asphyxia EEG and behavioural seizures. The effects of hypercarbia were mimicked by intraperitoneal or intravenous application of both highly membrane-permeant and impermeant inhibitors of carbonic anhydrase (CAIs). Conclusions: The increase in CO_2 which is always associated with birth asphyxia has brain-sparing effects (elevated oxygenation; suppression of the ictogenic action of hypoxia). These effects can be enhanced and prolonged by elevation of the ambient CO_2 level or by application of CAIs during the post-asphyxia recovery.

Snake Genome Sequencing: Results and Future Prospects.
Snake genome sequencing is in its infancy-very much behind the progress made in sequencing the genomes of humans, model organisms and pathogens relevant to biomedical research, and agricultural species. We provide here an overview of some of the snake genome projects in progress, and discuss the biological findings, with special emphasis on toxinology, from the small number of draft snake genomes already published. We discuss the future of snake genomics, pointing out that new sequencing technologies will help overcome the problem of repetitive sequences in assembling snake genomes. Genome sequences are also likely to be valuable in examining the clustering of toxin genes on the chromosomes, in designing recombinant antivenoms and in studying the epigenetic regulation of toxin gene expression.

A physiologically validated rat model of term birth asphyxia with seizure generation after, not during, brain hypoxia.
Birth asphyxia (BA) is often associated with seizures that may exacerbate the ensuing hypoxic-ischemic encephalopathy. In rodent models of BA, exposure to hypoxia is used to evoke seizures, that commence already during the insult. This is in stark contrast to clinical BA, in which seizures are typically seen upon recovery. Here, we introduce a term-equivalent rat model of BA, in which seizures are triggered after exposure to asphyxia.

Carbonic anhydrase inhibitors suppress seizures in a rat model of birth asphyxia.
Seizures are common in neonates recovering from birth asphyxia but there is general consensus that current pharmacotherapy is suboptimal and that novel antiseizure drugs are needed. We recently showed in a rat model of birth asphyxia that seizures are triggered by the post-asphyxia recovery of brain pH. Here our aim was to investigate whether carbonic anhydrase inhibitors (CAIs), which induce systemic acidosis, block the post-asphyxia seizures.

Forebrain-independent generation of hyperthermic convulsions in infant rats.
Febrile seizures are the most common type of convulsive events in children. It is generally assumed that the generalization of these seizures is a result of brainstem invasion by the initial limbic seizure activity. Using precollicular transection in 13-day-

old rats to isolate the forebrain from the brainstem, we demonstrate that the forebrain is not required for generation of tonic-clonic convulsions induced by hyperthermia or kainate. Compared with sham-operated littermate controls, latency to onset of convulsions in both models was significantly shorter in pups that had undergone precollicular transection, indicating suppression of the brainstem seizure network by the forebrain in the intact animal. We have shown previously that febrile seizures are precipitated by hyperthermia-induced respiratory alkalosis. Here, we show that triggering of hyperthermia-induced hyperventilation and consequent convulsions in transected animals are blocked by diazepam. The present data suggest that the role of endogenous brainstem activity in triggering tonic-clonic seizures should be re-evaluated in standard experimental models of limbic seizures. Our work sheds new light on the mechanisms that generate febrile seizures in children and, therefore, on how they might be treated.

Extracts of the tropical Cinderella plant *Synedrella nodiflora* are used traditionally to manage convulsive conditions in the West African sub-region. This study sought to determine the neuronal basis of the effectiveness of these plant extracts to suppress seizure activity. Using the hippocampal slice preparation from rats, the ability of the extract to depress excitatory synaptic transmission and *in vitro* seizure activity were investigated. Bath perfusion of the hydro-ethanolic extract of *Synedrella nodiflora* (SNE) caused a concentration-dependent depression of evoked field excitatory postsynaptic potentials (fEPSPs) recorded extracellularly in the CA1 region of the hippocampus with maximal depression of about 80% and an estimated IC_{50} of 0.06 mg/ml. The SNE-induced fEPSP depression was accompanied by an increase in paired pulse facilitation. The fEPSP depression only recovered partially after 20 min washing out. The effect of SNE was not stimulus dependent as it was present even in the absence of synaptic stimulation. Furthermore, it did not show desensitization as repeat application after 10 min washout produced the same level of fEPSP depression as the first application. The SNE effect on fEPSPs was not via adenosine release as it was neither blocked nor reversed by 8-CPT, an adenosine A_1 receptor antagonist. In addition, SNE depressed *in vitro* seizures induced by zero Mg^{2+} and high K^+ -containing artificial cerebrospinal fluid (aCSF) in a concentration-dependent manner. The results show that SNE depresses fEPSPs and spontaneous bursting activity in hippocampal neurons that may underlie its ability to abort convulsive activity in persons with epilepsy.

Transcutaneous electrical nerve stimulation in the management of calf muscle spasticity in cerebral palsy: A pilot study.
This study sets out to evaluate the effectiveness of transcutaneous electrical nerve stimulation (TENS) in the management of

calf muscle spasticity in children with cerebral palsy. The study follows a one group pre-test-post-test design involving fifteen children with spastic cerebral palsy, presenting with calf muscle spasticity. Spasticity was assessed before and after a 30 min application of TENS to the bilateral calf muscles. The H-reflex (electromyography) of the calf muscles and Modified Ashworth Scale (MAS) served as a measure of spasticity. A goniometer was used to measure the range of motion (ROM) angles for ankle dorsiflexion. We report here no significant difference ($p > 0.05$) between the left and right H-reflex responses, MAS scores, and ROM scores recorded at baseline (pre-test). Correlation analysis show no correlation ($p > 0.05$) between the pre-test HA Max (maximum H-reflex amplitude)/MA Max (maximum M-Wave Amplitude) ratio and MAS scores of both the left and right calf muscles. However, TENS significantly reduced ($p < 0.05$) the HA of the left calf muscle and MAS scores of the left and right calf muscles. Additionally, TENS significantly increased the ROM scores of the left and right calf muscles. Our findings lend support to existing evidence that TENS is effective in reducing spasticity. The potential mechanism underlying this effect is a reduction in neuron excitability.

Auditory nerve perinodal dysmyelination in noise-induced hearing loss.
Exposure to loud sound (acoustic overexposure; AOE) induces hearing loss and damages cellular structures at multiple locations in the auditory pathway. Whether AOE can also induce changes in myelin sheaths of the auditory nerve (AN) is an important issue particularly because these changes can be responsible for impaired action potential propagation along the AN. Here we investigate the effects of AOE on morphological and electrophysiological features of the centrally directed part of the rat AN projecting from the cochlear spiral ganglion to brainstem cochlear nuclei. Using electron microscopy and immunocytochemistry, we show that AOE elongates the AN nodes of Ranvier and triggers notable perinodal morphological changes. Compound action potential recordings of the AN coupled to biophysical modeling demonstrated that these nodal and perinodal structural changes were associated with decreased conduction velocity and conduction block. Furthermore, AOE decreased the number of release sites in the cochlear nuclei associated with the reduced amplitudes of EPSCs evoked by AN stimulation. In conclusion, AN dysmyelination may be of fundamental importance in auditory impairment following exposure to loud sound.

Acoustic overexposure increases the expression of VGLUT-2 mediated projections from the lateral vestibular nucleus to the dorsal cochlear nucleus.
The dorsal cochlear nucleus (DCN) is a first relay of the central auditory system as well as a site for integration of multimodal information. Vesicular glutamate transporters VGLUT-1 and VGLUT-2 selectively package glutamate into synaptic vesicles and are found to have different patterns of organization in the DCN. Whereas auditory nerve fibers predominantly co-label with VGLUT-1, somatosensory inputs predominantly co-label with VGLUT-2. Here, we used retrograde and anterograde transport of fluorescent conjugated dextran amine (DA) to demonstrate that the lateral vestibular nucleus (LVN) exhibits ipsilateral projections to both fusiform and deep layers of the rat DCN. Stimulating the LVN induced glutamatergic synaptic currents in fusiform cells and granule cell interneurones. We combined the dextran amine neuronal tracing method with immunohistochemistry and showed that labeled projections from the LVN are co-labeled with VGLUT-2 by contrast to VGLUT-1. Wistar rats were exposed to a loud single tone (15 kHz, 110 dB SPL) for 6 hours. Five days after acoustic overexposure, the level of expression of VGLUT-1 in the DCN was decreased whereas the level of expression of VGLUT-2 in the DCN was increased including terminals originating from the LVN. VGLUT-2 mediated projections from the LVN to the DCN are likely to play a role in the head position in response to sound. Amplification of VGLUT-2 expression after acoustic overexposure could be a compensatory mechanism from vestibular inputs in response to hearing loss and to a decrease of VGLUT-1 expression from auditory nerve fibers.

Saturation of long-term potentiation in the dorsal cochlear nucleus and its pharmacological reversal in an experimental model of tinnitus.
Animal models have demonstrated that tinnitus is a pathology of dysfunctional excitability in the central auditory system, in particular in the dorsal cochlear nucleus (DCN) of the brainstem. We used a murine model and studied whether acoustic over-exposure leading to hearing loss and tinnitus, affects long-term potentiation (LTP) at DCN multisensory synapses. Whole cell and field potential recordings were used to study the effects on release probability and synaptic plasticity, respectively in brainstem slices. Shifts in hearing threshold were quantified by auditory brainstem recordings, and gap-induced prepulse inhibition of the acoustic startle reflex was used as an index for tinnitus. An increased release probability that saturated LTP and thereby induced metaplasticity at DCN multisensory synapses, was observed 4-5days following acoustic over-exposure. Perfusion of an NMDA receptor antagonist or decreasing extracellular calcium concentration,

decreased the release probability and restored LTP following acoustic over-exposure. In vivo administration of magnesium-threonate following acoustic over-exposure restored LTP at DCN multisensory synapses, and reduced gap detection deficits observed four months following acoustic over-exposure. These observations suggest that consequences of noise-induced metaplasticity could underlie the gap detection deficits that follow acoustic over-exposure, and that early therapeutic intervention could target metaplasticity and alleviate tinnitus.

PROBING CORTICAL EXCITABILITY UNDER GABAERGIC MODULATION IN HUMANS WITH EPILEPSY

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Ellen Van Maren[1], Juan Anso[2], Markus Fuchs[3], Werner Z'Graggen[3], Kaspar Schindler[3], Claudio Pollo[3], Maxime Baud[1]
[1]University of Bern, Center For Experimental Neurology, Dept Of Neurology, Bern, Switzerland, [2]ARTORG Center for Biomedical Engineering Research, University Of Bern, Bern, Switzerland, [3]Sleep-Wake-Epilepsy Center, Department Of Neurology, Inselspital University Hospital Bern, Bern, Switzerland

Background In focal epilepsy, seizures result from subnetworks of abnormally high cortical excitability (CE) within a relatively normal brain. Practical means of monitoring CE in the human brain, for example to assess the effects of anti-seizure medications are currently lacking. We asked whether directly probing the brain with minute electrical pulses and recording cortico-cortical evoked potentials (CCEPs) may help quantify CE before and after administration of a benzodiazepine (BZD). Methods In seven epilepsy patients undergoing cortical recordings for diagnostic reasons (median number of electrode contacts: 68 [48, 111]), we probed CE with repeated single pulses (median N= 168 [151, 204]) systematically varying in intensity (0.2 – 12mA). All brain responses, before and after administration of clonazepam (0.75-1mg) were clustered into subnetworks using NMF (Non-negativity matrix factorization) based on the dynamics of CCEPs. CE in each subnetwork was quantified by the magnitude of the NMF activation coefficients. Results Across patients, NMF delineated a total of 20 subnetworks that encompassed a collection of brain areas with shorter- and longer-range connections responding conjointly to the administered probing stimulations with CCEPs. Across these subnetworks, CE was significantly decreased after BZD administration (Wilcoxon signed-rank test: p=0.0003). Conclusion Combining probing neurostimulations with unsupervised pattern recognition algorithms, we introduce a novel method to quantify CE in the human brain. As a proof-of-principle, we apply this method to uncover the network effects of a well-known GABA agonist on CE. Applying such methods over longer durations, may help monitor non-linear dynamics in the human cortex, including in epilepsy.

Voltage-gated sodium channel $Na_V1.1$ (*SCN1A*) loss of function variants cause the severe epilepsy Dravet syndrome (DS), as well as milder genetic epilepsy with febrile seizures plus (GEFS+). Gain of function (GOF) *SCN1A* variants are associated with familial hemiplegic migraine (FHM3). Other phenotypes have been described for *SCN1A* variants, including early infantile developmental and epileptic encephalopathy (EIDEE). We describe the clinical spectrum, genetic and functional evaluation of patients with early onset. We included 35 patients via an international collaborative network and from the literature, and identified three distinct clinical presentations. 1) The most severe phenotype (13 patients) was neonatal developmental and epileptic encephalopathy with movement disorder and arthrogryposis (NDEEMA) 2) 21 patients presented later (2 weeks-3 months) with a severe EIDEE and a movement disorder. 3) One patient presented after 3 months with DEE only. Functional studies of representative variants revealed GOF, in keeping with neuronal hyperexcitability. Notably, GOF epilepsy variants show a moderate effect, leading to a moderate increase in action current amplitude, much smaller compared to that of FHM3 variants, which lead to a larger increase of action current amplitude, consistent with stronger GOF. Differently than for DS, treatment with sodium channel blockers reduced seizure frequency in most of the patients, without evidence of symptom exacerbation. Our study expands the spectrum of gain of function *SCN1A*-related epilepsy phenotypes, defines clinical features, provides novel insights into disease mechanisms between *SCN1A*-related epilepsy and FHM3, and identifies sodium channel blockers as potentially efficacious therapies.

A NEW RELIABLE PILOCARPINE-CAFFEINE MOUSE MODEL OF TEMPORAL LOBE EPILEPSY

POSTER SESSION 01 - SECTION: EPILEPSY & SEIZURES

Alexandre Vigier, Valérie Crépel, Thomas Marissal
INMED (Inserm), Umr1249, Marseille, France

Aims: Our work aims to understand the cellular alterations occurring in Temporal Lobe Epilepsy (TLE), a disabling and often drug-resistant disease, that represent 1% of adult neurological disorder worldwide. Systemic pilocarpine treatment is one of the most reliable means of inducing temporal lobe epilepsy (TLE) in rodent models. However, the traditional pilocarpine injection protocol using mice was associated with a high death rate, possibly because of cardiorespiratory collapse following status epilepticus (SE). To prevent this, we developed a modified procedure of pilocarpine SE induction. Methods: The modified procedure of pilocarpine SE induction included a single injection of a moderate dose of caffeine during the induction phase. That new protocol was also based on the use of young male mice, as well as on a refined Racine's scale. Results: Using the modified procedure and the refined Racine's scale, we reported a substantially increased survival rate, thus enabling the generation of a large cohort of epileptic mice. Moreover, those mice display the cardinal features that are found in TLE human patients (i) hippocampal sclerosis, (ii) ictal/interictal events, (iii) mossy fiber sprouting and (iiii) behavioural impairment. Conclusion: Our refined caffeine- and pilocarpine-based protocol substantially improves the outcome of the reliable pilocarpine mouse model of TLE.

GLIAL ACTIVATION CONTRIBUTES TO INCREASED SENSITIVITY OF SPINAL TRPV1 RECEPTORS IN PACLITAXEL INDUCED NEUROPATHIC PAIN.

POSTER SESSION 01 - SECTION: PAIN AND INFLAMMATION

Jakub Slepicka[1], Pavel Adamek[2], Jiri Palecek[2]
[1]Czech Academy of Sciences, Institute Of Physiology, Praha , Czech Republic, [2]Czech Academy of Sciences, Institute Of Physiology, Praha, Czech Republic

Paclitaxel induced peripheral neuropathy (PIPN) is often accompanied with neuropathic pain. Its analgesic treatment is unsatisfactory and brings serious side effects. In previous publications, we showed that the mechanical hyperalgesia in rodents is partially mediated by sensitization of presynaptic TRPV1 receptors in the spinal cord dorsal horn (SCDH)[1] and this effect is dependent on activation of Toll-like 4 receptors (TLR4)[2]. TLR4 are expressed also in glial cells. In the current experiments, we have studied whether glial cells activation is involved in the TRPV1 sensitization. Male rats were used to prepare spinal cord slices for whole-cell patch-clamp recordings of miniature excitatory postsynaptic currents (mEPSC) from superficial SCDH neurons. Minocycline was used as a glial cell activation inhibitor. Capsaicin (200 nM) application resulted in a potent increase of mEPSC frequency that was significantly reduced upon repetition. This was attenuated by acute paclitaxel (50 nM) application[1,2]. *In vitro* (90 min) incubation with minocycline (100 µM) reduced the paclitaxel effect on the TRPV1 mediated response to capsaicin, while acute minocycline application did not have a significant effect. Our results suggest that glial activation plays an important role in the paclitaxel-induced enhancement of TRPV1 responsiveness in the SCDH. Further experiments will evaluate this neuron-glia interaction also in the Bortezomib induced neuropathy. Supported by GAUK 251898, GACR 20-19136S. [1]Adamek et al. Dual PI3Kδ/γ Inhibitor Duvelisib Prevents Development of Neuropathic Pain in Model of Paclitaxel-Induced Peripheral Neuropathy.
The development of painful paclitaxel-induced peripheral neuropathy (PIPN) represents a major dose-limiting side effect of paclitaxel chemotherapy. Here we report a promising effect of duvelisib (Copiktra), a novel FDA-approved PI3Kδ/γ isoform-specific inhibitor, in preventing paclitaxel-induced pain-like behavior and pronociceptive signaling in DRGs and spinal cord dorsal horn (SCDH) in rat and mouse model of PIPN. Duvelisib blocked the development of mechanical hyperalgesia in both males and females. Moreover, duvelisib prevented paclitaxel-induced sensitization of TRPV1 receptors, and increased PI3K/Akt signaling in small-diameter DRG neurons and an increase of CD68 cells within DRGs. Specific optogenetic stimulation of inhibitory neurons combined with patch-clamp recording revealed that duvelisib inhibited paclitaxel-induced weakening of inhibitory, mainly glycinergic control on SCDH excitatory neurons. Enhanced excitatory and reduced inhibitory neurotransmission in the SCDH following PIPN was also alleviated by duvelisib application. In summary, duvelisib showed a promising ability to prevent neuropathic pain in PIPN. The potential use of our findings in human medicine may be augmented by the fact that duvelisib is an FDA-approved drug with known side effects. We show that duvelisib, a novel FDA-approved PI3Kδ/γ isoform-specific inhibitor, prevents the development of paclitaxel-induced pain-like behavior in males and females and prevents pronociceptive signaling in DRGs and spinal cord dorsal horn in rat and mouse model of paclitaxel-induced peripheral neuropathy.

CUTANEOUS C-FIBER SUBTYPES BASED ON NERVE TERMINAL RESPONSIVENESS

POSTER SESSION 01 - SECTION: PAIN AND INFLAMMATION

Danica Jurcakova[1], Marian Grendar[2], Milos Tatar[1], Bradley Undem[3]
[1]Jessenius Faculty of Medicine, Comenius University, Department Of Pathological Physiology, Martin, Slovak Republic, [2]Comenius University, Biomedical Center Martin, Martin, Slovak Republic, [3]Johns Hopkins University, School Of Medicine, Baltimore, United States of America

Sensory neurons in the dorsal root ganglia are diverse cells with transcriptional profiling identifying 6-14 subtypes. Transcriptional studies inform nerve phenotypes, but they are at best cautiously translated to nerve function. Moreover, these studies have focused on the whole ganglia comprising neurons innervating different organs. We evaluated sensory C-fibre phenotypes based on the responsiveness of nerve terminals specifically innervating the dorsal skin of the mouse. Using an *ex vivo* mouse skin-spinal nerve preparation we invested the responses of 193 individual C-fibres to chemical (chloroquine (CQ), BAM8-22, histamine, bradykinin, ß-alanine, serotonin, ATP, lysophosphatidic acid and TRPV1, V3, V4, A1, C3/6, M2) agonists and mechanical stimulation. The C-fibres in mouse skin can be subcategorized into low mechanical threshold and high mechanical threshold C-fibres (C-LTMs (8%) and C-HTMs (92%), respectively). C-LTMs were unresponsive to all chemical mediators except the TRPV4 agonist GSK1016790A. The C-HTMs could be subdivided broadly into two subgroups, one responding strongly to pruritogens such as chloroquine, histamine or BAM8-22 (n=58, 30%), but not other mediators; the other failing to respond to pruritic stimuli, but respond strongly to ATP, serotonin or lysophosphatidic acid. Of the latter, about 50% also respond to the MrgprD stimulant ß-alanine; these ß-alanine responsive C-fibres were the only subtype that responded to the TRPV3 channel agonist farnesyl pyrophosphate (10µM). We hypothesize that activating the chloroquine/histamine sensitive C-HTMs likely evokes pruritic sensations; the more promiscuous, CQ/histamine insensitive C-fibres likely subserve more varied sensations including cutaneous pain. This work was funded by VEGA 1/0306/18.

Allergen-induced histaminergic and non-histaminergic activation of itch C-fiber nerve terminals in mouse skin.
Acute cutaneous exposure to allergen often leads to itch, but seldom pain. The effect of mast cell activation on cutaneous C-fibers was studied using innervated isolated mouse skin preparation that allows for intra-arterial delivery of chemicals to the nerve terminals in the skin. Allergen (ovalbumin) injection into the isolated skin of actively sensitized mice strongly stimulated chloroquine (CQ)-sensitive C-fibers (also referred to as "itch" nerves); on the other hand, CQ-insensitive C-fibers were activated only modestly, if at all. The histamine H1 receptor antagonist pyrilamine abolished itch C-fibers response to histamine, but failed to significantly reduce the response to ovalbumin. Ovalbumin also strongly activated itch C-fibers in skin isolated from Mrgpr-cluster Δ mice. When pyrilamine was studied in the Mrgpr-cluster Δ mice thereby eliminating the influence of both histamine H1 and Mrgpr receptors (MrgprA3 and C11 are selectively expressed by itch nerves), the ovalbumin response was very nearly eliminated. The data indicate that the acute activation of itch C-fibers in mouse skin is largely secondary to the combined effect of activation of histamine H1 and Mrpgr receptors.

Voltage-Gated Sodium Channels Regulating Action Potential Generation in Itch-, Nociceptive-, and Low-Threshold Mechanosensitive Cutaneous C-Fibers.
We evaluated the effect of voltage-gated sodium channel 1 (Na1) blockers in three nonoverlapping C-fiber subtypes in the mouse skin: chloroquine (CQ)-sensitive C-fibers with high mechanical thresholds- second, CQ-insensitive, capsaicin-sensitive C-fibers with high mechanical thresholds- and CQ and capsaicin-insensitive C-fibers with a very low mechanical threshold-C-LTMs. Na1-blocking drugs were applied to the nerve terminal receptive fields using an innervated isolated dorsal mouse skin-nerve preparation where the drugs are delivered into the skin intra-arterially. We combined these studies with an analysis of the mRNA expression of the -subunits of Na1 in individual dorsal root ganglia neurons labeled from the same region of the skin. Our results show that virtually all nociceptors and itch C-fibers expressed the tetrodotoxin (TTX)-resistant channels Na1.8 and Na1.9. However, TTX applied selectively into the skin abolished the action potential firing in response to

mechanical stimulation in 75% of the itch C-fibers, 100% of the nociceptors, and 100% of C-LTMs. Na1.7 was the most commonly expressed TTX-sensitive Na1 in all three C-fiber subtypes innervating the dorsal skin. Selectively blocking Na1.7 abolished responses in about 40% of itch C-fibers, 65% of nociceptors, but only 20% of C-LTMs. Blocking Na1.8 alone had no affect on the firing sensitivity of the C-fibers. However, in itch and nociceptive C-fibers where the activation was not inhibited with a Na1.7 blocker, adding the Na1.8 blocker silenced action potential discharge.

Mechanisms of pruritogen-induced activation of itch nerves in isolated mouse skin.
Chloroquine (CQ) stimulates itch nerves and causes intense scratching in mice by activating the G-protein coupled receptor (GPCR) MrgprA3; it is not known how stimulation of MrgprA3 (or other GPCRs) leads to activation of the itch nerve terminals in the skin, but previous studies have found that transient receptor potential A1 (TRPA1) gene deletion blocks CQ-induced scratching. In the present study we used a novel dorsal skin-nerve preparation to evaluate mechanisms underlying CQ- and histamine-induced action potential discharge in itch nerve terminals. We found that CQ activation of the nerves requires the beta3 isoform of phospholipase C, but TRPA1 or other TRP channel are not required. Evidence is provided for a role for calcium-activated chloride channels such as TMEM16a in GPCR-activation of itch nerve terminals. The mechanism by which TRP channels participate in pruritogen-induced scratching may involve sites of action other than the primary afferent terminals.

CONTRIBUTION OF TTX-RESISTANT NAV CHANNELS TO THE GENERATION OF MEMBRANE POTENTIAL INSTABILITIES IN MOUSE TRIGEMINAL NEURONS

POSTER SESSION 01 - SECTION: PAIN AND INFLAMMATION

Enrique Velasco[1,2], Julio Álvarez[2], Víctor Meseguer[1,3], Juana Gallar[1,3], Karel Talavera[2]
[1]Universidad Miguel Hernández, Instituto De Neurociencias, San Juan de Alicante (Sant Joan d'Alacant), Spain, [2]KULeuven, Laboratory Of Ion Channels Research, Leuven, Belgium, [3]European University for Brain and Technology, Instituto De Neurociencias, San Juan de Alicante (Sant Joan d'Alacant), Spain

Introduction. Peripheral sensory neurons are fundamental for stimulus detection, but many of their properties remain poorly understood, as the display of membrane potential instabilities (MPIs). MPIs are enhanced in pain states, but their functional significance and molecular bases remain unknown. We aimed at determining MPIs voltage modulation, relationship to action potential firing during stimulation and their molecular determinants. **Methods.** We used whole-cell current-clamp recordings on primary cultured mouse trigeminal neurons to record MPIs (144 WT neurons, 22 *$Na_V1.8$*-KO and 22 from *$Na_V1.9$*-KO). We used current injection, temperature, TTX, capsaicin and menthol to stimulate the neurons. Finally, we developed scripts in Python3.0 to analyze individual MPIs. **Results.** All MPIs characteristic showed dependencies with membrane voltage ($p < 0.0001$). The modelling of the relationship between MPIs and action potential generation indicated that MPIs are at the core of ongoing activity generation. Amplitude and maximal first derivative of the MPI determine if an action potential is triggered or not ($R^2 = 0.81$, $p < 0.0001$). The blockade of TTX-Sensitive channels did not affect MPIs ($p > 0.1$) while blocking TTX-Resistant channels ($Na_V1.8$-1.9) disrupted every MPIs characteristic ($p < 0.001$). *$Na_V1.8$* and *$Na_V1.9$-KO* mice neurons displayed MPIs with smaller amplitude and maximal first derivative ($p < 0.0001$). In addition, the frequency of MPIs of *$Na_V1.9$* KO neurons was significantly reduced ($p < 0.0001$). **Conclusion.** MPIs are a TTX-R channels dependent phenomenon, which determines ongoing action potential generation, a crucial feature in the sensory encoding of slow-ramp stimulus like cold, heat and chemical compounds

Membrane potential instabilities in sensory neurons: mechanisms and pathophysiological relevance.
Peripheral sensory neurons transduce physicochemical stimuli affecting somatic tissues into the firing of action potentials that are conveyed to the central nervous system. This results in conscious perception, adaptation, and survival, but alterations of the firing patterns can result in pain and hypersensitivity conditions. Thus, understanding the molecular mechanisms underlying action potential firing in peripheral sensory neurons is essential in sensory biology and pathophysiology. Over the past 30 years, it has been consistently reported that these cells can display membrane potential instabilities (MPIs), in the form of subthreshold membrane potential oscillations or depolarizing spontaneous fluctuations. However, research on this subject remains sparse, without a clear conductive thread to be followed. To address this, we here provide a synthesis of the description, molecular bases, mathematical models, physiological roles, and pathophysiological implications of MPIs in peripheral sensory neurons. Membrane potential instabilities have been reported in trigeminal, dorsal root, and Mes-V ganglia, where they are believed to support repetitive firing. They are proposed to have roles also in intercellular communication, ectopic firing, and responses to tonic and slow natural stimuli. We highlight how MPIs are of great interest for the study of sensory transduction physiology and how they may represent therapeutic targets for many pathological conditions, such as acute and chronic pain, itch, and altered sensory perceptions. We identify future research directions, including the elucidation of the underlying molecular determinants and modulation mechanisms, their relation to the encoding of natural stimuli and their implication in pain and hypersensitivity conditions.

Deciphering the Action of Perfluorohexyloctane Eye Drops to Reduce Ocular Discomfort and Pain.
Perfluorohexyloctane (F6H8) eyedrops have been recently introduced in Europe as a product to treat dry eye disease, based on its ability to reduce tear film instability in Meibomian gland dysfunction and evaporative dry eye disease, although its mechanism of action is still unknown. In the present pilot study, we evaluated the effects of the ocular instillation of a single

drop of commercial F6H8 eyedrops in 20 healthy humans (9 women/11 men), measuring: (a) Corneal surface temperature (CST) from infrared video images; (b) tear volume using phenol red threads; (c) blinking frequency; and (d) ocular surface sensations (cold, dryness, pricking, foreign body, burning, itching, gritty, eye fatigue, watering eyes, and light-evoked discomfort sensations; scored using 10 cm Visual Analog Scales), before and 5-60 min after F6H8 or saline treatment. CST decreased and tearing and blinking frequency increased significantly after F6H8 but not after saline solution. When applied unilaterally, CST decreased only in the F6H8-treated eye. No sensations were evoked after F6H8 or saline. The corneal surface temperature reduction produced by topical F6H8 does not evoke conscious ocular sensations but is sufficient to increase the activity of corneal cold thermoreceptors, leading to an increased reflex lacrimation and blinking that may relieve dry eye condition thus reducing ocular discomfort and pain.

Effects of Percutaneous Electrolysis on Endogenous Pain Modulation: A Randomized Controlled Trial Study Protocol.
Percutaneous electrolysis consists of the application of a galvanic electrical current throughout an acupuncture needle. It has been previously hypothesized that needling procedures' neurophysiological effects may be related to endogenous pain modulation (EPM). This protocol study describes the design of a double-blind (participant, assessor) randomized controlled trial with the aim to investigate whether percutaneous electrolysis is able to enhance EPM and whether the effect is different between two applications depending on the dosage of the galvanic electrical current. Seventy-two asymptomatic subjects not reporting the presence of pain symptoms the previous 6 months before the study, aged 18-40 years, are randomized into one of four groups: a control group who does not receive any intervention, a needling group who receives a needling intervention without electrical current, a low-intensity percutaneous electrolysis group (0.3 mA × 90 s), and a high-intensity percutaneous electrolysis group (three bouts of 3 mA × 3 s). Needling intervention consists of ultrasound-guided insertion of the needle on the common extensor tendon of the lateral epicondyle. The primary outcome is conditioned pain modulation (CPM), and secondary outcomes include widespread pressure pain sensitivity (pressure pain thresholds (PPT) over the lateral epicondyle, the cervical spine, and the tibialis anterior muscle) and temporal summation (TS). We expected that percutaneous electrolysis would have a greater influence on CPM than an isolated needling procedure and no intervention. In addition, we also postulated that there might be differences in outcome measures depending on the intensity of the electrical current during the percutaneous electrolysis application. This study makes a new contribution to the field of neurophysiological effects of percutaneous electrolysis and needling interventions.

Reversed Polarity bi-tDCS over M1 during a Five Days Motor Task Training Did Not Influence Motor Learning. A Triple-Blind Clinical Trial.
Transcranial direct current stimulation (tDCS) has been investigated as a way of improving motor learning. Our purpose was to explore the reversal bilateral tDCS effects on manual dexterity training, during five days, with the retention component measured after 5 days to determine whether somatosensory effects were produced. In this randomized, triple-blind clinical trial, 28 healthy subjects (14 women) were recruited and randomized into tDCS and placebo groups, although only 23 participants (13 women) finished the complete protocol. Participants received the real or placebo treatment during five consecutive days, while performing a motor dexterity training program of 20 min. The motor dexterity and the sensitivity of the hand were assessed pre- and post-day 1, post 5 days of training, and 5 days after training concluded. Training improved motor dexterity, but tDCS only produced a tendency to improve retention. The intervention did not produce changes in the somatosensory variables assessed. Thus, reversal bi-tDCS had no effects during motor learning on healthy subjects, but it could favor the retention of the motor skills acquired. These results do not support the cooperative inter-hemispheric model.

A genetic compensatory mechanism regulated by and modulates the expression of distinct class IIa to ensure peripheral nerve myelination and repair.

The class IIa histone deacetylases (HDACs) have pivotal roles in the development of different tissues. Of this family, Schwann cells express , , and but not . Here, we show that a transcription factor regulated genetic compensatory mechanism within this family of proteins, blocks negative regulators of myelination ensuring peripheral nerve developmental myelination and remyelination after injury. Thus, when and are knocked-out from Schwann cells in mice, a JUN-dependent mechanism induces the compensatory overexpression of permitting, although with a delay, the formation of the myelin sheath. When , , and are simultaneously removed, the myocyte-specific enhancer-factor d (MEF2D) binds to the promoter and induces the de novo expression of , and although several melanocytic lineage genes are misexpressed and Remak bundle structure is disrupted, myelination proceeds after a long delay. Thus, our data unveil a finely tuned compensatory mechanism within the class IIa family, coordinated by distinct transcription factors, that guarantees the ability of Schwann cells to myelinate during development and remyelinate after nerve injury.

Epithelial and sensory mechanisms of nasal hyperreactivity.
"Nasal hyperreactivity" is a key feature in various phenotypes of upper airway diseases, whereby reactions of the nasal epithelium to diverse chemical and physical stimuli are exacerbated. In this review, we illustrate how nasal hyperreactivity can result from at least three types of mechanisms: (1) impaired barrier function, (2) hypersensitivity to external and endogenous stimuli, and (3) potentiation of efferent systems. We describe the known molecular basis of hyperreactivity related to the functional impairment of epithelial cells and somatosensory innervation, and indicate that the thermal, chemical, and mechanical sensors determining hyperreactivity in humans remain to be identified. We delineate research directions that may provide new insights into nasal hyperreactivity associated with rhinitis/rhinosinusitis pathophysiology and therapeutics. The elucidation of the molecular mechanisms underlying nasal hyperreactivity is essential for the treatment of rhinitis according to the precepts of precision medicine.

Sensorimotor effects of plasticity-inducing percutaneous peripheral nerve stimulation protocols: a blinded, randomized clinical trial.
Electrical stimulation of skin afferents can induce somatosensory plasticity in humans. Nevertheless, it is unknown if this is possible to do through percutaneous stimulation of a peripheral nerve, which will allow for regional anaesthesia interventions. Furthermore, potentiation protocols applied over mainly non-nociceptive fibres inhibit nociception in rodents, but this has not been tested in humans.

TARGETING MU OPIOID RECEPTOR TO ALLEVIATE DRY EYE DISEASE-ASSOCIATED CHRONIC CORNEAL ALLODYNIA IN MICE

POSTER SESSION 01 - SECTION: PAIN AND INFLAMMATION

Adrian Guerrero-Moreno[1], Elodie Reboussin[1], Christophe Baudouin[1,2,3], Stéphane Melik Parsadaniantz[1], Annabelle Réaux-Le Goazigo[1]

Aims: Chronic corneal pain associated with dry eye disease (DED) is very disabling and difficult to treat. Analgesic effects of topical mu-opioid receptor (MOR) agonist have been reported in mice developing acute inflammatory corneal pain. This work evaluates the use of these agonists in a model of chronic corneal allodynia in mice. **Methods:** DED-associated corneal allodynia was induced by unilateral excision of the harderian and extraorbital lacrimal glands of adult male mice. Controls were performed by sham surgery. Topical ocular instillation with the MOR-selective ligand DAMGO ([D-Ala^2,N-Me-Phe^4,Gly^5-ol] enkephalin, 50 µM) or phosphate-buffered saline were performed twice/day. Ocular discomfort, mechanical and chemical corneal sensitivities were quantified by aperture ratio, von Frey test and NaCl 2M and capsaicin 10 µM challenge test, respectively. Those behavioural tests were performed before and every week until 21 day (D21) post-surgery. At D21, mice were perfused and MOR expression was investigated on corneal nerves and trigeminal ganglion (TG) by immunohistochemistry and *in situ* hybridization (RNAScope). **Results:** We detected MOR immunoreactivity in subbasal corneal nerves. MOR RNA expression was significantly higher in the ophthalmic branch of the TG from DED-associated allodynia mice compared with sham animals. RNAscope experiments revealed a high co-expression between MOR and TRPV1$^+$ and TRPM8$^+$ in the trigeminal primary sensory neurons from both DED-associated allodynia and sham mice. Finally, we found that chronic topical DAMGO reduced significantly ocular discomfort, mechanical and chemical allodynia in DED mice compared with controls. **Conclusions:** MOR agonist may constitute a therapeutic target for the treatment of DED-associated chronic corneal allodynia.

EVALUATION OF TACAN AS A NEW TARGET FOR TREATING OSTEOARTHRITIS PAIN

POSTER SESSION 01 - SECTION: PAIN AND INFLAMMATION

Lise Rabiller
McGill, Physiology, Montreal, Canada

Joint pain is the most prominent symptom of osteoarthritis (OA). Patients suffering from OA experience mechanical allodynia which is due in large part to a dysfunction in pain-sensing nerves (nociceptors). We demonstrated that during OA, mechanosensitive ion channels (MSIC) become sensitized and are important contributors of the mechanical allodynia. The central component of this apparatus is a high-threshold mechanosensitive ion channel that converts high-intensity mechanical forces into electrical signals. We showed that blocking MSICs can be analgesic in a preclinical model of OA pain. However, the molecular identity of these channels remains unknown and prevents progress toward improved OA pain management. Our group recently identified an ion channel expressed in mouse nociceptors called TACAN, essential to the sensation of mechanical pain. In this project, we hypothesize that TACAN contributes to OA pain. We used behavioural tests for assessing mechanical allodynia and pain during OA in mice and histological analyses of the knee joint. We generated a mouse in which TACAN deletion can be induced in nociceptors specifically by tamoxifen injection. Our experiment indicate that TACAN plays an important role in the mechanical allodynia observed in OA pain. Further investigation is being conducted at the cellular and molecular levels in mice deleted for TACAN to obtain a mechanistic readout of these effects.

Pain sensing neurons promote tissue regeneration in adult mice.
Tissue repair after injury in adult mammals, usually results in scarring and loss of function in contrast to lower vertebrates such as the newt and zebrafish that regenerate. Understanding the regulatory processes that guide the outcome of tissue repair is therefore a concerning challenge for regenerative medicine. In multiple regenerative animal species, the nerve dependence of regeneration is well established, but the nature of the innervation required for tissue regeneration remains largely undefined. Using our model of induced adipose tissue regeneration in adult mice, we demonstrate here that nociceptive nerves promote regeneration and their removal impairs tissue regeneration. We also show that blocking the receptor for the nociceptive neuropeptide calcitonin gene-related peptide (CGRP) inhibits regeneration, whereas CGRP administration induces regeneration. These findings reveal that peptidergic nociceptive neurons are required for adult mice tissue regeneration.

Driving regeneration, instead of healing, in adult mammals: the decisive role of resident macrophages through efferocytosis.
Tissue repair after lesion usually leads to scar healing and thus loss of function in adult mammals. In contrast, other adult vertebrates such as amphibians have the ability to regenerate and restore tissue homeostasis after lesion. Understanding the control of the repair outcome is thus a concerning challenge for regenerative medicine. We recently developed a model of induced tissue regeneration in adult mice allowing the comparison of the early steps of regenerative and scar healing processes. By using studies of gain and loss of function, specific cell depletion approaches, and hematopoietic chimeras we demonstrate here that tissue regeneration in adult mammals depends on an early and transient peak of granulocyte producing reactive oxygen species and an efficient efferocytosis specifically by tissue-resident macrophages. These findings highlight key and early cellular pathways able to drive tissue repair towards regeneration in adult mammals.

Tissue Regeneration: The Dark Side of Opioids.
Opioids are regarded as among the most effective analgesic drugs and their use for the management of pain is considered

standard of care. Despite their systematic administration in the peri-operative period, their impact on tissue repair has been studied mainly in the context of scar healing and is only beginning to be documented in the context of true tissue regeneration. Indeed, in mammals, growing evidence shows that opioids direct tissue repair towards scar healing, with a loss of tissue function, instead of the regenerative process that allows for recovery of both the morphology and function of tissue. Here, we review recent studies that highlight how opioids may prevent a regenerative process by silencing nociceptive nerve activity and a powerful anti-inflammatory effect. These data open up new perspectives for inducing tissue regeneration and argue for opioid-restricted strategies for managing pain associated with tissue injury.

Opioids prevent regeneration in adult mammals through inhibition of ROS production.
Inhibition of regeneration and induction of tissue fibrosis are classic outcomes of tissue repair in adult mammals. Here, using a newly developed model of regeneration in adult mammals i.e. regeneration after massive resection of an inguinal fat pad, we demonstrate that both endogenous and exogenous opioids prevent tissue regeneration in adults, by inhibiting the early production of reactive oxygen species (ROS) that generally occurs after lesion and is required for regeneration. These effects can be overcome and regeneration induced by the use of an opioid antagonist. The results obtained in both our new model and the gold standard adult zebrafish demonstrate that this mechanism can be considered as a general paradigm in vertebrates. This work clearly demonstrates that ROS is required for tissue regeneration in adult mammals and shows the deleterious effect of opioids on tissue regeneration through the control of this ROS production. It thus raises questions about opioid-based analgesia in perioperative care.

Benzydamine is a well-known anti-inflammatory active principle with an associated and recognized local anaesthetic/analgesic activity. It is widely used in oral affections due to its high efficacy and robust safety profile by local application. Although, several studies showed the multi target action of benzydamine on inflammatory system, its role as neuronal excitability modulator has been less explored. The aim of this project is to evaluate the capacity of benzydamine to decrease neuronal activity in an inflammatory sensitized DRG model by electrophysiological approach, supporting the local pain signal suppression action of the compound. Neurons isolated from dorsal root ganglia of Wistar rats were incubated for 24-hours with or without a specific inflammatory cocktail. The action potential firing was recorded by Multi Electrode Assay after acute exposure to the same inflammatory cocktail, acid pH, or potassium chloride. A dose-related inhibition of neuronal excitability by benzydamine triggered by either the inflammatory cocktail or the acidic pH was shown in sensitized nociceptors and in basal conditions in MEA recording. Notably, a higher potency over basal conditions, was shown under inflammatory sensitized situation, with a significant shift of the dose response curve of benzydamine. To confirm these results, electrophysiological studies based on single cells assay are currently performed on DRG neurons in the same experimental conditions and with longer time of exposure to benzydamine. The results obtained should add insights on the molecular mechanism of benzydamine with regards to the inhibition of neuronal excitability, suggesting complementary effects with the well-known anti-inflammatory activity.

The lionfish (*Pterois volitans*) is a venomous species endemic to the Indo-Pacific, but that has now invaded the Northwestern Atlantic as well as the Caribbean and Mediterranean Seas. It poses a growing health problem due to the increase in frequency of painful stings that it delivers, for which no treatment or antidote exists. A prior collaborative study by our group characterized the pain and inflammation caused by the lionfish venom and provided the first insight into the venom's cellular target in the peripheral nervous system – nonpeptidergic nociceptors. The aim of this research project is to isolate the algogenic toxin in the venom and identify its receptor target to understand the molecular mechanism for the pain caused by lionfish venom. The toxin was isolated using high pressure liquid chromatography and mass spectrometry in order to identify its sequence. Preliminary results point to the venom's receptor target, which has been verified using calcium imaging, behaviour and patch-clamp electrophysiology experiments. We have cloned the venom's target from *Gymnothorax favagineus* (Honeycomb moray eel), a predator of the lionfish, as well as from the lionfish itself to evaluate these targets' sensitivity to lionfish venom using calcium imaging and electrophysiology. These results will 1) identify novel modulators of the pain pathway and 2) provide insights into the parallel evolution of the algogenic toxin in lionfish venom and its target in predators.

PERIPHERAL VOLTAGE-GATED CALCIUM CHANNELS IN SKIN ARE ESSENTIAL FOR TRANSIENT HEAT HYPERSENSITIVITY IN MICE

POSTER SESSION 01 - SECTION: PAIN AND INFLAMMATION

E. Javier Lopez Soto[1], Daniel Dubreuil[2], Simon Daste[3], Remy Meir[3], Alexander Fleischmann[3], Diane Lipscombe[3]

$Ca_V2.2$ voltage-gated calcium channels are the dominant Ca_V channel expressed in nociceptors. $Ca_V2.2$ channel inhibitors applied to the spinal cord relieve pain in humans and rodents, especially during pathological pain. $Ca_V2.2$ channels are expressed at nociceptor pre-synaptic terminals, soma, and peripheral axons, but a biological function of nociceptor $Ca_V2.2$ channels outside pre-synaptic terminals is rarely considered. Here, we demonstrate that $Ca_V2.2$ channels at nociceptors free nerve endings in skin are required for heat hypersensitivity. We used Hargreaves and automatic von Frey assays to evaluate heat and mechanical sensitivities in wild-type and in a new $Ca_V2.2$-null mice. We assessed the role of peripheral $Ca_V2.2$ channels in skin, in particular in capsaicin-induced hypersensitivity. Intraplantar injection of capsaicin, a TRPV1 channels agonist, induces transient hypersensitivity to mechanical and heat stimuli at 15 mins with returning to baseline responses within 30 mins. Capsaicin-induced heat, but not mechanical, hypersensitivity was 60% reduced in $Ca_V2.2$-null as compared to wild-type mice. To assess the role of peripheral $Ca_V2.2$ channels in skin we used intraplantar ω-conotoxin MVIIA. In wild-type mice, capsaicin-induced heat hypersensitivity was consistently reduced by co-injecting conotoxin with capsaicin, compared to capsaicin alone. We then directly assessed the contribution of $Ca_V2.2$ gating to the Ca^{2+} signal triggered by capsaicin in the skin by 2-photon microscopy live imaging. We found that capsaicin-induced Ca^{2+} signal in nociceptor projections was reduced ~60% by conotoxin. Our data reveal that local activation of peripheral $Ca_V2.2$ channels in nociceptor termini in skin *in vivo* are required for capsaicin-induced heat hypersensitivity, but not mechanical hypersensitivity.

BEHAVIORAL RESPONSES EVOKED BY OPTOGENETIC ACTIVATION OF CACNA1H-EXPRESSING LOW THRESHOLD MECHANORECEPTORS IN MICE

POSTER SESSION 01 - SECTION: PAIN AND INFLAMMATION

Remy Meir[1], Diane Lipscombe[2]
[1]Brown University, Neuroscience, Providence, United States of America, [2]Brown University, Department Of Neuroscience, Providence, United States of America

Voltage-gated calcium (Ca_V) channels play a critical role in transmitting information about various sensory modalities including thermal and mechanical stimuli. We recently discovered that $Ca_V2.2$ channels (*Cacna1b*) in peripheral nerve endings of *Trpv1* nociceptors are critical for capsaicin-induced transient hypersensitivity to heat but not mechanical stimuli (DuBreuil et al., 2021). Here we explore the role of $Ca_V3.2$ channels (*Cacna1h*), which are expressed in C and Aδ low threshold mechanoreceptors (LTMRs), in regulating mechanosensitivity. $Ca_V3.2$ channels are implicated in regulating mechanosensitivity thresholds in a pro-excitatory manner, but their precise mechanism of action is not fully elucidated. We generated a *Cacna1h*$^{Cre\ +/+}$ knock-in mouse model to express Cre-dependent reporters, including ChannelRhodopsin (ChR2), in C and Aδ LTMRs. LED light (465 nm) directed at glabrous skin of *Cacna1h*$^{ChR2\text{-}YFP+/-}$ hindpaws triggered robust, intensity dependent plantar paw withdrawal responses, consistent with tactile-free activation of Aδ LTMRs. Intraplantar capsaicin induced robust mechanical hypersensitivity within 15 mins but, interestingly, the sensitivity of optogenetically evoked responses were unaltered. Intraplantar Complete Freund's Adjuvant (CFA) triggers longer lasting hypersensitivity to tactile stimuli within 1 day of treatment and, in contrast to capsaicin, this model exhibited 8.6-fold greater paw withdrawal sensitivity to LED stimulation (75 mA) ipsilateral compared to contralateral. Our findings show that optogenetic activation of *Cacna1h*-expressing Aδ LTMRs can model CFA-enhanced behavioral responses, but not capsaicin-induced transient mechanical hypersensitivity.

Heat But Not Mechanical Hypersensitivity Depends on Voltage-Gated Ca2.2 Calcium Channel Activity in Peripheral Axon Terminals Innervating Skin.
Voltage-gated Ca2.2 calcium channels are expressed in nociceptors at presynaptic terminals, soma, and axons. Ca2.2 channel inhibitors applied to the spinal cord relieve pain in humans and rodents, especially during pathologic pain, but a biological function of nociceptor Ca2.2 channels in processing of nociception, outside presynaptic terminals in the spinal cord, is underappreciated. Here, we demonstrate that functional Ca2.2 channels in peripheral axons innervating skin are required for capsaicin-induced heat hypersensitivity in male and female mice. We show that Ca2.2 channels in TRPV1-nociceptor endings are activated by capsaicin-induced depolarization and contribute to increased intracellular calcium. Capsaicin induces hypersensitivity of both thermal nociceptors and mechanoreceptors, but only heat hypersensitivity depends on peripheral Ca2.2 channel activity, and especially a cell-type-specific Ca2.2 splice isoform. Ca2.2 channels at peripheral nerve endings might be important therapeutic targets to mitigate certain forms of chronic pain. It is generally assumed that nociceptor termini in the spinal cord dorsal horn are the functionally significant sites of Ca2.2 channel in control of transmitter release and the transmission of sensory information from the periphery to central sites. We show that peripheral Ca2.2 channels are essential for the classic heat hypersensitivity response to develop in skin following capsaicin exposure. This function of Ca2.2 is highly selective for heat, but not mechanical hypersensitivity induced by capsaicin exposure, and is not a property of closely related Ca2.1 channels. Our findings suggest that interrupting Ca2.2-dependent calcium entry in skin might reduce heat hypersensitivity that develops after noxious heat exposure and may limit the degree of heat hypersensitivity associated with certain other forms of pain.

The sad weekend: A perilous North American tradition.
Obesity is a global concern and affects millions of Americans who consume poor-quality diets. Diets directly affect the gut microbiota, which can have subsequent effects on inflammation and contribute to other chronic states. Previously we have

shown that a Standard American Diet (SAD) increased immune cell activation and prolonged recovery and that a beneficial diet could reduce these negative effects. Here, male and female mice were given access to regular chow (REG), SAD, our Anti-Inflammatory Diet (AID) or a combination of SAD and AID. This latter group was modeled on the commonplace dietary pattern of healthy eating during the week (AID: Monday-Friday) and relaxed eating patterns on the weekend (SAD: Saturday-Sunday). After 14 weeks of diet consumption and an inflammatory injury, we found that the SAD prolonged and the AID promoted recovery. However, recovery was significantly delayed in those mice consuming the AID-SAD, regardless of weekly healthy diet access. In addition, fecal samples taken during the study revealed dramatic differences in microbial community composition, relative abundance of abundant bacterial phyla and alpha diversity. These data confirm the impact of diet on gut microbiota and suggest a relation between abundance of specific bacterial taxa and susceptibility to prolonged recovery from injury.

PKA-II ACTIVATION IN NOCICEPTIVE NEURONS BY CAPSAICIN AND AITC BUT NOT BY IONOMYCIN

POSTER SESSION 01 - SECTION: PAIN AND INFLAMMATION

Jörg Isensee, Alexandra Hohnen, Tim Hucho
University of Cologne, Department Of Anesthesiology And Intensive Care Medicine, Translational Pain Research, University Hospital Of Cologne, Cologne, Germany

We identified KCl- or Veratridine-depolarization to activate PKA-II in nociceptive neurons. This was calcium and L-type voltage-gated-calcium-channel Cav1.2-dependent and resulted in a feed forward manner in sensitization of Cav1.2 and prolonged mechanical hyperalgesia. If calcium entry also through ligand gated ion channels such as TRPV1 and TRA1 results in PKA-II activation and if this is negatively regulated by the phosphatase calcineurin (CaN) is not known. Using High Content Screening (HCS) microscopy, we found that also the TRPV1 agonist, capsaicin, and the TRPA1 agonist, allyl isothiocyanate (AITC), induced PKA-II activity, whereas the calcium ionophore ionomycin was ineffective. CaN inhibitors increased PKA-II activity and phosphorylation of downstream targets upon capsaicin and KCl depolarization, but not upon AITC or ionomycin treatment. In particular, CaN inhibitors increased the phosphorylation of CaV1.2 upon KCl and capsaicin, but not upon AITC or ionomycin treatment. Our findings demonstrates that also ligand gated ion channels initiate the novel process of nociceptor-depolarization-induced PKA-II activation. Interestingly, while converging onto the same kinase, the regulatory mechanisms were strictly stimulus-specific.

TRPM8 (*Transient Receptor Potential Melastatin member 8*) is an ionic channel activated both by cool temperatures, below 25°C, and by an array of natural and synthetic agonists, endogenous compounds and intracellular acidic pH values. This channel plays a role in thermoregulation, cold analgesia and, paradoxically, in cold hypersensitivity and cold pain. Although modulation of TRPM8 by inflammatory mediators is not yet completely understood, it has been shown that mediators which activate $G\alpha_q$-coupled receptors, potently inhibit TRPM8 activation. This inhibition is reported to happen independently of PLCβ (*Phospholipase C beta*) activation, via direct interaction between the activated $G\alpha_q$ and the ionic channel. The prostacyclin receptor IP is a GPCR (*G-protein coupled receptor*), preferentially activated by prostaglandin I_2 (PGI_2), involved in acute inflammation, inflammatory pain and a series of severe cardiovascular and pulmonary diseases. The IP receptor couples both with $G\alpha_s$, in platelets and smooth muscle cells, and $G\alpha_q$, in DRG (*Dorsal Root Ganglia*). Our research aim was to investigate the signaling pathways involved in the modulation of the TRPM8 channel by a series of selective IP receptor agonists. For this purpose, we co-transfected HEK 293T cells with TRPM8 and the IP receptor and treated them with cicaprost and iloprost, two synthetic analogs of prostacyclin. Then, using non-ratiometric calcium microfluorimetry, we monitored how the activation of the IP receptor affects the activation of TRPM8. Our results demonstrate that the signaling pathway triggered by the IP receptor depends on the specific agonist and this effect leads to differential modulation of TRPM8.

MU-OPIOID RECEPTOR DESENSITIZATION IN THE SPINAL CORD DORSAL HORN IS REDUCED BY THE ENDOGENOUS TRPV1 AGONIST N-OLEOYLDOPAMINE.

POSTER SESSION 01 - SECTION: PAIN AND INFLAMMATION

Mario Heles, Pavel Adamek, Diana Spicarova, Jiri Palecek
Czech Academy of Sciences, Institute Of Physiology, Praha, Czech Republic

Opioid receptors are expressed throughout the afferent pain pathway, including central terminals of primary afferent neurons in the spinal cord dorsal horn (SCDH), where opioids exert inhibitory control of the nociceptive transmission. At these presynaptic endings opioid receptors co-express at the first nociceptive synapse with the transient receptor potential vanilloid type 1 (TRPV1) channel, known for its role in the development of thermal and mechanical hyperalgesia during pathological states. Our study focused on the interaction of TRPV1 and μ-opioid receptor (MOR) in agonist-induced desensitization of MOR. We used whole-cell patch-clamp recordings of miniature excitatory postsynaptic currents (mEPSCs) from SCDH neurons in rat spinal cord slices. Short application of MOR agonist DAMGO (1 μM, 3 min) depressed mEPSC frequency to 62.3 ± 3.6 %. To induce robust MOR desensitization, we incubated slices with 1 μM DAMGO for 2 hours; acute application of DAMGO after the incubation failed to depress the mEPSC frequency. Addition of endogenous TRPV1 agonist N-oleoyldopamine (OLDA) to DAMGO during incubation prevented the MOR desensitization. Short DAMGO application in slices incubated with DAMGO+OLDA evoked a decrease of mEPSC frequency to 66.94 ± 9.6 %. In slices from animals with chronic constriction injury (CCI) model of neuropathic pain, acute DAMGO application induced only reduced inhibition compared to the controls (74.71 ± 11 %). Our data reveal how endogenous TRPV1-mediated pathways may interact with MOR function, reduce MOR desensitization and thus promote the efficacy of opioids. Further study of the underlying mechanisms could contribute to improved opioid-mediated analgesia. Supported by GACR20-19136S.

Chemokine CCL2 prevents opioid-induced inhibition of nociceptive synaptic transmission in spinal cord dorsal horn.
Opioid analgesics remain widely used for pain treatment despite the related serious side effects. Some of those, such as opioid tolerance and opioid-induced hyperalgesia may be at least partially due to modulation of opioid receptors (OR) function at nociceptive synapses in the spinal cord dorsal horn. It was suggested that increased release of different chemokines under pathological conditions may play a role in this process. The goal of this study was to investigate the crosstalk between the μOR, transient receptor potential vanilloid 1 (TRPV1) receptor and C-C motif ligand 2 (CCL2) chemokine and the involvement of spinal microglia in the modulation of opioid analgesia.

Dual PI3Kδ/γ Inhibitor Duvelisib Prevents Development of Neuropathic Pain in Model of Paclitaxel-Induced Peripheral Neuropathy.
The development of painful paclitaxel-induced peripheral neuropathy (PIPN) represents a major dose-limiting side effect of paclitaxel chemotherapy. Here we report a promising effect of duvelisib (Copiktra), a novel FDA-approved PI3Kδ/γ isoform-specific inhibitor, in preventing paclitaxel-induced pain-like behavior and pronociceptive signaling in DRGs and spinal cord dorsal horn (SCDH) in rat and mouse model of PIPN. Duvelisib blocked the development of mechanical hyperalgesia in both males and females. Moreover, duvelisib prevented paclitaxel-induced sensitization of TRPV1 receptors, and increased PI3K/Akt signaling in small-diameter DRG neurons and an increase of CD68 cells within DRGs. Specific optogenetic stimulation of inhibitory neurons combined with patch-clamp recording revealed that duvelisib inhibited paclitaxel-induced weakening of inhibitory, mainly glycinergic control on SCDH excitatory neurons. Enhanced excitatory and reduced inhibitory neurotransmission in the SCDH following PIPN was also alleviated by duvelisib application. In summary, duvelisib showed a promising ability to prevent neuropathic pain in PIPN. The potential use of our findings in human medicine may be augmented by the fact that duvelisib is an FDA-approved drug with known side effects. We show that duvelisib, a novel FDA-approved PI3Kδ/γ isoform-specific inhibitor, prevents the development of paclitaxel-induced pain-like behavior in males and females and prevents pronociceptive signaling in DRGs and spinal cord dorsal horn in rat and mouse model of paclitaxel-

induced peripheral neuropathy.

Mechanical allodynia and enhanced responses to capsaicin are mediated by PI3K in a paclitaxel model of peripheral neuropathy.
Paclitaxel chemotherapy treatment often leads to neuropathic pain resistant to available analgesic treatments. Recently spinal Toll-like receptor 4 (TLR4) and the transient receptor potential cation channel subfamily V member 1 (TRPV1) were identified to be involved in the pro-nociceptive effect of paclitaxel. The aim of this study was to investigate the role of phosphatidylinositol 3-kinase (PI3K) and serine/threonine kinases in this process, with the use of their antagonists (wortmannin, LY-294002, and staurosporine). The single paclitaxel administration (8 mg/kg i.p.) in mice induced robust mechanical allodynia measured as a reduced threshold to von Frey filament stimulation and generated reduced tachyphylaxis of capsaicin-evoked responses, recorded as changes in mEPSC frequency in patch-clamp recordings of dorsal horn neurons activity in vitro, for up to eight days. Paclitaxel application also induced increased Akt kinase phosphorylation in rat DRG neurons. All these paclitaxel-induced changes were prevented by the wortmannin in vivo pretreatment. Acute co-application of wortmannin or LY-294002 with paclitaxel in spinal cord slices also attenuated the paclitaxel effect on capsaicin-evoked responses. Staurosporine was effective in the acute in vitro experiments and on the first day after the paclitaxel treatment in vivo, but in contrast to wortmannin, it did not have a significant impact later. Our data suggest that the inhibition of PI3K signaling may help alleviate pathological pain syndromes in the paclitaxel-induced neuropathy.

ROLE OF DOPAMINE D4 RECEPTOR IN THE DEVELOPMENT OF MORPHINE-INDUCED ANALGESIC TOLERANCE

POSTER SESSION 01 - SECTION: PAIN AND INFLAMMATION

Marina Ponce Velasco[1], M Angeles Real Avilés[1], Belén Gago[2], Alicia Rivera[1]
[1]Universidad de Malaga, Biologia Celular, Genetica Y Fisiologia, Malaga, Spain, [2]Universidad de Málaga, Instituto de Investigación Biomédica de Málaga, Facultad De Medicina, Málaga, Spain

Morphine is one of the most effective drugs used for pain management. However, prolonged exposition to morphine produces effects such as tolerance to analgesia and addiction. Downregulation of the mu opioid receptor (MOR) and its uncoupling to G-proteins in the dorsal horn are likely to contribute to the development of morphine tolerance. Previous studies demonstrated that dopamine D_4 receptor (D_4R) activation prevents morphine addiction by modulating dopamine signaling from nigral dopamine cells. This effect seems to be the result of an antagonistic receptor-receptor interaction involving a D_4R-MOR heteroreceptor which could exist in the dorsal striatum. As D_4R is expressed in dorsal horn neurons, we hypothesize that D_4R could interfere in the development of morphine-induced tolerance to its analgesic effects. Here, using a chronic paradigms of combined treatment of morphine with the D_4R agonist PD168.077, we investigated the nociceptive response to three noxious stimuli: thermal (tail-flick test), mechanical (von Frey test) and chemical (formalin test). Moreover, using immunohistochemical techniques, we have evaluated alterations in the primary circuitry of pain (peptidergic and non-peptidergic C fibers and spinal projections neurons NK1-R) and the balance between glutamate and GABA within dorsal horn. Results from the evaluation of analgesic activity of chronic combined treatment of morphine with PD168,077 showed that D_4R prevents the development of morphine-induced analgesic tolerance. This results give support for the existence of antagonistic functional D_4R-MOR interaction in the dorsal horn that could help to the development of a new pharmacology strategy for treatment of pain. ORGANIC ANION TRANSPORTER 1 IS AN HDAC4-REGULATED MEDIATOR OF PERSISTENT INFLAMMATORY PAIN

POSTER SESSION 01 - SECTION: PAIN AND INFLAMMATION

Christian Litke[1], Anna Hagenston[1], Ann-Kristin Kenkel[1], Eszter Paldy[2], Jianning Lu[2], Rohini Kuner[2], Daniela Mauceri[1]

Persistent pain is sustained by maladaptive changes in gene transcription resulting in altered function of the relevant circuits; therapies are still unsatisfactory. The epigenetic mechanisms and affected genes linking nociceptive activity to transcriptional changes and pathological sensitivity are unclear. Here, we found that, among several histone deacetylases (HDACs), synaptic activity specifically affects HDAC4 in spinal cord dorsal horn neurons: stimuli that induce long-lasting inflammatory pain cause nuclear export and inactivation of HDAC4. The development of inflammation-associated mechanical hypersensitivity, but neither acute nor basal sensitivity, is impaired by the expression of a constitutively nuclear localized HDAC4 mutant. Next generation RNA-sequencing revealed an inflammatory pain-dependent HDAC4-regulated gene program comprising known and novel mediators of sensitization including the organic anion transporter OAT1, known for its renal transport function. Using pharmacological and molecular tools to modulate OAT1 activity or expression, we causally link OAT1 to persistent inflammatory pain. Thus, HDAC4 is a key epigenetic regulator of pain that translates nociceptive activity into sensitization by regulating OAT1, a novel and appealing target for pain-relieving therapies.

LOCKED NUCLEIC ACID ANTISENSE OLIGONUCLEOTIDES: A NEW GENETIC TOOL TO KNOCKDOWN THE GENE ENCODING NAV1.7 IN HUMAN INDUCED-PLURIPOTENT STEM CELL-DERIVED PERIPHERAL SENSORY NEURONS

POSTER SESSION 01 - SECTION: PAIN AND INFLAMMATION

Aims
Chronic pain affects millions of people worldwide. The voltage-gated sodium channel (Nav) 1.7 is predominantly expressed in nociceptors and plays a key role in pain signaling. Nav1.7 gain-of-function mutations lead to chronic pain. Here, we aimed to knockdown the *SCN9a* gene encoding Nav1.7 in human induced-pluripotent stem (hiPS) cell-derived peripheral sensory neurons with the aim to decrease their excitability *in vitro*. Methods
The Chambers differentiation protocol was used to generate peripheral sensory neurons from two hiPS cell lines: a control cell line and a cell line carrying the Nav1.7/I848T mutation responsible for inherited erythromelalgia (IEM). The neurons were treated with locked nucleic acid antisense oligonucleotides (LNA ASO) targeting *SCN9a* or scrambled LNA ASO. The *SCN9a* mRNA expression and the excitability of the neurons were investigated through RT-qPCR and whole-cell patch-clamp experiments at DIV52-58. Results
Although mRNA of *SCN9a* was significantly down-regulated in both control- and IEM-neurons, we did not detect changes in Nav gating properties nor action potential (AP) properties of the control neurons. However, IEM-neurons treated with *SCN9a*–specific LNA ASO displayed a more depolarized resting membrane potential than the scrambled LNA ASO-treated IEM-neurons. They had a smaller AP amplitude and they generated less APs following high current injections. Conclusion
The *SCN9a*–specific LNA ASO treatment did not alter the excitability of the control neurons but decreased firing of the IEM-neurons. These results suggest a more specific role of Nav1.7 downregulation in neurons carrying a Nav1.7 mutation, which is currently subject of further studies.

The difficulty to model Huntington's disease in vitro using striatal medium spiny neurons differentiated from human induced pluripotent stem cells.
Huntington's disease (HD) is an autosomal dominant neurodegenerative disorder caused by an expanded polyglutamine repeat in the huntingtin gene. The neuropathology of HD is characterized by the decline of a specific neuronal population within the brain, the striatal medium spiny neurons (MSNs). The origins of this extreme vulnerability remain unknown. Human induced pluripotent stem cell (hiPS cell)-derived MSNs represent a powerful tool to study this genetic disease. However, the differentiation protocols published so far show a high heterogeneity of neuronal populations in vitro. Here, we compared two previously published protocols to obtain hiPS cell-derived striatal neurons from both healthy donors and HD patients. Patch-clamp experiments, immunostaining and RT-qPCR were performed to characterize the neurons in culture. While the neurons were mature enough to fire action potentials, a majority failed to express markers typical for MSNs. Voltage-clamp experiments on voltage-gated sodium (Nav) channels revealed a large variability between the two differentiation protocols. Action potential analysis did not reveal changes induced by the HD mutation. This study attempts to demonstrate the current challenges in reproducing data of previously published differentiation protocols and in generating hiPS cell-derived striatal MSNs to model a genetic neurodegenerative disorder in vitro.

Assessing the impact of pain-linked Nav1.7 variants: An example of two variants with no biophysical effect.

Mutations in the voltage-gated sodium channel Nav1.7 are linked to human pain. The Nav1.7/N1245S variant was described before in several patients suffering from primary erythromelalgia and/or olfactory hypersensitivity. We have identified this variant in a pain patient and a patient suffering from severe and life-threatening orthostatic hypotension. In addition, we report a female patient suffering from muscle pain and carrying the Nav1.7/E1139K variant. We tested both Nav1.7 variants by whole-cell voltage-clamp recordings in HEK293 cells, revealing a slightly enhanced current density for the N1245S variant when co-expressed with the β1 subunit. This effect was counteracted by an enhanced slow inactivation. Both variants showed similar voltage dependence of activation and steady-state fast inactivation, as well as kinetics of fast inactivation, deactivation, and use-dependency compared to WT Nav1.7. Finally, homology modeling revealed that the N1245S substitution results in different intramolecular interaction partners. Taken together, these experiments do not point to a clear pathogenic effect of either the N1245S or E1139K variant and suggest they may not be solely responsible for the patients' pain symptoms. As discussed previously for other variants, investigations in heterologous expression systems may not sufficiently mimic the pathophysiological situation in pain patients, and single nucleotide variants in other genes or modulatory proteins are necessary for these specific variants to show their effect. Our findings stress that biophysical investigations of ion channel mutations need to be evaluated with care and should preferably be supplemented with studies investigating the mutations in their context, ideally in human sensory neurons.

The role of Nav1.7 in human nociceptors: insights from human induced pluripotent stem cell-derived sensory neurons of erythromelalgia patients.
The chronic pain syndrome inherited erythromelalgia (IEM) is attributed to mutations in the voltage-gated sodium channel (NaV) 1.7. Still, recent studies targeting NaV1.7 in clinical trials have provided conflicting results. Here, we differentiated induced pluripotent stem cells from IEM patients with the NaV1.7/I848T mutation into sensory nociceptors. Action potentials in these IEM nociceptors displayed a decreased firing threshold, an enhanced upstroke, and afterhyperpolarization, all of which may explain the increased pain experienced by patients. Subsequently, we investigated the voltage dependence of the tetrodotoxin-sensitive NaV activation in these human sensory neurons using a specific prepulse voltage protocol. The IEM mutation induced a hyperpolarizing shift of NaV activation, which leads to activation of NaV1.7 at more negative potentials. Our results indicate that NaV1.7 is not active during subthreshold depolarizations, but that its activity defines the action potential threshold and contributes significantly to the action potential upstroke. Thus, our model system with induced pluripotent stem cell-derived sensory neurons provides a new rationale for NaV1.7 function and promises to be valuable as a translational tool to profile and develop more efficacious clinical analgesics.

A novel human pain insensitivity disorder caused by a point mutation in ZFHX2.
Chronic pain is a major global public health issue causing a severe impact on both the quality of life for sufferers and the wider economy. Despite the significant clinical burden, little progress has been made in terms of therapeutic development. A unique approach to identifying new human-validated analgesic drug targets is to study rare families with inherited pain insensitivity. Here we have analysed an otherwise normal family where six affected individuals display a pain insensitive phenotype that is characterized by hyposensitivity to noxious heat and painless bone fractures. This autosomal dominant disorder is found in three generations and is not associated with a peripheral neuropathy. A novel point mutation in ZFHX2, encoding a putative transcription factor expressed in small diameter sensory neurons, was identified by whole exome sequencing that segregates with the pain insensitivity. The mutation is predicted to change an evolutionarily highly conserved arginine residue 1913 to a lysine within a homeodomain. Bacterial artificial chromosome (BAC) transgenic mice bearing the orthologous murine p.R1907K mutation, as well as Zfhx2 null mutant mice, have significant deficits in pain sensitivity. Gene expression analyses in dorsal root ganglia from mutant and wild-type mice show altered expression of genes implicated in peripheral pain mechanisms. The ZFHX2 variant and downstream regulated genes associated with a human pain-insensitive phenotype are therefore potential novel targets for the development of new analgesic drugs.awx326media15680039660001.

CAV1.2-DEPENDENT EXCITATION-TRANSCRIPTION COUPLING IN NOCICEPTORS

POSTER SESSION 01 - SECTION: PAIN AND INFLAMMATION

Jörg Isensee, Maximilian Löchte, Tim Hucho
University of Cologne, Department Of Anesthesiology And Intensive Care Medicine, Translational Pain Research, University Hospital Of Cologne, Cologne, Germany

Repetitive firing of peripheral nociceptors induces the chronification of pain due to synaptic plasticity within the central nervous system, but associated changes within nociceptors remain largely enigmatic. We have recently discovered that depolarization of nociceptors activates type-II protein kinase A (PKA-II) by calcium influx through CaV1.2 channels leading to mechanical hyperalgesia. In other neurons, however, CaV1 associated signaling translates electrical activity into transcriptional regulation known as excitation-transcription (E-T) coupling. If CaV1.2 also mediates E-T coupling in nociceptors is currently unknown. Using High Content Screening microscopy, we found that depolarization of nociceptors with potassium chloride (KCl) leads to phosphorylation of the transcriptional regulating signaling components CREB and ERK1/2. Accordingly, CREB localization to the nucleus increased. This was inhibited by blocking CaV1 or PKA and reinforced by calcineurin inhibition. RNA-Seq revealed a dose-dependent regulation of up to 1563 genes ($q < 0.05$, >1.5-fold) 6 hours after depolarization. To address the impact of calcium influx through CaV1, we included combinations of low [KCl] (10 mM) and the CaV1 agonist BayK8644 as well as high [KCl] (40 mM) and the CaV1 blocker verapamil. Supporting a CaV1-dependent regulation, multiple genes showed opposing regulation by BayK8644 and verapamil including known activity-regulated transcripts such as Fosb, Npas4, and Rasd1. The cellular basis is currently investigated using fluorescent *in-situ* hybridization. In conclusion, our data suggest a CaV1-dependent E-T coupling mechanism in nociceptors. Further studies need to address which of the regulated genes alters which nociceptive function in short-term activation as well as in the context of chronic pain.

ANALGESIC EFFECTS OF KB-R7943 IN A STREPTOZOTOCIN-INDUCED RAT'S DIABETIC NEUROPATHY MODEL

POSTER SESSION 01 - SECTION: PAIN AND INFLAMMATION

Pavlina Gateva, Milen Hristov, Natasha Ivanova, Slavina Surcheva
Medical University of Sofia, Pharmacology And Toxicology, Sofia, Bulgaria

Diabetic neuropathy (DN) is one of the most common chronic complications of poorly treated diabetes mellitus. Amitriptyline (ATL) is a tricyclic antidepressant and often the first-choice option for DN treatment. This study aimed to evaluate the potential analgesic effect of KB-R7943, an inhibitor of NCX, in a model of diabetic neuropathy. Diabetic neuropathic pain was induced by a single intraperitoneal injection (i.p.) of streptozotocin at a dose of 55 mg/kg. After the development of neuropathy, KB-R7943 was administered by oral gavage at two doses, 5 mg/kg and 10 mg/kg, for ten days. Amitriptyline 10 mg/kg was used as a positive control. The following groups were assigned: controls treated with vehicle (C-Veh), rats with DN treated with vehicle (DN-veh), rats with DN and treated with KB-R7943 at 5 mg/kg (DN-KB-R7943-5 mg), rats with DN and treated with KB-R7943 at 10 mg/kg (DN-KB-R7943-10 mg), and rats with DN and ATL 10 mg/kg (DN-ATL-10 mg/kg) (n=7 in each group). A blockade of the reverse-mode sodium-calcium exchanger (NCX) and desensitization of N-methyl-D-aspartate receptor (NMDAR) was demonstrated among its multiple molecular targets. Analgesic effect was assessed by the threshold from Randle-Stellito paw pressure test, cold plate test, and duration of the antinociceptive behavior after intraplantar injection of 0.5% formalin. Both ATL and KB-R7943 at the dose of 10 mg/kg increased the threshold of the Randle-Stellito and decreased the second phase of the formalin test. The present data suggest that developing pain therapy based on selective NCX blockers in DN is promising. Acknowledgments: Supported by BNSF КП-06-Rusia 25/16.12.2020.

Serotonin mediates its physiological functions by activating serotonin receptors. Among them, the serotonin 5-HT_7R receptor (5-HT_7R) belongs to the superfamily of the G proteins coupled receptors (GPCRs) and is coupled to the heterotrimeric G protein Gs which in turn leads to adenylate cyclase activation and initiates specific signaling cascade including activation of MAP/ERK kinases. In the last decade, 5-HT_7 receptor has become a promising target for the treatment of neuropsychiatric and neurologic disorders. In this study, we characterized the pharmacological profile of new 5-HT_7R ligands derived from pharmacomodulation studies. For that purpose, we studied their capacity to activate specific signaling pathways and defined their agonist, inverse agonist or antagonist activity by measurement of cAMP levels in HEK cells stably expressing the 5-HT_7R. We also investigated their ability to activate others signaling pathways using BRET, TR-FRET or Alphascreen methods. In particular BRET studies allow us to follow the recruitment of intracellular partners in real time and in living cells. Our results demonstrate that 5-HT_7R can engage a signaling pathway not described for this receptor until now. Considering the unique pharmacological profile of our molecules, we also investigated their therapeutically potential. By using WT and 5-HT7 KO mice, we demonstrated their specificity of action. Then, we performed various behavioral assays allowing us to demonstrate their therapeutic potential. In conclusion, by using various functional cellular assays and behavioral tests in mice, we characterized an original 5-HT_7R- ligand able to stabilize specific active conformation of 5-HT7R and to reduce sensory dysfunction.

GREEN LIGHT-INDUCED ANTINOCICEPTION INVOLVES DESCENDING MODULATION OF MECHANICAL SENSITIVITY.

POSTER SESSION 01 - SECTION: PAIN AND INFLAMMATION

Kevin Cheng[1], Laurent Martin[1], Millie Denton[2], Stephanie Washington[2], Mohab Ibrahim[1], Amol Patwardhan[2]
[1]University of Arizona, Department Of Pharmacology, Tucson, United States of America, [2]University of Arizona, Department Of Anesthesiology, Tucson, United States of America

Green light therapy (GLED) has been shown to be a novel, efficacious, nonpharmacologic pain therapeutic in humans for chronic pain conditions including migraine and fibromyalgia. Previous animal studies suggest that GLED acts on central descending pain modulation areas such as the rostral ventromedial medulla (RVM). Additionally, the involvement of the endogenous opioid (EO) system has been demonstrated. However, the role of EO in the RVM in GLED-induced antinociception has not been confirmed. Therefore, we hypothesized that GLED causes antinociception via opioid receptor agonist stimulation by EO in the RVM. We performed microinjections of naltrexone in the RVM of rats with gp120-induced HIV-related neuropathic pain that had received 6 days of GLED exposure for 8 hours/day. At 1 hour after RVM naltrexone microinjections, mechanical antinociception induced by GLED was reversed, whereas no changes in thermal sensitivity were observed. These results prompted investigation of opioid receptor expression on GABAergic cells, as recent reports indicated that RVM GABAergic neurons are responsible for facilitation of mechanical, but not thermal, pain. In-situ RNA hybridization identified co-localization of Slc31a1, Oprm1, and Oprd1 signals in RVM sections, indicating the presence of opioid-sensitive GABAergic neurons in the RVM. Overall, these results suggest that opioid receptor agonist stimulation in the RVM due to GLED exposure is required for GLED-induced mechanical, but not thermal, antinociception. Future gene editing experiments selectively in GABAergic neurons may confirm the hypothesis that inhibition of pronociceptive GABAergic neurons by endogenous opioids is responsible for GLED-induced mechanical antinociception.

Green Light Antinociceptive and Reversal of Thermal and Mechanical Hypersensitivity Effects Rely on Endogenous Opioid System Stimulation.
Benefits of phototherapy were characterized in multiple diseases including depression, circadian rhythm disruptions, and neurodegeneration. Studies on migraine and fibromyalgia patients revealed that green light-emitting diodes (GLED) exposure provides a pragmatic and safe therapy to manage chronic pain. In rodents, GLED reversed hypersensitivity related to neuropathic pain. However, little is known about the underlying mechanisms of GLED efficacy. Here, we sought to understand how green light modulates the endogenous opioid system. We first characterized how exposure to GLED stimulates release of β-endorphin and proenkephalin in the central nervous system of male rats. Moreover, by individually editing each of the receptors, we found that μ- and δ-opioid receptors are required for green light's antinociceptive effect in naïve rats and a model of HIV-induced peripheral neuropathy. We investigated how GLED could increase pain thresholds, and explored its potential in reversing hypersensitivity in a model of HIV-related neuropathy. Through behavioral and gene editing approaches, we identified that green light provides antinociception via modulation of the endogenous opioid system in the spinal cord. This work identifies a previously unknown mechanism by which GLED can improve pain management. Clinical translation of these results will advance the development of an innovative therapy devoid of adverse effects. PERSPECTIVE: Development of new pain management therapies, especially for HIV patients, is crucial as long-term opioid prescription is not recommended due to adverse side effects. Green light addresses this necessity. Characterizing the underlying mechanisms of this potentially groundbreaking and safe antinociceptive therapy will advance its clinical

translation.

Mechanisms and Pathways of Pain Photobiomodulation: A Narrative Review.
A growing body of evidence supports the modulation of pain by light exposure. As such, phototherapy is being increasingly utilized for the management of a variety of pain conditions. The modes of delivery, and hence applications of phototherapy, vary by wavelength, intensity, and route of exposure. As such, differing mechanisms of action exist depending upon those parameters. Cutaneous application of red light (660 nm) has been shown to reduce pain in neuropathies and complex regional pain syndrome-I, whereas visual application of the same wavelength of red light has been reported to exacerbate migraine headache in patients and lead to the development of functional pain in animal models. Interestingly visual exposure to green light can result in reduction in pain in variety of pain conditions such as migraine and fibromyalgia. Cutaneous application typically requires exposure on the order of minutes, whereas visual application requires exposure on the order of hours. Both routes of exposure elicit changes centrally in the brainstem and spinal cord, and peripherally in the dorsal root ganglia and nociceptors. The mechanisms of photobiomodulation of pain presented in this review provide a foundation in furtherance of exploration of the utility of phototherapy as a tool in the management of pain. PERSPECTIVE: This review synopsizes the pathways and mechanisms through which light modulates pain and the therapeutic utility of different colors and exposure modalities of light on pain. Recent advances in photobiomodulation provide a foundation for understanding this novel treatment for pain on which future translational and clinical studies can build upon.

Short Link N promotes disc repair in a rabbit model of disc degeneration.
The degeneration of the intervertebral disc (IVD) is characterized by proteolytic degradation of the extracellular matrix, and its repair requires the production of an extracellular matrix with a high proteoglycan-to-collagen ratio characteristic of a nucleus pulposus (NP)-like phenotype in vivo. At the moment, there is no medical treatment to reverse or even retard disc degeneration. The purpose of the present study was to determine if a low dose of short link N (sLN), a recently discovered fragment of the link N peptide, could behave in a manner similar to that of link N in restoring the proteoglycan content and proteoglycan-to-collagen ratio of the disc in a rabbit model of IVD degeneration, as an indication of its potential therapeutic benefit in reversing disc degeneration.

Morphology of intervertebral disc ruptures evaluated by vacuum phenomenon using multi-detector computed tomography: association with lumbar disc degeneration and canal stenosis.
The progression of intervertebral disc (IVD) degeneration leads to rupture within IVD tissues. The location and appearance of areas of gaseous radiolucency in the IVD, known as vacuum phenomena (VPs), are considered to indirectly indicate the position and extent of IVD rupture. The clinical significance of VPs in degenerated IVDs is not fully understood. The purpose of this study is to assess and classify the morphology of IVD ruptures by the presence of intradiscal VPs, and to examine the association between morphological VP-positive IVD ruptures and degenerative lumbar diseases.

Three-dimensional micro-computed tomography analysis for spinal instability after lumbar facetectomy in the rat.
Intervertebral disc degeneration is thought to contribute to low back pain. However, the pathophysiological mechanisms remain controversial. In a previous study, we developed an animal model that showed delayed gait disturbance after lumbar facetectomy in the rat. We believe that this gait disturbance was caused by low back pain, although the mechanisms of this gait abnormality remain unknown. The purpose of this study was to evaluate structural changes of the lumbar spine after facetectomy in the rat utilizing three-dimensional micro-computed tomography (3DμCT) compared to histology.

DISTINCT ACTIVITY OF ENDOCANNABINOID-HYDROLYZING ENZYMES MAGL AND FAAH IN KEY REGIONS OF PERIPHERAL AND CENTRAL NERVOUS SYSTEM IMPLICATED IN MIGRAINE

POSTER SESSION 01 - SECTION: PAIN AND INFLAMMATION

Adriana Della Pietra[1], Rashid Giniatullin[1], Juha Savinainen[2]
[1]University of Eastern Finland, A.i. Virtanen Institute, Kuopio, Finland, [2]University of Eastern Finland, Institute Of Biomedicine, Kuopio, Finland

In migraine pain, cannabis has a promising analgesic action, which, however, is associated with side psychotropic effects. To overcome these adverse effects of exogenous cannabinoids, we propose migraine pain relief via activation of the endogenous cannabinoid system (ECS) by inhibiting enzymes degrading endocannabinoids. To provide a functional platform for such purpose in the peripheral and central parts of the rat nociceptive system relevant to migraine, we measured by activity-based protein profiling (ABPP) the activity of the main endocannabinoid-hydrolases, mon-oacylglycerol lipase (MAGL) and fatty acid amide hydrolase (FAAH). We found that in trigeminal ganglia, the MAGL activity was nine-fold higher than that of FAAH. MAGL activity exceeded FAAH activity also in DRG, spinal cord and brainstem. However, activities of MAGL and FAAH were comparably high in the cerebellum and cerebral cortex implicated in migraine aura. MAGL and FAAH activities were identified and blocked by the selective and potent inhibitors JJKK-048/KML29 and JZP327A, respectively. The high MAGL activity in trigeminal ganglia implicated in the generation of nociceptive signals suggests this part of ECS as a priority target for blocking peripheral mechanisms of migraine pain. In the CNS, both MAGL and FAAH represent potential targets for attenuation of migraine-related enhanced cortical excitability and pain transmission.

The Emerging Role of Mechanosensitive Piezo Channels in Migraine Pain.
Recently discovered mechanosensitive Piezo channels emerged as the main molecular detectors of mechanical forces. The functions of Piezo channels range from detection of touch and pain, to control of the plastic changes in different organs. Recent studies suggested the role of Piezo channels in migraine pain, which is supposed to originate from the trigeminovascular nociceptive system in meninges. Interestingly, migraine pain is associated with such phenomenon as mechanical hypersensitivity, suggesting enhanced mechanotransduction. In the current review, we present the data that propose the implication of Piezo channels in migraine pain, which has a distinctive pulsatile character. These data include: (i) distribution of Piezo channels in the key elements of the trigeminovascular nociceptive system; (ii) the prolonged functional activity of Piezo channels in meningeal afferents providing a mechanistical basis for mechanotransduction in nociceptive nerve terminals; (iii) potential activation of Piezo channels by shear stress and pulsating blood flow; and (iv) modulation of these channels by emerging chemical agonists and modulators, including pro-nociceptive compounds. Achievements in this quickly expanding field should open a new road for efficient control of Piezo-related diseases including migraine and chronic pain.

CHEMICALLY-INDUCED NOCICEPTION IN PLANARIA AND ITS REGULATION BY MORPHINE AND OTHER ANTINOCICEPTIVE COMPOUNDS.

POSTER SESSION 01 - SECTION: PAIN AND INFLAMMATION

Guillaume Reho, Yannick Goumon, Vincent Lelièvre, Hervé Cadiou
Université de Strasbourg, Inci Cnrs Upr3212, Strasbourg, France

Aim : In addition to their regeneration abilities, planarians have been extensively studied in the context of behavior, pharmacology and toxicology during the past 200 years. Most of these assays only looked at basic locomotor behavior such as speed and distance while only a few implemented a full behavior analysis in reaction to different stimuli, with a special interest on 'gliding' vs. 'scrunching' displacement modes. Among these stimuli, some have been linked to nociception, especially due to the involvement of well-known nociceptive ion channels such as TRPV1 and TRPA1. However, nociception in planarians remains poorly investigated and in particular its regulation by common antinociceptive compounds. Methods : We developed a nociceptive assay in the planarian *Girardia dorotocephala* by placing the animal in an arena with various concentrations of allyl isothiocyanate (AITC), a TRPA1 agonist. As a measure of nociception, the 'scrunching' behavior of the animal was assessed. Results : Worms exposed to 0% of AITC displayed normal locomotor behavior (81.87±3.14% of the total time) whereas animals subjected to 100µM of AITC displayed the nociceptive 'scrunching' behavior (74.44±6.43% of the total time). Pre-incubating the worms with morphine 1 µM during 2 hours shifted the dose response curve. For instance at 50 µM AITC, the 'scrunching' behavior went from 61.49±6.41% without morphine to 16.93±4.05% with morphine pre-incubation. Conclusion : Using the same experimental paradigm we aim to investigate the effects of NSAIDs on the planarian nociceptive response thus validating this animal model for antinociceptive drug screening.

Chronic pain is a common and complex problem that has a profound impact on individuals and society. The involvement of different brain regions like the anterior cingulate cortex (ACC) in processing pains' affective component has been established; however, a characterization of its main output neurons in pain has not been performed. To characterize neuron subtypes, we performed whole-cell patch clamp in pyramidal neurons from layer 5 of ACC, followed by anatomical reconstruction. As a model of chronic pain, we injected Complete Freund's Adjuvant (CFA) in the hindpaw of male mice generating inflammation. To investigate how the peripheral injury changes the general neuronal activity, we recorded in brain slices from CFA and saline mice. Cluster analysis of physiological and morphological parameters revealed two subtypes among the sampled neurons: contralateral projecting and subcortical projecting (SC). CFA mice developed mechanical and thermal hyperalgesia, as compared to the saline. At the cellular level, we observed significant changes in intrinsic electrical properties between CFA and saline mice. Changes occur only in a subpopulation of neurons projecting to subcortical areas. Dissecting the underlying circuit mechanisms, we determined the role of ACC-SC neurons projecting to the periaqueductal gray (PAG), subcortical structure with crucial role in the descending modulation of pain. Chemogenetic manipulation of ACC inputs to PAG differentially influence pain sensitivity in different pain conditions. The current study is therefore the first to systematically dissect the effects of inflammatory pain on pyramidal neurons of layers 5 in the ACC, providing evidence for intralayer-specific alterations of electrophysiological properties.

Erroneous protein synthesis disrupts cellular fitness causing a variety of disease phenotypes. Neurons are especially sensitive to translational dysregulation owning to the fact that it is essential for synaptic plasticity and neuronal survival. Hence, a precise regulation of translation initiation plays a critical role in learning and memory. Defects in this process have been linked to numerous cognitive disorders including addiction, fragile X syndrome and autism and has also been related to several neurodegenerative disorders like Parkinson's disease. In this line, this group recently stated that loss of translational control in the striatum leading to an aberrantly increased global cap-dependent protein synthesis is a relevant mechanism in Huntington's disease (HD) pathophysiology. Additionally, its normalization by intraventricular injection of 4EGI-1, an inhibitor of the eIF4E/eIF4G complex assembly, prevented the development of motor deficits in the R6/1 mouse model of HD. In this present work, we explore the potential of a set of repurposed drug candidates, shown to decrease protein synthesis in cellular models and mouse brain, for HD treatment through the normalization of protein synthesis in the striatum. Furthermore, we show that alterations involving translational control extend to other brain regions such as the hippocampus suggesting its involvement in, not only in motor deficits, but also in cognitive and memory impairment also occurring in HD pathology.

Neuron type-specific increase in lamin B1 contributes to nuclear dysfunction in Huntington's disease.
Lamins are crucial proteins for nuclear functionality. Here, we provide new evidence showing that increased lamin B1 levels contribute to the pathophysiology of Huntington's disease (HD), a CAG repeat-associated neurodegenerative disorder. Through fluorescence-activated nuclear suspension imaging, we show that nucleus from striatal medium-sized spiny and CA1 hippocampal neurons display increased lamin B1 levels, in correlation with altered nuclear morphology and nucleocytoplasmic transport disruption. Moreover, ChIP-sequencing analysis shows an alteration of lamin-associated chromatin domains in hippocampal nuclei, accompanied by changes in chromatin accessibility and transcriptional dysregulation. Supporting lamin B1 alterations as a causal role in mutant huntingtin-mediated neurodegeneration, pharmacological normalization of lamin B1 levels in the hippocampus of the R6/1 mouse model of HD by betulinic acid administration restored nuclear homeostasis and prevented motor and cognitive dysfunction. Collectively, our work points increased lamin B1 levels as a new pathogenic mechanism in HD and provides a novel target for its intervention.

Isoform-Specific Reduction of the Basic Helix-Loop-Helix Transcription Factor TCF4 Levels in Huntington's Disease.
Huntington's disease (HD) is an inherited neurodegenerative disorder with onset of characteristic motor symptoms at midlife, preceded by subtle cognitive and behavioral disturbances. Transcriptional dysregulation emerges early in the disease course and is considered central to HD pathogenesis. Using wild-type (wt) and HD knock-in mouse striatal cell lines we observed a HD genotype-dependent reduction in the protein levels of transcription factor 4 (TCF4), a member of the basic helix-loop-helix (bHLH) family with critical roles in brain development and function. We characterized mouse gene structure and expression of alternative mRNAs and protein isoforms in cell-based models of HD, and in four different brain regions of male transgenic HD mice (R6/1) from young to mature adulthood. The largest decrease in the levels of TCF4 at mRNA and specific protein isoforms were detected in the R6/1 mouse hippocampus. Translating this finding to human disease, we found reduced

expression of long TCF4 isoforms in the postmortem hippocampal CA1 area and in the cerebral cortex of HD patients. Additionally, TCF4 protein isoforms showed differential synergism with the proneural transcription factor ASCL1 in activating reporter gene transcription in hippocampal and cortical cultured neurons. Induction of neuronal activity increased these synergistic effects in hippocampal but not in cortical neurons, suggesting brain region-dependent differences in TCF4 functions. Collectively, this study demonstrates isoform-specific changes in TCF4 expression in HD that could contribute to the progressive impairment of transcriptional regulation and neuronal function in this disease.

Lack of Annexin A6 Exacerbates Liver Dysfunction and Reduces Lifespan of Niemann-Pick Type C Protein-Deficient Mice. Niemann-Pick type C (NPC) disease is a lysosomal storage disorder characterized by cholesterol accumulation caused by loss-of-function mutations in the Npc1 gene. NPC disease primarily affects the brain, causing neuronal damage and affecting motor coordination. In addition, considerable liver malfunction in NPC disease is common. Recently, we found that the depletion of annexin A6 (ANXA6), which is most abundant in the liver and involved in cholesterol transport, ameliorated cholesterol accumulation in Npc1 mutant cells. To evaluate the potential contribution of ANXA6 in the progression of NPC disease, double-knockout mice (Npc1/Anxa6) were generated and examined for lifespan, neurologic and hepatic functions, as well as liver histology and ultrastructure. Interestingly, lack of ANXA6 in NPC1-deficient animals did not prevent the cerebellar degeneration phenotype, but further deteriorated their compromised hepatic functions and reduced their lifespan. Moreover, livers of Npc1/Anxa6 mice contained a significantly elevated number of foam cells congesting the sinusoidal space, a feature commonly associated with inflammation. We hypothesize that ANXA6 deficiency in Npc1 mice not only does not reverse neurologic and motor dysfunction, but further worsens overall liver function, exacerbating hepatic failure in NPC disease.

Aims: Although promising gene-silencing therapies are being tested for Huntington's disease (HD), no disease-modifying treatments are available. Thus, study of molecular mechanisms underneath Htt-mutation must continue to identify easily druggable targets. Cytoplasmic polyadenylation element binding proteins 1–4 (CPEB1–4) are RNA-binding proteins that repress or activate translation of CPE-containing transcripts by shortening or elongating their poly(A) tail. Our aim was to analyze CPEBs and polyadenylation in HD. Identify easily druggable targets among genes mis-expressed due to altered CPEB-dependent polyadenylation, to assay them in HD mice. Methods: a) Western blot and immunostaining of CPEBs in brains of HD patients and mouse models. b) Genome-wide poly(A)-tail analysis through poly(U) chromatography+gene chip. c) status of CPEB targets and related metabolites by western blot and HPLC. d) radiological, neuropathological and behavioural analysis of HD mice receiving target-related treatment. Results: There is a CPEB1/4 imbalance in HD striatum with concomitant altered transcriptome polyadenylation affecting many neurodegeneration-linked genes like PSEN1, MAPT, SNCA, LRRK2, PINK1, DJ1, SOD1, TARDBP, FUS and HTT. Among top deadenylated genes was SLC19A3 (ThTr2 thiamine transporter) whose mutation causes biotin+thiamine responsive basal ganglia disease (BTBGD). Decreased ThTr2 in HD and HD mice led us to discover that HD is in part a BTBG-like thiamine deficiency. Remarkably, high dose biotin+thiamine treatment prevented the thiamine deficiency of HD mice and attenuated their radiological, neuropathological and motor phenotypes. Conclusions: This study unveils altered polyadenylation as a new molecular mechanism in neurodegeneration uncovering HD as a thiamine deficiency and, therefore, an easy to implement therapy.

CPEB alteration and aberrant transcriptome-polyadenylation lead to a treatable SLC19A3 deficiency in Huntington's disease. Huntington's disease (HD) is a hereditary neurodegenerative disorder of the basal ganglia for which disease-modifying

treatments are not yet available. Although gene-silencing therapies are currently being tested, further molecular mechanisms must be explored to identify druggable targets for HD. Cytoplasmic polyadenylation element binding proteins 1 to 4 (CPEB1 to CPEB4) are RNA binding proteins that repress or activate translation of CPE-containing transcripts by shortening or elongating their poly(A) tail. Here, we found increased CPEB1 and decreased CPEB4 protein in the striatum of patients and mouse models with HD. This correlated with a reprogramming of polyadenylation in 17.3% of the transcriptome, markedly affecting neurodegeneration-associated genes including , , , , , , , , and and suggesting a new molecular mechanism in neurodegenerative disease etiology. We found decreased protein content of top deadenylated transcripts, including striatal atrophy–linked genes not previously related to HD, such as and the easily druggable (the ThTr2 thiamine transporter). Mutations in cause biotin-thiamine–responsive basal ganglia disease (BTBGD), a striatal disorder that can be treated with a combination of biotin and thiamine. Similar to patients with BTBGD, patients with HD demonstrated decreased thiamine in the cerebrospinal fluid. Furthermore, patients and mice with HD showed decreased striatal concentrations of thiamine pyrophosphate (TPP), the metabolically active form of thiamine. High-dose biotin and thiamine treatment prevented TPP deficiency in HD mice and attenuated the radiological, neuropathological, and motor HD-like phenotypes, revealing an easily implementable therapy that might benefit patients with HD.

Huntington's disease-specific mis-splicing unveils key effector genes and altered splicing factors.
Correction of mis-splicing events is a growing therapeutic approach for neurological diseases such as spinal muscular atrophy or neuronal ceroid lipofuscinosis 7, which are caused by splicing-affecting mutations. Mis-spliced effector genes that do not harbour mutations are also good candidate therapeutic targets in diseases with more complex aetiologies such as cancer, autism, muscular dystrophies or neurodegenerative diseases. Next-generation RNA sequencing (RNA-seq) has boosted investigation of global mis-splicing in diseased tissue to identify such key pathogenic mis-spliced genes. Nevertheless, while analysis of tumour or dystrophic muscle biopsies can be informative on early stage pathogenic mis-splicing, for neurodegenerative diseases, these analyses are intrinsically hampered by neuronal loss and neuroinflammation in post-mortem brains. To infer splicing alterations relevant to Huntington's disease pathogenesis, here we performed intersect-RNA-seq analyses of human post-mortem striatal tissue and of an early symptomatic mouse model in which neuronal loss and gliosis are not yet present. Together with a human/mouse parallel motif scan analysis, this approach allowed us to identify the shared mis-splicing signature triggered by the Huntington's disease-causing mutation in both species and to infer upstream deregulated splicing factors. Moreover, we identified a plethora of downstream neurodegeneration-linked mis-spliced effector genes that-together with the deregulated splicing factors-become new possible therapeutic targets. In summary, here we report pathogenic global mis-splicing in Huntington's disease striatum captured by our new intersect-RNA-seq approach that can be readily applied to other neurodegenerative diseases for which bona fide animal models are available.

Autism-like phenotype and risk gene mRNA deadenylation by CPEB4 mis-splicing.
Common genetic contributions to autism spectrum disorder (ASD) reside in risk gene variants that individually have minimal effect sizes. As environmental factors that perturb neurodevelopment also underlie idiopathic ASD, it is crucial to identify altered regulators that can orchestrate multiple ASD risk genes during neurodevelopment. Cytoplasmic polyadenylation element binding proteins 1-4 (CPEB1-4) regulate the translation of specific mRNAs by modulating their poly(A)-tails and thereby participate in embryonic development and synaptic plasticity. Here we find that CPEB4 binds transcripts of most high-confidence ASD risk genes. The brains of individuals with idiopathic ASD show imbalances in CPEB4 transcript isoforms that result from decreased inclusion of a neuron-specific microexon. In addition, 9% of the transcriptome shows reduced poly(A)-tail length. Notably, this percentage is much higher for high-confidence ASD risk genes, correlating with reduced expression of the protein products of ASD risk genes. An equivalent imbalance in CPEB4 transcript isoforms in mice mimics the changes in mRNA polyadenylation and protein expression of ASD risk genes and induces ASD-like neuroanatomical, electrophysiological and behavioural phenotypes. Together, these data identify CPEB4 as a regulator of ASD risk genes.

Aims: Molecular mechanisms underlying cognitive deficits in Huntington's disease (HD), a striatal polyglutamine-related neurodegenerative disorder, remain relatively unexplored. Here, we aim to interrogate transcriptional and epigenetic mechanisms interconnection with striatal-dependent cognitive deficits in HD. **Methods:** We challenged the transgenic HD R6/1 mice in a striatum-dependent egocentric spatial memory task, the double-H test, and investigated chromatin and transcriptomic signatures in behaving vs resting control HD R6/1 and wild-type mice by using RNA-seq, ChIP-seq and 4C-seq. **Results:** Our data, including integrated analysis with cell-type specific striatal databases, showed a prominent alteration of activity-regulated transcriptomic and epigenetic regulatory mechanisms in HD mice, involving both neuronal and glial genes implicated in striatal plasticity, accompanying egocentric memory deficits. During memory acquisition, spatial chromatin remodeling and transcriptional induction of BDNF-related effectors of neuronal plasticity were compromised. In addition, we demonstrated that while both, histone H3 acetylation at lysine 27 and 9 (H3K27ac and H3K9ac, respectively) were strongly impaired in HD R6/1 mice, only H3K9ac was modulated during memory processing. Specifically, H3K9ac-mediated epigenetic memory was established during memory consolidation/recall at glia-enriched TGF-beta-associated genes, regulating extracellular matrix and myelination, and this mechanism was compromised in HD mice. These alterations affected protein regulation of key striatal markers of neural plasticity, including the immediate early gene Egr1, myelination and extracellular-matrix-based perineuronal networks, suggesting a disruption of activity-induced re-organization of striatal circuitry required memory process. **Conclusions:** Altogether, our study identified H3K9 acetylation and TGF-beta signaling as new targets of striatal plasticity, which might offer innovative leads to improve cognition in HD.

Hippocampal Cannabinoid 1 Receptors Are Modulated Following Cocaine Self-administration in Male Rats.
Cocaine addiction is a complex pathology inducing long-term neuroplastic changes that, in turn, contribute to maladaptive behaviors. This behavioral dysregulation is associated with transcriptional reprogramming in brain reward circuitry, although the mechanisms underlying this modulation remain poorly understood. The endogenous cannabinoid system may play a role in this process in that cannabinoid mechanisms modulate drug reward and contribute to cocaine-induced neural adaptations. In this study, we investigated whether cocaine self-administration induces long-term adaptations, including transcriptional modifications and associated epigenetic processes. We first examined endocannabinoid gene expression in reward-related brain regions of the rat following self-administered (0.33 mg/kg intravenous, FR1, 10 days) cocaine injections. Interestingly, we found increased Cnr1 expression in several structures, including prefrontal cortex, nucleus accumbens, dorsal striatum, hippocampus, habenula, amygdala, lateral hypothalamus, ventral tegmental area, and rostromedial tegmental nucleus, with most pronounced effects in the hippocampus. Endocannabinoid levels, measured by mass spectrometry, were also altered in this structure. Chromatin immunoprecipitation followed by qPCR in the hippocampus revealed that two activating histone marks, H3K4Me3 and H3K27Ac, were enriched at specific endocannabinoid genes following cocaine intake. Targeting CB1 receptors using chromosome conformation capture, we highlighted spatial chromatin re-organization in the hippocampus, as well as in the nucleus accumbens, suggesting that destabilization of the chromatin may contribute to neuronal responses to cocaine. Overall, our results highlight a key role for the hippocampus in cocaine-induced plasticity and broaden the understanding of neuronal alterations associated with endocannabinoid signaling. The latter suggests that epigenetic

modifications contribute to maladaptive behaviors associated with chronic drug use.

Age-related and disease locus-specific mechanisms contribute to early remodelling of chromatin structure in Huntington's disease mice.
Temporal dynamics and mechanisms underlying epigenetic changes in Huntington's disease (HD), a neurodegenerative disease primarily affecting the striatum, remain unclear. Using a slowly progressing knockin mouse model, we profile the HD striatal chromatin landscape at two early disease stages. Data integration with cell type-specific striatal enhancer and transcriptomic databases demonstrates acceleration of age-related epigenetic remodelling and transcriptional changes at neuronal- and glial-specific genes from prodromal stage, before the onset of motor deficits. We also find that 3D chromatin architecture, while generally preserved at neuronal enhancers, is altered at the disease locus. Specifically, we find that the HD mutation, a CAG expansion in the Htt gene, locally impairs the spatial chromatin organization and proximal gene regulation. Thus, our data provide evidence for two early and distinct mechanisms underlying chromatin structure changes in the HD striatum, correlating with transcriptional changes: the HD mutation globally accelerates age-dependent epigenetic and transcriptional reprogramming of brain cell identities, and locally affects 3D chromatin organization.

Neuron type-specific increase in lamin B1 contributes to nuclear dysfunction in Huntington's disease.
Lamins are crucial proteins for nuclear functionality. Here, we provide new evidence showing that increased lamin B1 levels contribute to the pathophysiology of Huntington's disease (HD), a CAG repeat-associated neurodegenerative disorder. Through fluorescence-activated nuclear suspension imaging, we show that nucleus from striatal medium-sized spiny and CA1 hippocampal neurons display increased lamin B1 levels, in correlation with altered nuclear morphology and nucleocytoplasmic transport disruption. Moreover, ChIP-sequencing analysis shows an alteration of lamin-associated chromatin domains in hippocampal nuclei, accompanied by changes in chromatin accessibility and transcriptional dysregulation. Supporting lamin B1 alterations as a causal role in mutant huntingtin-mediated neurodegeneration, pharmacological normalization of lamin B1 levels in the hippocampus of the R6/1 mouse model of HD by betulinic acid administration restored nuclear homeostasis and prevented motor and cognitive dysfunction. Collectively, our work points increased lamin B1 levels as a new pathogenic mechanism in HD and provides a novel target for its intervention.

Epigenetic mechanisms underlying enhancer modulation of neuronal identity, neuronal activity and neurodegeneration.
Neurodegenerative diseases, including Huntington's disease (HD) and Alzheimer's disease (AD), are progressive conditions characterized by selective, disease-dependent loss of neuronal regions and/or subpopulations. Neuronal loss is preceded by a long period of neuronal dysfunction, during which glial cells also undergo major changes, including neuroinflammatory response. Those dramatic changes affecting both neuronal and glial cells associate with epigenetic and transcriptional dysregulations, characterized by defined cell-type-specific signatures. Notably, increasing studies support the view that altered regulation of transcriptional enhancers, which are distal regulatory regions of the genome capable of modulating the activity of promoters through chromatin looping, play a critical role in transcriptional dysregulation in HD and AD. We review current knowledge on enhancers in HD and AD, and highlight challenging issues to better decipher the epigenetic code of neurodegenerative diseases.

Increased Levels of Rictor Prevent Mutant Huntingtin-Induced Neuronal Degeneration.
Rictor associates with mTOR to form the mTORC2 complex, which activity regulates neuronal function and survival. Neurodegenerative diseases are characterized by the presence of neuronal dysfunction and cell death in specific brain regions such as for example Huntington's disease (HD), which is characterized by the loss of striatal projection neurons leading to motor dysfunction. Although HD is caused by the expression of mutant huntingtin, cell death occurs gradually suggesting that neurons have the capability to activate compensatory mechanisms to deal with neuronal dysfunction and later cell death. Here, we analyzed whether mTORC2 activity could be altered by the presence of mutant huntingtin. We observed that Rictor levels are specifically increased in the striatum of HD mouse models and in the putamen of HD patients. Rictor-mTOR interaction and the phosphorylation levels of Akt, one of the targets of the mTORC2 complex, were increased in the striatum of the R6/1 mouse model of HD suggesting increased mTORC2 signaling. Interestingly, acute downregulation of

Rictor in striatal cells in vitro reduced mTORC2 activity, as shown by reduced levels of phospho-Akt, and increased mutant huntingtin-induced cell death. Accordingly, overexpression of Rictor increased mTORC2 activity counteracting cell death. Furthermore, normalization of endogenous Rictor levels in the striatum of R6/1 mouse worsened motor symptoms suggesting an induction of neuronal dysfunction. In conclusion, our results suggest that increased Rictor striatal levels could counteract neuronal dysfunction induced by mutant huntingtin.

Targeting CAG repeat RNAs reduces Huntington's disease phenotype independently of huntingtin levels.
Huntington's disease (HD) is a polyglutamine disorder caused by a CAG expansion in the Huntingtin (HTT) gene exon 1. This expansion encodes a mutant protein whose abnormal function is traditionally associated with HD pathogenesis; however, recent evidence has also linked HD pathogenesis to RNA stable hairpins formed by the mutant HTT expansion. Here, we have shown that a locked nucleic acid-modified antisense oligonucleotide complementary to the CAG repeat (LNA-CTG) preferentially binds to mutant HTT without affecting HTT mRNA or protein levels. LNA-CTGs produced rapid and sustained improvement of motor deficits in an R6/2 mouse HD model that was paralleled by persistent binding of LNA-CTG to the expanded HTT exon 1 transgene. Motor improvement was accompanied by a pronounced recovery in the levels of several striatal neuronal markers severely impaired in R6/2 mice. Furthermore, in R6/2 mice, LNA-CTG blocked several pathogenic mechanisms caused by expanded CAG RNA, including small RNA toxicity and decreased Rn45s expression levels. These results suggest that LNA-CTGs promote neuroprotection by blocking the detrimental activity of CAG repeats within HTT mRNA. The present data emphasize the relevance of expanded CAG RNA to HD pathogenesis, indicate that inhibition of HTT expression is not required to reverse motor deficits, and further suggest a therapeutic potential for LNA-CTG in polyglutamine disorders.

Hepatic Primary and Secondary Cholesterol Deposition and Damage in Niemann-Pick Disease.
Niemann-Pick C disease is a neurovisceral disorder caused by mutations in the NPC gene that result in systemic accumulation of intracellular cholesterol. Although neurodegeneration defines the disease's severity, in most patients it is preceded by hepatic complications such as cholestatic jaundice or hepatomegaly. To analyze the contribution of the hepatic disease in Niemann-Pick C disease progression and to evaluate the degree of primary and secondary hepatic damage, we generated a transgenic mouse with liver-selective expression of NPC1 from embryonic stages. Hepatic NPC1 re-expression did not ameliorate the onset and progression of neurodegeneration of the NPC1-null animal. However, the mice showed reduced hepatomegalia and dramatic, although not complete, reduction of hepatic cholesterol and serum bile salts, bilirubin, and transaminase levels. Therefore, hepatic primary and secondary cholesterol deposition and damage occur simultaneously during Niemann-Pick C disease progression.

Early down-regulation of PKCδ as a pro-survival mechanism in Huntington's disease.
A balance between cell survival and apoptosis is crucial to avoid neurodegeneration. Here, we analyzed whether the pro-apoptotic protein PKCδ, and the pro-survival PKCα and βII, were dysregulated in the brain of R6/1 mouse model of Huntington's disease (HD). Protein levels of the three PKCs examined were reduced in all the brain regions analyzed being PKCδ the most affected isoform. Interestingly, PKCδ protein levels were also decreased in the striatum and cortex of R6/2 and Hdh(Q111/Q111) mice, and in the putamen of HD patients. Nuclear PKCδ induces apoptosis, but we detected reduced PKCδ in both cytoplasmic and nuclear enriched fractions from R6/1 mouse striatum, cortex and hippocampus. In addition, we show that phosphorylation and ubiquitination of PKCδ are increased in 30-week-old R6/1 mouse brain. All together these results suggest a pro-survival role of reduced PKCδ levels in response to mutant huntingtin-induced toxicity. In fact, we show that over-expression of PKCδ increases mutant huntingtin-induced cell death in vitro, whereas over-expression of a PKCδ dominant negative form or silencing of endogenous PKCδ partially blocks mutant huntingtin-induced cell death. Finally, we show that the analysis of lamin B protein levels could be a good marker of PKCδ activity, but it is not involved in PKCδ-mediated cell death in mutant huntingtin-expressing cells. In conclusion, our results suggest that neurons increase the

degradation of PKCδ as a compensatory pro-survival mechanism in response to mutant huntingtin-induced toxicity that can help to understand why cell death appears late in the disease.

The AMPA receptor positive allosteric modulator S 47445 rescues in vivo CA3-CA1 long-term potentiation and structural synaptic changes in old mice.
Positive allosteric modulators of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (AMPARs) are small molecules that decrease deactivation of AMPARs via an allosteric site. These molecules keep the receptor in an active state. Interestingly, this type of modulator has been proposed for treating cognitive decline in ageing, dementias, and Alzheimer's disease (AD). S 47445 (8-cyclopropyl-3-[2-(3-fluorophenyl)ethyl]-7,8-dihydro-3H-[1,3]oxazino[6,5-g][1,2,3]benzotriazine-4,9-dione) is a novel AMPAR positive allosteric modulator (AMPA-PAM). Here, the mechanisms by which S 47445 could improve synaptic strength and connectivity were studied and compared between young and old mice. A single oral administration of S 47445 at 10 mg/kg significantly increased long-term potentiation (LTP) in CA3-CA1 hippocampal synapses in alert young mice in comparison to control mice. Moreover, chronic treatment with S 47445 at 10 mg/kg in old alert animals significantly counteracted the deficit of LTP due to age. Accordingly, chronic treatment with S 47445 at 10 mg/kg seems to preserve synaptic cytoarchitecture in old mice as compared with young control mice. It was shown that the significant decreases in number and size of pre-synaptic buttons stained for VGlut1, and post-synaptic dendritic spines stained for spinophilin, observed in old mice were significantly prevented after chronic treatment with 10 mg/kg of S 47445. Altogether, by its different effects on LTP, VGlut1-positive particles, and spinophilin, S 47445 is able to modulate both the structure and function of hippocampal excitatory synapses known to be involved in learning and memory processes. These results open a new window for the treatment of specific age-dependent cognitive decline and dementias such as AD.

Aims: Huntington's disease (HD) is a neurodegenerative disorder that can result in motor, mood, and cognitive symptoms. HD mood symptomatology correlates with neuronal death in the cingulate cortex. Neuroinflammation, involving reactive glial cells and inflammatory mediators in the brain parenchyma, may influence HD pathophysiology. Accumulation of mutant huntingtin (mHTT) aggregates has also been linked to neuroinflammation and neuronal loss. Importantly, the degree to which these neuroinflammatory changes are detrimental to neurons and contribute to HD pathology progression is not well understood. **Methods:** Using fluorescent immunohistochemistry, we labeled HD and control post-mortem human midcingulate cortex tissue with HLA DP/DQ/DR, an inflammatory marker, and Iba-1, labeling microglia. We qualitatively and quantitatively assessed activation and morphology changes, indicating neuroinflammation, and mHTT levels - linking neuroinflammation and mHTT burden. **Results:** We found increased activated microglial morphologies across all HD cases (53.82%), and increased ramified microglia in control cases (67.41%). HD cases showed a decreased number of ramified and ameboid microglia. Activated microglia were localized close to neurons containing mHTT aggregates in HD cases, which positively correlated with mHTT burden. The total microglia number did not increase in HD cases. **Conclusions:** Total microglia number remaining constant between HD and control cases suggests ramified microglia change to activated states in HD, increasing neuroinflammation. This data indicates an association between mHTT burden and neuroinflammation in HD.

The effect of age and sex on the expression of GABA signaling components in the human hippocampus and entorhinal cortex.
Gamma-aminobutyric acid (GABA) is the primary inhibitory neurotransmitter in the nervous system. The GABA signaling system in the brain is comprised of GABA synthesizing enzymes, transporters, GABAA and GABAB receptors (GABAR and GABAR). Alterations in the expression of these signaling components have been observed in several brain regions throughout aging and between sexes in various animal models. The hippocampus is the memory centre of the brain and is impaired in several age-related disorders. It is composed of two main regions: the Cornu Ammonis (CA1-4) and the Dentate Gyrus (DG), which are interconnected with the Entorhinal Cortex (ECx). The age- and sex-specific changes of GABA signaling components in these regions of the human brain have not been examined. This study is the first to determine the effect of age and sex on the expression of GABA signaling components-GABAR α1,2,3,5, β1-3, γ2, GABAR R1 and R2 subunits and the GABA synthesizing enzymes GAD 65/67-in the ECx, and the CA1 and DG regions of the human hippocampus using Western blotting. No significant differences were found in GABAR α1,2,3,5, β1-3, γ2, GABAR R1 and R2 subunit and GAD65/76 expression levels in the ECx, CA1 and DG regions between the younger and older age groups for both sexes. However, we observed a significant negative correlation between age and GABAR α1subunit level in the CA1 region for females; significant negative correlation between age and GABAR β1, β3 and γ2 subunit expression in the DG region for males. In females a significant positive correlation was found between age and GABAR γ2 subunit expression in the ECx and GABAR R2 subunit expression in the CA1 region. The results indicate that age and sex do not affect the expression of GAD 65/67. In conclusion, our results show age- and sex-related GABAR subunit alterations in the ECx and hippocampus that might significantly influence GABAergic neurotransmission and underlie disease susceptibility and progression.

EAAT2 Expression in the Hippocampus, Subiculum, Entorhinal Cortex and Superior Temporal Gyrus in Alzheimer's Disease.

Alzheimer's disease (AD) is a neuropathological disorder characterized by the presence and accumulation of amyloid-beta plaques and neurofibrillary tangles. Glutamate dysregulation and the concept of glutamatergic excitotoxicity have been frequently described in the pathogenesis of a variety of neurodegenerative disorders and are postulated to play a major role in the progression of AD. In particular, alterations in homeostatic mechanisms, such as glutamate uptake, have been implicated in AD. An association with excitatory amino acid transporter 2 (EAAT2), the main glutamate uptake transporter, dysfunction has also been described. Several animal and few human studies examined EAAT2 expression in multiple brain regions in AD but studies of the hippocampus, the most severely affected brain region, are scarce. Therefore, this study aims to assess alterations in the expression of EAAT2 qualitatively and quantitatively through DAB immunohistochemistry (IHC) and immunofluorescence within the hippocampus, subiculum, entorhinal cortex, and superior temporal gyrus (STG) regions, between human AD and control cases. Although no significant EAAT2 density changes were observed between control and AD cases, there appeared to be increased transporter expression most likely localized to fine astrocytic branches in the neuropil as seen on both DAB IHC and immunofluorescence. Therefore, individual astrocytes are not outlined by EAAT2 staining and are not easily recognizable in the CA1-3 and dentate gyrus regions of AD cases, but the altered expression patterns observed between AD and control hippocampal cases could indicate alterations in glutamate recycling and potentially disturbed glutamatergic homeostasis. In conclusion, no significant EAAT2 density changes were found between control and AD cases, but the observed spatial differences in transporter expression and their functional significance will have to be further explored.

The Effects of General Anaesthesia and Light on Behavioural Rhythms and GABA Receptor Subunit Expression in the Mouse SCN.
General anaesthesia (GA) is known to affect the circadian clock. However, the mechanisms that underlie GA-induced shifting of the clock are less well understood. Activation of γ-aminobutyric acid (GABA)type A receptors (GABAR) in the suprachiasmatic nucleus (SCN) can phase shift the clock and thus GABA and its receptors represent a putative pathway via which GA exerts its effect on the clock. Here, we investigated the concurrent effects of the inhalational anaesthetic, isoflurane, and light, on mouse behavioural locomotor rhythms and on α1, β3, and γ2 GABAR subunit expression in the SCN of the mouse brain. Behavioural phase shifts elicited by exposure of mice to four hours of GA (2% isoflurane) and light (400 lux) (n = 60) were determined by recording running wheel activity rhythms in constant conditions (DD). Full phase response curves for the effects of GA + light on behavioural rhythms show that phase shifts persist in anaesthetized mice exposed to light. Daily variation was detected in all three GABAR subunits in LD 12:12. The γ2 subunit expression was significantly increased following GA in DD (compared to light alone) at times of large behavioural phase delays. We conclude that the phase shifting effect of light on the mouse clock is not blocked by GA administration, and that γ2 may potentially be involved in the phase shifting effect of GA on the clock. Further analysis of GABAR subunit expression in the SCN will be necessary to confirm its role.

Glutamatergic receptor expression changes in the Alzheimer's disease hippocampus and entorhinal cortex.
Alzheimer's Disease (AD) is the leading form of dementia worldwide. Currently, the pathological mechanisms underlying AD are not well understood. Although the glutamatergic system is extensively implicated in its pathophysiology, there is a gap in knowledge regarding the expression of glutamate receptors in the AD brain. This study aimed to characterize the expression of specific glutamate receptor subunits in post-mortem human brain tissue using immunohistochemistry and confocal microscopy. Free-floating immunohistochemistry and confocal laser scanning microscopy were used to quantify the density of glutamate receptor subunits GluA2, GluN1, and GluN2A in specific cell layers of the hippocampal sub-regions, subiculum, entorhinal cortex, and superior temporal gyrus. Quantification of GluA2 expression in human post-mortem hippocampus revealed a significant increase in the stratum (str.) moleculare of the dentate gyrus (DG) in AD compared with control. Increased GluN1 receptor expression was found in the str. moleculare and hilus of the DG, str. oriens of the CA2 and CA3, str. pyramidale of the CA2, and str. radiatum of the CA1, CA2, and CA3 subregions and the entorhinal cortex. GluN2A expression was significantly increased in AD compared with control in the str. oriens, str. pyramidale, and str. radiatum of the CA1 subregion. These findings indicate that the expression of glutamatergic receptor subunits shows brain region-specific changes in AD, suggesting possible pathological receptor functioning. These results provide evidence of specific glutamatergic receptor subunit changes in the AD hippocampus and entorhinal cortex, indicating the requirement for further research to elucidate the pathophysiological mechanisms it entails, and further highlight the potential of glutamatergic receptor subunits as therapeutic targets.

The Interplay Between Beta-Amyloid 1-42 (Aβ)-Induced Hippocampal Inflammatory Response, p-tau, Vascular Pathology, and Their Synergistic Contributions to Neuronal Death and Behavioral Deficits.
Alzheimer's disease (AD), the most common chronic neurodegenerative disorder, has complex neuropathology. The principal neuropathological hallmarks of the disease are the deposition of extracellular β-amyloid (Aβ) plaques and neurofibrillary tangles (NFTs) comprised of hyperphosphorylated tau (p-tau) protein. These changes occur with neuroinflammation, a compromised blood-brain barrier (BBB) integrity, and neuronal synaptic dysfunction, all of which ultimately lead to neuronal cell loss and cognitive deficits in AD. Aβ was stereotaxically administered bilaterally into the CA1 region of the hippocampi of 18-month-old male C57BL/6 mice. This study aimed to characterize, utilizing immunohistochemistry and behavioral testing, the spatial and temporal effects of Aβ on a broad set of parameters characteristic of AD: p-tau, neuroinflammation, vascular pathology, pyramidal cell survival, and behavior. Three days after Aβ injection and before significant neuronal cell loss was detected, acute neuroinflammatory and vascular responses were observed. These responses included the up-regulation of glial fibrillary acidic protein (GFAP), cell adhesion molecule-1 (PECAM-1, also known as CD31), fibrinogen labeling, and an increased number of activated astrocytes and microglia in the CA1 region of the hippocampus. From day 7, there was significant pyramidal cell loss in the CA1 region of the hippocampus, and by 30 days, significant localized up-regulation of p-tau, GFAP, Iba-1, CD31, and alpha-smooth muscle actin (α-SMA) in the Aβ-injected mice compared with controls. These molecular changes in Aβ-injected mice were accompanied by cognitive deterioration, as demonstrated by long-term spatial memory impairment. This study is reporting a comprehensive examination of a complex set of parameters associated with intrahippocampal administration of Aβ in mice, their spatiotemporal interactions and combined contribution to the disease progression. We show that a single Aβ injection can reproduce aspects of the inflammatory, vascular, and p-tau induced pathology occurring in the AD human brain that lead to cognitive deficits.

Impaired Expression of GABA Signaling Components in the Alzheimer's Disease Middle Temporal Gyrus.
γ-aminobutyric acid (GABA) is the primary inhibitory neurotransmitter, playing a central role in the regulation of cortical excitability and the maintenance of the excitatory/inhibitory (E/I) balance. Several lines of evidence point to a remodeling of the cerebral GABAergic system in Alzheimer's disease (AD), with past studies demonstrating alterations in GABA receptor and transporter expression, GABA synthesizing enzyme activity and focal GABA concentrations in post-mortem tissue. AD is a chronic neurodegenerative disorder with a poorly understood etiology and the temporal cortex is one of the earliest regions in the brain to be affected by AD neurodegeneration. Utilizing NanoString nCounter analysis, we demonstrate here the transcriptional downregulation of several GABA signaling components in the post-mortem human middle temporal gyrus (MTG) in AD, including the GABA receptor α, α, α, α, β, β, β, δ, γ, γ, and θ subunits and the GABA receptor 2 (GABAR2) subunit. In addition to this, we note the transcriptional upregulation of the betaine-GABA transporter (BGT1) and GABA transporter 2 (GAT2), and the downregulation of the 67 kDa isoform of glutamate decarboxylase (GAD), the primary GABA synthesizing enzyme. The functional consequences of these changes require further investigation, but such alterations may underlie disruptions to the E/I balance that are believed to contribute to cognitive decline in AD.

Amyloid-beta induced glutamatergic receptor and transporter expression changes in the mouse hippocampus.
Alzheimer's disease (AD) is the leading type of dementia worldwide. With an increasing burden of an aging population coupled with the lack of any foreseeable cure, AD warrants the current intense research effort on the toxic effects of an increased concentration of beta-amyloid (Aβ) in the brain. Glutamate is the main excitatory brain neurotransmitter and it plays an essential role in the function and health of neurons and neuronal excitability. While previous studies have shown alterations in expression of glutamatergic signaling components in AD, the underlying mechanisms of these changes are not well understood. This is the first comprehensive anatomical study to characterize the subregion- and cell layer-specific long-term effect of Aβ on the expression of specific glutamate receptors and transporters in the mouse hippocampus, using immunohistochemistry with confocal microscopy. Outcomes are examined 30 days after Aβ stereotactic injection in aged male C57BL/6 mice. We report significant decreases in density of the glutamate receptor subunit GluA1 and the

vesicular glutamate transporter (VGluT) 1 in the conus ammonis 1 region of the hippocampus in the Aβ injected mice compared with artificial cerebrospinal fluid injected and naïve controls, notably in the stratum oriens and stratum radiatum. GluA1 subunit density also decreased within the dentate gyrus dorsal stratum moleculare in Aβ injected mice compared with artificial cerebrospinal fluid injected controls. These changes are consistent with findings previously reported in the human AD hippocampus. By contrast, glutamate receptor subunits GluA2, GluN1, GluN2A, and VGluT2 showed no changes in expression. These findings indicate that Aβ induces brain region and layer specific expression changes of the glutamatergic receptors and transporters, suggesting complex and spatial vulnerability of this pathway during development of AD neuropathology. An 5 GABAA Receptor Inverse Agonist, 5IA, Attenuates Amyloid Beta-Induced Neuronal Death in Mouse Hippocampal Cultures.
Alzheimer's disease (AD) is a progressive neurodegenerative disorder for which no cognition-restoring therapies exist. Gamma-aminobutyric acid (GABA) is the primary inhibitory neurotransmitter in the brain. Increasing evidence suggests a remodeling of the GABAergic system in AD, which might represent an important therapeutic target. An inverse agonist of 5 subunit-containing GABAA receptors (α5GABAARs), 3-(5-Methylisoxazol-3-yl)-6-[(1-methyl-1,2,3-triazol-4-yl)methyloxy]-1,2,4-triazolo[3-]phthalazine (5IA) has cognition-enhancing properties. This study aimed to characterize the effects of 5IA on amyloid beta (A)-induced molecular and cellular changes. Mouse primary hippocampal cultures were exposed to either A alone, or 5IA alone, 5IA with A or vehicle alone, and changes in cell viability and mRNA expression of several GABAergic signaling components were assessed. Treatment with 100 nM of 5IA reduced A-induced cell loss by 23.8% (< 0.0001) after 6 h and by 17.3% after 5 days of treatment (< 0.0001). Furthermore, we observed an A-induced increase in ambient GABA levels, as well as upregulated mRNA expression of the GABAAR α2,α5,2/3 subunits and the GABABR R1 and R2 subunits. Such changes in GABARs expression could potentially disrupt inhibitory neurotransmission and normal network activity. Treatment with 5IA restored A-induced changes in the expression of α5GABAARs. In summary, this compound might hold neuroprotective potential and represent a new therapeutic avenue for AD.

PREMATURE AGING OF NEURAL STEM CELLS IN HUNTINGTON'S DISEASE

POSTER SESSION 01 - SECTION: HUNTINGTON'S DISEASE

Camille Lafage, Sandrine Humbert, Fabienne Agasse
Univ. Grenoble Alpes, Inserm U1216, Gin Grenoble Institute Neurosciences, Grenoble, France

Neural stem cells (NSC) in the adult Rodent subventricular zone (SVZ) generate neurons throughout life. Neurogenesis persists in the adult Human brain with new interneurons, probably born in the nearby SVZ, adding to the striatum. Interestingly, striatal neurogenesis decreases in Huntington's disease (HD) patients. HD is a fatal neurodegenerative disorder with an adult onset caused by an autosomal dominant mutation of the huntingtin gene. The mutation is an abnormal expansion of a polymorphic CAG repeat leading to an abnormal polyglutamine stretch at the N-terminus of the huntingtin protein (HTT). We showed that mutant HTT (mHTT) decreases SVZ neurogenesis by altering NSC properties. In vitro NSC demonstrate restricted potency and limited capacity to self-renew and proliferate, suggesting a decreased NSC pool. We further hypothesize that this reduction may be due to accelerated aging features observed in HD, triggering stem cells entry in senescence. Preliminary experiments indeed show that HD stem cells express high levels of p16 mRNA as compared to WT counterparts. We will perform further genetic and epigenetic analysis to screen changes in gene expression associated with stemness and aging. Understanding the regulation of NSC in the SVZ may help to design new therapies to sustain neurogenesis in the old and diseased brain.

BRAIN CONNECTIVITY IN HUNTINGTON'S DISEASE

POSTER SESSION 01 - SECTION: HUNTINGTON'S DISEASE

Laetitia Capellano, Jean Christophe Deloulme, Frédéric Saudou, Sandrine Humbert
Inserm, U1216, Grenoble Institut Neurosciences, Univ. Grenoble Alpes, Grenoble, France

Huntington’s disease (HD) is a neurodegenerative disorder characterized by the loss of neurons predominantly in the striatum and the cortex. It is caused by an abnormal CAG expansion in the first exon of the Huntingtin gene, which results in a polyglutamine expansion in the N-terminal part of the huntingtin protein (HTT). HD manifestations appear in adults, but growing evidence suggests a developmental contribution to HD. Neuronal tracts are affected in early-stage HD patients such as the corticospinal tract or the fornix, but no evidence has been found yet in mice models of HD. Using brain clearing approaches, we are investigating if these defects are established during development in the CAG140 mouse model of HD. We observed that tracts such as the anterior commissure and the post-commissural fornix may be altered during postnatal development. As the establishment of neuronal connectivity relies on growth cone dynamics, we are studying this process in cortical neurons using microfluidics devices. Overall, our project will describe the mechanisms underlying early alterations in circuit connectivity in the HD brain.

KCC2 FUNCTION IS ALTERED IN THE INDIRECT PATHWAY OF THE BASAL GANGLIA IN HUNTINGTON'S DISEASE.

POSTER SESSION 01 - SECTION: HUNTINGTON'S DISEASE

Melissa Serranilla
University of Toronto, Department Of Cell And Systems Biology, Ramsay Wright Biological Laboratories, Toronto, Canada

Huntington's disease (HD) is an inherited neurodegenerative disorder caused by a CAG trinucleotide repeat expansion in Htt gene. The primary sites of degeneration are a group of nuclei called the basal ganglia which are essential for motor planning and voluntary movement. The basal ganglia consists of two major pathways: the direct and indirect, which promote and inhibit unwanted movement, respectively. The indirect pathway is known to degenerate earlier in HD, though the cause of this enhanced susceptibility remains unclear. Accumulating evidence suggests that impaired synaptic inhibition within the basal ganglia circuitry may contribute to this specific pattern of degeneration. Synaptic inhibition in the mature brain is largely mediated through GABA, which exerts fast hyperpolarizing inhibition by binding to Cl- -permeable GABAA receptors. GABAergic inhibition requires low intracellular Cl - concentration ([Cl-]i), which is maintained by the potassium-chloride cotransporter, KCC2. However, when KCC2 function is reduced, [Cl-]i increases, consequently weakening synaptic inhibition. Using electrophysiology and behavioural assays, we determined that KCC2 function was reduced in the indirect pathway of HD mice. In addition, GABAergic signaling was reversed in the output structure of the indirect pathway of early symptomatic HD mice. In addition, pharmacological reduction of intracellular Cl- with bumetanide delayed the onset of motor impairments in HD. This work demonstrates that the impaired GABAergic inhibition in the indirect pathway may be a key mechanism underlying circuitry and motor defects in HD, whereby KCC2 may serve as a potential therapeutic target in the treatment of HD.

Striatal Chloride Dysregulation and Impaired GABAergic Signaling Due to Cation-Chloride Cotransporter Dysfunction in Huntington's Disease.
Intracellular chloride (Cl) levels in mature neurons must be tightly regulated for the maintenance of fast synaptic inhibition. In the mature central nervous system (CNS), synaptic inhibition is primarily mediated by gamma-amino butyric acid (GABA), which binds to Cl permeable GABA receptors (GABARs). The intracellular Cl concentration is primarily maintained by the antagonistic actions of two cation-chloride cotransporters (CCCs): Cl-importing Na-K-Cl co-transporter-1 (NKCC1) and Cl -exporting K-Cl co-transporter-2 (KCC2). In mature neurons in the healthy brain, KCC2 expression is higher than NKCC1, leading to lower levels of intracellular Cl, and Cl influx upon GABAR activation. However, in neurons of the immature brain or in neurological disorders such as epilepsy and traumatic brain injury, impaired KCC2 function and/or enhanced NKCC1 expression lead to intracellular Cl accumulation and GABA-mediated excitation. In Huntington's disease (HD), KCC2- and NKCC1-mediated Cl-regulation are also altered, which leads to GABA-mediated excitation and contributes to the development of cognitive and motor impairments. This review summarizes the role of Cl (dys)regulation in the healthy and HD brain, with a focus on the basal ganglia (BG) circuitry and CCCs as potential therapeutic targets in the treatment of HD.

Alterations in Hippocampal Inhibitory Synaptic Transmission in the R6/2 Mouse Model of Huntington's Disease.
Huntington's disease (HD) is a genetic neurodegenerative disorder of the central nervous system characterized by choreatic movements, behavioral and psychiatric disturbances and cognitive impairments. Deficits in learning and memory are often the first signs of disease onset in both HD patients and mouse models of HD and are in part regulated by the hippocampus. In the R6/2 mouse model of HD, GABAergic transmission can be excitatory in the hippocampus and restoring inhibition can rescue the associated memory deficits. In the present study we determine that hippocampal GABAergic neurotransmission in the R6/2 mouse is disrupted as early as 4 weeks of age and is accompanied by alterations in the expression of key inhibitory proteins. Specifically, spontaneous inhibitory postsynaptic currents were initially increased in frequency at 4 postnatal weeks and subsequently decreased after the mice displayed the typical R6/2 behavioral phenotype at 10 weeks of age. Symptomatic mice also exhibited a change in the probability of GABA release and changes in the basic membrane properties

including neuronal excitability and input resistance. These electrophysiological changes in presymptomatic and symptomatic R6/2 mice were further accompanied by alterations in the protein expression level of pre- and postsynaptic inhibitory markers. Taken together, the present findings demonstrate profound alterations in the inhibitory neurotransmission in the hippocampus across the lifespan of the disease, including prior to neuronal degeneration, which suggests that the inhibitory hippocampal synapses may prove useful as a target for future therapeutic design.

FUNCTIONAL AND TRANSCRIPTOMIC ANALYSIS OF INDUCED PLURIPOTENT STEM CELL MICROGLIA IN HUNTINGTON'S DISEASE

POSTER SESSION 01 - SECTION: HUNTINGTON'S DISEASE

Nina Stöberl[1], Jasmine Donaldson[2], Thomas Massey[2], Hazel Hall-Roberts[3], Lesley Jones[2], Nicholas Allen[1]
[1]Cardiff University, School Of Biosciences, Cardiff, United Kingdom, [2]Cardiff University, Division Of Psychological Medicine And Clinical Neurosciences, Mrc Centre For Neuropsychiatric Genetics And Genomics, Cardiff, United Kingdom, [3]Cardiff University, Uk Dementia Research Institute At Cardiff, Cardiff, United Kingdom

Huntington's disease (HD) is a neurodegenerative disorder caused by a dominantly inherited CAG repeat expansion in the huntingtin gene (*HTT*). Recent findings indicate an involvement of neuroinflammation in HD pathology, including several PET studies demonstrating that microglial activation correlates with disease severity in HD patients. Nonetheless, an open question is whether mutant *HTT* expression leads to cell-autonomous transcriptional and functional changes in microglia, which potentially contribute to disease onset and progression. We used a patient-derived induced pluripotent stem cell (iPSC) model of HD microglia with 109 CAG repeats, and isogenic controls with a corrected wild-type length of 22 repeats. Differentiated iPSC-derived myeloid precursors and microglia were characterized by flow cytometry and immunohistochemistry. Fundamental microglia phenotypes were investigated, including morphology, attachment to fibronectin, secreted cytokines, and phagocytosis of pHrodo-labelled *E. coli* beads. HD and control microglia underwent bulk RNA sequencing under basal conditions and after pro-inflammatory stimulation with IFNγ/LPS. We found that HD myeloid precursors exhibit an impaired attachment to fibronectin and differentiated HD microglia developed a less complex morphology compared to the controls. HD microglia showed an increased secretion of inflammatory-related cytokines, and additionally an impairment in phagocytosis, one of microglia's key functions. The transcriptome analysis revealed significant differences between HD and control microglia in the unstimulated state, and a divergent transcriptional response to pro-inflammatory stimulation. These observations indicate a cell-autonomous altered basal activation state of HD microglia independent of the HD brain environment and might highlight a role of microglia in HD onset and progression.

Modulation of the Hypothalamic Nutrient Sensing Pathways by Sex and Early-Life Stress.
There are sex differences in metabolic disease risk, and early-life stress (ES) increases the risk to develop such diseases, potentially in a sex-specific manner. It remains to be understood, however, how sex and ES affect such metabolic vulnerability. The hypothalamus regulates food intake and energy expenditure by sensing the organism's energy state via metabolic hormones (leptin, insulin, ghrelin) and nutrients (glucose, fatty acids). Here, we investigated if and how sex and ES alter hypothalamic nutrient sensing short and long-term. ES was induced in mice by limiting the bedding and nesting material from postnatal day (P)2-P9, and the expression of genes critical for hypothalamic nutrient sensing were studied in male and female offspring, both at P9 and in adulthood (P180). At P9, we observed a sex difference in both and expression, while the latter was also increased in ES-exposed animals relative to controls. In adulthood, we found sex differences in , , and expression, whereas ES did not affect the expression of genes involved in hypothalamic nutrient sensing. Thus, we observe a pervasive sex difference in nutrient sensing pathways and a targeted modulation of this pathway by ES early in life. Future research is needed to address if the modulation of these pathways by sex and ES is involved in the differential vulnerability to metabolic diseases.

Effects of Early-Life Stress, Postnatal Diet Modulation and Long-Term Western-Style Diet on Peripheral and Central Inflammatory Markers.
Early-life stress (ES) exposure increases the risk of developing obesity. Breastfeeding can markedly decrease this risk, and it is thought that the physical properties of the lipid droplets in human milk contribute to this benefit. A concept infant milk formula (IMF) has been developed that mimics these physical properties of human milk (Nuturis, N-IMF). Previously, we have

shown that N-IMF reduces, while ES increases, western-style diet (WSD)-induced fat accumulation in mice. Peripheral and central inflammation are considered to be important for obesity development. We therefore set out to test the effects of ES, Nuturis and WSD on adipose tissue inflammatory gene expression and microglia in the arcuate nucleus of the hypothalamus. ES was induced in mice by limiting the nesting and bedding material from postnatal day (P) 2 to P9. Mice were fed a standard IMF (S-IMF) or N-IMF from P16 to P42, followed by a standard diet (STD) or WSD until P230. ES modulated adipose tissue inflammatory gene expression early in life, while N-IMF had lasting effects into adulthood. Centrally, ES led to a higher microglia density and more amoeboid microglia at P9. In adulthood, WSD increased the number of amoeboid microglia, and while ES exposure increased microglia coverage, Nuturis reduced the numbers of amoeboid microglia upon the WSD challenge. These results highlight the impact of the early environment on central and peripheral inflammatory profiles, which may be key in the vulnerability to develop metabolic derangements later in life.

RalGTPases contribute to Schwann cell repair after nerve injury via regulation of process formation.
RalA and RalB are small GTPases that are involved in cell migration and membrane dynamics. We used transgenic mice in which one or both GTPases were genetically ablated to investigate the role of RalGTPases in the Schwann cell (SC) response to nerve injury and repair. RalGTPases were dispensable for SC function in the naive uninjured state. Ablation of both RalA and RalB (but not individually) in SCs resulted in impaired axon remyelination and target reinnervation following nerve injury, which resulted in slowed recovery of motor function. Ral GTPases were localized to the leading lamellipodia in SCs and were required for the formation and extension of both axial and radial processes of SCs. These effects were dependent on interaction with the exocyst complex and impacted on the rate of SC migration and myelination. Our results show that RalGTPases are required for efficient nerve repair by regulating SC process formation, migration, and myelination, therefore uncovering a novel role for these GTPases.

Effects of early-life stress on peripheral and central mitochondria in male mice across ages.
Exposure to early-life stress (ES) increases the vulnerability to develop metabolic diseases as well as cognitive dysfunction, but the specific biological underpinning of the ES-induced programming is unknown. Metabolic and cognitive disorders are often comorbid, suggesting possible converging underlying pathways. Mitochondrial dysfunction is implicated in both metabolic diseases and cognitive dysfunction and chronic stress impairs mitochondrial functioning. However, if and how mitochondria are impacted by ES and whether they are implicated in the ES-induced programming remains to be determined. ES was applied by providing mice with limited nesting and bedding material from postnatal day (P)2-P9, and metabolic parameters, cognitive functions and multiple aspects of mitochondria biology (i.e. mitochondrial electron transport chain (ETC) complex activity, mitochondrial DNA copy number, expression of genes relevant for mitochondrial function, and the antioxidant capacity) were studied in muscle, hypothalamus and hippocampus at P9 and late adulthood (10-12 months of age). We show that ES altered bodyweight (gain), adiposity and glucose levels at P9, but not in late adulthood. At this age, however, ES exposure led to cognitive impairments. ES affected peripheral and central mitochondria in an age-dependent manner. At P9, both muscle and hypothalamic ETC activity were affected by ES, while in hippocampus, ES altered the expression of genes involved in fission and antioxidant defence. In adulthood, alterations in ETC complex activity were observed in the hypothalamus specifically, whereas in muscle and hippocampus ES affected the expression of genes involved in mitophagy and fission, respectively. Our study demonstrates that ES affects peripheral and central mitochondria biology throughout life, thereby uncovering a converging mechanism that might contribute to the ES-induced vulnerability for both metabolic diseases and cognitive dysfunction, which could serve as a novel target for intervention.

AXONAL VESICLES ARE PENTOSE PHOSPHATE PATHWAY MOBILE PLATFORMS CRUCIAL FOR ROS DETOXIFICATION AND NEURONAL SURVIVAL

POSTER SESSION 01 - SECTION: HUNTINGTON'S DISEASE

Anca Radu, Marta Prieto Garcia, Emeline Cuoc, Frédéric Saudou
Grenoble Institut des Neurosciences, équipe Saudou, Univ Grenoble Alpes, La Tronche, France

Huntington's disease (HD) is a rare hereditary neurodegenerative pathology inducing motor, cognitive and/or psychiatric disorders. This disease is caused by an abnormal polyQ expansion in the N-terminal part of the huntingtin protein. We have demonstrated that the cortico-striatal connection is affected in HD, especially the fast axonal transport (FAT) of BDNF vesicles. Recent studies of the team emphasized that glycolysis is crucial for FAT in neurons. The team has observed by quantitative proteomic analysis that not only glycolysis is present on vesicles but also the pentose phosphate pathway (PPP). This metabolic pathway is derived from glycolysis and allows ROS detoxification through NADPH production. This is why it is mostly used by neurons upon oxidative stress. However, nothing is known for the moment about the presence and the role of these PPP enzymes on vesicles. Using biochemical approaches and super-resolution microscopy on microfluidic brain-on-a-chip devices, we observe that PPP enzymes like glucose-6 phosphate dehydrogenase (G6PD) are selectively associated with vesicles. Their vesicular localization is increased upon oxidative stress and their enzymatic activity is essential for their recruitment on vesicles. We have also shown that G6PD regulates the FAT of vesicles and maintains the antioxidant status inside the axons. Oxidative stress plays a central role in the pathophysiology of HD. Exploring the antioxidant role of vesicular PPP enzymes in HD is currently under progress. Altogether, these findings highlight the novel and crucial role of PPP enzymes during FAT and could provide key information on new therapeutic strategies in HD.

Despite the advances in the understanding of Huntington's disease (HD), no disease-modifying treatments exist, and therapeutic development and HD-clinical trials continue to fail. Major efforts are being invested in the assessment of measurable outcomes in early diagnosis and prognosis for optimal therapeutic response. Recent insights on Huntington's disease have pointed to a profound role of RNA in the neuropathogenesis of the disorder. Specifically, growing evidence indicates that small non-coding RNA (sRNA) are key players in the disease. The profiling of extracellular sRNAs (exRNA), found in body fluids as freely circulating, associated to protein-complexes, and/or encapsulated in extracellular vesicles (EVs), supposes a promising approach for defining non-invasive biomarkers that reflect disease status. Using an optimal method for plasma sub-fractionation and EVs purification by Size-exclusion chromatography (SEC) and Ultrafiltration (UF), we explored sRNA content in EVs and Non-EVs compartments, providing a deep exRNA analysis and offering a complementary source of valuable information. Characterization of plasma-EVs from three different cohorts, including healthy controls, premanifest HD, and manifest HD, revealed no differences in size and morphology of EVs. Using SeqCluster bioinformatic tool for sRNA annotation and quantification, we highlighted that most differentially expressed sRNAs in HD-EVs are downregulated in comparison to Control-EVs, with many changes occurring at premanifest stages. Those sRNAs showing the most differential profile between groups were validated as potential future biomarkers for HD. These findings suggest that alterations in circulating exRNAs may reflect early clinical and pathological changes in HD patients.

Non-Coding RNAs as Sensors of Oxidative Stress in Neurodegenerative Diseases.
Oxidative stress (OS) results from an imbalance between the production of reactive oxygen species and the cellular antioxidant capacity. OS plays a central role in neurodegenerative diseases, where the progressive accumulation of reactive oxygen species induces mitochondrial dysfunction, protein aggregation and inflammation. Regulatory non-protein-coding RNAs (ncRNAs) are essential transcriptional and post-transcriptional gene expression controllers, showing a highly regulated expression in space (cell types), time (developmental and ageing processes) and response to specific stimuli. These dynamic changes shape signaling pathways that are critical for the developmental processes of the nervous system and brain cell homeostasis. Diverse classes of ncRNAs have been involved in the cell response to OS and have been targeted in therapeutic designs. The perturbed expression of ncRNAs has been shown in human neurodegenerative diseases, with these changes contributing to pathogenic mechanisms, including OS and associated toxicity. In the present review, we summarize existing literature linking OS, neurodegeneration and ncRNA function. We provide evidences for the central role of OS in age-related neurodegenerative conditions, recapitulating the main types of regulatory ncRNAs with roles in the normal function of the nervous system and summarizing up-to-date information on ncRNA deregulation with a direct impact on OS associated with major neurodegenerative conditions.

Huntington's disease (HD) is an incurable, genetic, neurodegenerative disease that damages primarily the striatum and leads to motor, cognitive and psychiatric symptoms. The HD striatum undergoes early specific epigenetic gene reprograming, progressively leading to impairment of striatal neuron identity and function. Notably, the mechanism implicates decreased H3K27 acetylation (H3K27ac) at neuronal identity genes. Energy metabolism is also early impaired in the HD striatum. Since histone acetylation is strongly connected to energy metabolism through Acetyl-CoA (ACoA), the only donor of acetyl group for histone acetylation, altered energy metabolism might underlie H3K27ac dysregulation in HD striatal neurons. The aim of the project is to explore the hypothesis that deficient energy metabolism interplays with histone acetylation changes in the HD striatum, impairing ACoA regulation. Using HD mouse models, we further characterize HD striatal histone acetylome, implementing ChIPseq/CUT&Tag approach at cell-type-specific level (in sorted striatal neurons). Our preliminary data indicate that H3K9ac and H3K18ac are also dysregulated in HD striatal neurons, supporting broad impairment of histone acetylome. Furthermore, our preliminary proteomic analyses on histones extracted from HD mouse striatum suggest that additional acylation marks may be modified by the HD mutation. Finally, our molecular and histological analyses indicate that key regulators of nuclear ACoA production, *e.g.* ATP citrate lyase (Acly), Acyl-CoA synthetase (Acss2) and pyruvate-dehydrogenase complex (PDC), are dysregulated in HD mouse striatum. Together, this supports the hypothesis of interplay between altered energy metabolism and histone acylome dysregulation in the HD striatum.

In neurons, cAMP modulate metabotropic responses and induce many intracellular signalling pathways, including synaptic plasticity. Phytochrome photoreceptors can act as adenylate cyclase and produce cAMP in cells upon photoactivation, allowing spatio-temporal modulation of cAMP, which can be particularly relevant in neurodegenerative diseases such as Huntington's disease (HD). HD is characterized by motor disturbances, associated to a progressive disconnection of the cortico-striatal circuitry. Therefore, our main goal is to evaluate the potential of phytochromes as a novel tool to induce long-term neuronal plasticity in HD's specific brain circuits. We first explored cAMP levels at distinct brain regions and along HD progression by ELISA. Then, we evaluated how cAMP modulates neuronal activity dynamics by analysing Fluo4 calcium fluorescence intensity changes, as well as individual and collective spontaneous neuronal activity by Forskolin application, in WT and R6/1 mice primary cortical cultures at 14 DIV, using the NETCAL software. We observed that Forskolin increases the number of neurons firing collectively, while single neuronal activity (number of spikes, ISI, IBI) remains unaltered. Moreover, this effect was not observed in HD cultures. Accordingly, primary cultures from WT and HD were infected at 7 DIV with an AAV expressing Phytochromes (AAV9-CamKII-DdPAC-Flag-tag) and calcium dynamics induced by phytochrome activation are currently being analysed. We are also implementing fiber photometry tools to study phytochrome effects in vivo by using the calcium sensor GCamp6f and/or cAMP sensor Pink Flamindo. Altogether, these results contribute to the development of new approaches towards modulating brain activity and uncover circuit dynamics in Huntington's disease.

Progressive motor alterations and selective death of medium-sized spiny neurons in the caudate and putamen are key pathological hallmarks of Huntington's disease (HD), a neurodegenerative disorder caused by a CAG trinucleotide repeat expansion in the coding region of the huntingtin (*HTT*) gene. Growing evidence indicates that expanded CAG repeats within mutant *HTT* mRNA and derived small CAG repeat RNAs (sCAG) participate in HD pathophysiology. However, the role of other classes of small RNAs (sRNA) that are strongly perturbed in HD is uncertain. Our most recent data indicate that sRNA produced in the putamen of HD patients are sufficient to induce HD pathology *in vivo*. This observation prompted us to deeply characterize the sRNA transcriptome and identify which sRNA species are enriched in HD putamen and show neurotoxic potential. Specifically, we have observed a massive increase in tRNA fragments (tRFs). tRFs are bioactive molecules that regulate gene expression at multiple levels, whose biogenesis is linked with cellular stress and regulated by post-transcriptional modifications. Our analyses suggest that many of the tRFs over-represented in HD are dependent on the methylation status of the precursor, mature tRNAs. Validating these results, we have detected altered expression of enzymes regulating tRNA post-transcriptional modifications in HD human and mouse brains. We have also studied the potential modifications in the tRNAs, which provides an additional source of pathogenic alterations in HD. These results highlight that multiple sRNA species are contributing to striatal neuropathology, favouring therapeutic strategies based on the blockage of sRNA biogenesis and/or toxic activity.

Increased translation as a novel pathogenic mechanism in Huntington's disease.
Huntington's disease is a neurodegenerative disorder caused by a CAG repeat expansion in exon 1 of the huntingtin gene. Striatal projection neurons are mainly affected, leading to motor symptoms, but molecular mechanisms involved in their vulnerability are not fully characterized. Here, we show that eIF4E binding protein (4E-BP), a protein that inhibits translation, is inactivated in Huntington's disease striatum by increased phosphorylation. Accordingly, we detected aberrant de novo protein synthesis. Proteomic characterization indicates that translation specifically affects sets of proteins as we observed upregulation of ribosomal and oxidative phosphorylation proteins and downregulation of proteins related to neuronal structure and function. Interestingly, treatment with the translation inhibitor 4EGI-1 prevented R6/1 mice motor deficits, although corticostriatal long-term depression was not markedly changed in behaving animals. At the molecular level, injection of 4EGI-1 normalized protein synthesis and ribosomal content in R6/1 mouse striatum. In conclusion, our results indicate that dysregulation of protein synthesis is involved in mutant huntingtin-induced striatal neuron dysfunction.

Non-Coding RNAs as Sensors of Oxidative Stress in Neurodegenerative Diseases.
Oxidative stress (OS) results from an imbalance between the production of reactive oxygen species and the cellular antioxidant capacity. OS plays a central role in neurodegenerative diseases, where the progressive accumulation of reactive oxygen species induces mitochondrial dysfunction, protein aggregation and inflammation. Regulatory non-protein-coding RNAs (ncRNAs) are essential transcriptional and post-transcriptional gene expression controllers, showing a highly regulated

expression in space (cell types), time (developmental and ageing processes) and response to specific stimuli. These dynamic changes shape signaling pathways that are critical for the developmental processes of the nervous system and brain cell homeostasis. Diverse classes of ncRNAs have been involved in the cell response to OS and have been targeted in therapeutic designs. The perturbed expression of ncRNAs has been shown in human neurodegenerative diseases, with these changes contributing to pathogenic mechanisms, including OS and associated toxicity. In the present review, we summarize existing literature linking OS, neurodegeneration and ncRNA function. We provide evidences for the central role of OS in age-related neurodegenerative conditions, recapitulating the main types of regulatory ncRNAs with roles in the normal function of the nervous system and summarizing up-to-date information on ncRNA deregulation with a direct impact on OS associated with major neurodegenerative conditions.

Huntington's disease brain-derived small RNAs recapitulate associated neuropathology in mice.
Progressive motor alterations and selective death of striatal medium spiny neurons (MSNs) are key pathological hallmarks of Huntington's disease (HD), a neurodegenerative condition caused by a CAG trinucleotide repeat expansion in the coding region of the huntingtin (HTT) gene. Most research has focused on the pathogenic effects of the resultant protein product(s); however, growing evidence indicates that expanded CAG repeats within mutant HTT mRNA and derived small CAG repeat RNAs (sCAG) participate in HD pathophysiology. The individual contribution of protein versus RNA toxicity to HD pathophysiology remains largely uncharacterized and the role of other classes of small RNAs (sRNA) that are strongly perturbed in HD is uncertain. Here, we demonstrate that sRNA produced in the putamen of HD patients (HD-sRNA-PT) are sufficient to induce HD pathology in vivo. Mice injected with HD-sRNA-PT show motor abnormalities, decreased levels of striatal HD-related proteins, disruption of the indirect pathway, and strong transcriptional abnormalities, paralleling human HD pathology. Importantly, we show that the specific blockage of sCAG mitigates HD-sRNA-PT neurotoxicity only to a limited extent. This observation prompted us to identify other sRNA species enriched in HD putamen with neurotoxic potential. We detected high levels of tRNA fragments (tRFs) in HD putamen, and we validated the neurotoxic potential of an Alanine derived tRF in vitro. These results highlight that HD-sRNA-PT are neurotoxic, and suggest that multiple sRNA species contribute to striatal dysfunction and general transcriptomic changes, favoring therapeutic strategies based on the blockage of sRNA-mediated toxicity.

Disruption of basal ganglia (BG) circuits underlie several movement disorders, such as Huntington's disease (HD). Recent functional studies reveal that distinct BG sub-circuits modulate different behavioral domains, i.e dorso-medial striatum (DMS) seems more involved in goal-directed action control while dorso-lateral striatum (DLS) in habit and skill learning. Here, we unravel functional implications of DLS and DMS and its main striatal output pathways: direct and indirect (expressing D1 or A2a receptors respectively), in HD pathophysiology. First, we analyzed functional connectivity alterations of DLS and DMS using rs-fMRI in the R6/1 mouse model of HD. DLS showed reduced functional connectivity with all cortical subregions and thalamus, while DMS connectivity was less affected. Then, we bilaterally injected AAV-DIO-ChR2 in the DLS or DMS of Drd1-Cre and A2A-Cre mouse lines crossed with R6/1 mice. In WT animals, optogenetic stimulation of DLS direct pathway increases locomotion, whereas DLS indirect pathway activation improves motor learning, assessed in an accelerating rotarod. These effects were not observed in symptomatic HD mice, or when DMS selective pathways were stimulated. Then, we expressed the GCaMP6f calcium sensor in Drd1-neurons in the DLS or DMS during the accelerated rotarod task, and recorded fluorescence changes using fiber photometry. We found an abnormal neuronal engagement of the direct pathway in the DLS but not the DMS during all phases of skill learning. We are currently analyzing the contribution of the indirect pathway in this task. Altogether, our data suggests a major involvement of the DLS in HD pathophysiology.

M2 cortex-dorsolateral striatum stimulation reverses motor symptoms and synaptic deficits in Huntington's disease.
Huntington's disease (HD) is a neurological disorder characterized by motor disturbances. HD pathology is most prominent in the striatum, the central hub of the basal ganglia. The cerebral cortex is the main striatal afferent, and progressive cortico-striatal disconnection characterizes HD. We mapped striatal network dysfunction in HD mice to ultimately modulate the activity of a specific cortico-striatal circuit to ameliorate motor symptoms and recover synaptic plasticity. Multimodal MRI in vivo indicates cortico-striatal and thalamo-striatal functional network deficits and reduced glutamate/glutamine ratio in the striatum of HD mice. Moreover, optogenetically-induced glutamate release from M2 cortex terminals in the dorsolateral striatum (DLS) was undetectable in HD mice and striatal neurons show blunted electrophysiological responses. Remarkably, repeated M2-DLS optogenetic stimulation normalized motor behavior in HD mice and evoked a sustained increase of synaptic plasticity. Overall, these results reveal that selective stimulation of the M2-DLS pathway can become an effective therapeutic strategy in HD.

IN VIVO STRIATAL ACTIVITY DURING MOTOR SKILL LEARNING AND SPONTANEOUS BEHAVIOUR IN HUNTINGTON'S DISEASE MICE

POSTER SESSION 01 - SECTION: HUNTINGTON'S DISEASE

Ellen Koch, Judy Cheng, Marja Sepers, Ryan Yeung, Lynn Raymond
UBC Djavad Mowafaghian Center for Brain Health, Psychiatry, Vancouver, Canada

Huntington's disease (HD) is a neurodegenerative disorder characterized by motor, cognitive and psychiatric deficits. The dorsal striatum is the major site of neurodegeneration. Studies have shown aberrant cortico-striatal signalling in HD mice, including changes to the activity of D1- and D2-SPNs, aberrant neurotransmitter signalling, and deficits in cortico-striatal plasticity. We were interested in how changes to cortico-striatal signalling *in vitro* correlate with behaviour *in vivo*. We combined the accelerating rotarod and open field with calcium imaging using fiber photometry in the striatum of HD mouse models (YAC128 and Q175). This includes imaging of overall striatal activity with GCaMP7f, as well as population specific imaging of D1-SPNs and D2-SPNs using green and red calcium sensors. When imaging activity of all striatal neurons, we found that both WT and YAC128 mice showed increased striatal activity when they performed the rotarod, which reduced over training. 2-3 month YAC128 mice showed no deficit in latency to fall from the rotarod, however, the correlation between striatal activity and behaviour on the rotarod and open field in YAC128 was significantly weaker. Interestingly, YAC128 showed deficits in paw kinematics, including increased paw slips below the rotarod, which was associated with aberrant striatal activity. At 6-7 months, YAC128 mice were severely impaired on the rotarod and had significantly increased striatal activity. YAC128 mice also showed elevated striatal activity at rest in the open field. This work begins to bridge the gap between changes to striatal signalling determined from in vitro studies and the behavioural deficits observed in vivo.

Dysfunctional striatal dopamine signaling in Huntington's disease.
Dopamine signaling in the striatum is critical for a variety of behaviors including movement, behavioral flexibility, response to reward and many forms of learning. Alterations to dopamine transmission contribute to pathological features of many neurological diseases, including Huntington's disease (HD). HD is an autosomal dominant genetic disorder caused by a CAG repeat expansion in the Huntingtin gene. The striatum is preferentially degenerated in HD, and this region receives dopaminergic input from the substantia nigra. Studies of HD patients and genetic rodent models have shown changes to levels of dopamine and its receptors in the striatum, and alterations in dopamine receptor signaling and modulation of other neurotransmitters, notably glutamate. Throughout his career, Dr. Michael Levine's research has furthered our understanding of dopamine signaling in the striatum of healthy rodents and HD mouse models. This review will focus on the work of his group and others in elucidating alterations to striatal dopamine signaling that contribute to pathophysiology in HD mouse models, and how these findings relate to human HD studies. We will also discuss current and potential therapeutic interventions for HD that target the dopamine system, and future research directions for this field.

Direct assessment of presynaptic modulation of cortico-striatal glutamate release in a Huntington's disease mouse model.
Glutamate is the main excitatory neurotransmitter in the brain, and impairments in its signaling are associated with many neurological disorders, including Huntington's disease (HD). Previous studies in HD mouse models demonstrate altered glutamate receptor distribution and signaling at cortico-striatal synapses, and some studies suggest that glutamate release is altered; however, traditional methods to study synaptic glutamate release are indirect or have poor temporal resolution. Here we utilize iGluSnFR, a modified green fluorescent protein reporter for real-time imaging of glutamate transmission, to study presynaptic modulation of cortical glutamate release in the striatum of the YAC128 HD mouse model. We determined that iGluSnFR can be used to accurately measure short- and long-term changes in glutamate release caused by modulation of extracellular Ca levels, activation of presynaptic receptors, and high-frequency stimulation (HFS) protocols. We also confirmed a difference in the expression of HFS-induced long-term depression in YAC128. Together, this research demonstrates the utility of iGluSnFR in studying presynaptic modulation of glutamate release in healthy mice and disease

models that display impairments in glutamate signaling. NEW & NOTEWORTHY We use iGluSnFR to directly assess presynaptic modulation of cortico-striatal glutamate release in brain slice and compare changes in glutamate release between wild type and a Huntington's disease mouse model, YAC128. We observed reductions in glutamate release after low extracellular Ca and activation of various presynaptic receptors. We also demonstrate a presynaptic mechanism of reduced glutamate release in high-frequency stimulation-induced long-term depression and show this to be altered in YAC128.

Starvation-Induced Depotentiation of Bitter Taste in Drosophila.
Nutrient deprivation can lead to dramatic changes in feeding behavior, including acceptance of foods that are normally rejected. In flies, this behavioral shift depends in part on reciprocal sensitization and desensitization of sweet and bitter taste, respectively. However, the mechanisms for bitter taste modulation remain unclear. Here, we identify a set of octopaminergic/tyraminergic neurons, named OA-VLs, that directly modulate bitter sensory neuron output in response to starvation. OA-VLs are in close proximity to bitter sensory neuron axon terminals and show reduced tonic firing following starvation. We find that octopamine and tyramine potentiate bitter sensory neuron responses, suggesting that starvation-induced reduction in OA-VL activity depotentiates bitter taste. Consistent with this model, artificial silencing of OA-VL activity induces a starvation-like reduction in bitter sensory neuron output. These results demonstrate that OA-VLs mediate a critical step in starvation-dependent bitter taste modulation, allowing flies to dynamically balance the risks associated with bitter food consumption against the threat of severe starvation.

Huntington's disease (HD) is a fatal hereditary disorder with severe neurodegeneration in the striatum and cortex. Despite the monogenic nature of HD, disease pathogenesis is insufficiently understood and effective disease-modifying treatments are lacking to date. Here, we uncover hepatoma-derived growth factor (HDGF) as a neuroprotective protein in the context of HD. HDGF counteracts mutant huntingtin aggregation and cell death in murine primary cortical neurons. Expression levels of HDGF in mouse brain are inversely correlated with vulnerability of brain regions and individual neuronal populations to HD. In R6/2 HD model mice, HDGF deficiency exacerbates motor defects and reduces life span, while viral HDGF delivery into the nervous system significantly improves locomotor activity. Mechanistic studies in cell culture models of HD demonstrate that the neuroprotective activity of HDGF is independent of its subcellular localization: Nuclear and cytoplasmic HDGF are equally effective in rescuing mutant huntingtin toxicity. Moreover, extracellular application of recombinant HDGF is sufficient to improve viability of mutant huntingtin-expressing primary neurons via a mechanism distinct from canonical growth factor signaling. Taken together, this study provides new insights into HDGF function in the diseased brain and unravels the therapeutic potential of HDGF in HD.

Huntington disease (HD) is an inherited neurological disease caused by a pathological CAG repeat expansion in the *HTT* gene encoding an abnormal glutamine repeat in the huntingtin protein (HTT). Given the adult-onset of this disease, the neurological symptoms, and the neuronal cell death, many studies focused on describing the effects of the mutant protein in adult neurons. However, HTT is expressed very early and plays a fundamental role in brain development. Specifically, HTT is required for mitotic spindle orientation, for maintaining the pool of cortical progenitors and at later stages for multipolar-bipolar transition and migration of newborn neurons in the mouse cortex. Mutant HTT impairs these mechanisms, resulting in thinner cortex in HD mice. In presymptomatic mouse models and patients, brain MRI studies have revealed cortical and striatal abnormalities decades before overt clinical signs. These defects could arise from an abnormal brain development in HD. For these reasons, we initiated a program to explore human brain development in HD and found that mutant HTT reduces the number of proliferating cells and triggers more neural progenitors to prematurely enter lineage specification. Yet, a lot remains unknown on the underlying molecular mechanisms. Here, we performed an RNAseq analysis on the developing cortex of fetuses carrying an HD-causing mutation compared to control fetuses at the same age. We show that mutant HTT impairs transcriptional regulations of human neurodevelopment and postulate that this may affect disease progression or onset.

LXR SIGNALING IN THE STRIATUM AND NEUROPROTECTION IN HUNTINGTON'S DISEASE

POSTER SESSION 01 - SECTION: HUNTINGTON'S DISEASE

Coline Mounier, Maxime Brilland, Peter Vanhoutte, Jocelyne Caboche, Sandrine Betuing
Sorbonne University, Neuroscience Paris Seine, Paris, France

Huntington's disease (HD) is a rare neurodegenerative disease associated to several cellular dysfunctions, including cholesterol metabolism deregulation. Brain cholesterol is catabolized by the neuronal enzyme CYP46A1 into 24S-hydroxycholesterol (24S-OHC), a ligand of Liver X Receptor (LXR). Restoration of CYP46A1 in HD mice induces a neuroprotection with an upregulation of LXR target genes; therefore, we hypothesized their involvement in CYP46A1 neuroprotection in HD. There are two LXR isoforms, LXRβ enriched in the brain for cholesterol metabolism regulation and LXRα mainly expressed in the liver which activation can induces side effects on lipogenesis. The aim of the project is to investigate the role of LXR activation in HD, with the use of new LXRβ agonists. LXR agonists bioactivity were validated in primary cultures of striatal neurons and astrocytes, and their neuroprotective role was studied in a HD cellular model. A treatment protocol with LXR agonist was validated in Wild Type mice. In neurons and astrocytes culture, LXR agonists induce an increase of mRNA level of LXR target genes, involved in cholesterol metabolism and known to be downregulated in HD. The agonists induce a neuroprotection in HD striatal neurons in culture, with a decrease of mHTT aggregates and an increase of cell survival, dependent of proteasome and autophagy mechanisms. ***These results support the biological efficacy of these new LXR compounds and their neuroprotective role in HD striatal neurons. The mechanisms involved in LXR effect in vitro*** **are now investigated, and** ***their role is studied on motor and cognitive symptoms in HD mouse model.***

Medium Spiny Neuron (MSN) degeneration is a major pathological hallmark in the dominantly inherited condition Huntington's Disease (HD) for which there is currently no disease-modifying treatment. Understanding pathogenic mechanisms underlying neuronal degeneration is key to developing therapeutic strategies. The causal mutation is in the Huntingtin (HTT) gene. Our aim is to analyse interactions of mutant HTT (mHTT) with other genes and proteins implicated in the networks that control MSN differentiation and which are dysregulated in HD. One example is FoxP1, a transcription factor that can interact with mHTT and is required for MSN differentiation in mice. Our objective is to determine whether FoxP1 has a role in HD pathogenesis. In a shuttle approach between two model systems, we use the Drosophila eye as an in vivo 'test tube' to analyse the effect of manipulating genes of interest on mHTT-induced neurodegeneration, and then explore interesting results in the R6/1 and knock-in Q150 mouse models of HD. We use Drosophila eye phenotype and rhabdomere counts and mouse histological analysis and stereology to investigate the effect of manipulating FoxP1 expression. Reduction of FoxP1-positive neuronal cell number and levels of protein expression were early events in the course of striatal degeneration in both HD mouse models, consistent with a role for FoxP1 in mHTT-induced neurodegeneration. Overexpression of a FoxP1 fragment rescued mHTT-induced eye degeneration in the Drosophila model. Viral vector mediated overexpression of FoxP1 via stereotactic injection into the striatum of HD mice will be used to extend these findings into the mammalian brain.

THE DEDICATOR OF CYTOKINESIS 7 (DOCK7) AFFECTS INTRACELLULAR TRAFFICKING OF ENDOLYSOSOMES

POSTER SESSION 01 - SECTION: HUNTINGTON'S DISEASE

Georg Pitschelatow, Julia Reichard, Jenice Linde, Can Yildiz, Geraldine Zimmer-Bensch
RWTH Aachen University, Biology 2 - Functional Epigenetics In The Animal Model, Aachen, Germany

Proteostasis networks are essential for neuronal integrity and homeostasis, being disturbed in various neurodegenerative diseases. Proteostasis involves the bidirectional intracellular trafficking of endosomes and lysosomes along microtubules. Therefore, microtubule stability is a critical parameter. The microtubule stability is fine-tuned by specific proteins, such as the dedicator of cytokinesis 7 (DOCK7). DOCK7 stabilizes microtubules via its guanine nucleotide exchange activity and the following phosphorylation cascades of microtubule destabilizer proteins, such as stathmin/Op18. However, whether DOCK7 affects intracellular trafficking of degradative organelles, especially in the context of neurodegenerative diseases, is not clear yet. To this end, we monitored intracellular trafficking of endolysosomal compartments in live cell imaging experiments in murine CB (Cerebellar granule cells) and N2a (Neuroblastoma cells) cells that were co-transfected with *Dock7*-siRNA and a CD63-GFP-DNA-plasmid construct, labeling late endosomes and lysosomes. We found that siRNA-mediated depletion of *Dock7* caused a significant acceleration of the intracellular trafficking of endolysosomal organelles. As degradative networks modulate neuronal degeneration, we next investigated whether DOCK7 has an effect on mutant Huntingtin (HTT)-induced neurotoxicity. Indeed, we found an improved survival of mutant HTT expressing cells upon *Dock7* depletion, which revealed to improve intracellular trafficking. We hypothesize that DOCK7-mediated regulation of intracellular trafficking affects aggresome formation of mutant HTT, shown to be cytoprotective. In sum, we conclude that DOCK7 affects the intracellular trafficking of degradative vesicles in the proteostasis network, putatively through its microtubule stabilizer property.

DNA Methyltransferase 1 (DNMT1) Acts on Neurodegeneration by Modulating Proteostasis-Relevant Intracellular Processes.
The limited regenerative capacity of neurons requires a tightly orchestrated cell death and survival regulation in the context of longevity, as well as age-associated and neurodegenerative diseases. Subordinate to genetic networks, epigenetic mechanisms, such as DNA methylation and histone modifications, are involved in the regulation of neuronal functionality and emerge as key contributors to the pathophysiology of neurodegenerative diseases. DNA methylation, a dynamic and reversible process, is executed by DNA methyltransferases (DNMTs). DNMT1 was previously shown to act on neuronal survival in the aged brain, whereby a DNMT1-dependent modulation of processes relevant for protein degradation was proposed as an underlying mechanism. Properly operating proteostasis networks are a mandatory prerequisite for the functionality and long-term survival of neurons. Malfunctioning proteostasis is found, inter alia, in neurodegenerative contexts. Here, we investigated whether DNMT1 affects critical aspects of the proteostasis network by a combination of expression studies, live cell imaging, and protein biochemical analyses. We found that DNMT1 negatively impacts retrograde trafficking and autophagy, with both being involved in the clearance of aggregation-prone proteins by the aggresome-autophagy pathway. In line with this, we found that the transport of GFP-labeled mutant huntingtin (HTT) to perinuclear regions, proposed to be cytoprotective, also depends on DNMT1. Depletion of accelerated perinuclear HTT aggregation and improved the survival of cells transfected with mutant HTT. This suggests that mutant HTT-induced cytotoxicity is at least in part mediated by DNMT1-dependent modulation of degradative pathways.

The Expression of the Cancer-Associated lncRNA Is Modulated by EphrinA5-Induced Signaling.
The Eph receptor tyrosine kinases and their respective ephrin-ligands are an important family of membrane receptors, being involved in developmental processes such as proliferation, migration, and in the formation of brain cancer such as glioma. Intracellular signaling pathways, which are activated by Eph receptor signaling, are well characterized. In contrast, it is unknown so far whether ephrins modulate the expression of lncRNAs, which would enable the transduction of environmental stimuli into our genome through a great gene regulatory spectrum. Applying a combination of functional in vitro assays, RNA

sequencing, and qPCR analysis, we found that the proliferation and migration promoting stimulation of mouse cerebellar granule cells (CB) with ephrinA5 diminishes the expression of the cancer-related lncRNA In a human medulloblastoma cell line (DAOY) ephrinA5 stimulation similarly reduced expression. Computational analysis identified triple-helix-mediated DNA-binding sites of in promoters of genes found up-regulated upon ephrinA5 stimulation and known to be involved in tumorigenic processes. Our findings propose a crucial role of downstream of ephrinA5-induced signaling in regulating gene transcription in the nucleus. These findings could be potentially relevant for the regulation of tumorigenic processes in the context of glioma.

The endoplasmic reticulum-resident serpentine receptor SR10 has important functions for asexual and sexual blood stage development of Plasmodium falciparum.

Serpentine receptors (SRs) are transmembrane proteins generally acting as mediators to facilitate the communication between a cell and its environment. At least six putative SR-like proteins are encoded in the genome of the malaria parasite Plasmodium falciparum. For two of them, roles in cell stress control were reported; however, for most of the SR-like proteins the functions are not yet known. In this study, we provide a first phenotypic analysis of the plasmodial SR10. The transmembrane protein is expressed in the asexual and sexual blood stages of P. falciparum. Co-localization and co-immunoprecipitation assays demonstrated an association of SR10 with the endoplasmic reticulum protein ERC. Gene disruption of SR10 leads to impaired intraerythrocytic replication and strongly reduces gametocyte numbers. We thus propose that SR10 is a protein associated with the endoplasmic reticulum that has important functions for asexual and sexual blood stage development.

CREATINE KINASE B PROVIDES AN ALTERNATIVE ENERGY SOURCE FOR FAST AXONAL TRANSPORT: ROLE IN HEALTH AND HUNTINGTON'S DISEASE

POSTER SESSION 01 - SECTION: HUNTINGTON'S DISEASE

Emeline Cuoc, Marta Prieto Garcia, Chiara Scaramuzzino, Frédéric Saudou
Univ. Grenoble Alpes, Inserm U1216, CHU Grenoble Alpes,, Grenoble Institut Neuroscience, Grenoble, France

Aims: Fast axonal transport (FAT) is ensured by molecular motors that requires energy to carry a wide range of organelles such as the brain-derived neurotrophic factor (BDNF) along microtubules. We have established that the glycolytic machinery is on-board on vesicles generating ATP that is then used by the motors. Using proteomic approaches, we identified the brain specific isoform of the creatine kinase (CKB) as being an additional resident on vesicles. CKB is an essential player of energy homeostasis. We hypothesized that CKB may provide an additional source of ATP to vesicular motors by dephosphorylating phosphocreatine into creatine. **Methods**: We are using microfluidic devices developed in the lab and reconstituting mature neuronal circuits (Virlogeux et al. 2018) to investigate axonal transport, especially of BDNF. **Results**: We confirmed by biochemical and immunostaining approaches that CKB resides on BDNF vesicles. Secondly, we found that CKB participates to FAT by recording BDNF trafficking using spinning disk videomicroscopy. Silencing CKB or expressing an inactive mutant in neurons decreased the number of motile vesicles. Conversely, activation of CKB by its substrate, creatine, induced the movement of vesicles. **Conclusions**: Altogether, we propose that CKB may play a role in the initiation of vesicular motility. Huntingtin protein (HTT) scaffolds glycolytic enzymes on vesicles, and when mutated in Huntington disease (HD), it leads to the decrease of BDNF trafficking. We are now investigating whether CKB might be altered in HD neurons.

Huntington Disease is a genetic neurodegenerative disorder caused by the abnormal expansion of a glutamine-encoding CAG repeat in the huntingtin (HTT) gene. This pathology is characterized by the dysfunction and death of neurons in the brain, particularly in the cortex and the striatum. HTT, a scaffolding protein, is involved in the axonal transport of vesicles containing Brain-Derived Neurotrophic Factor (BDNF). In HD, mutated HTT impaired the BDNF trafficking and leads to a reduction in the amounts of BDNF provided to the striatum, which in turn leads to death of both striatal and cortical neurons. The laboratory has developed microfluidic devices to reconstitute a mature neuronal network, in which presynaptic, synaptic and postsynaptic events are compartmentalized. Culturing primary neurons from HD mouse model already provides us a “disease-on-a-chip” platform ideal to fully decipher presynaptic dynamics, synaptic morphology and transmission, postsynaptic trafficking and signaling, as well as global network dynamics in healthy and pathogenic conditions. Here, we developed an human HD brain-on-a-chip by using human cortical neurons derived from induced pluripotent stem cells (iPSCs) to reconstruct HD functional cortico-cortical networks in our microfluidic devices. We used neurons derived from HD patient-specific induced pluripotent stem cells that contained both wild type and mutated *HTT* gene. We are currently characterizing this network by different methods (immunocytochemistry, functional tests, network connectivity) in order to propose a functional model of human HD neuronal network, thus providing a predictive model for drug testing and for the investigation of disease mechanisms.

Many pathological features of neurodegenerative diseases, such as the development of synaptic dysfunction, appear with age. Direct reprogramming preserves the age of induced neurons. However, the low efficiency of direct reprogramming methods limits their utility as a tool for neurodegenerative diseases modeling. In the present study, we modified a direct reprogramming protocol-based microRNAs, transcription factors, and small molecules and obtain a homogenous population of induced medium spiny neurons (iMSN), the most vulnerable cell type in Huntington's disease (HD) from dermal fibroblasts with an efficiency more than 80 percent. At the end of the reprogramming procedure, iMSNs are positively stained for canonical neuronal markers and respond to potassium chloride and glutamate stimulation. Induced excitatory neurons (iEN) can also be obtained from primary fibroblasts to study the pathogenesis of cognitive impairments observed in the case of HD. Moreover, iMSN and iEN are capable to form synaptic connections which makes it possible to study defects in synaptic transmission during the development of HD pathology. Thus the modified protocol makes it possible to obtain a homogeneous population of iEN and iMSN. This protocol might be useful in both studying the molecular and cellular basis of HD pathogenesis and drug discovery as well as in the development of a personalized approach for therapy.

Huntington's disease (HD) is a currently incurable neurodegenerative disorder that manifests through motor and cognitive symptoms due to a predominant loss of striatal Medium Spiny Neurons (MSNs). Growing evidence show that developmental alterations could be a key factor on the disease progression, determining the future vulnerability of certain cell types, such as striatal MSNs. Here we show an early HD-related expression pattern elucidated by bulk and 10X single cell RNA-seq performed on wt and HD isolated striatal primordia at different developmental stages. Histological analyses were used to validate alterations of crucial developmental events occurring in HD. We found that early alterations in cell cycle progression and cell fate determination in HD embryos give rise to an imbalance between specific neural precursors and mature neurons, affecting specifically the indirect MSNs (iMSNs) linage generation. Moreover, iMSNs undergo into specific apoptosis postnatally in HD. Development finally ends up with a reduction of the iMSNs population in the adult striatum in HD. In conclusion, we show that iMSNs embryonic developmental alterations set the stage in HD, altering the basal ganglia cell homeostasis. Thus, targeting specific neural populations during development could constitute a therapeutic approach for HD.

SUPPRESSION OF MUTANT HUNTINGTIN IMPROVES COGNITIVE SYMPTOMS IN THE R6/1 MOUSE MODEL OF HUNTINGTON'S DISEASE

POSTER SESSION 01 - SECTION: HUNTINGTON'S DISEASE

Cian Gavin, Gemma Deegan, Marian Tsanov
University College Dublin, School Of Medicine, Dublin, Ireland

Introduction: Huntington's disease (HD) is a monogenic neurodegenerative disorder caused by a mutation in the huntingtin (*HTT*) gene. Although HD is typically considered a motor disorder, cognitive symptoms often appear first and are the primary cause of functional decline. **Aim:** To explore the effect of HTT-lowering on memory formation in an acute mouse model of HD. **Methods:** R6/1 transgenic mice were treated with antisense oligonucleotide (ASO) or vehicle by injecting directly into the right lateral ventricle. Allocentric spatial memory and recognition memory were assessed using the Barnes maze and novel object tests respectively. Wild-type (WT) C57BL6/J mice were used as non-transgenic controls. **Results:** On a test of allocentric spatial memory, ASO-treated transgenics and non-transgenic controls employed the optimal spatial search strategy significantly more than the chance level would predict to escape the Barnes maze. Conversely, vehicle-treated HD mice did not learn to use this strategy. HTT suppression also improved memory on novel object tests, where ASO-treated mice spent significantly more time exploring novel contexts compared to vehicle-treated transgenics. This preference for novelty was also seen in non-transgenic controls. Taken together, our data suggests that suppression of mutant HTT in early-symptomatic R6/1 mice partially improves cognitive impairments. **Conclusions:** HTT-lowering ameliorates cognitive symptoms in R6/1 mice. Single ASO injection improved allocentric navigation and object recognition memory. ASO-mediated gene suppression is promising as a treatment for HD, but additional experiments are required to reveal the optimal approach for therapeutic efficacy.

Neuroblastoma Invasion Strategies Are Regulated by the Extracellular Matrix.
Neuroblastoma is a paediatric malignancy of the developing sympathetic nervous system. About half of the patients have metastatic disease at the time of diagnosis and a survival rate of less than 50%. Our understanding of the cellular processes promoting neuroblastoma metastases will be facilitated by the development of appropriate experimental models. In this study, we aimed to explore the invasion of neuroblastoma cells and organoids from patient-derived xenografts (PDXs) grown embedded in 3D extracellular matrix (ECM) hydrogels by time-lapse microscopy and quantitative image analysis. We found that the ECM composition influenced the growth, viability and local invasion of organoids. The ECM compositions induced distinct cell behaviours, with Matrigel being the preferred substratum for local organoid invasion. Organoid invasion was cell line- and PDX-dependent. We identified six distinct phenotypes in PDX-derived organoids. In contrast, NB cell lines were more phenotypically restricted in their invasion strategies, as organoids isolated from cell line-derived xenografts displayed a broader range of phenotypes compared to clonal cell line clusters. The addition of FBS and bFGF induced more aggressive cell behaviour and a broader range of phenotypes. In contrast, the repression of the prognostic neuroblastoma marker, , resulted in less aggressive cell behaviour. The combination of PDX organoids, real-time imaging and the novel 3D culture assays developed herein will enable rapid progress in elucidating the molecular mechanisms that control neuroblastoma invasion.

CONTRIBUTION OF ASTROCYTIC MITOCHONDRIA TO STRIATAL VULNERABILITY IN HUNTINGTON'S DISEASE

POSTER SESSION 01 - SECTION: HUNTINGTON'S DISEASE

Laura Lopez Molina[1,2,3], Alba Pereda-Velarde[3], Silvia Ginés[1,2,3]
[1]Institut d'Investigacions Biomèdiques August Pi i Sunyer, (idibaps), Barcelona, Spain, [2](CIBERNED), Centro De Investigación Biomédica En Red Sobre Enfermedades Neurodegenerativas, Madrid, Spain, [3]Universitat de Barcelona, Biomedicine, Barcelona, Spain

Huntington's Disease (HD) is a neurodegenerative disorder characterized by the selective loss of striatal medium spiny neurons. Although the molecular mechanisms of this striatal vulnerability remain unclear, compelling evidence points out that mitochondrial dysfunction could play a major role. However, much of what we know regarding the mechanisms underlying mitochondrial disturbances in HD has been gained from studies conducted in neurons. Less is known about the role and regulation of mitochondrial dynamics in astrocytes, the most abundant cell population in the striatum after neurons. Indeed, relatively unexplored is whether mitochondrial dysfunction in astrocytes may also contribute to neuron disturbances and therefore, to pathology in HD. Hence, we aimed to define the specific contribution of astrocytic mitochondria as well as the communication between neurons and astrocytes mediated by mitochondria in HD. In this work, we used the transgenic R6/1 mouse model of HD to either isolate adult astrocytes at different stages of the disease and to culture primary striatal astrocytes. Since astrocytes is a complex and heterogeneous population, we evaluated several astrocyte markers at the striatum of R6/1 mouse throughout the disease using biochemical and immunofluorescence assays. Then, we assessed mitochondrial functionality and metabolism in WT and R6/1 astrocytes. Finally, we investigated the mechanisms mediating mitochondrial communication from astrocytes to neurons. Overall, we hypothesized that alterations in mitochondrial function in striatal astrocytes could contribute to the striatal neuronal vulnerability that occurs in HD.

Huntington's disease (HD) is a neurodegenerative disorder caused by the expression of the mutant huntingtin (mHtt). Motor dysfunction and cognitive impairment are two characteristic symptoms of HD and they are associated to the degeneration of striatum and the dysfunction of hippocampus, respectively. Pituitary Adenylate Cyclase-Activating Polypeptide (PACAP) is a multifunctional neuropeptide that acts through three receptors named PAC1R, VPAC1R, and VPAC2R. Recently, we found PACAP improves cognitive and motor symptoms in HD mice mainly through PAC1R. Unfortunately, therapeutic use of PACAP is hindered because its poor metabolic stability and because the activation of VPAC2R is associated with peripheral side effects. Here, we study the therapeutic potential of the Acetyl- [Ala15, Ala20] PACAP-38-propylamide (PACAP-alg), a PACAP analogue showing greater biostability and higher affinity to PAC1R. We found that PACAP-alg (30ug/Kg/day) administrated intranasally for 12 days in R6/1 mice improves motor function evaluated using Rotarod and Balance beam tests, and cognitive impairment analyzed by T-MAZE test. In the striatum, PACAP-alg induces the increase of number and size of DARPP-32 positive neurons and reduces the number of mHtt aggregates, determined by immunofluorescence. In the hippocampus, PACAP-alg also reduced the number of mHtt aggregates. Moreover R6/1 mice treated with PACAP-alg showed an increase in number of dendritic spines in CA1 measured by Golgi stain. In conclusion, PACAP-alg administration improves motor and cognitive deficits of R6/1 mice improving neuronal function and enhancing the synaptic plasticity. Thus, the use of this analogue could be considered as a good therapeutic strategy to fight the symptomatology of HD.

Synaptic composition and morphogenesis of dendritic tree and spines is prone to constant remodeling during development and learning. We address how synaptic molecular arrangement can be revealed and analysed with super-resolution microscopy. **SENSEI** project (Segmentation of neurons using Standard & super-resolution microscopy) objectives are to deliver novel image processing tools along with innovative microscopy-based imaging modalities dedicated to advancing breakthroughs in 3D neuronal segmentation and morphometrics. Specifically, SENSEI aims at accurately quantifying neuronal morphology at tissue and molecular levels through the development of intelligent segmentation-based image processing algorithms and at improving the quality of neuronal imaging using new membrane probes for conventional and super-resolution imaging technologies. The proposed tools are tested for accuracy and reproducibility using different imaging techniques and protocols to deal with data at different spatial scales (from tissue to molecular range) on mouse neurons both *in vitro* for 2D (hippocampal, cortical neurons) and in situ for 3D (tissue slices and clarified brains) in cortex, cerebellum and hippocampus. Once optimized on rodents, new imaging modalities and segmentation protocols will be tested on human brain tissues coming from surgical resections. Samples will be imaged both with confocal microscopy, accounting for 80 % of user needs, and advanced imaging modalities, thus bringing either high resolution details on fixed dendritic spines (e.g., STED, STORM) or on live neurons (i.e. 3D SOFI). In addition to the sub-diffraction resolution, an optical device encoding probe information in the microscope point-spread function will be constructed, allowing the fast acquisition of cellular nanostructuring in full-3D.

Despite the adaptation of major clinical imaging modalities for small animals, optical bioluminescence imaging technology is the main approach readily reporting gene activity. Yet, in vivo bioluminescence monitoring requires the administration and diffusion of a substrate to the tissues of interest, resulting in experimental variability, high reagent cost, long acquisition time, and stress to the animal. In our study, we avoid such issues upon generating a new transgenic mouse (GFAP-E2crimson) expressing the far-red fluorescent protein E2-Crimson under the control of the glial fibrillary acidic protein (GFAP) promoter. Using microscopy, we validated the selective expression of the reporter in the astrocyte cell population and by non-invasive in vivo fluorescence imaging its detection through the scalps and skulls of live animals. In addition, we performed a longitudinal study validating by in vivo imaging that the E2-crimson fluorescence signal is up-regulated, in pups during astrogenesis and in adult mice during astrogliosis upon kainic acid administration. Furthermore, upon crossing GFAP-E2crimson transgenic with 5XFAD Alzheimer's disease mice model, we were able to quantify the chronic inflammation triggered by amyloid deposit and ageing over 18 months. As many diseases and conditions can trigger neuroinflammation, we believe that the GFAP-E2crimson reporter mice model delivers tremendous value for the non-invasive quantification of astrogliosis responses in living animals.

The axon initial segment (AIS) is a unique neuronal compartment responsible for the generation of action potentials. To fulfil this important role, AIS has a distinctive molecular organization that is characterized by high-density clusters of the voltage-gated sodium channels (Na_V), cell adhesion molecules, such as 186 kDa neurofascin isoform (NF186), and scaffolding and cytoskeletal proteins. Due to the highly complex AIS organization, the number of methods that allow live imaging studies of its components is limited. To overcome this limitation, we established a minimally invasive approach for direct fluorescent labeling of two large AIS components, NF186 (186 kDa) and $Na_V1.6$ (260 kDa). Our approach is based on the site-specific incorporation of unnatural amino acids (UAAs) into target proteins via genetic code expansion. Subsequently, UAAs are labeled by biorthogonal click chemistry. The minimal size of the UAA tags and the possibility to introduce them virtually anywhere into target proteins make our approach particularly convenient for labeling of complex and densely packed proteins, such as NF186 and $Na_V1.6$. This approach allowed us to perform widefield and confocal microscopy of click-labeled NF186 and $Na_V1.6$ in fixed and living neurons. We also used click labeling to study localization of two epilepsy causing $Na_V1.6$ variants with loss-of-function effect. To further improve UAA incorporation and click labeling efficiency, we developed adeno-associated viral (AAV) vectors that provided delivery of orthogonal translational machinery to large number of neurons. This will facilitate applications of click labeling in more complex biological systems, such as slice cultures, organoids, and animal models.

Investigating the network dynamics of neural populations in cortical areas involved in vision with photostimulation is one of the hot topics of the past few years. However, measurement protocols, visual paradigms, and experimental scenarios were all limited by the technological limitations of conventional microscope systems. We applied the advantages of AO scanning to 3D photostimulation from a volume of 500x500x500 μm^3. We demonstrate that we can effectively stimulate and measure up to 250 cells simultaneously while maintaining subcellular spatial resolution to avoid off-target stimulation. Next, we developed novel analytic software modules to automatically detect responding neurons and to define, among the acquired cell-level activity patterns, those that are involved in the perception of specific visual stimuli (i.e. representing a latent task variable of a task). Stimulation of perception-specific cellular patterns became possible by the combination of these developments.

Two-photon GCaMP6f imaging of infrared neural stimulation evoked calcium signals in mouse cortical neurons in vivo.
Infrared neural stimulation is a promising tool for stimulating the brain because it can be used to excite with high spatial precision without the need of delivering or inserting any exogenous agent into the tissue. Very few studies have explored its use in the brain, as most investigations have focused on sensory or motor nerve stimulation. Using intravital calcium imaging with the genetically encoded calcium indicator GCaMP6f, here we show that the application of infrared neural stimulation induces intracellular calcium signals in Layer 2/3 neurons in mouse cortex in vivo. The number of neurons exhibiting infrared-induced calcium response as well as the amplitude of those signals are shown to be both increasing with the energy density applied. By studying as well the spatial extent of the stimulation, we show that reproducibility of the stimulation is achieved mainly in the central part of the infrared beam path. Stimulating in vivo at such a degree of precision and without any exogenous chromophores enables multiple applications, from mapping the brain's connectome to applications in systems neuroscience and the development of new therapeutic tools for investigating the pathological brain.

Theoretical Design, Synthesis, and In Vitro Neurobiological Applications of a Highly Efficient Two-Photon Caged GABA Validated on an Epileptic Case.
In this paper, we present an additional, new cage-GABA compound, called 4-amino-1-(4'-dimethylaminoisopropoxy-5',7'-dinitro-2',3'-dihydro-indol-1-yl)-1-oxobutane-γ-aminobutyric acid (iDMPO-DNI-GABA), and currently, this compound is the only photoreagent, which can be applied for GABA uncaging without experimental compromises. By a systematic theoretical design and successful synthesis of several compounds, the best reagent exhibits a high two-photon efficiency within the 700-760 nm range with excellent pharmacological behavior, which proved to be suitable for a complex epileptic study. Quantum chemical design showed that the optimal length of the cationic side chain enhances the two-photon absorption by 1 order of magnitude due to the cooperating internal hydrogen bonding to the extra nitro group on the core. This feature increased solubility while suppressing membrane permeability. The efficiency was demonstrated in a systematic, wide range of in vitro single-cell neurophysiological experiments by electrophysiological as well as calcium imaging techniques. Scalable inhibitory

ion currents were elicited by iDMPO-DNI-GABA with appropriate spatial-temporal precision, blocking both spontaneous and evoked cell activity with excellent efficiency. Additionally, to demonstrate its applicability in a real neurobiological study, we could smoothly and selectively modulate neuronal activities during artificial epileptic rhythms first time in a neural network of GCaMP6f transgenic mouse brain slices.

PRESYNAPTIC NETWORKS. Single-cell-initiated monosynaptic tracing reveals layer-specific cortical network modules. Individual cortical neurons can selectively respond to specific environmental features, such as visual motion or faces. How this relates to the selectivity of the presynaptic network across cortical layers remains unclear. We used single-cell-initiated, monosynaptically restricted retrograde transsynaptic tracing with rabies viruses expressing GCaMP6s to image, in vivo, the visual motion-evoked activity of individual layer 2/3 pyramidal neurons and their presynaptic networks across layers in mouse primary visual cortex. Neurons within each layer exhibited similar motion direction preferences, forming layer-specific functional modules. In one-third of the networks, the layer modules were locked to the direction preference of the postsynaptic neuron, whereas for other networks the direction preference varied by layer. Thus, there exist feature-locked and feature-variant cortical networks.

Fast 3D Imaging of Spine, Dendritic, and Neuronal Assemblies in Behaving Animals.
Understanding neural computation requires methods such as 3D acousto-optical (AO) scanning that can simultaneously read out neural activity on both the somatic and dendritic scales. AO point scanning can increase measurement speed and signal-to-noise ratio (SNR) by several orders of magnitude, but high optical resolution requires long point-to-point switching time, which limits imaging capability. Here we present a novel technology, 3D DRIFT AO scanning, which can extend each scanning point to small 3D lines, surfaces, or volume elements for flexible and fast imaging of complex structures simultaneously in multiple locations. Our method was demonstrated by fast 3D recording of over 150 dendritic spines with 3D lines, over 100 somata with squares and cubes, or multiple spiny dendritic segments with surface and volume elements, including in behaving animals. Finally, a 4-fold improvement in total excitation efficiency resulted in about 500 × 500 × 650 μm scanning volume with genetically encoded calcium indicators (GECIs).

Fast two-photon in vivo imaging with three-dimensional random-access scanning in large tissue volumes.
The understanding of brain computations requires methods that read out neural activity on different spatial and temporal scales. Following signal propagation and integration across a neuron and recording the concerted activity of hundreds of neurons pose distinct challenges, and the design of imaging systems has been mostly focused on tackling one of the two operations. We developed a high-resolution, acousto-optic two-photon microscope with continuous three-dimensional (3D) trajectory and random-access scanning modes that reaches near-cubic-millimeter scan range and can be adapted to imaging different spatial scales. We performed 3D calcium imaging of action potential backpropagation and dendritic spike forward propagation at sub-millisecond temporal resolution in mouse brain slices. We also performed volumetric random-access scanning calcium imaging of spontaneous and visual stimulation-evoked activity in hundreds of neurons of the mouse visual cortex in vivo. These experiments demonstrate the subcellular and network-scale imaging capabilities of our system.

Sunhyun Park[1], Ki-Suk Kim[2]
[1]Korea Institute of Toxicology, R&d Center For Advanced Pharmaceuticals & Evaluation, Daejon, Korea, Republic of, [2]Korea Institute of Toxicology, R&d Center For Advanced Pharmaceuticals & Evaluation, Deajeon, Korea, Republic of

Despite recent advances in tissue cleraring methods, the challenge of reproducibility and simplification remains difficult due to the complexity and cost limitations of the method. We have developed a new tissue cleaing method to overcome current problems by simplifying the tissue removal process, increasing reproducibility and reducing costs. The new tissue clearing method was able to protect against protein loss without the use of nanoporous hydrogel hybrid foam. This method also made undamaged tissue clear without the use of organic solvents or harsh detergents or conditions. Finally, the new tissue cleaing method preserved the fluorescent protein for several months, overcoming the working distance of the microscope and reducing the size of clear tissue or organoids. Using thenew tissue cleaing method, the entire clear brain is imaged under a lightsheet microscope to show that there are significant differences in the distribution of excitatory and inhibitory neurons in the hippocampal region. In addition, we were able to quickly discover the extent of drug diffusion and side effects in the brain in a drug delivery system. Therefore, this method can be applied to read the latest research on the development of diseases and therapeutic agents.

IMAGING THE BRAIN IN ACTION: AN ACTIVE OPTICAL ROTARY JOINT FOR WIDE FIELD FIBROSCOPY IN FREELY MOVING ANIMALS

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

Timothé Jost-Mousseau, Max Chalabi-Prat, Daniel Shulz, Isabelle Ferezou
Paris-Saclay Institute of Neuroscience, Université Paris Saclay, CNRS, Department Of Integrative And Computational Neuroscience, Saclay, France

Our understanding of the neuronal processes governing behaviour is boosted by the constant development of technological strategies allowing the optical recording of large neuronal assemblies in awake behaving mice. Nowadays, the most common approaches consist in using either miniaturized microscopes directly mounted on animals' head, or sophisticated closed-loop virtual reality systems operating around mice accustomed to be firmly fixed by the head below cutting-edge optical imaging systems. The former limits the quality of the recorded signals due to the constrains in size and weight of the optics required for their portability, the later suffers from the restriction of the

movement repertoire of the animal and the quality of the virtual environment, which hardly reproduces the complexity of natural multi-sensory scenes. Another strategy which takes advantage from both approaches consists in the use of a fiber-bundle interface to carry optical signals from a moving animal to a conventional imaging system. However, as the bundle is usually fixed below the optics, its torsion resulting from rotations of the animal inevitably constrains the behavior over long recordings. To overcome this major limitation of fiberscopic imaging, we developed a motorized optical rotary joint. Here we show its principle of operation, demonstrate its efficacy, and propose several modes of operation for a wide range of experimental designs.

3D IMAGING OF CLEARED HUMAN TISSUES AND TUMORS

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

Hans-Ulrich Dodt[1,2], Sabina Kirnbauer[2], James Oakes[2], Christoph Fuchssteiner[2], Massih Foroughipour[1], Meraaj Foroughipour[1], Klaus Becker[1], Saiedeh Saghafi[1]
[1]TU Wien, Bioelectronics, Fke, Wien, Austria, [2]Center for Brain Research, MUW, Section Of Bioelectronics, Wien, Austria

Light sheet microscopy has been applied very successfully to the investigation of chemically cleared mouse brains. However its application to human tissue has been hampered by difficulties to obtain specific cellular staining. The use of endogenous fluorescent marker is not possible in humans and staining with antibodies is cumbersome due to diffusion problems. Furthermore standard clearing protocols like 3DISCO take weeks to months to clear human tissue. Notoriously difficult to clear are tumors due to their high cell density. We therefore developed in the last years a new clearing protocol, pathoDISCO, which allows clearing of tumor tissue in the centimetre range within days[1]. This method used boosted autofluorescence for cellular visualization but did not yet provide specific subcellular staining. We now searched for specific fluorescent stainings for cytoplasm and nuclei which also survive our harsh tumor clearing. Applying suitable image processing we were able to generate Hematoxilin/Eosin (HE) stained like images of various human tissues. With our ultramicroscope volume recordings of pathology cassette sized tumor pieces of 4 mm thickness could be obtained with subcellular resolution. Our single optical sections provide a resolution and appearance equivalent to histological slides but now for whole tissue volumes. We applied our technology to various human tissues like brain, mamma and colon. We are confident that this approach will open up completely new ways for histological diagnostics in pathology. VINE-SEG: SELF-IMPROVING VISIBLE NEURON SEGMENTATION FROM CALCIUM IMAGING DATA IN AN USER-INTEGRATING INTERFACE

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

Nicolas Ruffini[1,2], Saleh Altahini[2], Nico Weber[3], Anna Wierczeiko[1,2], Hendrik Backhaus[2], Albrecht Stroh[2,4]
[1]Institute of Human Genetics, University Medical Center Mainz, Mainz, Germany, [2]Leibniz Institute for Resilience Research, Leibniz Association, Mainz, Germany, [3]Fraunhofer Institute for Industrial Mathematics ITWM, Fraunhofer Association, Kaiserslautern, Germany, [4]University Medical Center of the Johannes Gutenberg-University Mainz & Leibniz Institute for Resilience Research, Mainz, Institute Of Pathophysiology, Mainz, Germany

Aims: Segmentation of neuronal somata is a crucial and typically the most time-consuming step of the analysis of optical microcircuit imaging experiments. Therefore, recently a variety of auto-segmentation tools, typically using deep learning approaches, emerged to make the segmentation process faster and more consistent. As autosegmentation tools still show problems with false positive and false negative segmentation results, especially when applied to data with a high signal-to-noise ratio and as they are mainly applicable to detect active neuronal somata, we developed ViNe-Seg: A self-improving segmentation tool for all visible neurons that incorporates the user's supervision, offers several segmentation models and can learn from the manual corrections made by the user. **Methods:** We used publicly available labeled Ca-Imaging data from the Allen Brain Obervatory, as well as inhouse data for training our deep learning model. For the neural network we chose the widely used U-Net architecture with two input channels, applying different preprocessing steps, namely the Contrast Limiting Adaptive Histogram Equalization and the non-local means preprocessing on the original data. **Results & Conclusion:** We here present ViNe-Seg, a segmentation tool, embedded in a graphical user interface to ensure easy human supervision and refinement of the segmentation result, with the possibility to add those refined data for enhancing the underlying deep learning model making the whole analysis become more consistent and faster. Accordingly, the semi-automatic approach of ViNe-Seg provides a user-integrating approach for segmentation, that does no longer feel like a black box.

IntelliPy: A GUI for analyzing IntelliCage data.
The IntelliCage systems offer the possibility to conduct long-term behavioral experiments on mice in social groups without human intervention. Although this setup provides new findings, only about 150 studies with the IntelliCage system have been published in the last two decades, which is also caused by the challenging problems of processing and handling the large and heterogeneous amounts of captured data. This application note introduces the Python-GUI IntelliPy, especially designed for users not very experienced in using programming languages. IntelliPy allows users to quickly analyze the IntelliCage output in a user-friendly way, thus making the systems more accessible to a broader audience.

Acitretin reverses early functional network degradation in a mouse model of familial Alzheimer's disease.
Aberrant activity of local functional networks underlies memory and cognition deficits in Alzheimer's disease (AD). Hyperactivity was observed in microcircuits of mice AD-models showing plaques, and also recently in early stage AD mutants prior to amyloid deposition. However, early functional effects of AD on cortical microcircuits remain unresolved. Using two-photon calcium imaging, we found altered temporal distributions (burstiness) in the spontaneous activity of layer II/III visual cortex neurons, in a mouse model of familial Alzheimer's disease (5xFAD), before plaque formation. Graph theory (GT) measures revealed a distinct network topology of 5xFAD microcircuits, as compared to healthy controls, suggesting degradation of parameters related to network robustness. After treatment with acitretin, we observed a re-balancing of those network measures in 5xFAD mice; particularly in the mean degree distribution, related to network development and resilience, and post-treatment values resembled those of age-matched controls. Further, behavioral deficits, and the increase of excitatory synapse numbers in layer II/III were reversed after treatment. GT is widely applied for whole-brain network analysis in human neuroimaging, we here demonstrate the translational value of GT as a multi-level tool, to probe networks at

different levels in order to assess treatments, explore mechanisms, and contribute to early diagnosis.

Common Factors in Neurodegeneration: A Meta-Study Revealing Shared Patterns on a Multi-Omics Scale.
Neurodegenerative diseases such as Alzheimer's disease (AD), Parkinson's disease (PD), Huntington's disease (HD), and amyotrophic lateral sclerosis (ALS) are heterogeneous, progressive diseases with frequently overlapping symptoms characterized by a loss of neurons. Studies have suggested relations between neurodegenerative diseases for many years (e.g., regarding the aggregation of toxic proteins or triggering endogenous cell death pathways). We gathered publicly available genomic, transcriptomic, and proteomic data from 177 studies and more than one million patients to detect shared genetic patterns between the neurodegenerative diseases on three analyzed omics-layers. The results show a remarkably high number of shared differentially expressed genes between the transcriptomic and proteomic levels for all conditions, while showing a significant relation between genomic and proteomic data between AD and PD and AD and ALS. We identified a set of 139 genes being differentially expressed in several transcriptomic experiments of all four diseases. These 139 genes showed overrepresented gene ontology (GO) Terms involved in the development of neurodegeneration, such as response to heat and hypoxia, positive regulation of cytokines and angiogenesis, and RNA catabolic process. Furthermore, the four analyzed neurodegenerative diseases (NDDs) were clustered by their mean direction of regulation throughout all transcriptomic studies for this set of 139 genes, with the closest relation regarding this common gene set seen between AD and HD. GO-Term and pathway analysis of the proteomic overlap led to biological processes (BPs), related to protein folding and humoral immune response. Taken together, we could confirm the existence of many relations between Alzheimer's disease, Parkinson's disease, Huntington's disease, and amyotrophic lateral sclerosis on transcriptomic and proteomic levels by analyzing the pathways and GO-Terms arising in these intersections. The significance of the connection and the striking relation of the results to processes leading to neurodegeneration between the transcriptomic and proteomic data for all four analyzed neurodegenerative diseases showed that exploring many studies simultaneously, including multiple omics-layers of different neurodegenerative diseases simultaneously, holds new relevant insights that do not emerge from analyzing these data separately. Furthermore, the results shed light on processes like the humoral immune response that have previously been described only for certain diseases. Our data therefore suggest human patients with neurodegenerative diseases should be addressed as complex biological systems by integrating multiple underlying data sources.

Neurovascular coupling, the intricate link between neural activity and local changes in cerebral blood flow, is critical for brain function and prone to disruption in pathological conditions. Studying neurovascular coupling requires precise measurements of the spatial and temporal relationships of neuronal activity and changes in blood flow. We have developed a dual color miniscope, the nVue system, that allows simultaneous imaging of neural activity and blood flow in freely behaving animals. The nVue system acquires dual color data by multiplexing two LEDs at up to 100 Hz, enabling direct visualization of both blood flow and calcium activity. To facilitate analysis, we have extended the Inscopix Data Processing Software package to include a module that provides time-varying estimates of both vascular diameter and red blood cell (RBC) velocity in vessels of interest. Diameter is measured as the full-width at half max of a Lorentzian function fit to a vessel cross section. RBC velocity is measured by calculating time-lagged cross correlations between a seed pixel at each location of interest and all pixels in a neighboring region. The distances between correlation peaks are then tracked as a function of time. The algorithms were benchmarked against ground truth manual annotation data. To our knowledge this represents the first demonstration of simultaneous acquisition of high resolution blood flow and neural circuit activity signals in freely moving animals which, coupled with with out of the box analysis solutions, opens new avenues of study for both basic and translational neuroscience areas.

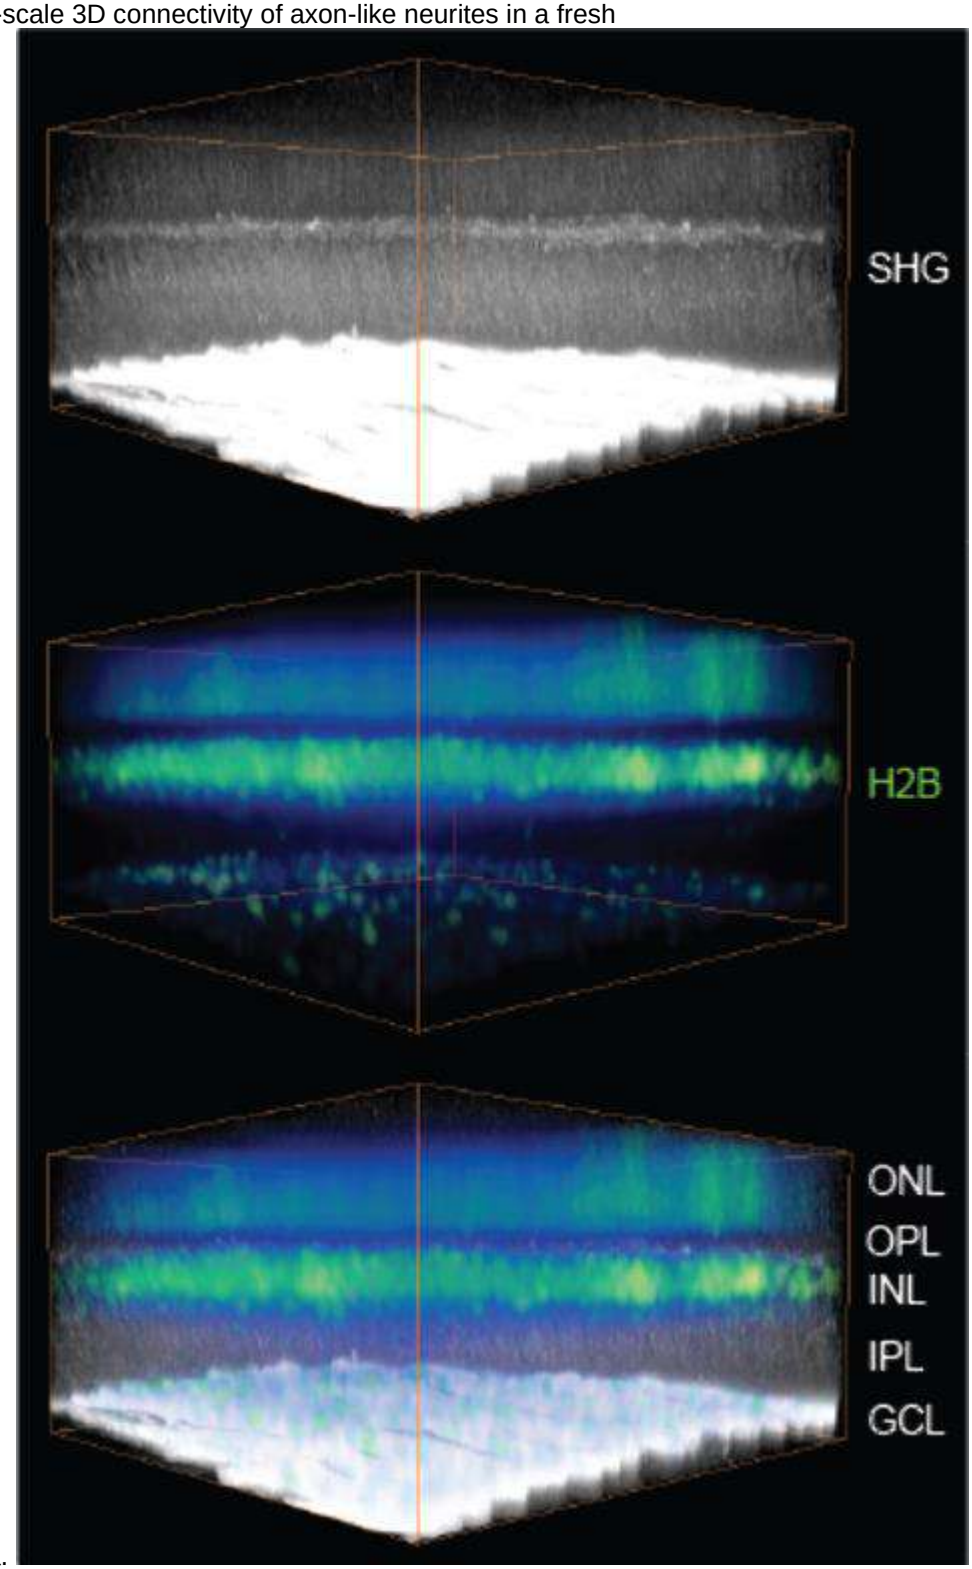
SECOND-HARMONIC GENERATION IMAGING OF AXON-LIKE NEURITES IN THE UNFIXED, UNLABELED RETINA

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

Hyungsik Lim, Arafat Meah, Vinessia Boodram
CUNY Hunter College, Physics And Astronomy, New York, United States of America

We demonstrate a novel microscopy method for studying the axons in the unfixed, wholemount retina. Second-harmonic generation (SHG) from uniformly polarized microtubules was utilized for visualizing the single axon-like neurites of major retinal neurons, including photoreceptors, horizontal cells, bipolar cells, amacrine cells, as well as the retinal ganglion cells. To confirm the molecular and cellular origin, the nonlinear optical signal was co-registered with GFP/YFP in the retinas of transgenic strains, expressed under the control of GUS, Thy1, ChAT, and GFAP. The axons of visual integration were reconstructed using SHG. In the vertical pathways, the bipolar cell axons terminated in the specific sublayers of inner plexiform layer (IPL) in a cell-type-specific manner. The lateral fibers within the IPL neuropil were also visualized by SHG originating from a specific subset of amacrine cells, i.e., axon-bearing types. To validate the utility of retinal SHG imaging, the pathological degeneration in glaucoma was investigated using a mouse model, DBA/2, and the non-glaucomatous control, DBA/2-*Gpnmb*+. Our results show that there is no loss of compartments of the inner retina pre-synaptic to the RGCs during pathogenesis. In conclusion, retinal SHG imaging provides a valuable tool for interrogating, without exogenous labeling, the

large-scale 3D connectivity of axon-like neurites in a fresh



retina.

DUAL COLOR IMAGING IN FREELY-BEHAVING RODENTS USING HEAD-MOUNTABLE ONE PHOTON MINISCOPE

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

Norbert Hogrefe[1], Srishti Gulati[2], Kevin Zitelli[2], Douglas Ollerenshaw[2], Alice Stamatakis[2]
[1]Inscopix, Inc, Field Scientific Consultant Team, Mountain View, United States of America, [2]Inscopix, Inc, Science R&d - Product & Applications, Mountain View, United States of America

We have developed a miniscope system that enables dual color imaging in freely-behaving rodents, thus greatly expanding the current range of *in vivo* imaging applications. The nVue™ system enables numerous applications, including simultaneous imaging of Ca^{2+} activity in two distinct cell populations, imaging Ca^{2+} activity with static markers identifying neurons based on projection, activity, or genetics and imaging Ca^{2+} activity alongside neurotransmitter release or blood flow. To enable dual color imaging, we have integrated two separate LEDs to image green and red indicators without optical and biological crosstalk. These LEDs are multiplexed rapidly during imaging, enabling simultaneous visualization of green and red fluorescent signals. To correct for chromatic shifts in green and red focal planes, we have developed novel GRIN lenses that minimize axial chromatic aberrations. Furthermore, we use electronic focusing capabilities of our miniscope to automatically correct for residual color aberration. Here, we present two *in vivo* applications to demonstrate use cases of the nVue system. To demonstrate static + dynamic imaging, we imaged mPFC neurons expressing GCaMP6m and contralaterally-projecting neurons labeled with TdTomato. To demonstrate dual dynamic imaging, we imaged in the dorsal striatum the release of dopamine, using RDA1m, alongside neuronal activity, using GCaMP6m. Demonstration of blood flow imaging, using a rhodamine-dextran dye, alongside neuronal activity, using GCaMP, is presented in a separate poster. These applications demonstrate the utility of the nVue system for exploring the intricacies of how two distinct brain signals interact during free behavior, enabling deeper insights into central nervous system functions.

Aim Striatal cholinergic interneurons (CINs) use both acetylcholine (ACh) and glutamate (Glut) to regulate the striatal network. CINs express vesicular transporters for acetylcholine (VAChT) and Glut (VGLUT3) with a high degree of coexpression in cholinergic varicosities. Whether VAChT and VGLUT3 are present on the same or on different pools of synaptic vesicles (SVs) remains an open question. This is an important issue since the vesicular sorting of both transporters could lead to simultaneous and/or independent release of ACh and/or Glut from CINs. **Methods** We used super-resolution STimulated Emission Depletion microscopy to characterize and quantify the distribution of VAChT and VGLUT3 in CINs SVs. **Results** Nearest-neighbor distances analysis between VAChT and VGLUT3-immunofluorescent spots revealed that 34% of cholinergic SVs contain both VAChT and VGLUT3. 40% of CINS SVs express only VAChT, while 26% contain only VGLUT3. Thus, we propose that CINs terminals have the potential to store and release simultaneously or independently ACh and/or Glut. We also determined the distribution in VAChT and/or VGLUT3 expressing SVs, of vesicular associated membrane proteins (VAMPs), proteins of the SNARE complex involved in neurotransmitter release. Fluorescent in situ hybridization demonstrated that only VAMP2 and VAMP7 are expressed by CINS. We observed that the canonical VAMP2 is expressed in a large part of VAChT and VGLUT3 striatal SVs (63% and 86%). Interestingly, in the shell part of nucleus accumbens, 25% of VAChT and VGLUT3-immunopositive SVs are also VAMP7-positive. **Conclusion** Our results advocate for an unexpected level of anatomical and functional heterogeneity of SVs in CINs varicosities.

To map the brain with high temporal and spatial resolution, multimodal neuroimaging methods provide a solution. Combining two-photon microscopy with electrophysiological signal recording is feasible with using transparent electrode materials. We aimed to demonstrate a multimodal neuroimaging scheme using a thiol-ene acrylate based cortical implant. The micro-electrocorticography (μECoG) device's feasibility of measuring intracranial EEG and fluorescent GCamP6 signals using two-photon imaging through the device is presented in mice. The stability of electrode yield was presented with *in vivo* impedance measurement over 75 days. The recording quality was shown by monitoring the signal-to-noise ratio and theta power of the spectrum throughout the experiment. The chronic immune response was characterized by Glial Fibrillary Acidic Protein (GFAP) staining of astrocytes and fluorescent Nissl (NeuroTrace) staining of neurons. To determine the effect of the device on optical distortion and resolution, the sizes of different objects were determined without and under the transparent device placed in the light path of the two-photon microscope. In addition, the change in the relative intensity of fluorescent signals was determined in *in vivo* images under the long-term (22 weeks) implanted device. During the impedance measurement, no sign of delamination or material degradation appeared. After 80 days of implantation, the histological analysis revealed only a modest foreign body response, and no significant difference was shown between implanted and control cortices. During the 22 weeks *in vivo* measurements, the fluorescent activity remained stable and Ca^{2+}signals were captured. Based on the results our device is suitable for multimodal imaging.

AIMS We introduce a novel approach for segmenting neurons from confocal datasets representing clarified samples. This approach deals with several well-known issues concerning the segmentation of neurons, such as their dense packing and the low contrast affecting small dendrite identification. We propose to improve neuronal segmentation by including volumetric and topological information. Functions of second order derivatives have been used in literature to extract filament-like structures from 2d images. Nonetheless, soma and branch surfaces present irregularities of interest such as those given by dendritic spines. The possibility to build a model-free, topologically-informed approach to 3d neuron segmentation is explored. METHODS An intensity-based k-means clustering approach is coupled with second order spatial derivatives computed along the three main axes. The algorithm is tested on 40x confocal microscopy datasets and compared with manual segmentation and intensity-based clustering. Among the 6 classes, two of them, showing high mean intensity and negative mean second order derivatives, are observed to capture the neural structures (Fig1A-1B). The sixth class, providing the core of each neuron, is dilated into the fifth to include thinner, low-intensity branches (Fig1B). RESULTS Our approach enables us to distinguish and isolate single neurons. The algorithm overperforms manual segmentation (Fig1C) and intensity-based clustering (Fig1D), and captures low-intensity branches. CONCLUSIONS We provide an algorithm that segments the single neurons in 3d image stacks within a single iteration. In future advances, it could be adapted to the segmentation of multi-scale structures (soma, dendrites and dendritic spines) in high-resolution

images.

Mapping dependencies of BOLD signal change to end-tidal CO: Linear and nonlinear modeling, and effect of physiological noise correction.

Disentangling physiological noise and signal of interest is a major issue when evaluating BOLD-signal changes in response to breath holding. Currently-adopted approaches for retrospective noise correction are general-purpose, and have non-negligible effects in studies on hypercapnic challenges.

Functional connectome of arousal and motor brainstem nuclei in living humans by 7 Tesla resting-state fMRI.
Brainstem nuclei play a pivotal role in many functions, such as arousal and motor control. Nevertheless, the connectivity of arousal and motor brainstem nuclei is understudied in living humans due to the limited sensitivity and spatial resolution of conventional imaging, and to the lack of atlases of these deep tiny regions of the brain. For a holistic comprehension of sleep, arousal and associated motor processes, we investigated in 20 healthy subjects the resting-state functional connectivity of 18 arousal and motor brainstem nuclei in living humans. To do so, we used high spatial-resolution 7 Tesla resting-state fMRI, as well as a recently developed in-vivo probabilistic atlas of these nuclei in stereotactic space. Further, we verified the translatability of our brainstem connectome approach to conventional (e.g. 3 Tesla) fMRI. Arousal brainstem nuclei displayed high interconnectivity, as well as connectivity to the thalamus, hypothalamus, basal forebrain and frontal cortex, in line with animal studies and as expected for arousal regions. Motor brainstem nuclei showed expected connectivity to the cerebellum, basal ganglia and motor cortex, as well as high interconnectivity. Comparison of 3 Tesla to 7 Tesla connectivity results indicated good translatability of our brainstem connectome approach to conventional fMRI, especially for cortical and subcortical (non-brainstem) targets and to a lesser extent for brainstem targets. The functional connectome of 18 arousal and motor brainstem nuclei with the rest of the brain might provide a better understanding of arousal, sleep and accompanying motor functions in living humans in health and disease.
Neuroimage, 2022; 249

Functional connectome of brainstem nuclei involved in autonomic, limbic, pain and sensory processing in living humans from 7 Tesla resting state fMRI.
Despite remarkable advances in mapping the functional connectivity of the cortex, the functional connectivity of subcortical regions is understudied in living humans. This is the case for brainstem nuclei that control vital processes, such as autonomic, limbic, nociceptive and sensory functions. This is because of the lack of precise brainstem nuclei localization, of adequate sensitivity and resolution in the deepest brain regions, as well as of optimized processing for the brainstem. To close the gap between the cortex and the brainstem, on 20 healthy subjects, we computed a correlation-based functional connectome of 15 brainstem nuclei involved in autonomic, limbic, nociceptive, and sensory function (superior and inferior colliculi, ventral tegmental area-parabrachial pigmented nucleus complex, microcellular tegmental nucleus-prabigeminal nucleus complex, lateral and medial parabrachial nuclei, vestibular and superior olivary complex, superior and inferior medullary reticular formation, viscerosensory motor nucleus, raphe magnus, pallidus, and obscurus, and parvicellular reticular nucleus - alpha part) with the rest of the brain. Specifically, we exploited 1.1mm isotropic resolution 7 Tesla resting-state fMRI, ad-hoc coregistration and physiological noise correction strategies, and a recently developed probabilistic template of brainstem nuclei. Further, we used 2.5mm isotropic resolution resting-state fMRI data acquired on a 3 Tesla scanner to assess the translatability of our results to conventional datasets. We report highly consistent correlation coefficients across subjects, confirming available literature on autonomic, limbic, nociceptive and sensory pathways, as well as high interconnectivity within the central autonomic network and the vestibular network. Interestingly, our results showed evidence of vestibulo-autonomic interactions in line with previous work. Comparison of 7 Tesla and 3 Tesla findings showed high translatability of results to conventional settings for brainstem-cortical connectivity and good yet weaker translatability for brainstem-brainstem connectivity. The brainstem functional connectome might bring new insight in the understanding of autonomic, limbic, nociceptive and sensory function in health and disease.

Exploring the supra linear relationship between PetCO2 and fMRI signal change with ICA.
The relationships between brain functions and the respiratory system are complex. Disentangling brain activity related to CO changes from nonspecific vasoreactivity is a challenge when studying brain activity involved in the control of breathing with fMRI. In this work, we analyzed a dose dependent relationship between arterial CO levels and brain response. To accomplish this goal, we developed a gas administration protocol, together with multi-subject ICA and specific nonlinear post-processing analysis. Our results highlighted a supra-linear response to CO challenges in brainstem, thalamus and putamen. Results were discussed in the light of current knowledge about the central respiratory network.

On the Use of Linear-Modelling-based Algorithms for Physiological Noise Correction in fMRI Studies of the Central Breathing Control.

A full characterization of the physiological behavior of human central chemoreceptors through fMRI is crucial to understand the pathophysiology of central abnormal breathing patterns. In this scenario, physiological noise and activity of interest may be naturally correlated. Here, we examined the adequacy of linear-modelling-based retrospective physiological noise correction for studies of the central breathing control. We focused on the relationship between a nonlinear model of BOLD response, hypothesized to describe neuronal specific activity, and noise modelled by correction algorithms. Analyses were performed on fMRI acquisitions from healthy subjects during a breath hold task. A general linear model including static nonlinearities in the response to end-tidal CO was applied to data preprocessed both with and without physiological noise correction. Relations between physiological noise and PETCO were explored both with linear and nonlinear measures. Lastly, parametric maps of noise spatial distribution were extracted. Our results evidenced that correction algorithms based on linear modelling remove components that are both linearly and nonlinearly related to end-tidal CO, whereas uncorrected data showed spurious activations in regions outside gray matter. Thus, despite a correction step is fundamental, these algorithms are shown to be over-conservative approaches to noise correction and need to be adapted to the specific purpose.

3D Custom Access Serial Holography (3D-CASH) is an advanced acquisition method for *in-vivo* 3D multiphoton excitation microscopy improving upon the intrinsic slowness of volumetric multi-plane imaging of neuronal activity. 3D-CASH combines serial 3D random-access of neuronal targets with holographically patterned excitation to increase the photon yield per target and the number of sampled targets per second[1]. However, besides shaping the focal volume, holographic modulation increases background emission compared to an unmodulated Gaussian beam due to enhanced excitation of fluorescent objects outside of the focal volume, resulting in an effective sensitivity loss of the probe and manifesting, for instance, as diminishment of the untreated response amplitude. For a modulated beam generating a 5x5 focus grid of 16x16 μm^2 size covering the somatic and peri-somatic space of a targeted cell, we measured a sensitivity loss of up to 70 % for GCaMP6f expressed in layer 2/3 neurons of mouse visual cortex at 100 to 200 µm focal depth, in agreement with the loss calculated from the modeled 3D distribution of the light field in a scattering medium resembling brain tissue. We hypothesized that this loss can be partially rescued by suppressing the neuropil background through soma-restricted expression of the probe. We first tested this hypothesis computationally by removing the neuropil component from the modeled medium, which reduced the loss to 10 to 20 % depending on focal depth. Finally, we tested the prediction experimentally in visual cortex neurons expressing ribosome-targeted GCaMPs. [1] Akemann et al. Nature Methods 19, 100-110, 2022

COMPARING CLEARING METHODS AND IMAGING PROCEDURES IN LIGHT SHEET MICROSCOPY

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

Marie Habart[1], Antoine Ameloot[1], Amelie Soumier[2], Guillaume Lio[2], Caroline Demily[2], Angela Sirigu[2]
[1]Centre National de la Recherche Scientifique, Institut Des Sciences Cognitives - Marc Jeannerod Umr5229, VILLEURBANNE, France, [2]iMIND Center of Excellence for Autism, Vinatier Psychiatric Hospital, Lyon, France, Bron, France

Recently, there has been a considerable development of clearing techniques associated with the use of light-sheet-microscopy. The clearing method makes a tissue sample transparent while allowing proteins labelling to be imaged in a 3D representation without the need to slice the tissue. Many clearing procedures are available but it is difficult to choose the most appropriate one for a given biochemical tissue (proteins, lipids, and glucids). Biological samples such as embryos, brains, hearts or bones have a different structure and, therefore, the choice of the right clearing procedure requires a careful consideration. Here we employed several clearing methods in rodents and non-human primates and compared their performance for transparency and staining quality on brain tissues but also lungs, gut, and whole pup samples. We found that the iDISCO+ protocol is most suitable for clearing the mouse brain. However, when performed on a thick bloc of monkey brain tissue, it produces a transparent dark sample with low antibody penetration. The PEGASOS method gives the best clearing result for the gut although it is disappointing when applied to brain tissue. Finally, we use the light-sheet-microscopy to image our 3D samples. We observed that the signal intensity depends on parameters such as the laser power and wavelength. The 568nm laser power is the strongest available on the light sheet, but it should be employed when expecting weak staining. Our findings provide some heuristics to aid decisions on the best match between clearing, immunostaining and 3D-light-sheet imaging.

SIMULTANEOUS TWO PHOTON IMAGING ON MULTIPLE NEURONS IN THREE DIMENSIONS

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

Paolo Pozzi[1], Miriam Cavagnini[1], Gabriele Losi[2], Michele Zoli[1], Jonathan Mapelli[1]

AIM: Two photon microscopy (2PM) is considered the state of the art method for the detection of calcium activity from neurons in three dimensional brain tissues and in vivo. However, it is generally limited by its laser scanning nature to imaging of bidimensional planes, severely limiting the information content of the acquired dataset. We present a method, based on computer generated holography, for the simultaneous imaging of multiple neurons axially displaced up to 100 µm. **Methods:** 3D-2PM images area acquired through a conventional raster scanning procedure. A spatial light modulator is then employed to split light from a Ti:Sa laser in multiple diffraction limited foci each positioned on neurons location either automatically identified through a custom-developed algorithm or selected by the user. All laser foci are scanned simultaneously in a raster pattern, and the fluorescence emitted is recorded by a high speed camera. Nonnegative matrix factorization methods are used to unmix the fluorescence signals from different ROIs, allowing to reconstruct multiple raster scanning image sequences. **Results:** The proposed method has been tested in brain slices stained with Fura-2, and in-vivo in mice expressing GCaMP proteins. 10x10 pixel images reporting calcium signals could be acquired simultaneously from tens of neurons within a 400x400x100 μm^3 volume at 10 Hz, demonstrating the that the proposed experimental and software pipeline allows to monitor the functional activity of 3D neuronal circuits with single cells resolution.

Plug-and-play adaptive optics for commercial laser scanning fluorescence microscopes based on an adaptive lens.
In this Letter, we present a solution for simple implementation of adaptive optics in any existing laser scanning fluorescence microscope. Adaptive optics are implemented by the introduction of a multiactuator adaptive lens between the microscope body and the objective lens. Correction is performed with a sensorless method by optimizing the quality of the images presented on screen by the microscope software. We present the results acquired on both a commercial linear excitation confocal microscope and a custom-made multiphoton excitation microscope.

Real Time Generation of Three Dimensional Patterns for Multiphoton Stimulation.
The advent of optogenetics has revolutionized experimental research in the field of Neuroscience and the possibility to selectively stimulate neurons in 3D volumes has opened new routes in the understanding of brain dynamics and functions. The combination of multiphoton excitation and optogenetic methods allows to identify and excite specific neuronal targets by means of the generation of cloud of excitation points. The most widely employed approach to produce the points cloud is through a spatial light modulation (SLM) which works with a refresh rate of tens of . However, the computational time requested to calculate 3D patterns ranges between a few seconds and a few minutes, strongly limiting the overall performance of the system. The maximum speed of SLM can in fact be employed either with high quality patterns embedded into pre-calculated sequences or with low quality patterns for real time update. Here, we propose the implementation of a recently developed compressed sensing Gerchberg-Saxton algorithm on a consumer graphical processor unit allowing the generation of high quality patterns at video rate. This, would in turn dramatically reduce dead times in the experimental sessions, and could enable applications previously impossible, such as the control of neuronal network activity driven by the feedback from single neurons functional signals detected through calcium or voltage imaging or the real time compensation of motion artifacts.

Anisoplanatic adaptive optics in parallelized laser scanning microscopy.
Inhomogeneities in the refractive index of a biological microscopy sample can introduce phase aberrations, severely impairing

the quality of images. Adaptive optics can be employed to correct for phase aberrations and improve image quality. However, conventional adaptive optics can only correct a single phase aberration for the whole field of view (isoplanatic correction) while, due to the highly heterogeneous nature of biological tissues, the sample induced aberrations in microscopy often vary throughout the field of view (anisoplanatic aberration), limiting significantly the effectiveness of adaptive optics. This paper reports on a new approach for aberration correction in laser scanning confocal microscopy, in which a spatial light modulator is used to generate multiple excitation points in the sample to simultaneously scan different portions of the field of view with completely independent correction, achieving anisoplanatic compensation of sample induced aberrations, in a significantly shorter time compared to sequential isoplanatic correction of multiple image subregions. The method was tested in whole Drosophila brains and in larval Zebrafish, each showing a dramatic improvement in resolution and sharpness when compared to conventional isoplanatic adaptive optics.

Experimental determination of shift-less aberration bases for sensorless adaptive optics in nonlinear microscopy.
Adaptive optics can improve the performance of optical systems and devices by correcting phase aberrations. While in most applications wavefront sensing is employed to drive the adaptive optics correction, some microscopy methods may require sensorless optimization of the wavefront. In these cases, the correction is performed by describing the aberration as a linear combination of a base of influence functions, optimizing an image quality metric as a function of the coefficients. The influence functions base is generally chosen to either efficiently represent the adaptive device used or to describe generic wavefronts in an orthogonal fashion. A rarely discussed problem is that most correction bases have elements which introduce, together with a correction of the aberration, a shift of the imaging field of view in three dimensions. While simple methods to solve the problem are available for linear microscopy methods, nonlinear microscopy techniques such as multiphoton or second harmonic generation microscopy require non-trivial base determination. In this paper, we discuss the problem, and we present a method for calibrating a shift-less base on a spatial light modulator for two-photon microscopy.

Fast Calculation of Computer Generated Holograms for 3D Photostimulation through Compressive-Sensing Gerchberg-Saxton Algorithm.
The use of spatial light modulators to project computer generated holograms is a common strategy for optogenetic stimulation of multiple structures of interest within a three-dimensional volume. A common requirement when addressing multiple targets sparsely distributed in three dimensions is the generation of a points cloud, focusing excitation light in multiple diffraction-limited locations throughout the sample. Calculation of this type of holograms is most commonly performed with either the high-speed, low-performance random superposition algorithm, or the low-speed, high performance Gerchberg-Saxton algorithm. This paper presents a variation of the Gerchberg-Saxton algorithm that, by only performing iterations on a subset of the data, according to compressive sensing principles, is rendered significantly faster while maintaining high quality outputs. The algorithm is presented in high-efficiency and high-uniformity variants. All source code for the method implementation is available as Supplementary Materials and as open-source software. The method was tested computationally against existing algorithms, and the results were confirmed experimentally on a custom setup for in-vivo multiphoton optogenetics. The results clearly show that the proposed method can achieve computational speed performances close to the random superposition algorithm, while retaining the high performance of the Gerchberg-Saxton algorithm, with a minimal hologram quality loss.

High-throughput spatial light modulation two-photon microscopy for fast functional imaging.
The optical monitoring of multiple single neuron activities requires high-throughput parallel acquisition of signals at millisecond temporal resolution. To this aim, holographic two-photon microscopy (2PM) based on spatial light modulators (SLMs) has been developed in combination with standard laser scanning microscopes. This requires complex coordinate transformations for the generation of holographic patterns illuminating the points of interest. We present a simpler and fully digital setup (SLM-2PM) which collects three-dimensional two-photon images by only exploiting the SLM. This configuration leads to an accurate placement of laser beamlets over small focal volumes, eliminating mechanically moving parts and making the system stable over long acquisition times. Fluorescence signals are diffraction limited and are acquired through a pixelated detector, setting the actual limit to the acquisition rate. High-resolution structural images were acquired by raster-scanning the sample with a regular grid of excitation focal volumes. These images allowed the selection of the structures to be further investigated through an interactive operator-guided selection process. Functional signals were collected by illuminating all the preselected points with a single hologram. This process is exemplified for high-speed (up to 1 kHz) two-photon calcium imaging on acute cerebellar slices.

The spatiotemporal organization of cerebellar network activity resolved by two-photon imaging of multiple single neurons. In order to investigate the spatiotemporal organization of neuronal activity in local microcircuits, techniques allowing the simultaneous recording from multiple single neurons are required. To this end, we implemented an advanced spatial-light modulator two-photon microscope (SLM-2PM). A critical issue for cerebellar theory is the organization of granular layer activity in the cerebellum, which has been predicted by single-cell recordings and computational models. With SLM-2PM, calcium signals could be recorded from different network elements in acute cerebellar slices including granule cells (GrCs), Purkinje cells (PCs) and molecular layer interneurons. By combining WCRs with SLM-2PM, the spike/calcium relationship in GrCs and PCs could be extrapolated toward the detection of single spikes. The SLM-2PM technique made it possible to monitor activity of over tens to hundreds neurons simultaneously. GrC activity depended on the number of spikes in the input mossy fiber bursts. PC and molecular layer interneuron activity paralleled that in the underlying GrC population revealing the spread of activity through the cerebellar cortical network. Moreover, circuit activity was increased by the GABA-A receptor blocker, gabazine, and reduced by the AMPA and NMDA receptor blockers, NBQX and APV. The SLM-2PM analysis of spatiotemporal patterns lent experimental support to the time-window and center-surround organizing principles of the granular layer.

LARGE-SCALE TWO-PHOTON CALCIUM IMAGING IN FREELY MOVING MICE

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

Weijian Zong[1], Horst Obenhaus[1], Emilie Skytøen[1], Hanna Eneqvist[1], Nienke Jong[1], Ruben Vale[1], Marina Jorge[1], May-Britt Moser[2], Edvard Moser[2]

Due to the unsuitability of benchtop two-photon (2P) imaging for behavior that requires voluntary movement, investigators have tried, for almost two decades, to develop miniature 2P microscopes – 2P miniscopes – that can be carried on the head of freely moving animals. Early 2P miniscopes faced major challenges, however, including temporal dispersion in the excitation fiber, image distortion due to slow scanning, heavy weight and inflexible optical cables. These constraints motivated the development of a new generation of 2P miniscopes (Zong, et al.,2017, Zong, et al.,2021) with 2P benchtop-comparable resolution, fast speed, z-scanning capability, and large field of view (FOV). However, while these 2P miniscopes represented major advances in imaging quality, their applicability in tasks that require movement remains limited, due to heavy weight, stiff optical cable, and low cell yield. Here we present a new generation of 2P miniscopes, MINI2P, that overcomes the limits of previous versions by both meeting requirements for fatigue-free exploratory behavior during extended recording periods and satisfying demands for further increasing the cell yield by an order of magnitude, to thousands of neurons. MINI2P is open source and can be built in most imaging labs. The performance and reliability of MINI2P are validated by recordings of spatially tuned neurons in three brain regions and in three behavioral assays. Imaging quality remained stable across regions and behaviors, and there was no significant difference in behavioral performance between trials with and without the MINI2P miniscope mounted on the animal's head.

Complex wiring between neurons underlies the information processing network enabling brain function, including thought and memory. Electron microscopy delivers nanometre-scale spatial resolution to reconstruct densely packed brain tissue in-silico at synaptic connectivity level but is limited to fixed specimens, delivering static snapshots of tissue architecture. Light microscopy allows observation of living systems and excels at highlighting specific molecules but lacks resolution for brain reconstruction due to light diffraction. Super-resolution optical imaging approaches overcome this resolution barrier but factors including photobleaching, tissue photo-burden, insufficient 3D-resolution and signal-to-noise ratio (SNR) have impeded nanoscale 3D modeling of nervous tissue. Here we demonstrate saturated reconstruction of living brain tissue. We developed an integrated imaging and analysis technology by adapting stimulated emission depletion (STED) microscopy for high-SNR and isotropic resolution in tissue and drastically reducing photo-burden by incorporating previous information on sample structure. This enables volumetric 3D-super-resolved imaging amenable to deep-learning based, saturated tissue reconstruction down to the level of an individual synapse. Moreover, it alllows combination with the full live-imaging toolbox including molecular labelling, electrophysiological recording, chemogenetic activation of specific neurons with simultaneous Ca^{2+} imaging and morphodynamic measurements of neurons and glia cells. This technology will provide yet unknown insight into live brain tissue (nano-)architecture in health and disease.

Pregnancy-associated diamine oxidase originates from extravillous trophoblasts and is decreased in early-onset preeclampsia.
Human extravillous trophoblast (EVT) invasion of the pregnant uterus constitutes a pivotal event for the establishment of the maternal-fetal interface. Compromised EVT function manifesting in inadequate arterial remodeling is associated with the severe pregnancy disorder early-onset preeclampsia (eoPE). Recent studies suggest that EVTs invade the entire uterine vasculature including arteries, veins and lymphatics in the first trimester of pregnancy. We therefore hypothesized that EVT-derived factors accumulate in the circulation of pregnant women early in gestation and may serve to predict eoPE. In contrast to published literature, we demonstrate that placenta-associated diamine oxidase (DAO) is not expressed by maternal decidual cells but solely by EVTs, especially when in close proximity to decidual vessels. Cultures of primary EVTs express and secret large amounts of bioactive DAO. ELISA measurements indicate a pregnancy-specific rise in maternal DAO plasma levels around gestational week (GW) 7 coinciding with vascular invasion of EVTs. Strikingly, DAO levels from eoPE cases were significantly lower (40%) compared to controls in the first trimester of pregnancy but revealed no difference at mid gestation. Furthermore, DAO-containing pregnancy plasma rapidly inactivates pathophysiologically relevant histamine levels. This study represents the first proof of concept suggesting EVT-specific signatures as diagnostic targets for the prediction of eoPE.

Function and control of human invasive trophoblast subtypes: Intrinsic vs. maternal control.
The establishment of a functional placenta is pivotal for normal fetal development and the maintenance of pregnancy. In the

course of early placentation, trophoblast precursors differentiate into highly invasive trophoblast subtypes. These cells, referred to as extravillous trophoblasts (EVTs), penetrate the maternal uterus reaching as far as the inner third of the myometrium. One of the most fundamental functions of EVTs is the transformation of spiral arteries to establish the uteroplacental blood circulation assuring an adequate nutrient and gas supply to the developing fetus. To achieve this, specialized EVT subpopulations interact with maternal immune cells, provoke elastolysis in the arterial wall and replace the endothelial cells lining the spiral arteries to induce intraluminal vascular remodeling. These and other trophoblast-mediated processes are tightly controlled by paracrine signals from the maternal decidua and furthermore underlie an intrinsic cell-type specific program. Various severe pregnancy complications such as preeclampsia or intrauterine growth retardation are associated with abnormal EVT function, shallow invasion, and decreased blood flow to the placenta. Hence a better understanding of human trophoblast invasion seems mandatory to improve therapeutic intervention. This approach, however, requires a profound knowledge of the human placenta, its various trophoblast subtypes and in particular a better understanding of the regulatory network that controls the invasive phenotype of EVTs.

Notch-dependent RBPJκ inhibits proliferation of human cytotrophoblasts and their differentiation into extravillous trophoblasts.

Abnormal development of invasive trophoblasts has been implicated in the pathogenesis of human pregnancy diseases such as pre-eclampsia. However, critical signalling pathways controlling formation and differentiation of these cells have been poorly elucidated. Here, we provide evidence that the canonical Notch pathway, operating through Notch-dependent activation of its key regulatory transcription factor RBPJκ, controls proliferation and differentiation in villous explant cultures and primary trophoblasts of early pregnancy. Immunofluorescence of first trimester placental tissue revealed expression of RBPJκ and its co-activators, the MAML proteins, in nuclei of proliferative cell column trophoblasts (CCT) and differentiated, extravillous trophoblasts (EVTs). However, RBPJκ expression, transcript levels of the Notch target gene HES1 and activity of a Notch/RBPJκ-dependent luciferase reporter decreased during in vitro differentiation of primary cytotrophoblasts on fibronectin. Silencing of RBPJκ using silencing RNAs (siRNAs) increased proliferation of CCTs in floating villous explant cultures analysed by outgrowth and BrdU labelling. Similarly, down-regulation of the transcription factor enhanced BrdU incorporation in isolated primary cultures. However, motility of these cells was not affected. In addition, gene silencing of RBPJκ increased cyclin D1 expression in the two trophoblast model systems as well as markers of the differentiated, EVT, i.e. integrin α1, ADAM12 and T-cell factor 4. In summary, the data suggest that Notch-dependent RBPJκ activity could be required for balanced rates of trophoblast proliferation and differentiation in human placental anchoring villi preventing exaggerated trophoblast overgrowth as well as premature formation of EVTs.

Genome amplification and cellular senescence are hallmarks of human placenta development.

Genome amplification and cellular senescence are commonly associated with pathological processes. While physiological roles for polyploidization and senescence have been described in mouse development, controversy exists over their significance in humans. Here, we describe tetraploidization and senescence as phenomena of normal human placenta development. During pregnancy, placental extravillous trophoblasts (EVTs) invade the pregnant endometrium, termed decidua, to establish an adapted microenvironment required for the developing embryo. This process is critically dependent on continuous cell proliferation and differentiation, which is thought to follow the classical model of cell cycle arrest prior to terminal differentiation. Strikingly, flow cytometry and DNAseq revealed that EVT formation is accompanied with a genome-wide polyploidization, independent of mitotic cycles. DNA replication in these cells was analysed by a fluorescent cell-cycle indicator reporter system, cell cycle marker expression and EdU incorporation. Upon invasion into the decidua, EVTs widely lose their replicative potential and enter a senescent state characterized by high senescence-associated (SA) β-galactosidase activity, induction of a SA secretory phenotype as well as typical metabolic alterations. Furthermore, we show that the shift from endocycle-dependent genome amplification to growth arrest is disturbed in androgenic complete hydatidiform moles (CHM), a hyperplastic pregnancy disorder associated with increased risk of developing choriocarinoma. Senescence is decreased in CHM-EVTs, accompanied by exacerbated endoreduplication and hyperploidy. We propose induction of cellular senescence as a ploidy-limiting mechanism during normal human placentation and unravel a link between excessive polyploidization and reduced senescence in CHM.

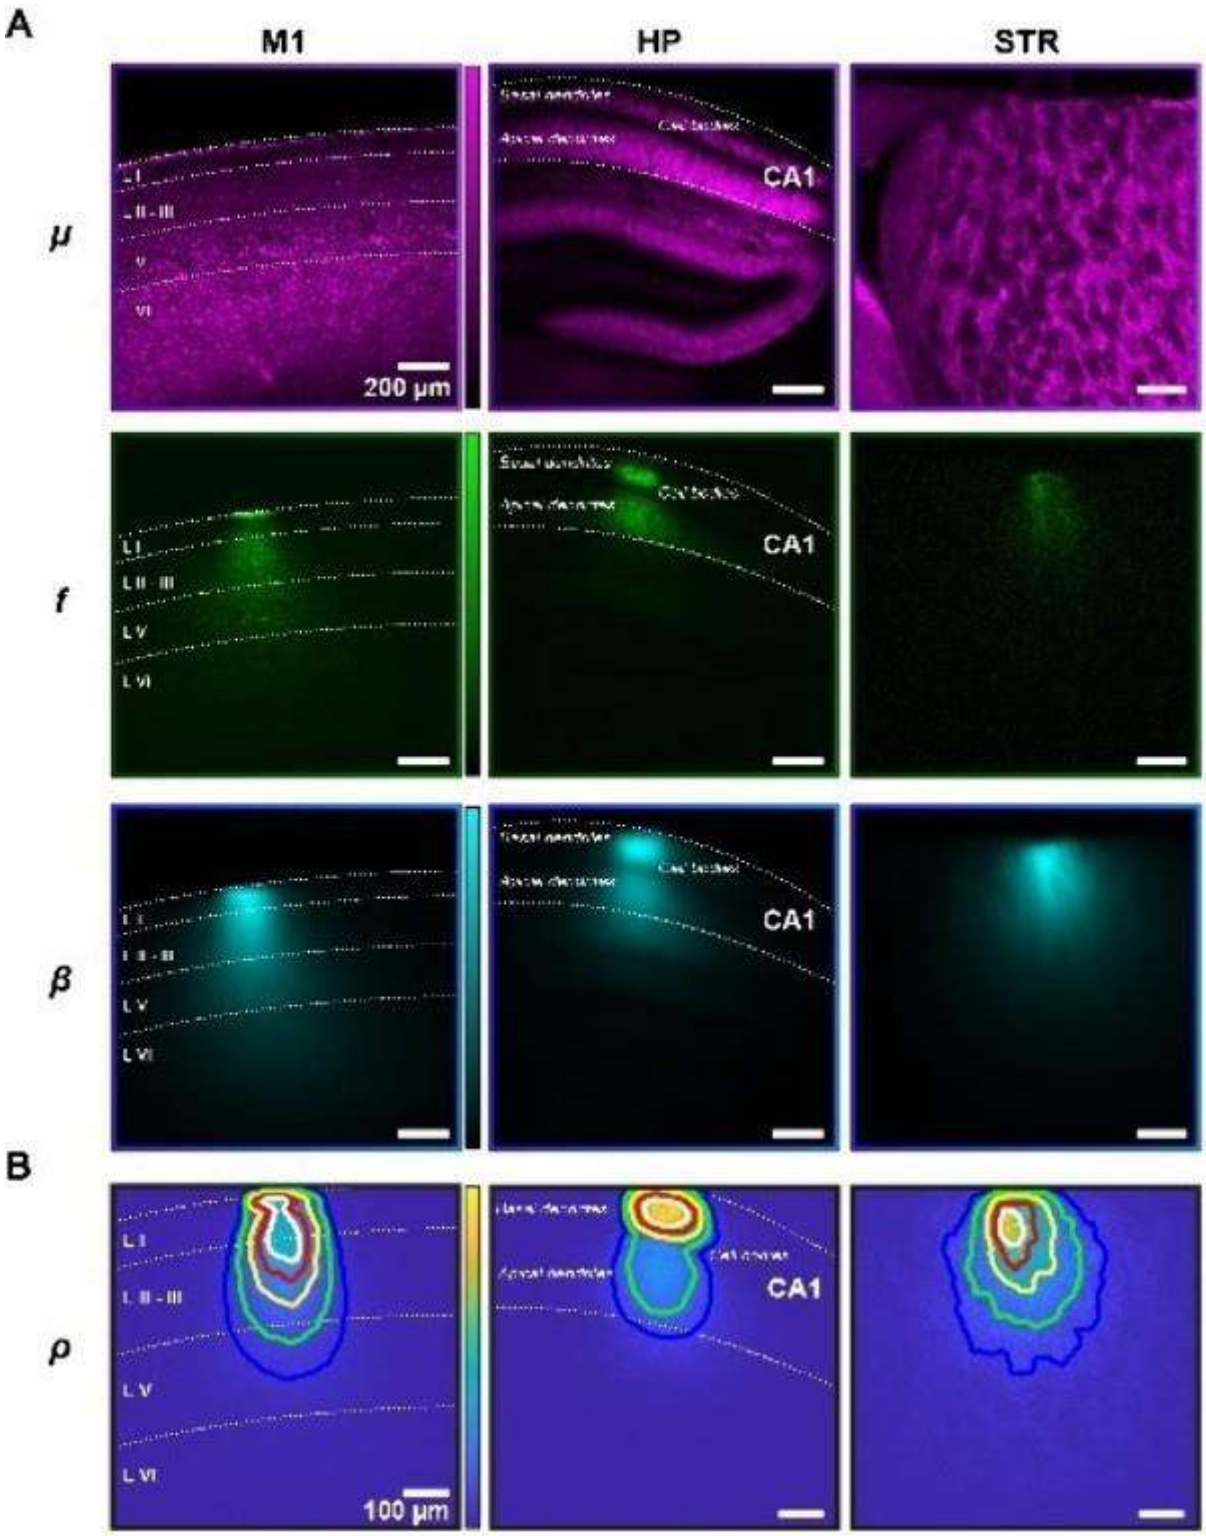
Fiber photometry (FP) is employed to probe in vivo time-dependent functional fluorescence variations related to several physiological phenomena (Piatkevich et al. Nature 2019; Patriarchi et al. Science 2018; Lee et al. Front. Neurosci. 2019). In its implementation, FP exploits an optical fiber (OF) placed next to the brain region of interest both to excite the genetically-encoded optical indicators of neural activity and to collect the resulting fluorescence. The optical properties of the brain are however uneven, suggesting that the same fiber employed in different regions of the brain could behave differently. In light of this, to identify the influence of anatomical structures on the spatial localization of FP signals, we used a two-photon microscope to measure the spatial distribution of excitation (β) and collection (η) collection photons of an OF positioned with the facet attached to the brain region of interest. The combination of η and β was then used to retrieve the photometry efficiency field (ρ) (Pisanello et al., Front. Neurosci 2019; Maglie et al. Opt. Lett. 2020), a direct measurement of the spatial sensitivity of the measurement. We compared light collection volume in the motor cerebral cortex (M1), the hippocampus (HP) and the striatum (STR), highlighting how shape and size of ρ is influenced by the anatomy across different brain regions (Fig.1) and within the same region (Montinaro et al., Biomed. Opt. Express



2021). Fig.1

Fluorescent proteins are excited by light that is polarized parallel to the dipole axis of the chromophore. In two-photon microscopy, polarized light is used for excitation. Here we reveal surprisingly strong polarization sensitivity in a class of genetically encoded, GPCR-based neurotransmitter sensors. In tubular structures such as dendrites, this effect led to a complete loss of membrane signal in dendrites running parallel to the polarization direction of the excitation beam. To reduce the sensitivity to dendritic orientation, we designed an optical device that generates interleaved pulse trains of orthogonal polarization. The passive device, which we inserted in the beam path of an existing two-photon microscope, removed the strong direction bias from fluorescence and second-harmonic (SHG) images. We conclude that for optical measurements of transmitter concentration with GPCR-based sensors, orthogonally polarized excitation is essential.

Efficient optogenetic silencing of neurotransmitter release with a mosquito rhodopsin.
Information is carried between brain regions through neurotransmitter release from axonal presynaptic terminals. Understanding the functional roles of defined neuronal projection pathways requires temporally precise manipulation of their activity. However, existing inhibitory optogenetic tools have low efficacy and off-target effects when applied to presynaptic terminals, while chemogenetic tools are difficult to control in space and time. Here, we show that a targeting-enhanced mosquito homolog of the vertebrate encephalopsin (eOPN3) can effectively suppress synaptic transmission through the G signaling pathway. Brief illumination of presynaptic terminals expressing eOPN3 triggers a lasting suppression of synaptic output that recovers spontaneously within minutes in vitro and in vivo. In freely moving mice, eOPN3-mediated suppression of dopaminergic nigrostriatal afferents induces a reversible ipsiversive rotational bias. We conclude that eOPN3 can be used to selectively suppress neurotransmitter release at presynaptic terminals with high spatiotemporal precision, opening new avenues for functional interrogation of long-range neuronal circuits in vivo.

The fate of hippocampal synapses depends on the sequence of plasticity-inducing events.
Synapses change their strength in response to specific activity patterns. This functional plasticity is assumed to be the brain's primary mechanism for information storage. We used optogenetic stimulation of rat hippocampal slice cultures to induce long-term potentiation (LTP), long-term depression (LTD), or both forms of plasticity in sequence. Two-photon imaging of spine calcium signals allowed us to identify stimulated synapses and to follow their fate for the next 7 days. We found that plasticity-inducing protocols affected the synapse's chance for survival: LTP increased synaptic stability, LTD destabilized synapses, and the effect of the last stimulation protocol was dominant over earlier stimulations. Interestingly, most potentiated synapses were resistant to depression-inducing protocols delivered 24 hr later. Our findings suggest that activity-dependent changes in the transmission strength of individual synapses are transient, but have long-lasting consequences for synaptic lifetime.

Changes in intracellular calcium concentration are correlated to neuronal activity and thus they have been extensively studied as proxy for neuronal status. GCaMP is the most widely used class of genetically encoded calcium indicators, but emerging evidence suggest that early or prolonged GCaMP expression is detrimental to neurons and to brain activity. In this study, we created a destabilized version of GCaMP (ddGCaMP) by adding a degradation domain to the sequence of GCaMP6f, so that it is constitutively degraded by the proteasome. Degradation can be suppressed by pharmacological means, causing a rapid rise in ddGCaMP concentration within hours. This represents a fast, reversible expression system, which minimizes the off-target effects of chronic GCaMP expression; this way, ddGCaMP expression is only induced immediately prior to the imaging session. Our tool is designed for studies of neurodevelopmental diseases, for which GCaMP needs to be transfected early during development. We show that mice transfected with intracerebroventricular injections at postnatal day 0 with an adeno-associated virus encoding ddGCaMP do not show the electrophysiological signs of neuronal hyperexcitability found in mice transfected with GCaMP6f. Interestingly, ddGCaMP exhibits a fluorescence decay twice as fast as that of GCaMP6f in acute cortical slices. We also show a modified reporter for Cre recombinase activity that allows the generation of tunable expression mosaics *in vivo*, also allowing to follow Ca activity in neurons of different genotype. We show the simultaneous calcium recording of wild type and PTEN knock-out neurons from a $PTEN^{flox/flox}$ mouse model of cortical dysplasia type II.

Modelling genetic mosaicism of neurodevelopmental disorders in vivo by a Cre-amplifying fluorescent reporter.
Genetic mosaicism, a condition in which an organ includes cells with different genotypes, is frequently present in monogenic diseases of the central nervous system caused by the random inactivation of the X-chromosome, in the case of X-linked pathologies, or by somatic mutations affecting a subset of neurons. The comprehension of the mechanisms of these diseases and of the cell-autonomous effects of specific mutations requires the generation of sparse mosaic models, in which the genotype of each neuron is univocally identified by the expression of a fluorescent protein in vivo. Here, we show a dual-color reporter system that, when expressed in a floxed mouse line for a target gene, leads to the creation of mosaics with tunable degree. We demonstrate the generation of a knockout mosaic of the autism/epilepsy related gene PTEN in which the genotype of each neuron is reliably identified, and the neuronal phenotype is accurately characterized by two-photon microscopy.

A PORCINE CRANIAL WINDOW MODEL TO STUDY THE GLYMPHATIC SYSTEM

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

Nicholas Bechet, Nagesh Shanbhag, Iben Lundgaard
Lund University, Emv, Lund, Sweden

The glymphatic system acts during sleep to remove waste products from the brain that are built up during the day. While the mainstay of glymphatic research has been carried out in rodents, some work has been done in humans using MRI, but the spatial resolution is not sufficient to explore more microscopic phenomena such as perivascular (PVS) flow. To this end we aimed to set up a large animal model to study the glymphatic system at high resolution both in vivo and ex vivo. First, fluorescent tracer was introduced into the cerebrospinal fluid (CSF) of adult male pigs via cisterna magna cannulation. Following tracer infusion a cranial window was created in the dorsal skull and CSF dynamics were captured using a customised large animal macroscope and real time video recordings, which were sufficient to capture PVS pulses both through the dura mater and after dural excision. After in vivo recordings, whole brains were extracted and processed using several advanced imaging techniques including confocal, light-sheet and electron microscopy which uncovered a glymphatic microarchitecture of tracer inflow into deep brain structures via PVS channels bounded by astrocytic endfeet. Furthermore the folded architecture of the gyrencephalic pig brain acted to enhance global tracer distribution. Taken together these data validate a new model to study the glymphatic system and bring us closer to understanding the nature of human glymphatics.

DATA PROCESSING TOOL FOR STUDYING SURFACE MOBILITY OF NMDARS.

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

Stepan Kortus[1], Marharyta Kolcheva[2,3], Kristyna Rehakova[3], Dominika Chalupska[4], Martin Klima[4], Martin Horak[3]
[1]The Institute of Experimental Medicine CAS, Department Of Neurochemistry, Prague , Czech Republic, [2]Faculty of Science, Charles University in Prague, Department Of Physiology, Prague, Czech Republic, [3]The Institute of Experimental Medicine CAS, Department Of Neurochemistry, Prague, Czech Republic, [4]Institute of Organic Chemistry and Biochemistry of the Czech Academy of Sciences, Department Of Molecular Biology And Biochemistry, Prague, Czech Republic

Aim: Specialized tools are available for tracking, drift correction, Mean Squared Displacement (MSD) analysis or visualization of single particle-based data. Our aim was to develop complex tool covering all needed steps for systematic research of surface mobility of NMDA receptors. **Methods:** We adapted approach to detecting and tracking the motion of the GluN1 subunit of the NMDA receptors on the neuronal cell surface, using quantum dots (QDs). **Results:** We developed software able to cover processing of the mobility data. The tool works in three steps: Tracking - Characterisation – Visualisation and allows to perform tracking within region of interest, correct for drift or detect Homer1 labelled synaptic areas. Characterisation helps to distinguish between synaptic and extra-synaptic trajectories based on the proximity of QDs to the identified synapses. Multiple descriptive parameters are calculated for each trajectory such as MSD, distance to synapse, mean velocity, active transport etc. Data are stored in database-like format and the visualization tool enables to easily compare multiple parameters and generate high quality charts. We identified the most critical steps in processing to obtain reliable measures.: drift correction and correct assignment of trajectories into different pools (synaptic, extrasynaptic, active transport). **Conclusion:** Mobility is a challenging technique requiring cyclic optimization with time consuming and operator dependent data processing. Proper analysing tool is essential to process and validate results in reasonable time and could be easily adapted for other microscopy-based tracking techniques. *Supported by the Czech Science Foundation (20-12420S) and Grant Agency of Charles University (GAUK: 320521).*

CALCIUM IMAGING TO DETERMINE THE PATHOGENIC EFFECTS OF NMDAR ANTIBODIES IN AUTOIMMUNE ENCEPHALITIS

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

Marina Cunquero Navarro[1], Esther Aguilar[2], Pablo Loza-Alvarez[1], Jesús Planagumà[1,2]
[1]ICFO - Institute of Photonic Sciences, Super-resolution Light Microscopy & Nanoscopy Lab, Castelldefels, Spain, [2]Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Neuroimmunology Department, Barcelona, Spain

Over the last 15 years a new category of antibody-mediated diseases of the central nervous system has been characterized and are now defined as “autoimmune encephalitis” (AE). There are currently 16 known autoimmune encephalitis syndromes and all are associated with antibodies against neuronal cell surface or synaptic proteins. The clinical syndromes are complex and vary according to the type of associated antibody. The best-known of these diseases is anti-N-methyl D-aspartate receptor (NMDAR) encephalitis which is a severe neuropsychiatric disorder that associates with prominent memory and behavioral deficits. The associated antibodies react with the N-terminal domain of the GluN1 subunit of the NMDAR. The approach most frequently used for the discovery and characterization of AE antibodies includes the culture of dissociated, fetal, rodent hippocampal neurons. During the process of antibody characterization, live neurons in culture are exposed to patients’ serum or CSF, and the detection of reactivity indicates that the serum or CSF samples of the patient contain antibodies against neuronal surface antigens. Hippocampal cultures can also be used to determine whether patients’ antibodies are potentially pathogenic by examining if they cause structural or functional alterations of the neurons. Here, we demonstrate how to determine the potential pathogenic effects of NMDAR antibodies with calcium imaging. Cellular activity studies in combination with techniques of identification of new autoantibodies open the possibility to initiate specific immunotherapies to improve patient’s outcome.

Engineering Polar Oxynitrides: Hexagonal Perovskite BaWON.
Non-centrosymmetric polar compounds have important technological properties. Reported perovskite oxynitrides show centrosymmetric structures, and for some of them high permittivities have been observed and ascribed to local dipoles induced by partial order of nitride and oxide. Reported here is the first hexagonal perovskite oxynitride BaWON , which shows a polar 6H polytype. Synchrotron X-ray and neutron powder diffraction, and annular bright-field in scanning transmission electron microscopy indicate that it crystalizes in the non-centrosymmetric space group P6 mc, with a total order of nitride and oxide at two distinct coordination environments in cubic and hexagonal packed BaX layers. A synergetic second-order Jahn-Teller effect, supported by first principle calculations, anion order, and electrostatic repulsions between W cations, induce large distortions at two inequivalent face-sharing octahedra that lead to long-range ordered dipoles and spontaneous polarization along the c axis. The new oxynitride is a semiconductor with a band gap of 1.1 eV and a large permittivity.

Strain I-1582, a Nematode Antagonist by Itself and Through the Plant.
I-1582 is approved in Europe for the management of on vegetable crops. However, little information about its modes of action and temperature requirements is available, despite the effect of these parameters in its efficacy. The cardinal temperatures for bacterial growth and biofilm formation were determined. The bacteria was transformed with GFP to study its effect on nematode eggs and root colonization of tomato () and cucumber () by laser-scanning confocal microscopy. Induction of plant resistance was determined in split-root experiments and the dynamic regulation of genes related to jasmonic acid (JA) and salicylic acid (SA) by RT-qPCR at three different times after nematode inoculation. The bacteria was able to grow and form biofilms between 15 and 45°C; it degraded egg-shells and colonized eggs; it colonized tomato roots more extensively than cucumber roots; it induced systemic resistance in tomato, but not in cucumber; SA and JA related genes were primed at different times after nematode inoculation in tomato, but only the SA-related gene was up-regulated at 7 days after nematode

inoculation in cucumber. In conclusion, I-1582 is active at a wide range of temperatures; its optimal growth temperature is 35°C; it is able to degrade eggs, and to colonize plant roots, inducing systemic resistance in a plant dependent species manner.

Tomato and Melon Resistant Rootstocks Improve Crop Yield but Melon Fruit Quality Is Influenced by the Cropping Season. Four rotation sequences consisting of ungrafted tomato cv. Durinta - melon cv. Paloma or tomato grafted onto the resistant rootstock 'Aligator' - melon grafted onto the resistant accession BGV11135, and in reverse order, were conducted from 2015 to 2017 in a plastic greenhouse infested or not with to determine the plant tolerance (), the minimum relative crop yield () and fruit quality. The relationship between densities in soil at transplanting () of each crop and the crop yield was assessed and and were estimated by the Seinhorst's damage model. In addition, the volume and the number of nuclei of single giant cells and the number of giant cells, its volume and the number of nuclei per feeding site in susceptible tomato and melon were compared to those in the resistant tomato and 15 days after nematode inoculation in pot test. The relationship between the and the relative crop yield fitted the Seinhorst's damage model in both ungrafted and grafted tomato and melon, but not for all years and cropping seasons. The estimated for ungrafted and grafted tomato did not differ but was lower in the former (34%) than the latter (67%). Sodium concentration in fruits from ungrafted but not from grafted tomato increased with nematode densities in spring 2015 and 2016. The estimated ungrafted melon did not differ from the grafted melon cultivated in spring, but it did when it was cultivated in summer. The relative crop yield of ungrafted melon was lower (2%) than the grafted cultivated in spring (62%) and summer (20%). Sodium concentration in melon fruits from ungrafted plants increased with nematode densities. No variations in fruit quality from grafted melon cultivated in spring were found, although less dry matter and soluble solid content at highest nematode densities were registered when it was cultivated in summer. Lower number of giant cells per feeding site was observed in both susceptible tomato germplasms compared to the resistant ones but they were more voluminous and held higher number of nuclei per giant cell and per feeding site.

Aims: Large-scale microscopy approaches relying on clearing or serial sectioning are increasingly used to study brain tissue organization and map circuitry in animal models. However, available imaging techniques often lack efficient multicolor and multicontrast modalities and often sacrifice either the spatial resolution, imaging contrast or acquisition speed. *Methods*: To address this issue, we recently introduced chromatic multiphoton serial (ChroMS) microscopy, a method combining multicolor two-photon excitation through wavelength mixing and serial block-face acquisition. This approach enables organ-scale imaging of spectrally distinct fluorescent proteins with intrinsic submicron channel registration and diffraction-limited resolution without slowing down the acquisition. *Results*: ChroMS microscopy is ideal to map mouse brain tissue expressing Brainbow transgenic markers and viral- or electroporation-based multicolor labels. We obtained continuous 3D color imaging over cubic millimeters as well as brain-wide serial 2D multichannel imaging. We present a series of improvements to the ChroMS microscopy workflow, with aiming at increasing the overall speed and robustness of the imaging process. We illustrate these advances in acquisitions of fixed mouse brains at different development states. *Conclusions*: These progress further expand the applicability of ChroMS microscopy for tissue-scale 3D color imaging with diffraction-limited resolution. *References*: Abdeladim et al, Nat Commun (2019). Glutamate receptors play key roles in neurotransmission at excitatory synapses and in the regulation of synaptic plasticity. We have recently developed a targeted covalently-attached photoswitch (TCP, Izquierdo-Serra et al., 2016) that allows the remote control of endogenous ionotropic glutamate receptors using light. We combined this photopharmacological effector with genetic and chemical calcium sensors to demonstrate all-optical reversible control of glutamate receptors at multiple levels of spatial resolution in the brain: we achieved the photoactivation of multiple neurons, individual neurons, and single synapses in rat hippocampal slices and in intact *Xenopus laevis* brain *in vivo*, which is challenging using other methods. We show that this compound selectively targets AMPA and kainate receptors. Labeled receptors remained functional for long periods of time (>8 hours). This allowed us to longitudinally track endogenous receptor physiology during events of synaptic plasticity, such as long-term depression (LTD). We could monitor the loss of functionality of AMPA/kainate receptors during NMDAR-dependent LTD in hippocampal neurons. TCPs are therefore a unique optical tool to label, photo-control and functionally track endogenous receptors in brain tissue without genetic manipulation.

ENGINEERING AND CHARACTERIZATION OF RHODOPSIN-BASED GENETICALLY-ENCODED TOOLS FOR THE ALL-OPTICAL DISSECTION OF NEURAL CIRCUITS USING 2-PHOTON ILLUMINATION

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

Christiane Grimm, Aysha Mohamed Lafirdeen, Ruth Sims, Imane Bendifallah, Eirini Papagiakoumou, Dimitrii Tanese, Valentina Emiliani
Institut de la Vision, Photonics Department, Paris, France

Establishing causal links between animal behaviuor and patterns of neuronal activity is a long-standing goal in neuroscience. Additionally, functionally mapping the synaptic connections in this neuron population is crucial for unraveling neural circuitry and ultimately understanding how the brain computes. The low-throughput nature of patch-clamp recordings from pre- and post-synaptic cells can be overcome by performing activity monitoring and manipulation with optical tools instead of electrodes. For such an all-optical experiment, channelrhodopsins under holographic 2-photon stimulation are used to modify the activity of individual neurons complemented by expression of calcium indicators which are employed to monitor activity of the neuron population. In a different line of experiments, presynaptically expressed channelrhodopsins and 2-photon parallel illumination techniques can be used to photoinduce spiking in targeted neurons and monitor post-synaptic sub-threshold responses with a voltage indicator.
Here, we characterise and develop optogenetic tools based on microbial rhodopsins for the use with 2-photon parallel illumination techniques in all-optical experiments. Our efforts entail exploring 2-photon activation of new optogenetic actuators for activity manipulation as well as engineering improved voltage sensors for activity interrogation. Initial characterisation in cultured cells is followed by viral expression in organotypic slices of mouse hippocampus and an in-depth analysis of the 2-photon usability. This *in-vitro* characterisation is fundamental to obtain the next generation of genetically encoded tools for the optical dissection of brain circuits.

One of the central goals of neuroscience is to decode the neural mechanisms of sensory perception and more specifically, to decipher the specific contributions of each coding dimension. Achieving this goal requires tools capable of precisely and non-invasively perturbing and monitoring the neural activity of selected neurons. Due to recent advances in neurophotonics, all-optical experiments based on the two-photon photostimulation of opsin expressing neurons and the simultaneous readout of neural activity using calcium indicators are now performed routinely. However, inferring neural activity using calcium indicators is lacking information regarding sub-threshold dynamics and complex spike waveforms, which can be overcome using voltage indicators. In combination with temporal focusing, parallel light sculpting methods such as Computer-Generated Holography, Generalized Phase Contrast and low numerical aperture Gaussian beams have been used to perform scanless two-photon photostimulation of multiple neurons. Here, by viral expression of JEDI-2P in organotypic slices of mouse hippocampus, we demonstrate that each of the different used light sculpting approaches developed for parallel two-photon optogenetic manipulation are also suitable for high-resolution two-photon voltage imaging of neural activity, and characterize the optimal acquisition parameters in each case. We show that high frequency spiking and subthreshold depolarizations can be recorded from multiple cells at kilohertz acquisition rates by combining targeted, parallel illumination with a widefield detection axis. Finally, we highlight the utility of performing simultaneous two-photon voltage imaging and photostimulation (by co-expression of the opsin ChroME) to validate the precise number, amplitude and timing of evoked action potentials in-situ during all-optical experiments.

Optogenetic suppression of presynaptic neurotransmitter release has been a long-standing goal in systems neuroscience.

FENS Forum 2022
9-13 July 2022 | Paris, France

We recently developed optogenetic tools based on G-protein coupled rhodopsins (optoGPCRs) that allow effective presynaptic silencing. To expand optoGPCRs palette with advantageous properties, we chose a literature mining approach to identify 50+ candidates for silencing synaptic transmission. To validate their applicability, we benchmarked 11 promising optoGPCRs against each other by comparing their expression, membrane targeting, GIRK-channel coupling efficiency, ability to suppress synaptic transmission and their G-protein coupling specificity. While only two of the new optoGPCRs studied exhibited the desired properties with regard to presynaptic inhibition, we were able to identify one new optoGPCR which can be reliably switched between active/inactive states with blue/green light, respectively, enabling multiplexing with other red-shifted tools. While previously utilized optoGPCRs (eOPN3/parapinopsin) couple to G_i- and G_o-proteins, our new candidate allows highly effective silencing of synaptic transmission, but does not couple to G_i-signaling and therefore does not perturb the activity of adenylate cyclases and leaves the cAMP-signaling pathway unchanged. The newly developed optoGPCR doesn't require UV-light for activation, is highly light-sensitive and allows high-efficacy silencing of CA3 to CA1 projections in organotypic slices. Validation of this new optogenetic tool in mice is still ongoing and further demonstrated synaptic silencing and behavioral effects in *C.elegans*. We believe that the new optoGPCRs will serve as highly potent tools for functionally dissecting neuronal circuits via silencing of long-range axonal projections. Fully reversible, the new range of inhibitory optoGPCRs provides temporally-precise control over synaptic transmission.

A FLEXIBLE TWO-PHOTON ENDOSCOPE FOR FAST ACTIVITY IMAGING AND CELL-PRECISE OPTOGENETIC PHOTO-STIMULATION OF NEURONS IN FREELY MOVING ANIMALS.

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

Francois Blot[1], Nicolo Accanto[1], Antonio Lorca Camara[1], Valeria Zampini[1], Vincent De Sars[1], Florence Bui[1], Christophe Tourain[1], Valentina Emiliani[1], Ori Katz[2], Noam Badt[2]
[1]Institut de la Vision, Photonics, Paris, France, [2]The Hebrew University of Jerusalem, Department Of Applied Physics, Jerusalem, Israel

We developed a flexible two-photon fiber-based microendoscope (2P-FENDO) capable of all-optical brain interrogation at cellular resolution in freely moving mice. The system performs two-photon (2P) fast functional imaging and 2P holographic photostimulation of single and multiple cells using axially confined extended spots. Proof-of-principle experiments were performed on head restrained and freely moving mice co-expressing jGcaMP7s and the opsin ChRmine in visual or barrel cortex. On a field of view of 250 µm in diameter, we demonstrated functional imaging at a frame rate of up to 100 Hz and precise photostimulation of single and multiple cells. With the capability to simultaneously image and control neuronal activity at single-cell resolution in freely moving animals, 2P-FENDO will enable to precisely define the functions of neurons in the brain and their interactions during naturalistic behaviours.

EFFICIENT OPTOGENETIC SILENCING OF SYNAPTIC TRANSMISSION USING THE BISTABLE OPTO-GPCR PDCO

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

Adrianna Nozownik[1], Mauro Pulin[1], Jonas Wietek[2], Ofer Yizhar[2], J. Simon Wiegert[1]
[1]Medical Centre Hamburg-Eppendorf, Centre For Molecular Neurobiology, Hamburg, Germany, [2]Weizmann Institute of Science, Department Of Brain Sciences, Rehovot, Israel

Optogenetics enables the perturbation of neuronal activity with superior spatiotemporal precision. While exciting neurons is relatively straightforward, silencing neuronal activity reliably for prolonged time is more challenging, especially when it comes to synaptic transmission. A recent strategy employs GPCR rhodopsins (opto-GPCRs), which activate endogenous Gi/o-pathways, similar to the chemogenetic silencing tool hM4Di. PdCO, a blue light-activated and green light-inactivated bistable GPCR from *Platynereis dumerilii*, is a promising new candidate for reversible optical synaptic inhibition. We used organotypic hippocampal slice cultures (OSC) to investigate light-mediated silencing at Schaffer collateral synapses in detail. PdCO was expressed in CA3 pyramidal cells via single-cell electroporation or local rAAV injections. We recorded Gi/o-protein coupled inwardly rectifying K^+ (GIRK) currents to estimate the optimal activation and inactivation light parameters. Compared to PPO, a switchable opto-GPCR from *Lethenteron camtschaticum/japonicum*, PdCO has a red-shifted activation spectrum and higher light-sensitivity. We further used GIRK current recordings to assess the compatibility of PdCO with two-photon imaging. Finally, by combining PdCO or PPO with a soma-localized red-shifted excitatory tool embedded in a tandem construct with a blue-light activated anion channel (somBiPOLES), we demonstrate all-optical control of synaptic transmission. Both opto-GPCRs efficiently decreased red light-evoked postsynaptic currents in a reversible manner. However, PdCO showed higher potency for synaptic silencing and approximately 10x higher light sensitivity than PPO. In summary, PdCO is a new, bistable opto-GPCR suitable for efficient, reversible synaptic silencing using light in the visible spectrum.

OPTOGENETIC STIMULATION REDUCES SPECTRAL SPREAD OF COCHLEAR IMPLANTS – A MODELING STUDY

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

Lakshay Khurana[1,2,3,4,5], Daniel Keppeler[1,3,4], Lukasz Jablonski[1,2,4], Tobias Moser[1,2,3,4,6]
[1]University Medical Center Goettingen, Institute For Auditory Neuroscience, Goettingen, Germany, [2]German Primate Center, Auditory Neuroscience And Optogenetics Laboratory, Goettingen, Germany, [3]Max Planck Institute for Multidisciplinary Sciences, Auditory Neuroscience & Synaptic Nanophysiology, Goettingen, Germany, [4]University Medical Center Goettingen, Innerearlab, Department Of Otolaryngology, Goettingen, Germany, [5]University of Goettingen, Goettingen Graduate Center For Neurosciences, Biophysics, And Molecular Biosciences (ggnb), Goettingen, Germany, [6]University of Goettingen, Cluster Of Excellence "multiscale Bioimaging: From Molecular Machines To Networks Of Excitable Cells" (mbexc), Goettingen, Germany

Electrical cochlear implants (eCIs) are the most successful neuroprosthetic devices, having partially restored hearing in about a million people worldwide. The eCI users, though obtain good speech perception in quiet environments, struggle to understand speech-in-noise and to appreciate music. This limitation is majorly caused by the wide spread of current in the cochlea which leads to broad neural excitation and limits the number of perceptually different channels. A possibility to reduce the spectral spread and to increase the number of independent channels is to advance towards optogenetic cochlear implants (oCIs). This project aims to assist the development of clinical oCIs by predicting the light spread in a human cochlea using an optical ray-tracing model. A reconstructed 3D cochlea model was imported to an optical engineering software to do an *in silico* investigation of the light spread. Ten light emitters were placed in the scala tympani, and simulated with different radiation profiles. The spectral spread was approximated from irradiance profiles in the Rosenthal's canal housing the somata of spiral ganglion neurons. The results showed that emitters having Gaussian profile (LASER-coupled waveguides) provide higher irradiance and lower spectral spread than those having Lambertian profile (LEDs). The spectral spread using optical stimulation was found to be lower than that with electrical stimulation. The emitter-to-neurons distance and orientation, and formation of scar tissue, impacted the irradiance, highlighting directions for development of oCIs and of soft surgery maintaining cochlear health. The modeling results strengthen the idea that oCIs would offer lower spectral spread than eCIs.

Around 5% of whole world's population can be affected by hearing impairment. The design of optical cochlear implants (oCIs) aims to improve hearing quality compared to the widely used electric cochlear implant. To provide light sensitivity to the auditory system we employ Channelrhodopsins (ChRs), naturally occurring photosensitive proteins. Optogenetic manipulation of spiral ganglion neurons (SGNs) has been reported, but efforts to improve the performance of ChRs for clinical translation are ongoing. We designed and characterized blue light activated ChRs that meet the needs of hearing restoration by oCIs: high light sensitivity and temporal fidelity. Both aspects are interconnected, and speed is usually in detriment of light sensitivity. Low light sensitivity can be compensated by higher membrane expression, achieved with membrane exporting sequences from Kir2.1 channel. Less desensitizing ChRs provide reproducible and sustained photoresponses over time for high frequency stimulation of SGNs. All these parameters were systematically compared in transiently transfected neuroblastomaglioma cells and in hippocampal neuron primary cultures. Neuronal activation was studied regarding light pulse length, frequency, and light intensity. Selected candidates optimized *in vitro*, were tested *in vivo* by direct injection of AAVs through the round window in early postnatal mice. *In vitro* measurements in cochlear nucleus show that light stimulation of SGN fibers evoke postsynaptic activity. Cochlear nucleus recordings help us to evaluate the effects of optogenetic manipulation in the auditory system. In conclusion, here we show new refined gain of function mutant ChRs with great potential to be tested in established animal models for future clinical translation.

Rationally designed azobenzene photoswitches for efficient two-photon neuronal excitation.
Manipulation of neuronal activity using two-photon excitation of azobenzene photoswitches with near-infrared light has been recently demonstrated, but their practical use in neuronal tissue to photostimulate individual neurons with three-dimensional precision has been hampered by firstly, the low efficacy and reliability of NIR-induced azobenzene photoisomerization compared to one-photon excitation, and secondly, the short cis state lifetime of the two-photon responsive azo switches. Here we report the rational design based on theoretical calculations and the synthesis of azobenzene photoswitches endowed with both high two-photon absorption cross section and slow thermal back-isomerization. These compounds provide optimized and sustained two-photon neuronal stimulation both in light-scattering brain tissue and in Caenorhabditis elegans nematodes, displaying photoresponse intensities that are comparable to those achieved under one-photon excitation. This finding opens the way to use both genetically targeted and pharmacologically selective azobenzene photoswitches to dissect intact neuronal circuits in three dimensions.

Control of Brain State Transitions with a Photoswitchable Muscarinic Agonist.

The ability to control neural activity is essential for research not only in basic neuroscience, as spatiotemporal control of activity is a fundamental experimental tool, but also in clinical neurology for therapeutic brain interventions. Transcranial-magnetic, ultrasound, and alternating/direct current (AC/DC) stimulation are some available means of spatiotemporal controlled neuromodulation. There is also light-mediated control, such as optogenetics, which has revolutionized neuroscience research, yet its clinical translation is hampered by the need for gene manipulation. As a drug-based light-mediated control, the effect of a photoswitchable muscarinic agonist (Phthalimide-Azo-Iper (PAI)) on a brain network is evaluated in this study. First, the conditions to manipulate M2 muscarinic receptors with light in the experimental setup are determined. Next, physiological synchronous emergent cortical activity consisting of slow oscillations-as in slow wave sleep-is transformed into a higher frequency pattern in the cerebral cortex, both in vitro and in vivo, as a consequence of PAI activation with light. These results open the way to study cholinergic neuromodulation and to control spatiotemporal patterns of activity in different brain states, their transitions, and their links to cognition and behavior. The approach can be applied to different organisms and does not require genetic manipulation, which would make it translational to humans.

Synthetic Photoswitchable Neurotransmitters Based on Bridged Azobenzenes.
Photoswitchable neurotransmitters of ionotropic kainate receptors were synthesized by tethering a glutamate moiety to disubstituted C2-bridged azobenzenes, which were prepared through a novel methodology that allows access to diazocines with higher yields and versatility. Because of the singular properties of these photochromes, photoisomerizable compounds were obtained with larger thermal stability for their inert cis isomer than for their biologically activity trans state. This enabled selective neuronal firing upon irradiation without background activity in the dark.

Optical Control of Cardiac Function with a Photoswitchable Muscarinic Agonist.
Light-triggered reversible modulation of physiological functions offers the promise of enabling on-demand spatiotemporally controlled therapeutic interventions. Optogenetics has been successfully implemented in the heart, but significant barriers to its use in the clinic remain, such as the need for genetic transfection. Herein, we present a method to modulate cardiac function with light through a photoswitchable compound and without genetic manipulation. The molecule, named PAI, was designed by introduction of a photoswitch into the molecular structure of an M2 mAChR agonist. In vitro assays revealed that PAI enables light-dependent activation of M2 mAChRs. To validate the method, we show that PAI photoisomers display different cardiac effects in a mammalian animal model, and demonstrate reversible, real-time photocontrol of cardiac function in translucent wildtype tadpoles. PAI can also effectively activate M2 receptors using two-photon excitation with near-infrared light, which overcomes the scattering and low penetration of short-wavelength illumination, and offers new opportunities for intravital imaging and control of cardiac function.

Optical control of endogenous receptors and cellular excitability using targeted covalent photoswitches.
Light-regulated drugs allow remotely photoswitching biological activity and enable plausible therapies based on small molecules. However, only freely diffusible photochromic ligands have been shown to work directly in endogenous receptors and methods for covalent attachment depend on genetic manipulation. Here we introduce a chemical strategy to covalently conjugate and photoswitch the activity of endogenous proteins and demonstrate its application to the kainate receptor channel GluK1. The approach is based on photoswitchable ligands containing a short-lived, highly reactive anchoring group that is targeted at the protein of interest by ligand affinity. These targeted covalent photoswitches (TCPs) constitute a new class of light-regulated drugs and act as prosthetic molecules that photocontrol the activity of GluK1-expressing neurons, and restore photoresponses in degenerated retina. The modularity of TCPs enables the application to different ligands and opens the way to new therapeutic opportunities.

IN VIVO HIGH-THROUGHPUT PROBING OF SYNAPTIC CONNECTIVITY USING TWO-PHOTON HOLOGRAPHIC OPTOGENETIC STIMULATION AND COMPRESSED SENSING STRATEGIES

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

I-Wen Chen[1], Chung Yuen Chan[1], Vincent De Sars[1], Emiliano Ronzitti[1], Phillip Navarro[2], Karim Oweiss[2], Dimitrii Tanese[1], Valentina Emiliani[1]

A comprehensive description of patterns and properties of synaptic connections between a population of neurons provides the most relevant insights into the neuronal circuits underlying brain functions. Here we investigated synaptic connectivity between putative excitatory neurons at layer 2/3 of mouse visual cortex in vivo by combining two-photon (2P) holographic optogenetic stimulation and whole-cell recording. Fast, temporally precise, and spatially selective action potential (AP) was induced in each of potential presynaptic neurons by using 2P holographic illumination onto opsin-expressing cell soma and the current activity in a postsynaptic neuron was monitored by inserting one patch pipette for voltage-clamp recording. Spatially-confined 2P holographic light-spot of 12-µm diameter was generated by using computer-generated holography plus temporal focusing and focused into the brain tissue in lightly anesthetized animals. By using soma-illumination of 2P holographic light of 0.15-0.3 mW/µm^2, AP of peak latency <10 ms and jitter <1 ms was induced in a potential presynaptic cell expressing the soma-restricted opsin ChroME. An optimized pipeline for fast sequential photostimulation of single cells enabled probing ~100 potential presynaptic cells in ~5 minutes. Connectivity mapping was further accelerated by a parallel multi-cell photostimulation strategy combined with a compressive sensing algorithm to retrieve the connections. Taken together, our approach allows high-throughput mapping of local synaptic connections to a postsynaptic neuron in vivo with unprecedented speed, precision, and accuracy.

Understanding how specific sets of neurons fire and wire together during cognitive-relevant activity is one of the most pressing questions in neuroscience. Two-photon, single-cell resolution optogenetics based on holographic light-targeting approaches enables generation of precise spatiotemporal activity patterns and has enabled a broad range of experimental configurations including high throughput connectivity mapping, probing how many neurons are sufficient for perception and investigation of functional connectivity. Yet, intrinsic limitations of the technology which currently enables holographic light patterning limit today the resolution for tuning the relative spiking time of distinct cells or cell ensemble to a few milliseconds and the achievable number of targets to several tens. To overcome these limitations and expand the capabilities of single-cell optogenetics, we introduce an optical configuration capable of ultrafast light targeting based on switching temporally focused beams between holograms at kHz rates. We used FLiT to demonstrate two new illumination methods, termed *hybrid-* and *cyclic-illumination* and achieve sub-millisecond control of sequential neuronal activation and high throughput multicell illumination both in vitro and in vivo while minimizing light-induced thermal rises, respectively. These approaches will be important for experiments that require rapid and precise cell stimulation with defined spatio-temporal activity patterns and optical control of large neuronal ensembles.

In case of deafness, cochlear implants (CIs) bypass dysfunctional or lost hair cells by direct stimulation of tonotopically organised spiral ganglion neurons (SGNs) which convey auditory inputs to the brain. The state-of-the-art implants, electrical CIs (eCIs), enables speech understanding in the quiet in most of the approximately 1 million users and hence are considered the most successful neuroprostheses. However, due to wide spread of SGN activation from each electrode, coding of spectral information is very limited resulting in poor speech understanding in background noise as well as reduced music appreciation. Thanks to the ability to confine light in space, optical CIs (oCIs) combined with optogenetics promise to overcome this shortcoming of eCIs by enabling more independent stimulation channels. This requires fast and power-efficient real-time sound analysis and control of multiple microscale light emitters. Here, we present a low-weight (8 g), battery-powered, and wireless-controlled sound processor for driving multichannel oCIs and its sister eCI system. These systems support behavioural experiments in freely moving rodents (e.g. rats) or non-human primates (e.g. marmosets) for assessing auditory percepts of the optogenetic stimulation and comparison off efficacy with electrical stimulation. This proof-of-concept multichannel oCI system paves the way for the future development of medical devices for human patients.

Aims: Nicotinic acetylcholine receptors (nAChRs) are pentameric ligand-gated ion channels made of a combination of α and β subunits. In the brain, nAChRs are activated by acetylcholine (ACh), a neuromodulator that broadcasts a diffuse signal. They are also activated by nicotine, the main active substance of tobacco. These receptors are widely expressed throughout the brain, notably in two circuits implicated in nicotine addiction : the mesolimbic dopamine system and the habenulo-interpeduncular pathway. Nicotine hijacks the normal functioning of these circuits to trigger reinforcement and aversion, respectively. Understanding the effect of ACh and nicotine on neural circuits and behaviors requires strategies for manipulating specific nAChR subtypes in targeted pathways. To this end, we have developped new chemogenetic tools for the manipulation of endogenous nAChR subtypes. **Method:** We have generated two transgenic mouse lines that contain a single amino acid substitution E61C on either the β2 or β4 nAChR subunit. The cysteine mutation does not alter receptor functioning, but is used for the covalent attachment of cysteine-reactive ligands. We have engineered different tethered ligands, notably an irreversible antagonist ($MPEG_4Ch$), and a photoswitchable antagonist (MAHoCh). **Results:** Using electrophysiology, we demonstrate the pharmacological specificity of these tools. While MAHoCh enables rapid on-off switching of receptors, $MPEG_4Ch$ can inhibit nAChRs for several days after a single injection in specific brain areas. **Conclusions:** By enabling the rapid *vs.* prolonged interruption of nicotinic neurotransmission in targeted circuits, these versatile tools will help dissect the various roles of ACh, and the many facets of nicotine, in behaving mice.

Optogenetic cochlear implants (oCI) promise to overcome the issue of current spread of electrical cochlear implants (eCI). However, proof on behavioral level has not been drawn yet. Here, we established a framework using wireless multichannel e/oCI-systems to train freely moving rats on CI-cued behavioral tasks. Rats (n=20) were trained in the ShuttleBox, a negative reinforcement paradigm encouraging avoidance behavior. Animals were implanted either with a multichannel-eCI (array from MED-El with 5 electrodes) or a multichannel-oCI (up to 10 LEDs). Position of the implant was confirmed via CT. Animals for oCI implantation had been postnatally injected with AAV carrying channelrhodopsin-2 variant *CatCh*. Using CI-system, animals were subjected to detection tasks via wireless communication to evaluate perceptual threshold. Secondly, animals were subjected to channel-discrimination paradigms. Functional expression of *CatCh* was confirmed in 87.5% of virus-injected rats by optically evoked auditory brainstem responses. In all animals, avoidance behavior could be evoked in response to stimulation of CI-system (eCI, n=8; oCI, n=6). This was also true when acoustic clicks were transformed to stimuli using CI-system in real time, rather than using pre-programmed stimuli. Using single stimulation channels, mean behavioral thresholds were ~75 µA for eCI and ~0.8 mW for oCIs. Frequency discrimination experiments with acoustic stimulation identified mean frequency difference limen of 0.08 Weber fraction. We established framework based on CI-systems handling multichannel e/oCIs and demonstrated that single LED-driven optogenetic stimulation evokes percept strong enough to elicit behavior. From here we aim to probe spatial selectivity of optogenetic vs. electrical stimulation on behavior level.

Intracellular transport is a vital process, especially in neurons. Axonal transport deficit is found in neurodegenerative diseases. Conventional methods used to measure intraneuronal transport are limited by moderate spatiotemporal resolutions. We developed a method using photostable optically active nanocrystals (NC) tracers spontaneously internalized in endosomes[1,2]. Here we demonstrate its application to zebrafish (Zf) larvae. We used NC exhibiting large second-order non-linear optical properties, injected in Zf brain. We harnessed these properties combined with fast raster scanning of the infrared laser beam to achieve 20 frames/s rate, allowing us to detect short pausing duration underpinning complex molecular mechanisms otherwise smeared out by low temporal resolution. Using this method in axons of neurons with known polarization, we were able to separate the retrograde from the anterograde phases of motion. Our pipeline of video dataset analysis extracts statistical distributions of transport metrics in normal and perturbed situations. To test the sensitivity of our assay, we modulated active motors concentration, either by applying dynapyrazole, a retrograde motor dynein inhibitor, or by using transgenic Zf engineered with loss-of-function alleles of the anterograde motor Kif5aa. Dynapyrazole induces a 32% reduction of mobile NC, with a 37% reduction of their retrograde run length. In *kif5aa* mutants the retrograde run length is increased by 46% compared to wildtype. The high sensitivity of our assay opens prospects in investigating in vivo endosomal transport molecular mechanism in depth. S. Haziza, et al., *Nat. Nanotechnol.*, 2017, **12**, 322–328. Q.-L. Monitoring extracellular glutamate dynamics provides a way to discern the engagement of excitatory activity that conducts the bulk of long-distance signaling in the mammalian brain. We recently introduced a molecular imaging approach that could permit noninvasive imaging of neurochemicals like glutamate using vasoactive sensors called AVATars. By coupling analyte detection to relaxation of vascular smooth muscle cells, these sensors induce artificial hemodynamic signals detectable by functional magnetic resonance imaging (fMRI) or functional ultrasound. Here we describe the design and *in vivo* validation of Glu-AVATar, a novel protein-based AVATar for selective hemodynamic imaging of extracellular glutamate in the brain. We demonstrate that this probe produces robust hemodynamic responses in the presence of exogenous glutamate, while control experiments performed with vehicle stimulation or control proteins do not result in signal changes. Glu-AVATar functionality is exhibited in both rodent and primate brains, indicating potential translatability of the technology. We further demonstrate that Glu-AVATar reveals correlations between probe-infused regions of the dorsal rat hippocampus and distal regions such as the ventral tegmental area and ventral hippocampus. These measurements constitute a neurochemically specific form of functional connectivity analysis that can be combined with conventional fMRI techniques to reveal correlates of excitatory signaling between different brain regions. Future AVATar-based molecular fMRI approaches will allow for more precise and less invasive methods for imaging extracellular glutamate dynamics over wide fields of view in intact brains.

CUSTOM LIGHT-SHEET MICROSCOPY SETUPS FOR LARGE-SCALE HUMAN AND MOUSE BRAIN MAPPING

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

Giacomo Mazzamuto[1,2,3], Ludovico Silvestri[1,2,3], Vladislav Gavryusev[2], Giuseppe Sancataldo[2,4], Francesco Saverio Pavone[1,2,3]
[1]National Research Council, National Institute Of Optics, Cnr-ino, Sesto Fiorentino, Italy, [2]University of Florence, European Laboratory For Non-linear Spectroscopy (lens), Sesto Fiorentino, Italy, [3]University of Florence, Department Of Physics And Astronomy, Sesto Fiorentino, Italy, [4]University of Palermo, Department Of Physics And Chemistry, Palermo, Italy

We describe two custom-designed Light Sheet Fluorescence Microscopy setups with different geometries for different types of samples: a dual view, inverted, dual color LSFM for large tissue slabs (up to 0.5mm in thickness, several cm in lateral size) and a single view, dual color LSFM for whole organs (e.g. whole mouse brains). These instruments have been used extensively for large acquisition campaigns: within the HBP to image a whole human hippocampus, within the NIH's Brain Initiative Cell Census Network to image large sections of the human Broca's area, and to image a large number of whole mouse brains for cfos-based activation mapping. The custom design of these devices concerns not only the hardware (custom sample holder, dual channel acquisition, autofocus), but also the software needed to efficiently run the whole pipeline on a daily basis. Indeed, LSFM poses significant challenges with data handling and processing, since these instruments easily produce large datasets, in the range of several TB each. For data acquisition, the system must be able to sustain high data rates, especially with dual-view imaging. To this aim, we have developed an open source set of hardware libraries and a dedicated data acquisition software, written in C++, that are able to control and synchronize multiple cameras and to automate the acquisition of big samples. Concerning image processing, we have developed an open source tool for stitching TB-sized datasets named ZetaStitcher. The tool is written in Python and features a handy API for virtual volumetric access of the fused tomography.

In vivo 2-photon imaging of the mouse brain has developed into a versatile tool for the analysis of single organelles and neuronal networks. Here, we present an open-source, fully customizable head stage with a running disc, which is easily produced at low cost using a commercial 3D printer. The lightweight head-fixation provides a remarkably high stability even during animal movement, which is partially superior to commercially available systems. Furthermore, the system offers the ability to influence the running speed of the mouse and switch between resting, freely and externally induced moving states. Using our newly developed system, we performed *in vivo* 2-photon imaging in the motor and visual cortex of mice expressing EGFP-tagged Connexin36 (Cx36-EGFP), allowing us to monitor the location of identified electrical synapses over time. We observed a striking positional stability of Cx36-EGFP punctae over months. 2-photon fluorescence recovery after photobleaching (2P-FRAP) of individual punctae revealed an estimated turnover half-life of 3-6 weeks. In contrast to this high stability, visual deprivation induced decoupling of electrical synapses of fast spiking interneurons in V1 as evidenced by paired patch-clamp recordings. In addition, confocal microscopy indicated a decrease in the size and intensity of Cx36-EGFP punctae after 24h of visual deprivation. *In vivo* verification of these plastic changes using two-photon awake imaging is ongoing. In summary, we present a novel, highly stable head-fixation and running system for imaging of awake mice that enabled us to investigate the stability and plasticity of electrical synapses in the mammalian brain for the first time.

The synaptic vesicle (SV) life cycle encompasses several steps that allow the formation, trafficking, recycling and eventually degradation of these pivotal organelles in the biology of neurons. While their roles in neurotransmission are extensively studied, several aspects that orchestrate their function and define their identity are still poorly understood. Nanobodies (Nbs) offer several advantages when compared to conventional larger binders such as antibodies. As an example, due to their reduced size Nbs minimize linkage errors, decrease molecular crowding while increasing the efficiency of target binding. Moreover, since their sequences can be easily isolated, they can be functionalized in different manners by fusing them to the required protein-based tags or sensors. Here, we present a toolset of Nbs against SV proteins, which have been engineered by fusing them to several reporters. With these, we performed local measures of pH, calcium transients and carried on high resolution imaging experiments in different modalities, including electron microscopy, uPAINT and MoNaLISA. By expressing these Nbs as intrabodies, we also modulated the trafficking of SVs and studied the composition of synapses at the nanoscale providing novel quantitative information about the SV life cycle.

DEVELOPING A SINGLE-MOLECULE PULL-DOWN (SIMPULL) ASSAY FOR CHARACTERISING PATHOLOGICAL TAU AGGREGATES

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

Melanie Swang*, Dorothea Böken*, David Klenerman
University of Cambridge, Uk Dementia Research Institute, Cambridge, United Kingdom

Aims: Hyper-phosphorylation and aggregation of tau protein is a common neuropathological hallmark of various neurological disorders such as Alzheimer's disease. However, the tau aggregates' morphological characteristics as well as their role in the pathogenesis and pathophysiology of these disorders remain a topical area of research. The aim of this study is to develop biophysical tools to study this. **Methods:** We adapted and optimised a method utilising an antibody-based, single-molecule pull-down (SiMPull) assay in order to detect and characterise tau aggregates in biological samples with high sensitivity and specificity. Similar to a sandwich ELISA, SiMPull uses a PEG-passivated surface along with biotin-neutravidin interactions to capture and detect tau oligomers and fibrils using single-molecule fluorescence microscopy. We then combined this method with super-resolution microscopy to perform size and shape measurements of the tau aggregates. **Results:** We first validated this method using Alzheimer's Braak VI brain homogenate samples, achieving a sensitivity of 750 pg/mL for total tau. Specificity for tau aggregates was determined using non-tau antibodies and samples containing aggregates of non-tau proteins. Super-resolution experiments demonstrated morphological differences between Alzheimer's and healthy control samples. After these validation steps, we demonstrated the applicability of this method to other biological and clinically relevant samples such as serum and cerebrospinal fluid. **Conclusions:** Our results provide a proof-of concept for a reliable, sensitive, specific, and efficient method for performing diffraction-limited and super-resolution imaging and characterisation of tau aggregates in biological samples, enabling us to further study the role of tau in the pathophysiology of different neurodegenerative diseases.

A STATISTICALLY BASED REGION GROWING APPROACH FOR SEGMENTING SUB-NEURONAL STRUCTURES FROM CONFOCAL AND SUPER-RESOLUTION IMAGES

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

Miriam Basile[1], Simone Cauzzo[2], Ester Bruno[1], Alejandro Callara[1], Lydia Danglot[3], Arti Ahluwalia[4], Nicola Vanello[5], Chiara Magliaro[1]

Piaggio, School Of Engineering, Pisa, Italy, [3]Institute of Psychiatry & Neuroscience of paris, Neuroscience, Paris, France, [4]University of Pisa, Department Of Information Engineering, Pisa, Italy, [5]Università di Pisa, Dipartimento Di Ingegneria Dell'informazione, Pisa, Italy

Spines are neuronal protrusions implied in signal transmission and their identification is a challenging task. In this work, we customized our smart region growing (SmRG) algorithm for their segmentation. We exploited a statistical approach to find the best (adaptative) threshold to segment the data. SmRG fits a mixture model on the image to describe the background noise, the fluorescence diffusion and the neuronal fluorescence with a gaussian and two negative-binomial distributions, respectively. Region growing schemes assume a connected structure to segment. However, even in high-magnification datasets (e.g. 63x, 93x), nonconnected structures belonging to the neuron, e.g. spines with thin necks, can be found. This may be due to the image noise, which prevents us from clearly detecting the edges of the neuron and thus the spines’ shape. To deal with this aspect, the algorithm was designed to include regions close (but not structurally-connected) to the neuron body by means of a dilation on its borders. As such, SmRG is enabled to identify the spines potentially belonging to the neuron we are segmenting. We tested our approach on 93x STED and 63x confocal images. We were able to segment the neuron and the spines in STED images. On the other hand, the higher amount of noise of confocal images may have limited the efficacy of our algorithm. Our results suggest that the statistical modeling of signal and noise of confocal and STED images may be a strategy for segmenting dendritic spines. Future developments will consider a generalization to different imaging techniques.

AIMS The growing interest on the morphology of whole neurons and dendritic spines demands for voxel-level precise segmentations. In images from ex-vivo clarified samples, the limited resolution of optical microscopy impairs the detection of gaps between close-by neurons in standard resolution and of spine necks in super-resolution images. This necessitates to post-process binary segmentations by splitting or grouping clusters, i.e. to define catchment basins for single neurons. We face this issue exploiting morphological reconstruction and topographic distance-based algorithms. METHODS We analyzed Purkinjie cells from L7GFP mouse cerebellum, processed with CLARITY protocol. We study two applications of the watershed transform: 1) to split the segmentation of dense 40x images into parcellations of separate whole-neuron structures; 2) to group clusters in a binary segmentation of branches and disconnected dendritic spines in 93x STED images. We employ Matlab routines to 1) morphologically reconstruct the image by imposing minima only within masks of disconnected neural cores; 2) apply a topographic distance-based watershed transform on the complement of the resulting image, to define the catchment basins. Final parcels are compared against manual segmentations. RESULTS On 40x images, we identified single neurons from densely connected segmentations (Fig1A). On 93x images, we obtained meaningful assignations of dendritic spines, with good scores when compared to manual gold-standard (Fig1B). CONCLUSIONS Topographic distance measures can be exploited to improve the usability of binary masks provided by neural segmentation tools that fails in isolating single neurons from dense structures. Moreover, we observed improvements in the characterization of spine

populations.

TWO PHOTON UNCAGING OF GLYCINE IN VITRO

POSTER SESSION 01 - SECTION: OPTOGENETICS & IMAGING

Graham Ellis-Davies[1], Simon Bossi[2], Dhanasak Dhanasobhon[3], Pierre Paoletti[2], Nelson Rebola[3]
[1]Mount Sinai, Neuroscience, New York, United States of America, [2]École normale supérieure Université PSL CNRS INSERM, Institut De Biologie De L'École Normale Supérieure (ibens), Paris, France, [3]Paris Brain Institute ICM, Cnrs, Inserm, Paris, France

In 1999-2000 I developed the first caged glutamate that was explicitly design for two-photon photolysis (Society for Neuroscience Annual Conference, 2000, 426.12). Electron-rich nitro-indolinyl caged acids such as MNI-glutamate and dinitro derivatives MDNI-Glu (aka DNI) and CNDI-Glu/GABA have proved extremely efficacious for photochemical probing of glutamate and GABA receptors in vitro. Here I describe the first example of a caged glycine designed for two-photon photolysis in complex brain tissue preparations in vitro. The caged glycine probe, called "CNI-Gly", was synthesized in 10 synthetic steps, and purified by preparative HPLC as its TFA salt. Comparative photolysis of CNI-Gly and MNI-Glu in cuvette revealed a quantum yield of photolysis of about 0.1. CNI-Gly was applied to interneurons from the dorsal horn of the spinal cord; irradiation with 1-ms pulses of 720 nm light evoked rapid, hyperpolaring currents. These were blocked by strychnine, indicating the expected inhibitory currents from classical ionotropic glycine receptors in this part of the CNS. We used CNI-Gly to probe the distribution of excitatory glycine receptors on pyramidal neurons in the basolateral amygdala. These currents arise from "unconventional" NMDA receptors consisting of GluN1 and GluN3a subunits. These currents were blocked by DKCA and enhanced by CGP-78608. No currents were detected in GluN3a knockout animals. Finally, unlike conventional NMDA receptors, no differential expression on spines versus dendritic shafts could be detected. Taken together, these data show CNI-Gly is a useful new photochemical probe for slice physiology using two-photon uncaging in vitro.

VISUAL ENCODING BY RETINAL GANGLION CELLS IN OPTOGENETIC MODELS FOR VISION RESTORATION

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Varsha Ramakrishna (She)[1,2,3], Tim Gollisch[2,3]
[1]International Max Planck Research School, Neurosciences, Goettingen, Germany, [2]Bernstein Center for Computational Neuroscience, Computational Neuroscience, Goettingen, Germany, [3]University Medical Center, Department Of Opthalmology, Goettingen, Germany

Retinal degeneration is one of the leading causes of blindness and optogenetics as a potential therapeutic measure has garnered much attention. Light-sensitive molecules like Channelrhodopsin (ChR2) and Opto-mGluR6, a chimeric GPCR consisting of mGluR6 and melanopsin (designed by van Wyk et al.,2015) are inserted into the neurons in the inner retina to play the role of photoreceptors after their loss. Previous studies showed responses of retinal ganglion cells (RGCs) to simple light stimuli in blind animal models with optogenetically modified retinas. Our study aims is to go beyond simple light stimuli and investigate encoding by RGCs responding to spatiotemporally complex stimuli in optogenetically modified retinas. Preliminary experiments using multielectrode array recordings with retinas expressing Opto-mGluR6 showed light-dependent construct-driven responses in the RGCs. On comparing the photoreceptor-evoked and construct-evoked responses, a sign inversion in the response polarity (ON to OFF) as reported in the original work was also seen here. However, weaker responses were seen to high frequency contrast changes on activation of the construct as compared to photoreceptor-evoked responses. This indicates that construct-evoked responses cannot drive temporal integration in the cells like those in a normal retina due to the kinetics of Opto-mGluR6 activation. Further detailed experiments are required to estimate how best the construct can be stimulated to mimic the responses of a normal retina and thus improve the methods to be the optimal candidate for vision restoration. NEURORETINAL CHANGES IN DIABETIC RETINOPATHY: COMPARISON BETWEEN HUMAN AND ZEBRAFISH MODEL

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Zulvikar Syambani Ulhaq[1,2]
[1]National Research and Innovation Agency, -, Jakarta, Indonesia, [2]Maulana Malik Ibrahim State Islamic University of Malang, Biomedical Science, Malang, Indonesia

Diabetic retinopathy (DR) is a frequent complication of diabetes, which comprises a complex interplay of microvascular changes and neurodegeneration. Retinal degeneration in DR is often irreversible and is closely attributed as a cause of blindness. Neuronal regeneration is usually impaired in diabetes, but its precise mechanisms have not been elucidated. Hence, this study aims to examine: 1) The changes of the retinal layer in patients with DR in comparison to the zebrafish model; 2) retina regeneration after insults in the zebrafish model of diabetes. 193 diabetic (51 NPDR and 142 PDR) and 83 healthy eyes were included. All retinal layers were significantly decreased in DR, but this observation was not found in the OPL. No significant changes of the retinal layers between NPDR and PDR. The findings indicated that the RNFL was potentially useful to identify the early development of DR in diabetic patients. In contrast to human findings, only the photoreceptor layer was decreased in the zebrafish model. The mechanical injury was performed to stimulate retina regeneration in zebrafish. Retina regeneration was suppressed in the injured retina exposed to 3% glucose, this plausibly due to the imbalance between cell death and proliferation mediated by the inhibition of Müller glia and brain aromatase activities. Interestingly, the addition of estradiol reversed the effects caused by glucose. Altogether, the results indicate that retinal thinning observed in DR may be associated with the impairment of retina regeneration and could be attributed to the dysfunction of Müller glia and aromatase.

Brain Aromatase Modulates Serotonergic Neuron by Regulating Serotonin Levels in Zebrafish Embryos and Larvae.
Teleost fish are known to express two isoforms of P450 aromatase, a key enzyme for estrogen synthesis. One of the isoforms, brain aromatase (AroB), , is highly expressed during early development of zebrafish, thereby suggesting its role in brain development. On the other hand, early development of serotonergic neuron, one of the major monoamine neurons, is considered to play an important role in neurogenesis. Therefore, in this study, we investigated the role of AroB in development of serotonergic neuron by testing the effects of (1) estradiol (E) exposure and (2) morpholino (MO)-mediated AroB knockdown. When embryos were exposed to E, the effects were biphasic. The low dose of E (0.005 μM) significantly increased serotonin (5-HT) positive area at 48 hour post-fertilization (hpf) detected by immunohistochemistry and relative mRNA levels of tryptophan hydroxylase isoforms (, and) at 96 hpf measured by semi-quantitative PCR. To test the effects on serotonin transmission, heart rate and thigmotaxis, an indicator of anxiety, were analyzed. The low dose also significantly increased heart rate at 48 hpf and decreased thigmotaxis. The high dose of E (1 μM) exhibited opposite effects in all parameters. The effects of both low and high doses were reversed by addition of estrogen receptor (ER) blocker, ICI 182,780, thereby suggesting that the effects were mediated through ER. When AroB MO was injected to fertilized eggs, 5-HT-positive area was significantly decreased, while the significant decrease in relative mRNA levels was found only with but not with two other isoforms. AroB MO also decreased heart rate and increased thigmotaxis. All the effects were rescued by co-injection with AroB mRNA and by exposure to E. Taken together, this study demonstrates the role of brain aromatase in development of serotonergic neuron in zebrafish embryos and larvae, implying that brain-formed estrogen is an important factor to sustain early development of serotonergic neuron.

Brain aromatase modulates cardiac functions in embryonic zebrafish.
Oestradiol (E) is known as a female reproductive hormone with pleiotropic effects on the cardiovascular system. Local E biosynthesis such as in the brain and myocardial cells have important physiological and pathophysiological roles. E production is catalysed by aromatase (Aro) enzyme. In teleost, two Aro isoforms are distinctly expressed in the ovary and

brain. In this study, the role of brain Aro (AroB) in modulating cardiovascular system is investigated. AroB MO-mediated knockdown decreased ventricular functions. Moreover, embryos injected with AroB MO displays a sign in developing heart failure. All the effects caused by AroB MO were partially reversed by exposure to E. Taken together, this study demonstrates the role of AroB in modulating normal cardiovascular function in zebrafish embryos.

The role of IL-6-174 G/C polymorphism and intraocular IL-6 levels in the pathogenesis of ocular diseases: a systematic review and meta-analysis.
Interleukin-6 (IL-6) is one of the key regulators behind the inflammatory and pathological process associated with ophthalmic diseases. The role of IL-6-174 G/C polymorphism as well as intraocular IL-6 levels among various eye disease patients differ across studies and has not been systematically reviewed. Thus, this study aims to provide a summary to understand the relationship between IL-6 and ophthalmic disease. In total, 8,252 and 11,014 subjects for IL-6-174 G/C and intraocular levels of IL-6, respectively, were retrieved from PubMed, Scopus and Web of Science. No association was found between IL-6-174 G/C polymorphisms with ocular diseases. Subgroup analyses revealed a suggestive association between the GC genotype of IL-6-174 G/C with proliferative diabetic retinopathy (PDR). Further, the level of intraocular IL-6 among ocular disease patients in general was found to be higher than the control group [standardized mean difference (SMD) = 1.41, 95% confidence interval (CI) 1.24-1.58, $P < 0.00001$]. Closer examination through subgroup analyses yielded similar results in several ocular diseases. This study thus indicates that the IL-6-174 G/C polymorphism does not predispose patients to ocular disease, although the GC genotype is likely to be a genetic biomarker for PDR. Moreover, intraocular IL-6 concentrations are related to the specific manifestations of the ophthalmic diseases. Further studies with larger sample sizes are warranted to confirm this conclusion.

A Brief Analysis of Proteomic Profile Changes during Zebrafish Regeneration.
Unlike mammals, zebrafish are capable to regenerate many of their organs, however, the response of tissue damage varies across tissues. Understanding the molecular mechanism behind the robust regenerative capacity in a model organism may help to identify and develop novel treatment strategies for mammals (including humans). Hence, we systematically analyzed the current literature on the proteome profile collected from different regenerated zebrafish tissues. Our analyses underlining that several proteins and protein families responsible as a component of cytoskeleton and structure, protein synthesis and degradation, cell cycle control, and energy metabolism were frequently identified. Moreover, target proteins responsible for the initiation of the regeneration process, such as inflammation and immune response were less frequently detected. This highlights the limitation of previous proteomic analysis and suggested a more sensitive modern proteomics analysis is needed to unfold the mechanism. This brief report provides a list of target proteins with predicted functions that could be useful for further biological studies.

Dopamine D2 receptor influences eye development and function in Zebrafish.
Dopamine is synthesized by tyrosine hydroxylase and is considered as a major catecholamine in the vertebrate retina, including zebrafish. However, little is known about the role of dopamine D2 receptor (DRD2) in retinal physiology. Therefore,

to elucidate the role of DRD2 in the eye development and function in zebrafish, fish were exposed to fluphenazine, quinpirole, or combination of both. Subsequently, the eye size, optic nerve diameter (ONd), and visual background adaptation were evaluated. The results showed that fluphenazine (fluphenazine, DRD2 antagonist) decreased eye size and optic nerve diameter followed by disruption of visual function. The addition of Quinpirole (quinpirole, DRD2 agonist) reversed the effects caused by fluphenazine, implying that DRD2 is necessary for normal eye development and function in zebrafish. Considering the role of dopaminergic neurons in retinal development and function, dysfunction of dopaminergic neuron signaling pathways in the retina may cause visual abnormalities, particularly in the involvement of dopamine in regulating light response.

TRANS-RESVERATROL EFFECTS ON DIABETES-INDUCED APOPTOSIS IN RETINAL PIGMENT EPITHELIUM IN WISTAR RATS

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Heba Alhussaini
Kuwait Health Science Center, Anatomy, Jabriya, Kuwait

Aim Diabetes-induced oxidative stress mediates retinal cell apoptosis leading to the onset of pathological changes related to diabetic retinopathy. This study investigated the modulatory effects of *trans*-resveratrol, a natural stilbene antioxidant, on type 1 diabetes-induced retinal pigment epithelial (RPE) cell apoptosis in Wistar rats. **Methods** Adult male rats (12-14-week-old) were segregated into 1) control, 2) control + *trans*-resveratrol (p.o., 5mg/kg/d for 90 days), 3) single dose Streptozotocin (55mg/kg, ip, glucose level >300 mg/kg considered diabetic) induced diabetic group, and 4) the diabetic group supplemented with *trans*-resveratrol. The eyeballs were dissected, the neural retina was separated from the RPE, and the eye cup containing the RPE was flat-mounted for immunofluorescence for caspases-9 and -3, and cytochrome C. The number and location of protein-labelled RPE cells were counted and mapped. The data were statistically analysed by the Mann-Whitney U test, and $p<0.05$ was considered significant. **Results** Immunofluorescence showed the clustering of apoptotic RPE cells, mainly at the centre of the RPE layer in the diabetic group. Diabetes increased the number of caspases-9 and -3 labelled RPE cells, but more caspase-3 positive cells, and showed a trend to increase the number of cytochrome C labelled cells. *Trans*-resveratrol supplementation showed a trend to reduce the positively labelled cells, but there were no statistically significant effects of the drug on induced apoptosis. **Conclusions** Prolonged type 1 diabetes increases the RPE cells to enter apoptotic phase, however, *trans*-resveratrol supplementation only shows a tendency to reduce the diabetes-induced apoptotic process in the RPE.

A NOVEL APPROACH TO ANALYZE WHITE NOISE ERGS IN MICE

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Nina Stallwitz, Anneka Joachimsthaler, Jan Kremers
University Hospital Erlangen, Eyeclinic, Erlangen, Germany

ERG measurements are a valuable tool to study retinal physiology. Normally they are recorded to bright flashes which are not physiological. We measured ERGs to temporal white noise (TWN) stimuli in mice, which are more natural. White noise ERGs (wnERGs) were recorded to luminance and opsin isolating TWN. Measurements were performed at different mean luminances (MLs); each recording was performed twice. To quantify the reproducibility, the ERG potentials of the two recordings were plotted against each other and the correlation coefficient (r^2_{repr}) of the linear regression was extracted. This was repeated for all MLs. For luminance stimuli r^2_{repr} values were minimal at -0.3 log cd/m² ML. r^2_{repr} values decreased with increasing MLs for rod isolating stimuli, whereas for cone isolating stimuli they increased with increasing ML. To study if underlying ERG mechanisms depend on ML, the ERG potentials at all MLs were plotted against those obtained at the highest ML for cones and at the lowest ML for rods. The r^2-coefficients (r^2_{ML}) of the linear regression were used to quantify the correlations between responses of different MLs. R^2_{ML} values for luminance, L- and S-opsin stimuli increased with increasing ML, whereas they decreased for rod stimuli. In conclusion rod signals drive the ERGs at low MLs and cones at high MLs.

Genetic disruption of bassoon in two mutant mouse lines causes divergent retinal phenotypes.
Bassoon (BSN) is a presynaptic cytomatrix protein ubiquitously present at chemical synapses of the central nervous system, where it regulates synaptic vesicle replenishment and organizes voltage-gated Ca channels. In sensory photoreceptor synapses, BSN additionally plays a decisive role in anchoring the synaptic ribbon, a presynaptic organelle and functional extension of the active zone, to the presynaptic membrane. In this study, we functionally and structurally analyzed two mutant mouse lines with a genetic disruption of Bsn-Bsn and Bsn -using electrophysiology and high-resolution microscopy. In both Bsn mutant mouse lines, full-length BSN was abolished, and photoreceptor synaptic function was similarly impaired, yet synapse structure was more severely affected in Bsn than in Bsn photoreceptors. The synaptic defects in Bsn retina coincide with remodeling of the outer retina-rod bipolar and horizontal cell sprouting, formation of ectopic ribbon synaptic sites-and death of cone photoreceptors, processes that did not occur in Bsn retina. An analysis of Bsn hybrid mice revealed that the divergent retinal phenotypes of Bsn and Bsn mice can be attributed to the expression of the Bsn allele, which triggers cone photoreceptor death and neurite sprouting in the outer retina. These findings shed new light on the existing Bsn mutant mouse models and might help to understand mechanisms that drive photoreceptor death.

Aims. Retinal dystrophies such as *Retinitis Pigmentosa* (*RP*) are the most common inherited progressive cause of blindness in developed countries affecting some 5.5 million patients, for which treatments are in demand. **Methods.** Retinal prostheses have been developed to stimulate the inner retinal network; however, the inner retinal circuits, although initially spared by neurodegeneration, undergo complex rearrangements and deteriorate in the advanced stages of the disease. We recently reported that conjugated polymer nanoparticles, by virtue of their intrinsic light-induced charge generation, persistently rescue visual activities when subretinally injected in the Royal College of Surgeons (RCS) rat model of *RP.* This rat strain bears a null mutation in the *Mertk* gene that impairs the function of the retinal pigment epithelium (RPE) causing a cone-rod degeneration. **Results.** Here, we demonstrate that conjugated polymer nanoparticles, when microinjected in 10-months-old RCS rats bearing fully light-insensitive and intensely remodeled retinas, reinstate visually driven activities at both subcortical and cortical levels. The efficacy of these nanoparticles in restoring vision is indicated by absence of any recovery in visual activities in sham-injected rats. **Conclusions.** These results highlight the potential clinical relevance of conjugated polymer nanoparticles in restoring visual functions in fully degenerate retinas, completely devoid of residual photoreceptors, and in the presence of a severe inner retinas rewiring, an advanced stage of the disease in which patients affected by *RP* are subjected to prosthetic interventions.

Evolution of spatially coexpressed families of type-2 vomeronasal receptors in rodents.
The vomeronasal organ (VNO) is an olfactory structure for the detection of pheromones. VNO neurons express three groups of unrelated G-protein-coupled receptors. Type-2 vomeronasal receptors (V2Rs) are specifically localized in the basal neurons of the VNO and are believed to sense protein pheromones eliciting specific reproductive behaviors. In murine species, V2Rs are organized into four families. Family-ABD V2Rs are expressed monogenically and coexpress with family-C V2Rs of either subfamily C1 (V2RC1) or subfamily C2 (V2RC2), according to a coordinate temporal diagram. Neurons expressing the phylogenetically ancient V2RC1 coexpress family-BD V2Rs or a specific group of subfamily-A V2Rs (V2RA8-10), whereas a second neuronal subset (V2RC2-positive) coexpresses a recently expanded group of five subfamily-A V2Rs (V2RA1-5) along with vomeronasal-specific Major Histocompatibility Complex molecules (H2-Mv). Through database mining and Sanger sequencing, we have analyzed the onset, diversification, and expansion of the V2R-families throughout the phylogeny of Rodentia. Our results suggest that the separation of V2RC1 and V2RC2 occurred in a Cricetidae ancestor in coincidence with the evolution of the H2-Mv genes; this phylogenetic event did not correspond with the origin of the coexpressing V2RA1-5 genes, which dates back to an ancestral myomorphan lineage. Interestingly, the evolution of receptors within the V2RA1-5 group may be implicated in the origin and diversification of some of the V2R putative cognate ligands, the exocrine secreting peptides. The establishment of V2RC2, which probably reflects the complex expansion and diversification of family-A V2Rs, generated receptors that have probably acquired a more subtle functional specificity.

Hyperinsulinemia Promotes Esophageal Cancer Development in a Surgically-Induced Duodeno-Esophageal Reflux Murine Model.
Hyperinsulinemia could have a role in the growing incidence of esophageal adenocarcinoma (EAC) and its pre-cancerous lesion, Barrett's Esophagus, a possible consequence of Gastro-Esophageal Reflux Disease. Obesity is known to mediate esophageal carcinogenesis through different mechanisms including insulin-resistance leading to hyperinsulinemia, which may mediate cancer progression via the insulin/insulin-like growth factor axis. We used the hyperinsulinemic non-obese FVB/N (Friend leukemia virus B strain) MKR (muscle (M)-IGF1R-lysine (K)-arginine (R) mouse model to evaluate the exclusive role of hyperinsulinemia in the pathogenesis of EAC related to duodeno-esophageal reflux. FVB/N wild-type (WT) and MKR mice underwent jejunum-esophageal anastomosis side-to end with the exclusion of the stomach. Thirty weeks after surgery, the esophagus was processed for histological, immunological and insulin/Insulin-like growth factor 1 (IGF1) signal transduction analyses. Most of the WT mice (63.1%) developed dysplasia, whereas most of the MKR mice (74.3%) developed squamous cell and adenosquamous carcinomas, both expressing Human Epidermal growth factor receptor 2 (HER2). Hyperinsulinemia significantly increased esophageal cancer incidence in the presence of duodenal-reflux. Insulin receptor (IR) and IGF1 receptor (IGF1R) were overexpressed in the hyperinsulinemic condition. IGF1R, through ERK1/2 mitogenic pattern activation, seems to be involved in cancer onset. Hyperinsulinemia-induced IGF1R and HER2 up-regulation could also increase the possibility of forming of IGF1R/HER2 heterodimers to support cell growth/proliferation/progression in esophageal carcinogenesis.

Axonal Odorant Receptors Mediate Axon Targeting.
In mammals, odorant receptors not only detect odors but also define the target in the olfactory bulb, where sensory neurons project to give rise to the sensory map. The odorant receptor is expressed at the cilia, where it binds odorants, and at the axon terminal. The mechanism of activation and function of the odorant receptor at the axon terminal is, however, still unknown. Here, we identify phosphatidylethanolamine-binding protein 1 as a putative ligand that activates the odorant receptor at the axon terminal and affects the turning behavior of sensory axons. Genetic ablation of phosphatidylethanolamine-binding protein 1 in mice results in a strongly disturbed olfactory sensory map. Our data suggest that the odorant receptor at the axon terminal of olfactory neurons acts as an axon guidance cue that responds to molecules originating in the olfactory bulb. The dual function of the odorant receptor links specificity of odor perception and axon targeting.

The role of the odorant receptors in the formation of the sensory map.
In the olfactory system, odorant receptors (ORs) expressed at the cell membrane of olfactory sensory neurons detect odorants and direct sensory axons toward precise target locations in the brain, reflected in the presence of olfactory sensory maps. This dual role of ORs is corroborated by their subcellular expression both in cilia, where they bind odorants, and at axon terminals, a location suitable for axon guidance cues. Here, we provide an overview and discuss previous work on the role of ORs in establishing the topographic organization of the olfactory system and recent findings on the mechanisms of activation and function of axonal ORs.

Altered Cl homeostasis hinders forebrain GABAergic interneuron migration in a mouse model of intellectual disability.
Impairments of inhibitory circuits are at the basis of most, if not all, cognitive deficits. The impact of OPHN1, a gene associate with intellectual disability (ID), on inhibitory neurons remains elusive. We addressed this issue by analyzing the postnatal migration of inhibitory interneurons derived from the subventricular zone in a validated mouse model of ID (OPHN1 mice). We found that the speed and directionality of migrating neuroblasts were deeply perturbed in OPHN1 mice. The significant reduction in speed was due to altered chloride (Cl) homeostasis, while the overactivation of the OPHN1 downstream signaling pathway, RhoA kinase (ROCK), caused abnormalities in the directionality of the neuroblast progression in mutants. Blocking the cation-Cl cotransporter KCC2 almost completely rescued the migration speed while proper directionality was restored upon ROCK inhibition. Our data unveil a strong impact of OPHN1 on GABAergic inhibitory interneurons and identify putative targets for successful therapeutic approaches.

Pericyte, but not astrocyte, hypoxia inducible factor-1 (HIF-1) drives hypoxia-induced vascular permeability in vivo.
Ways to prevent disease-induced vascular modifications that accelerate brain damage remain largely elusive. Improved understanding of perivascular cell signalling could provide unparalleled insight as these cells impact vascular stability and functionality of the neurovascular unit as a whole. Identifying key drivers of astrocyte and pericyte responses that modify cell-cell interactions and crosstalk during injury is key. At the cellular level, injury-induced outcomes are closely entwined with activation of the hypoxia-inducible factor-1 (HIF-1) pathway. Studies clearly suggest that endothelial HIF-1 signalling increases blood-brain barrier permeability but the influence of perivascular HIF-1 induction on outcome is unknown. Using novel mouse lines with astrocyte and pericyte targeted HIF-1 loss of function, we herein show that vascular stability in vivo is differentially impacted by perivascular hypoxia-induced HIF-1 stabilization.

A CAV1.4 L-TYPE CALCIUM CHANNEL TRUNCATION MUTATION AFFECTS THE RETINAL ROD PATHWAY

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Matthias Ganglberger[1], Dagmar Knoflach[2], Hartwig Seitter[1], Lucia Zanetti[1], Emilio Casanova[2], Bettina Wagner[3], Thomas Rülicke[3], Alexandra Koschak[1]
[1]University of Innbruck, Institute Of Pharmacy, Pharmacology And Toxicology Unit, Innsbruck, Austria, [2]Medical University of Vienna, Center For Physiology And Pharmacology, Vienna, Austria, [3]University of Veterinary Medicine, Department Of Biomedical Sciences, Vienna, Austria

L-type calcium channels (LTCC) are the main regulators for cellular events, like excitation-contraction coupling, transmitter release and hormone secretion. In the retina, the Cav1.4 LTCCs are predominantly expressed at the synaptic terminals of photoreceptors in the outer plexiform layer (OPL) to support tonic glutamate release. In patients, mutations in the *CACNA1F* gene, which encodes Cav1.4 channels can cause congenital stationary night blindness type 2 (CSNB2). In this study we investigated a C-terminal truncation mutation in the Cav1.4 channel (Cav1.4-RX). Heterologously expressed Cav1.4-RX channels showed calcium-dependent inactivation, which is normally not present in this LTCC isoform. The aim of the current study is to examine morphological and functional changes in mice carrying the truncation mutation Cav1.4-R1827X (Cav1.4-RX) comparing to a gain-of-function mutation, Cav1.4-I756T (Cav1.4-IT) and wildtype mice via immunohistochemical analyses and functional (multielectrode array, MEA) analyses. Initial immunohistochemical studies showed significant changes in the retinal morphology comparable to the Cav1.4-IT retinas: in addition to changes in the presynaptic ribbon structure we also found neurite sprouting of second-order neurons. However, cones seemed to be largely unaffected; a finding that is in contrast to Cav1.4-IT. This difference is also seen in MEA recordings in which ganglion cell responses were mainly affected under scotopic conditions suggesting that the truncation primarily affects the rod pathway. This observation could be explained by a difference in the protein composition in rod and cone photoreceptor terminals. Further investigations will include a proteomic approach to fully understand the molecular mechanism of the distal C-terminal part of Cav1.4 channels.

CHARACTERIZATION OF TWO PATHOLOGICAL CAV1.4 L-TYPE CALCIUM CHANNEL VARIANTS

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Thomas Heigl[1], Michael Netzer[1,2], Matthias Ganglberger[1], Xuechen Tang[3], Monica Fernandez-Quintero[3], Alexandra Koschak[1]
[1]University of Innsbruck, Institute Of Pharmacy, Pharmacology And Toxicology Unit, Innsbruck, Austria, [2]University of Vienna, Department: Pharmaceutical Sciences, Division Of Pharmacology And Toxicology, Vienna, Austria, [3]University of Innsbruck, General, Inorganic And Theoretical Chemistry, Innsbruck, Austria

Aims: Cav1.4 L-type calcium channels are predominantly expressed at retinal synapses, mediating neurotransmitter release. Mutations in its gene, *CACNA1F*, can cause congenital stationary night-blindness type 2 (CSNB2), an X-linked disease that can manifest in variable levels of night-blindness but also photophobia or low visual acuity. This project aims to elucidate the biophysical properties of two variants, Cav1.4-R964G and Cav1.4-R1288L (JF701915.1), both S4 charge-neutralizing mutants reported in CSNB2 patients. **Methods:** Cav1.4 variants were produced in Flp-In-293 cells, which stably expressed β3 and α2δ1 auxiliary subunits (electrophysiology), whereas tsA-201 cells were transiently co-transfected with their ancillary subunits (western blot). We combined homology modelling with molecular dynamics simulations to understand the functional effects at atomistic detail. **Results:** Cav1.4-R964G and Cav1.4-R1288L were less expressed in the membrane *in vitro*, indicated by western blot analyses. This finding is in accordance with whole-cell patch-clamp recordings, which revealed a reduction of current density compared to wild type channels, with Cav1.4-R964G having 23% and Cav1.4-R1288L 12.4% of the wild type current density. Consistent with a loss of gating charges, both substitutions lead to a significantly increased slope of voltage-dependent activation while Cav1.4-R1288L also shifts the voltage-dependence of activation towards more positive potentials. In agreement with these observations, we find that Cav1.4-R1288L destabilizes the activated state, while Cav1.4-R964G diminishes interactions in intermediate resting states with the inner negative cluster. **Conclusions:** The detected changes in expression level and biophysical properties for Cav1.4-R964G and Cav1.4-R1288L likely account for differences in signal transmission in retinal cells, thus leading to CSNB2.

The monothiol glutaredoxin GrxD is essential for sensing iron starvation in Aspergillus fumigatus.
Efficient adaptation to iron starvation is an essential virulence determinant of the most common human mold pathogen, Aspergillus fumigatus. Here, we demonstrate that the cytosolic monothiol glutaredoxin GrxD plays an essential role in iron sensing in this fungus. Our studies revealed that (i) GrxD is essential for growth; (ii) expression of the encoding gene, grxD, is repressed by the transcription factor SreA in iron replete conditions and upregulated during iron starvation; (iii) during iron starvation but not iron sufficiency, GrxD displays predominant nuclear localization; (iv) downregulation of grxD expression results in de-repression of genes involved in iron-dependent pathways and repression of genes involved in iron acquisition during iron starvation, but did not significantly affect these genes during iron sufficiency; (v) GrxD displays protein-protein interaction with components of the cytosolic iron-sulfur cluster biosynthetic machinery, indicating a role in this process, and with the transcription factors SreA and HapX, which mediate iron regulation of iron acquisition and iron-dependent pathways; (vi) UV-Vis spectra of recombinant HapX or the complex of HapX and GrxD indicate coordination of iron-sulfur clusters; (vii) the cysteine required for iron-sulfur cluster coordination in GrxD is in vitro dispensable for interaction with HapX; and (viii) there is a GrxD-independent mechanism for sensing iron sufficiency by HapX; (ix) inactivation of SreA suppresses the lethal effect caused by GrxD inactivation. Taken together, this study demonstrates that GrxD is crucial for iron homeostasis in A. fumigatus.

Cav1.4 dysfunction and congenital stationary night blindness type 2.
Cav1.4 L-type Ca channels are predominantly expressed in retinal neurons, particularly at the photoreceptor terminals where they mediate sustained Ca entry needed for continuous neurotransmitter release at their ribbon synapses. Cav1.4 channel gating properties are controlled by accessory subunits, associated regulatory proteins, and also alternative splicing. In

humans, mutations in the CACNA1F gene encoding for Cav1.4 channels are associated with X-linked retinal disorders such as congenital stationary night blindness type 2. Mutations in the Cav1.4 protein result in a spectrum of altered functional channel activity. Several mouse models broadened our understanding of the role of Cav1.4 channels not only as Ca source at retinal synapses but also as synaptic organizers. In this review, we highlight different structural and functional phenotypes of Cav1.4 mutations that might also occur in patients with congenital stationary night blindness type 2. A further important yet mostly neglected aspect that we discuss is the influence of alternative splicing on channel dysfunction. We conclude that currently available functional phenotyping strategies should be refined and summarize potential specific therapeutic options for patients carrying Cav1.4 mutations. Importantly, the development of new therapeutic approaches will permit a deeper understanding of not only the disease pathophysiology but also the physiological function of Cav1.4 channels in the retina. FUNCTIONAL RESPONSES OF THE RETINA AND STRUCTURE OF THE VISUAL PROJECTIONS IN ALBINO MICE

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Virginie Chotard, Francesco Trapani, Berat Sermet, Alain Chédotal, Pierre Yger, Olivier Marre, Alexandra Rebsam
Institut de la Vision, Sorbonne Université, Inserm, Cnrs, PARIS, France

Visual perception is based on a precise architecture of the retina and visual pathways. In albinism, the hypopigmentation of the retinal pigment epithelium (RPE) alters the structure of the visual pathways during development, resulting in poor visual acuity and abnormal binocular vision. Here, we characterize the deficits in the retina and visual projections of an albino mouse model ($Tyr^{c/c}$). First, we studied the ratio of RGC projections from both eyes into their brain targets as fewer RGCs project ipsilaterally in albino mammals. Using fluorescent tracers, iDISCO+ clearing and whole brain imaging with light-sheet microscopy, we showed that the volume of ipsilateral projections in the dorsal lateral geniculate nucleus of albino $Tyr^{c/c}$ mice are decreased compared to $Tyr^{c/+}$ mice, but similar in the suprachiasmatic nucleus (SCN). It suggests different targeting mechanisms for the RGCs innervating the SCN. Second, we compared the expression of various opsins labelling subtypes of photoreceptors (S- and M-opsin) or intrinsically photosensitive retinal ganglion cells (ipRGCs, melanopsin) in the retina, to determine whether their proportion and distribution are altered in albino mice. Finally, we recorded the electrophysiological responses of RGCs to light by multi-electrode array recording to determine whether a change in the RGC receptive field diameter could explain the low visual acuity in albino mice. Surprisingly, no difference was found, neither in the receptive field diameters nor in the functional population of RGCs, suggesting another origin for the low visual acuity. Multi-scale analysis of the albino phenotype is a prerequisite to study RPE regulation of retinal development.

CONTEXT-DEPENDENT SELECTIVITY TO NATURAL IMAGES IN THE RETINA

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Matías Goldin[1], Baptiste Lefebvre[1], Samuele Virgili[1], Alexander Ecker[2], Thierry Mora[3], Ulisse Ferrari[1], Olivier Marre[4]
[1]Institut de la Vision, Sorbonne Université, Inserm, Cnrs, Paris, France, [2]University of Göttingen, Institute Of Computer Science And Campus Institute Data Science, Göttingen, Germany, [3]Ecole normale supérieure, Laboratoire De Physique Ens, Cnrs, Psl University, Sorbonne University, And University Of Paris, PARIS, France, [4]Institut de la Vision, Sorbonne Université, Inserm, Cnrs, PARIS, France

Understanding how sensory neurons extract relevant information from natural scenes is a major challenge in neuroscience. Even in the retina, is not clear how Retinal ganglion cells (RGC) extract specific features from natural scenes and send this information to the brain. Many studies using simple, artificial stimuli have shown responses to local light increase (ON-responses), and/or decrease (OFF), but it is unclear if this selectivity is maintained when processing natural stimuli. Other works tried learning non-linear models to predict RGC responses to natural stimuli, but are hard to interpret. Here we address these issues using a novel perturbative approach taking the best of these two strategies, by probing selectivity with perturbations added to natural scenes. We stimulated mouse and axolotl retinas with natural images, adding small checkerboard-like perturbations on top. We found that ON-OFF selectivity strongly depended on the image. RGCs can thus switch from ON to OFF depending on the context. We designed a convolutional neural network model to explain this, and mapped it to specific retinal circuits. Pharmacological experiments and modeling showed that selectivity changes were due to the non-linear combination of retinal pathways. Finally, using dimensionality reduction and gradient field representations, we demonstrated that this context dependence is compatible with a robust computation of a more abstract feature: contrast. Our perturbative approach thus uncovers neuronal selectivity to more complex features than initially thought during natural scene stimulation and could be applied in other sensory systems to refine models or test hypotheses about features extracted from sensory inputs.

RETINAL VASCULAR DYSREGULATION IN ALTITUDINAL VISUAL FIELD DEFECTS IN GLAUCOMA

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Wanshu Zhou, Bernhard A. Sabel
Institute of Medical Psychology, Medical Faculty, Otto-von-guericke University Of Magdeburg, Magdeburg, Germany

Aims: Healthy vision depends on both, neuronal excitability and healthy neurovascular coupling (NVC). To relate the extend to vision loss to central neurovascular regulation, we imaged retinal blood vessels at high resolution to study the relationship between retinal vessel dynamics during neural activation and neurological (visual field) function in glaucoma. Methods: With the dynamic vessel analyzer (DVA) we quantified retinal vessel diameters and dilation responses following flickering light stimulation in 30 subjects with primary open angle glaucoma compared to 22 age-matched healthy subjects. Vessel dynamics was then related to severity of glaucomatous visual field loss. Results: The average vessels diameter in glaucoma was smaller than in controls (artery: 90.6 vs. 94.8 µm, p=0.003, vein: 104.9 vs. 107.3 µm, p=0.48), but when exposing the retina to flickering light, venous maximal dilation was greater in glacuoma patients (p<0.001), i.e. dilation reached normal values despite having smaller diameters. However, venous maximal dilation was smallest in regions of the retina correspond to regions of the visual field with moderate vision loss and largest in intact regions and those with mild or severe vision loss (p=0.029), with a similar tendency in arteries. Smaller vessels had the greatest vascular dysregulation. Conclusions: The observation that NVC-impairment was most pronounced in regions of moderate functional loss - not in regions of normal, mild or severe vision loss – was rather surprising. It suggests that vascular dysregulation is not distributed uniformly throughout the retina. The functional implications of why NVC is greatest in moderate functional loss needs further study.

IDENTIFICATION OF TYROSINE HYDROXYLASE-IMMUNOREACTIVE AMACRINE CELLS IN THE GERBIL RETINA

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Hansaem Chung, Chang-Jin Jeon
Kyungpook National University, Department Of Biology, School Of Life Sciences, Bk21 Four Knu Creative Bio-research Group, College Of Natural Sciences, Brain Science And Engineering Institute, Daegu, Korea, Republic of

Gerbil's diurnality, with a higher proportion of retinal cones compared to nocturnal mice and rats, gives specific advantages for studies on the central visual system. The purpose of this study was to characterize tyrosine hydroxylase (TH)-immunoreactive (IR) cells in the gerbil retina using immunocytochemistry and confocal microscopy. Based on dendritic morphologies and stratification patterns, at least four subtypes of TH-IR cells were observed. The first subtype had monostratified dense plexus in substrata (s) 1 of the inner plexiform layer. The second subtype had three stratifications of plexuses in s1, s3 and s5. The third subtype also had three stratifications like the second one, with additional processes ascending to the outer plexiform layer. The fourth subtype was displaced to the ganglion cell layer, which was less than 5 cells/retina. TH-IR cells were wide-field amacrine cells and typically had 2–5 primary processes, derived from the soma. The dendritic processes extensively overlapped with neighboring TH-IR cells forming thick dendritic plexuses. Double-immunofluorescence study with calcium-binding proteins showed that TH-IR cells colocalized only with some calbindin (CB)-IR cells, but not with calretinin (CR)- or parvalbumin (PV)-IR cells. Some CR-IR cells were encircled by the ring-like structures composed of processes of TH-IR cells. Vesicular nucleotide transporter expression was found in all TH-IR cells, indicating that ATP release from TH-IR cells. This study showed at least four subtypes of TH-IR cells in the gerbil retina and could provide valuable data for the diverse role of dopamine in the retina of diurnal animals.

The Organization of Somatostatin-Immunoreactive Cells in the Visual Cortex of the Gerbil.
Somatostatin (SST) is widely expressed in the brain and plays various, vital roles involved in neuromodulation. The purpose of this study is to characterize the organization of SST neurons in the Mongolian gerbil visual cortex (VC) using immunocytochemistry, quantitative analysis, and confocal microscopy. As a diurnal animal, the Mongolian gerbil provides us with a different perspective to other commonly used nocturnal rodent models. In this study, SST neurons were located in all layers of the VC except in layer I; they were most common in layer V. Most SST neurons were multipolar round/oval or stellate cells. No pyramidal neurons were found. Moreover, 2-color immunofluorescence revealed that only 33.50%, 24.05%, 16.73%, 0%, and 64.57% of SST neurons contained gamma-aminobutyric acid, calbindin-D28K, calretinin, parvalbumin, and calcium/calmodulin-dependent protein kinase II, respectively. In contrast, neuropeptide Y and nitric oxide synthase were abundantly expressed, with 80.07% and 75.41% in SST neurons, respectively. Our immunocytochemical analyses of SST with D and D dopamine receptors and choline acetyltransferase, α and β nicotinic acetylcholine receptors suggest that dopaminergic and cholinergic fibers contact some SST neurons. The results showed some distinguishable features of SST neurons and provided some insight into their afferent circuitry in the gerbil VC. These findings may support future studies investigating the role of SST neurons in visual processing.

CELL-TYPE-SPECIFIC DENDRITIC CHANGES IN THE MOUSE RETINA DURING DEVELOPMENT AND IN RESPONSE TO INJURY

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Joana Santos[1,2,3], Luca Masin[2], Bram Nuttin[1,2,3], Chen Li[1,2,3], Lieve Moons[2], Karl Farrow[1,2,3]
[1]imec, VIB, KU Leuven, Neuro-electronics Research Flanders (nerf), Leuven, Belgium, [2]KU Leuven, Department Of Biology & Leuven Brain Institute, Leuven, Belgium, [3]KU Leuven, Vib, Leuven, Belgium

In the central nervous system of adult mammals, neurons naturally fail to regenerate their axons after injury. During development, by contrast, neurons grow axons effectively. It has been shown that neuronal types differ dramatically in their resilience to injury or other insults. For example, among all the retinal ganglion cells (RGCs) that survived best are the alpha-RGCs. However, even among these molecularly defined cell types, their resilience differs with stratification. This makes alpha-RGCs a great starting point to understand what makes transcriptionally similar cells respond differently to injury. Here, we aim to understand the relationship between dendritic morphology and the ability of axons to regrow after injury. In this project, first, we documented the emergence of the characteristic dendritic features of RGCs physiology during development; to find the cell type-specific rules of dendritic growth. Second, we studied the selective resilience of mouse retinal ganglion cells following optic nerve crush, which results in traumatic damage to axons and leads to the death of 80% of retinal ganglion cells within a period of 2 weeks. We characterized the changes in dendritic morphology that preceded degeneration. As numerous neurodegenerative diseases have been linked to early dendritic defects, we believe that comparing these relationships will provide an important basis for future work on promoting neuronal repair in the damaged mammalian central nervous system and possible treatments for visual neuropathies. Understanding the mechanisms involved in the developmental growth and response to injury may give us insights into how to restore functioning neuronal connectivity after injury.

A Fair Assessment of Evaluation Tools for the Murine Microbead Occlusion Model of Glaucoma.
Despite being one of the most studied eye diseases, clinical translation of glaucoma research is hampered, at least in part, by the lack of validated preclinical models and readouts. The most popular experimental glaucoma model is the murine microbead occlusion model, yet the observed mild phenotype, mixed success rate, and weak reproducibility urge for an expansion of available readout tools. For this purpose, we evaluated various measures that reflect early onset glaucomatous changes in the murine microbead occlusion model. Anterior chamber depth measurements and scotopic threshold response recordings were identified as an outstanding set of tools to assess the model's success rate and to chart glaucomatous damage (or neuroprotection in future studies), respectively. Both are easy-to-measure, in vivo tools with a fast acquisition time and high translatability to the clinic and can be used, whenever judged beneficial, in combination with the more conventional measures in present-day glaucoma research (i.e., intraocular pressure measurements and post-mortem histological analyses). Furthermore, we highlighted the use of dendritic arbor analysis as an alternative histological readout for retinal ganglion cell density counts.

Validation of a prototype tau Thr231 phosphorylation CSF ELISA as a potential biomarker for Alzheimer's disease.
Alzheimer's disease (AD) is a progressive neurodegenerative disorder characterized by the presence of extracellular amyloid plaques (senile plaques) and intracellular neurofibrillary tangles formed by hyperphosphorylated tau protein. This process leads to neuronal degradation and neuronal death. Phosphorylation of tau protein at threonine 231 (p-tau231) has been shown to be characteristic in post-mortem brain tissue of patients with AD and it can be sensitively detected in cerebrospinal fluid (CSF). Therefore, it may serve as a biomarker to support the diagnosis of AD. In this study, we analysed how well p-tau231 could differentiate between patients suffering from dementia either due or not due to AD by a sandwich enzyme immunoassay. CSF p-tau231 was significantly higher in patients with dementia due to AD than in those with dementia due to other causes. In addition, we studied different factors affecting p-tau231 levels in CSF. We found that apolipoprotein E

genotype influences p-tau231 CSF levels. Gender and age did not affect p-tau231 levels in CSF. Our findings indicate that p-tau231 levels in CSF can be a valuable marker for the clinical diagnosis of AD.

THE INTERPHOTORECEPTOR MATRIX: INVESTIGATING THE ROLE OF IMPG2 IN ZEBRAFISH RETINAL DEVELOPMENT AND FUNCTION

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Maria Elena Castellini[1], Andrea Messina[1,2], Giovanni Spagnolli[1], Lucia Poggi[1,3], Emiliano Biasini[1,3], Simona Casarosa[1,3]
[1]University of Trento, Department Of Cibio, Trento, Italy, [2]University of Trento, Cimec, Rovereto, Italy, [3]University of Trento, Cismed, Trento, Italy

Retinitis pigmentosa (RP) is one of the most commonly inherited retinal dystrophies, characterized by progressive degeneration of photoreceptors. Recent studies have reported that nonsense mutations in the interphotoreceptor matrix proteoglycan 2 (IMPG2) gene are associated with autosomal recessive RP in humans. This gene encodes the proteoglycan IMPG2 expressed in the interphotoreceptor matrix that surrounds retinal photoreceptor outer segments and ellipsoids. We chose zebrafish to investigate Impg2 function and expression, as its retinal structure is similar to the human macula. Zebrafish has two Impg2 paralogues, Impg2a and Impg2b. Phylogenetic analysis confirmed that teleosts are the only vertebrate group with two paralogues, consistently with the whole genome duplication that occurred in the common teleosts ancestor. Homology modelling of IMPG2 conserved domains in human and in zebrafish, showed structure similarity of the domains in the two species. Moreover, expression analyses revealed that impg2a and impg2b starts to be expressed at 3 days post fertilization and their expression is eye-specific in the adult. Interestingly, we observed that Impg2 localization changes over time. Microinjection of antisense morpholino oligonucleotides, specific for impg2a and impg2b, provided preliminary evidence that Impg2 is involved in eye development. Finally, we are generating a zebrafish line carrying the human IMPG2 mutation, by using CRISPR/Cas9 technology. Preliminary experiments on Impg2a -/- mutant fish showed alteration of the photoreceptor layer with respect to the WT. We planned to better characterize the phenotype of single and double mutants and perform large-scale testing of therapeutic compounds on this new zebrafish model.

Impaired Neuronal Differentiation of Neural Stem Cells Lacking the Engrailed-2 Gene.
The Engrailed-2 (En2) gene codes for a homeobox-containing transcription factor, involved in midbrain-hindbrain embryonic development. In postnatal brain, En2 is expressed in the ventral mesencephalon, cerebellum, hippocampus and neocortex. Two single-nucleotide polymorphisms (SNPs) that are associated to autism spectrum disorders (ASD) have been identified in the human EN2 gene. Accordingly, mice lacking the En2 homeodomain (En2, referred to as En2) show molecular, anatomical and behavioral "ASD-like" features. Among these, we previously showed a partial loss of GABAergic interneurons in the En2 postnatal hippocampus and neocortex, accompanied by a marked decrease of brain-derived neurotrophic factor (BDNF) signaling, a crucial determinant of GABAergic differentiation. In order to better investigate the role of En2 in GABAergic interneuron differentiation, we generated and subsequently differentiated neural stem cells (NSCs) from basal ganglia and neocortex of En2 and En2 mouse embryos. Wild-type NSCs from both basal ganglia and neocortex express En2, while mutant ones do not, as expected. As compared to En2 NSCs, En2 NSCs derived from basal ganglia show impaired GABAergic differentiation accompanied by a reduced expression of the BDNF receptor trkB. Conversely, En2 NSCs derived from the neocortex expressed high levels of trkB and readily differentiated into neurons, as En2 NSCs. Our results suggest that En2 contributes to GABAergic neuron differentiation from basal ganglia NSCs through a trkB-dependent BDNF signaling, thus providing a possible explanation for the reduced number of GABAergic interneurons detected in the En2 postnatal forebrain.

HOW THE USE OF DIM RED-LIGHT DURING PREPARATION AFFECTS ERG RESPONSES OF MICE WITH LONG-WAVELENGTH SHIFTED OPSIN

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Anneka Joachimsthaler, Karin Stüwe, Jan Kremers
University Hospital Erlangen, Eyeclinic, Erlangen, Germany

Electroretinograms (ERGs) give insight in retinal integrity *in vivo*. For ERGs in mice, visible red light is often used for preparation. Here we show, how ERGs of (LIAIS) mice, expressing human L*-opsin instead of native M-opsin, are affected by the pre-recording use of visible red light, that may lead to L*-opsin activation. Recordings were performed on LIAIS and wildtype (WT) mice. Mice were dark adapted overnight and further handling was done either under dim red light or IR light performed in two separate sessions. Anesthetized animals were dark adapted for 10 min before scotopic flash ERGs with flash strengths increasing from 0.0002 to 6.3 cd.s/m² were recorded. For photopic flash ERGs, animals were adapted for 2 min to 25 cd/m² white background, before flashes between 0.63 to 16 cd.s/m² were presented upon the background. Responses to scotopic flash ERGs using red light were 10-16% smaller in LIAIS compared to WT mice. Use of IR light resulted in larger amplitudes of scotopic a- and b-wave for both genotypes, but the increase was 8-16% larger in LIAIS mice. OPs and implicit times did not depend on the light source used for preparation. For photopic flash ERGs, IR light usage pre-recording increased LIAIS amplitudes by 14%. The use of IR light for mouse handling resulted in larger ERG responses for both genotypes. Even though the use of IR light seems to ensure a more dark-adapted state for the animals, handling is quite challenging and substantially prolonged the total time of the experiment.

Cell Types and Synapses Expressing the SNARE Complex Regulating Proteins Complexin 1 and Complexin 2 in Mammalian Retina.
Complexins (Cplxs) 1 to 4 are components of the presynaptic compartment of chemical synapses where they regulate important steps in synaptic vesicle exocytosis. In the retina, all four Cplxs are present, and while we know a lot about Cplxs 3 and 4, little is known about Cplxs 1 and 2. Here, we performed in situ hybridization experiments and bioinformatics and exploited Cplx 1 and Cplx 2 single-knockout mice combined with immunocytochemistry and light microscopy to characterize in detail the cell type and synapse-specific distribution of Cplx 1 and Cplx 2. We found that Cplx 2 and not Cplx 1 is the main isoform expressed in normal and displaced amacrine cells and ganglion cells in mouse retinae and that amacrine cells seem to operate with a single Cplx isoform at their conventional chemical synapses. Surprising was the finding that retinal function, determined with electroretinographic recordings, was altered in Cplx 1 but not Cplx 2 single-knockout mice. In summary, the results provide an important basis for future studies on the function of Cplxs 1 and 2 in the processing of visual signals in the mammalian retina.

Genetic disruption of bassoon in two mutant mouse lines causes divergent retinal phenotypes.
Bassoon (BSN) is a presynaptic cytomatrix protein ubiquitously present at chemical synapses of the central nervous system, where it regulates synaptic vesicle replenishment and organizes voltage-gated Ca channels. In sensory photoreceptor synapses, BSN additionally plays a decisive role in anchoring the synaptic ribbon, a presynaptic organelle and functional extension of the active zone, to the presynaptic membrane. In this study, we functionally and structurally analyzed two mutant mouse lines with a genetic disruption of Bsn-Bsn and Bsn -using electrophysiology and high-resolution microscopy. In both Bsn mutant mouse lines, full-length BSN was abolished, and photoreceptor synaptic function was similarly impaired, yet synapse structure was more severely affected in Bsn than in Bsn photoreceptors. The synaptic defects in Bsn retina coincide with remodeling of the outer retina-rod bipolar and horizontal cell sprouting, formation of ectopic ribbon synaptic sites-and death of cone photoreceptors, processes that did not occur in Bsn retina. An analysis of Bsn hybrid mice revealed that the divergent retinal phenotypes of Bsn and Bsn mice can be attributed to the expression of the Bsn allele, which triggers cone

photoreceptor death and neurite sprouting in the outer retina. These findings shed new light on the existing Bsn mutant mouse models and might help to understand mechanisms that drive photoreceptor death.

Altered visual processing in the mdx52 mouse model of Duchenne muscular dystrophy.
The mdx52 mouse model of Duchenne muscular dystrophy (DMD) is lacking exon 52 of the DMD gene that is located in a hotspot mutation region causing cognitive deficits and retinal anomalies in DMD patients. This deletion leads to the loss of the dystrophin proteins, Dp427, Dp260 and Dp140, while Dp71 is preserved. The flash electroretinogram (ERG) in mdx52 mice was previously characterized by delayed dark-adapted b-waves. A detailed description of functional ERG changes and visual performances in mdx52 mice is, however, lacking. Here an extensive full-field ERG repertoire was applied in mdx52 mice and WT littermates to analyze retinal physiology in scotopic, mesopic and photopic conditions in response to flash, sawtooth and/or sinusoidal stimuli. Behavioral contrast sensitivity was assessed using quantitative optomotor response (OMR) to sinusoidally modulated luminance gratings at 100% or 50% contrast. The mdx52 mice exhibited reduced amplitudes and delayed implicit times in dark-adapted ERG flash responses, particularly in their b-wave and oscillatory potentials, and diminished amplitudes of light-adapted flash ERGs. ERG responses to sawtooth stimuli were also diminished and delayed for both mesopic and photopic conditions in mdx52 mice and the first harmonic amplitudes to photopic sine-wave stimuli were smaller at all temporal frequencies. OMR indices were comparable between genotypes at 100% contrast but significantly reduced in mdx52 mice at 50% contrast. The complex ERG alterations and disturbed contrast vision in mdx52 mice include features observed in DMD patients and suggest altered photoreceptor-to-bipolar cell transmission possibly affecting contrast sensitivity. The mdx52 mouse is a relevant model to appraise the roles of retinal dystrophins and for preclinical studies related to DMD.

Heterogeneous Presynaptic Distribution of Munc13 Isoforms at Retinal Synapses and Identification of an Unconventional Bipolar Cell Type with Dual Expression of Munc13 Isoforms: A Study Using Munc13-EXFP Knock-in Mice.
Munc13 isoforms are constituents of the presynaptic compartment of chemical synapses, where they govern important steps in preparing synaptic vesicles for exocytosis. The role of Munc13-1, -2 and -3 is well documented in brain neurons, but less is known about their function and distribution among the neurons of the retina and their conventional and ribbon-type chemical synapses. Here, we examined the retinae of Munc13-1-, -2-, and -3-EXFP knock-in (KI) mice with a combination of immunocytochemistry, physiology, and electron microscopy. We show that knock-in of Munc13-EXFP fusion proteins did not affect overall retinal anatomy or synapse structure, but slightly affected synaptic transmission. By labeling Munc13-EXFP KI retinae with specific antibodies against Munc13-1, -2 and -3, we found that unlike in the brain, most retinal synapses seem to operate with a single Munc13 isoform. A surprising exception to this rule was type 6 ON bipolar cells, which expressed two Munc13 isoforms in their synaptic terminals, ubMunc13-2 and Munc13-3. The results of this study provide an important basis for future studies on the contribution of Munc13 isoforms in visual signal processing in the mammalian retina.

Lack of a Retinal Phenotype in a Syne-2/Nesprin-2 Knockout Mouse Model.
Syne-2 (also known as Nesprin-2) is a member of a family of proteins that are found primarily in the outer nuclear membrane, as well as other subcellular compartments. Syne-2 contains a C-terminal KASH transmembrane domain and is part of a protein network that associates the nuclear envelope to the cytoskeleton via the binding to actin filaments. Syne-2 plays a role in nuclear migration, nuclear positioning during retinal development, and in ciliogenesis. In a previous study, we showed a connection between Syne-2 and the multifunctional scaffold protein Pericentrin (Pcnt). The elimination of the interaction of Syne-2 and Pcnt showed defects in nuclear migration and the formation of outer segments during retinal development, as well as disturbances in centrosomal migration at the beginning of ciliogenesis in general. In this study, the Syne-2 KO mouse model Nesprin-2△ABD (Syne-2, MGI) with special attention to Pcnt and ciliogenesis was analyzed. We show reduced

expression of Syne-2 in the retina of the Syne-2 KO mouse but found no significant structural-and only a minor functional-phenotype. For the first time, detailed expression analyses showed an expression of a Syne-2 protein larger than 400 kDa (~750 kDa) in the Syne2/Nesprin-2 KO mouse. In conclusion, the lack of an overt phenotype in Syne-2/Nesprin-2 KO mice suggests the usage of alternative translational start sites, producing Syne-2 splice variants with an intact Pcnt interaction site. Nevertheless, deletion of the actin-binding site in the Syne-2/Nesprin-2 KO mouse revealed a high variability in scotopic oscillatory potentials assuming a novel function of Syne-2 in synchronizing inner retinal processes.

A Multiple Piccolino-RIBEYE Interaction Supports Plate-Shaped Synaptic Ribbons in Retinal Neurons.
Active zones at chemical synapses are highly specialized sites for the regulated release of neurotransmitters. Despite a high degree of active zone protein conservation in vertebrates, every type of chemical synapse expresses a given set of protein isoforms and splice variants adapted to the demands on neurotransmitter release. So far, we know little about how specific active zone proteins contribute to the structural and functional diversity of active zones. In this study, we explored the nanodomain organization of ribbon-type active zones by addressing the significance of Piccolino, the ribbon synapse-specific splice variant of Piccolo, for shaping the ribbon structure. We followed up on previous results, which indicated that rod photoreceptor synaptic ribbons lose their structural integrity in a knockdown of Piccolino. Here, we demonstrate an interaction between Piccolino and the major ribbon component RIBEYE that supports plate-shaped synaptic ribbons in retinal neurons. In a detailed ultrastructural analysis of three different types of retinal ribbon synapses in Piccolo/Piccolino-deficient male and female rats, we show that the absence of Piccolino destabilizes the superstructure of plate-shaped synaptic ribbons, although with variable manifestation in the cell types examined. Our analysis illustrates how the expression of a specific active zone protein splice variant (e.g., Piccolino) contributes to structural diversity of vertebrate active zones. Retinal ribbon synapses are a specialized type of chemical synapse adapted for the regulated fast and tonic release of neurotransmitter. The hallmark of retinal ribbon synapses is the plate-shaped synaptic ribbon, which extends from the release site into the terminals' cytoplasm and tethers hundreds of synaptic vesicles. Here, we show that Piccolino, the synaptic ribbon specific splice variant of Piccolo, interacts with RIBEYE, the main component of synaptic ribbons. This interaction occurs via several PxDLS-like motifs located at the C terminus of Piccolino, which can connect multiple RIBEYE molecules. Loss of Piccolino disrupts the characteristic plate-shaped structure of synaptic ribbons, indicating a role of Piccolino in synaptic ribbon assembly.

Mesopic and Photopic Rod and Cone Photoreceptor-Driven Visual Processes in Mice With Long-Wavelength-Shifted Cone Pigments.
The clearer divergence in spectral sensitivity between native rod and human L-cone (L*-cone) opsins in the transgenic Opn1lwLIAIS mouse (LIAIS) allows normal visual processes mediated by these photoreceptor subtypes to be isolated effectively using the silent substitution technique. The objective of this study was to further characterize the influence of mean luminance and temporal frequency on the functional properties of signals originating in each photoreceptor separately and independently of adaptation state in LIAIS mice.

Electrophysiological Studies on The Dynamics of Luminance Adaptation in the Mouse Retina.
To date, most studies involving in vivo electroretinography in mice are performed on steady state adapted animals. In this study, we focused on the dynamics of adaptation to high and low light levels in the mouse retina. Two flash electroretinogram (ERG) protocols and one flicker ERG protocol were employed. In the two flash ERG protocols, the animals were adapted to either 25 or 40 cd/m white light and ERGs were recorded for up to 15 min of adaptation. Afterwards, flash ERGs were recorded for up to 45 min of dark adaptation. Amplitudes of the flash ERG increased during light adaptation, while implicit times of the different wave components decreased. During subsequent dark adaptation, the amplitudes further increased. The increase in a-to-b-wave ratio indicated adaptational processes at the photoreceptor synapse. In the flicker ERG protocol, the responses to 12 Hz sinusoidal luminance modulation during the adaptation to 25 cd/m and a 1 cd/m mean luminances were recorded. The amplitudes of the first harmonic components in the flicker protocol decreased during light adaptation but

increased during dark adaptation. This is at odds with the changes in the flash ERG, indicating that adaptation may be different in different retinal pathways.

GENERATION OF THREE DISTINCT INDUCIBLE NON-HUMAN PRIMATE MODELS OF OUTER RETINAL DEGENERATION

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Divya Ail[1], Diane Nava[1], In Pyo Hwang[1], Amin Benadjal[2], Elena Brazhnikova[3], Céline Nouvel-Jaillard[3], Corentin Joffrois[4], Lionel Rousseau[5], Julie Dégardin[3], Stephane Bertin[6], Olivier Goureau[7], Serge Picaud[4], Deniz Dalkara[1]
[1]Sorbonne Université, INSERM, CNRS, Institut de la Vision, Dept. Of Therapeutics, Paris, France, [2]Sorbonne Université, Inserm, CNRS, Institut de la Vision, Department Of Development, Paris, France, [3]Sorbonne Université, INSERM, CNRS, Institut de la Vision, Preclinical Ophthalmology, Paris, France, [4]Sorbonne Université, INSERM, CNRS, Institut de la Vision, Department Of Visual Information, PARIS, France, [5]ESIEE Paris, Neurodiam, Noisy-Le-Grand, France, [6]CHNO des Quinze-Vingts, Ophthalmology, Paris, France, [7]Sorbonne Université, INSERM, CNRS, Institut de la Vision, Department Of Development, Paris, France

Aim: The differences between the retinas of humans and most animal models poses a challenge for testing novel therapies. Non-human primate (NHP) retina is physiologically and anatomically closest to human retina. However, there is a lack of retinal degeneration NHP models for preclinical studies of vision restoration strategies. To address this unmet need we aimed to generate inducible NHP models of retinal degeneration. Methods: We generated cynomolgus macaque models – 1. by optogenetic ablation of rods; 2. by using a Crispr-Cas9 system disrupting the rhodopsin gene and 3. by inducing physical separation between the photoreceptors and Retinal Pigment Epithelium (RPE) using a polymer patch. In-vivo degeneration was evaluated by fundus imaging, optical coherence tomography (OCT), adaptive optics (AO) and electroretinography (ERG). The retinal tissues were fixed and immunolabelled after sacrifice. Results: Proof-of-concept experiments were first conducted in rodents to establish doses, light levels and adequate polymer materials. In the 'optogenetically-induced' and 'Crispr model' we observed punctuate areas of degeneration in the injected areas marked by disorganization of outer segments, loss of rod photoreceptors and thinning of the outer nuclear layer (ONL). In the 'physical model' the degeneration was faster, more severe involving both rods and cones but stayed restricted to the area of the patch. In all three models, there was a general trend in the reduction of ERG. Conclusion: We have generated three distinct non-human primate models with different features adequate for testing various gene and cell therapies.

MORPHOMETRIC ANALYSIS OF HORIZONTAL CELLS IN THE MOUSE RETINA

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Alejandra Acevedo Harnecker[1], Matteo Spinelli[2], Ulrike Janssen-Bienhold[2], Christian Puller[2], Karin Dedek[1]
[1]Carl von Ossietzky University, Neurosensorics/animal Navigation, Institute For Biology And Environmental Sciences, Oldenburg, Germany, [2]Carl von Ossietzky University, Visual Neuroscience, Department Of Neuroscience, Oldenburg, Germany

Aim: Mice have dichromatic vision with enhanced sensitivity for green light in the dorsal retina, often facing the ground, and for UV light in the ventral retina, often facing the sky. This asymmetry is also reflected in the spectral composition of the mouse habitat (Qiu et al., Curr Biol, 2021, 31:3233-3247.e6.) and the distribution of S-opsin (short-wavelength-sensitive) and M-opsin (medium-wavelength-sensitive) along the dorso-ventral axis of the retina. Horizontal cells (HCs) in the mouse retina are postsynaptic to S- and M-opsin-expressing photoreceptors and send feedback to them. Here, we investigated whether individual HCs also show non-uniform properties (e.g., morphologies, synaptic contacts) across the retina. **Methods:** Intracellular dye injections of HCs in living retinal whole-mounts were followed by fixation of the tissue and immunohistochemical staining of synaptic proteins, keeping track of the retinal orientation. We reconstructed >20 HCs from different retinal regions and analyzed morphometric parameters, such as the length and branching order of dendrites. We also compared the number of contacts with photoreceptors and the presence of electrical synapses across the different retinal axes. **Results:** In general, HCs located close to the optic nerve had smaller dendritic fields than peripheral HCs. However, dorsal HCs were larger than ventral HCs of the same eccentricity. In addition, preliminary data shows that also the distribution of distinct HCs synaptic proteins differed between cells in dorsal and ventral retina. **Conclusions**: Further quantifications are needed to see whether differences in the mouse visual field are indeed reflected in the morphology and connectivity of mouse horizontal cells.

A MULTI-METHODOLOGICAL APPROACH TO STUDY HORIZONTAL CELLS IN THE VERTEBRATE RETINA

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Bianca Pircher, Andreas Feigenspan
Friedrich-Alexander-University Erlangen-Nürnberg, Biology, Erlangen, Germany

Ever since the beginning of the study of the retina, horizontal cells (HCs) occupied a truly exceptional role. Research undertaken so far has HCs assigned to the tasks of modulating information flow from photoreceptors to bipolar cells as they provide negative feedback and feedforward signals to both cell types, respectively. However, there have been unclear and sometimes even contradictory results regarding feedback mechanisms and elementary functionality of HCs. Using electrophysiology, bioinformatics and immunocytochemistry we approached the signal generating properties of HCs. Therefore, we studied the expression and distribution of ionotropic glutamate receptors (iGluRs) in HCs and their respective subtypes in various vertebrate species.
First, we could show expression of AMPA, but not kainate receptors and found remarkable differences between mammalian and a non-mammalian species in their iGluR expression patterns. Additionally, we were able to reveal true indices for a "division of labor" among HC subtypes and even more noteworthy between individual HCs of the same subtype. Single cells showing different compositions of iGluR expression, which taken together shaping a characteristic composition of iGluRs in HC subtypes.
Second, we were investigating the role of calcium channels and calcium-based action potentials. Patch-clamp experiments revealed a detailed description of the biophysical properties of HCs, which in particular emphasizes the role of $Ca_V3.2$ for signal processing in the mouse retina.
Our results allow us to refine the picture of information processing and the functionality of HCs in the vertebrate retina.

IMPACT AND SUBCELLULAR LOCATION OF SEROTONERGIC MODULATION ON RETINAL GANGLION CELL SIGNALLING

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Tristan Wiessalla
EMBL Rome, Neuroscience, Monterotondo, Italy

A recent study has described collateral projections from the retina to both the superior colliculus (SC) and the dorsal raphe nucleus (DRN). Earlier studies have shown that serotonergic DRN neurons in turn send projections to the superficial layers of SC. DRN responds strongly to expanding dark disks (looming stimulus, LS). LS causes freezing behavior in the absence of a shelter and flight response in its presence. However, the impact of the serotonergic modulation on the processing of visual stimuli remains unknown. We are studying the types of retinal ganglion cells (RGCs) impacted by DRN_{5HT} projections and the exact intracellular location of the modulation. We have performed functional and spatial characterization of RGC response modulation using *in-vivo* two-photon calcium-imaging. Further details on the location of the modulation were gained by immunofluorescence (IF) analysis of the $5\text{-}HT_{1B}$ receptor location along the RGC axon. However, 5-HT is known to be released not only as a response to LS, but rather playing a role as a neurotransmitter in a wide range of stimulus responses, behaviors and overall brain states. This highlights a potential impact of non-visual brain activity on RGC activity in the SC. Future experiments will investigate the modulation of retinal signal by stimulus independent serotonergic activity.

ESTABLISHMENT AND MEASUREMENT OF MYOPIA IN MICE WITH ON-BIPOLAR CELL DEFECTS

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Baptiste Wilmet[1], Robert Duvoisin[2], Jacques Callebert[3], Ruben Goulet[1], Christophe Tourain[4], Christelle Michiels[1], Julie Dégardin[1], Helen Frederiksen[1], Quenol Cesar[1], Manuel Simonutti[1], Olivier Marre[1], José-Alain Sahel[1,5,6], Isabelle Audo[1,5], Serge Picaud[1], Christina Zeitz[1]
[1]Sorbonne-Université, INSERM, CNRS, Institut De La Vision, Paris, France, [2]Oregon Health & Science University, Department Of Chemical Physiology & Biochemistry, Portland, United States of America, [3]Hopital Lariboisière, Inserm, Paris, France, [4]Sorbonne-Université, Inserm, CNRS, Institut De La Vision, Paris, France, [5]INSERM-DGOS CIC 1423, Centre Hospitalier National D'ophtalmologie Des Quinze-vingts, Paris, France, [6]The University of Pittsburgh School of Medicine, Department Of Ophthalmology, Pittsburgh, United States of America

Aim: Myopia is the most common ocular dysfunction with an increasing prevalence world-wide. Complete congenital stationary night blindness (cCSNB) is a group of genetically and clinically heterogeneous retinal disorders caused by dysfunction of the retinal ON-bipolar cell (ON-BC) pathway. It is mainly characterized by impaired dim light vision but is also associated with high myopia. Here, we established a protocol to induce and measure myopia in cCSNB mouse models. **Method:** To assess refractive development and induced myopia, we evaluated the levels of retinal Dopamine (DOPA) and its metabolite 3,4-Dihydroxyphenylacetic acid (DOPAC), a commonly used marker of myopia, in three cCSNB mouse models lacking *Grm6, Gpr179* or *Lrit3*. We developed a lens-induced myopia (LIM) model and measured the refractive error using an infrared photorefractometer with and without myopia induction. **Results:** Our preliminary data revealed decreased levels of retinal DOPA and DOPAC in all tested cCSNB mouse models. WT Mice with LIM showed a myopic shift of ≈-10D after 21 days of induction. Therefore, LIM will be induced in cCSNB mouse models, myopic shift will be measured and compared to the respective wild-type mice to document the refractive errors induced by the ON-BC defect. **Conclusion:** These data suggest that cCSNB mouse models can mimic the human phenotype and ON-BC dysfunction can regulate the onset of myopia. These findings may help understand the development of high myopia in cCNSB patients, and myopia generally, as well as provide the basis for the development of pharmacological and optical therapies.

Reactive oxygen species (ROS) are generated by light stimuli in the retina. Although the retina possesses strategies to cope with oxidative stress, genetic defects and environmental factors can interfere with these mechanisms, leading to Age-related Macular Degeneration (AMD). Moreover, high levels of ROS accelerate the progression of inherited photoreceptor degenerations like Retinitis Pigmentosa (RP). Platinum nanoparticles (PtNPs) can mimic the effects of antioxidant enzymes, such as catalase and superoxide dismutase, exhibiting high catalytic activity and acting as ROS scavengers in the biological environment. Here we show that PtNP intravitreal injection is an efficient therapeutic tool for lowering ROS in a light-damaged albino rat model (LD) mimicking AMD, and Royal College of Surgeons (RCS) rat, model of RP. LD was obtained by exposing the animals to intense light for 24 hours. Two days later, rats were intravitreally injected with PtNPs or albumin as a control. After fifteen days, electroretinogram recordings were performed to evaluate visual function. RCS rats were injected at early stage of degeneration. After one month, Pupillary Light Reflex recordings were performed, complemented by *ex-vivo* high-density multielectrode array electrophysiology of light-evoked ganglion cells. Both animal models were subjected the light/dark box test to evaluate visually driven behaviour. Finally, retinal morphology was evaluated using *in vivo* optical coherence tomography and immunofluorescence. PtNPs efficiently mitigate neurodegeneration induced by exposure to high-intensity light and gene mutations. The treatment preserves visual function, photoreceptor number and decreases the degeneration-induced inflammation. Behavioural tests confirm the amelioration of the degeneration in PtNPs-injected animals respect to controls.

THE TRANSITION OF PHOTORECEPTOR GUANYLATE CYCLASE TYPE 1 TO THE ACTIVE STATE

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Manisha Kumari Shahu[1], Fabian Schuhmann[2], Alexander Scholten[1], Ilia Solov'Yov[2], Karl-Wilhelm Koch[1]
[1]Carl-von-Ossietzky University Oldenburg, Department Of Neuroscience, Oldenburg, Germany, [2]Carl-von-Ossietzky University Oldenburg, Institute Of Physics, Oldenburg, Germany

Introduction: Membrane-bound guanylate cyclases (GCs), which synthesize the second messenger guanosine-3',5'-cyclic monophosphate, differ in their activation modes to reach the active state. Hormone receptor type guanylate cyclases, for example undergo an 'α'-helix rotation upon encountering with peptide for activation, but the mechanism of calcium-regulated photoreceptor GCs is unclear. **Aim:** We aim to unravel the conformational switch of photoreceptor guanylate cyclase type 1, GC-E to the active state and compare it with a constitutionally active state, which is found in patients suffering from retinal cone-rod dystrophies. **Methods:** We simulated experimentally an 'α'-helix rotation by integration of alanine residues close to the transmembrane region by site directed mutagenesis and performed functional studies. We further investigated the enzymatic catalytic parameters of wildtype and the retinal disease-related mutant V902L of GC-E, and characterized the protein dynamics of a conformational switch by a computational approach based on molecular dynamics simulations. **Results:** Our data shows no involvement of an 'α'-helix rotation indicating a difference to hormone receptor GCs. The constitutively active state of the V902L mutant is therefore like the active state of wildtype GC-E that is reached by interacting with calcium-sensors. We detected a swinging movement of the dimerization domain in the V902L mutant as the critical conformational switch in the cyclase going from the low-to-high activity state. **Conclusion:** Our results show a principal difference in the activation modus between hormone receptor GCs and sensory GCs, which is relevant for understanding the molecular basis of retinal diseases.

IN VIVO BIOCOMPATIBILITY AND FUNCTIONALITY OF POROUS-GRAPHENE-BASED SUBRETINAL IMPLANTS FOR VISION RESTORATION.

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Julie Zhang[1], Vi Anh Nguyen[1], Julie Dégardin[1], Ruben Goulet[1], Quenol Cesar[1], Steven Walston[2], José Antonio Garrido[2], Fabrice Arcizet[1], Grégory Gauvain[1], Serge Picaud[1]
[1]Institut de la Vision, Sorbonne Université, INSERM, CNRS, Department Of Visual Information, Paris, France, [2]Catalan Institute of Nanoscience and Nanotechnology (ICN2), Advanced Electronic Materials And Devices Group, Bellaterra, Spain

Novel materials are sought to improve the unsatisfactory spatial resolution achieved by past or current retinal prostheses for vision restoration. The electrochemical properties of reduced graphene oxide (rGO) micro-electrodes (around 30 kΩ impedance at 1 kHz and up to 8 mC/cm² of CIC) are encouraging enough for efficient electric stimulation of the retinal neurons. We inserted porous graphene-based implants in the subretinal space of rodents (N=6) and investigated first their *in vivo* biocompatibility using post-hoc immunolabelling (DAPI, Iba1, GFAP and G0α). We performed chronic *in vivo* impedance spectroscopy and cyclic voltammetry tests for evaluation of rGO electrodes long-term electrochemical performance. Using functional ultrasound (fUS) imaging, we measured the neural activation in the visual cortex in response to monopolar stimulation of the rGO electrodes acutely and chronically implanted in the retina. We first noticed on the confocal images of the implanted retinas that there was no major inflammation above graphene electrodes compared to platinum electrodes (N=4) or sham polyimide device (N=5). Microglia cells numbering confirmed these results. Our preliminary results for the implant functionality indicate an increase of the impedance during the first week post-implantation with a stabilization occurring around one month, in concordance with literature. First results with fUS imaging show that the spatial resolution of neural activation in the cortex varies with increasing electrode size and frequency of stimulation. We also investigated the influence of pulse duration. Together, all these preliminary results provide great confidence in the graphene technology for the elaboration of the future generation of visual prostheses.

Cephalopods present one of the most complex invertebrate nervous systems. Their large, centralised brains support idiosyncratic behaviours such as camouflage and mimicry, and present higher-order abilities such as learning from observing others and tool manipulation. While widely divergent from vertebrates, cephalopods independently evolved common characteristics. A salient example is their camera-like eye, similar in anatomy, optics and function to the vertebrate eye and an evidence of convergent evolution. We aim at mapping the cephalopod's visual circuits to identify any similarities with those of vertebrates and insects, and therefore, given their independent evolutionary history, to potentially find optimal neural circuits for visual processing.
To this end, we imaged a volume containing an eye and optic lobe of an *Idiosepius hallami* pygmy squid free-living hatchling using a customised FIB-SEM (Focused Ion Beam Scanning Electron Microscope), at a resolution sufficient to resolve all neuronal arbours and synapses. Preliminary data from the reconstruction of photoreceptors and their axonal projections to the optic neuropil show an intriguing organisation. Basal photoreceptor dendrites within the retina contact spatially adjacent photoreceptors. Photoreceptor axons present, as they emerge from the retina, a long mitochondria-rich proximal segment of large calibre that subsequently subdivides into numerous thinner (~200 nm diameter) parallel axons that run the remainder of the optic nerve prior to entering the optic lobe. The reconstruction of the postsynaptic partners of photoreceptor axons within the optic lobe will enable the comparison with circuits of the vertebrate retina and the insect optic lobes.

Neural architectures in the light of comparative connectomics.
Since the Cambrian, animals diversified from a few body forms or bauplans, into many extinct and all extant species. A characteristic neural architecture serves each bauplan. How the connectome of each animal differs from that of closely related species or whether it converged into an optimal architecture shared with more distant ones is unknown. Recent technological innovations in molecular biology, microscopy, digital data storage and processing, and computational neuroscience have lowered the barriers for whole-brain connectomics. Comparative connectomics of suitable, relatively small, representative species across the phylogenetic tree can infer the archetypal neural architecture of each bauplan and identify any circuits that possibly converged onto a shared and potentially optimal, structure.

Development of the electric organ in embryos and larvae of the knifefish, Brachyhypopomus gauderio.
South American Gymnotiform knifefish possess electric organs that generate electric fields for electro-location and electro-communication. Electric organs in fish can be derived from either myogenic cells (myogenic electric organ/mEO) or neurogenic cells (neurogenic electric organ/nEO). To date, the embryonic development of EOs has remained obscure. Here we characterize the development of the mEO in the Gymnotiform bluntnose knifefish, Brachyhypopomus gauderio. We find that EO primordial cells arise during embryonic stages in the ventral edge of the tail myotome, translocate into the ventral fin and develop into syncytial electrocytes at early larval stages. We also describe a pair of thick nerve cords that flank the dorsal aorta, the location and characteristic morphology of which are reminiscent of the nEO in Apteronotid species, suggesting a common evolutionary origin of these tissues. Taken together, our findings reveal the embryonic origins of the mEO and provide a basis for elucidating the mechanisms of evolutionary diversification of electric charge generation by myogenic and neurogenic EOs.

Cardiovascular Effects and Molecular Mechanisms of Bisphenol A and Its Metabolite MBP in Zebrafish.
The plastic monomer bisphenol A (BPA) is one of the highest production volume chemicals in the world and is frequently detected in wildlife and humans, particularly children. BPA has been associated with numerous adverse health outcomes relating to its estrogenic and other hormonal properties, but direct causal links are unclear in humans and animal models. Here we simulated measured (1×) and predicted worst-case (10×) maximum fetal exposures for BPA, or equivalent concentrations of its metabolite MBP, using fluorescent reporter embryo-larval zebrafish, capable of quantifying Estrogen Response Element (ERE) activation throughout the body. Heart valves were primary sites for ERE activation by BPA and MBP, and transcriptomic analysis of microdissected heart tissues showed that both chemicals targeted several molecular pathways constituting biomarkers for calcific aortic valve disease (CAVD), including extra-cellular matrix (ECM) alteration. ECM collagen deficiency and impact on heart valve structural integrity were confirmed by histopathology for high-level MBP exposure, and structural defects (abnormal curvature) of the atrio-ventricular valves corresponded with impaired cardiovascular function (reduced ventricular beat rate and blood flow). Our results are the first to demonstrate plausible mechanistic links between ERE activation in the heart valves by BPA's reactive metabolite MBP and the development of valvular-cardiovascular disease states.

Gold nanoparticles ingested by oyster larvae are internalized by cells through an alimentary endocytic pathway.
The biological fate of nanoparticles (NPs) taken up by organisms from their environment is a crucial issue for assessing ecological hazard. Despite its importance, it has scarcely been addressed due to the technical difficulties of doing so in whole organism studies. Here, by using transmission electron microscopy and energy dispersive X-ray spectroscopy (TEM-EDS), we describe the key aspects that characterize the interaction between an aquatic organism of global ecological and economic importance, the early larval stage of the Japanese oyster (), and model gold NPs dispersed in their environment. The small size of the model organism allowed for a high-throughput visualization of the subcellular distribution of NPs, providing a comprehensive and robust picture of the route of uptake, mechanism of cellular permeation, and the pathways of clearance counterbalancing bioaccumulation. We show that NPs are ingested by larvae and penetrate cells through alimentary pinocytic/phagocytic mechanisms. They undergo intracellular digestion and storage inside residual bodies, before excretion with feces or translocation to phagocytic coelomocytes of the visceral cavity for potential extrusion or further translocation. Our mechanistically-supported findings highlight the potential of oyster larvae and other organisms which feature intracellular digestion processes to be exposed to man-made NPs and thus any risks associated with their inherent toxicity.

A single fungal MAP kinase controls plant cell-to-cell invasion by the rice blast fungus.
Blast disease destroys up to 30% of the rice crop annually and threatens global food security. The blast fungus invades plant tissue with hyphae that proliferate and grow from cell to cell, often through pit fields, where plasmodesmata cluster. We showed that chemical genetic inhibition of a single fungal mitogen-activated protein (MAP) kinase, Pmk1, prevents from infecting adjacent plant cells, leaving the fungus trapped within a single plant cell. Pmk1 regulates expression of secreted fungal effector proteins implicated in suppression of host immune defenses, preventing reactive oxygen species generation and excessive callose deposition at plasmodesmata. Furthermore, Pmk1 controls the hyphal constriction required for fungal growth from one rice cell to the neighboring cell, enabling host tissue colonization and blast disease.

Usefulness of zebrafish larvae to evaluate drug-induced functional and morphological renal tubular alterations.
Prediction and management of drug-induced renal injury (DIRI) rely on the knowledge of the mechanisms of drug insult and on the availability of appropriate animal models to explore it. Zebrafish (Danio rerio) offers unique advantages for assessing DIRI because the larval pronephric kidney has a high homology with its human counterpart and it is fully mature at 3.5 days post-fertilization. Herein, we aimed to evaluate the usefulness of zebrafish larvae as a model of renal tubular toxicity through a comprehensive analysis of the renal alterations induced by the lethal concentrations for 10% of the larvae for gentamicin, paracetamol and tenofovir. We evaluated drug metabolic profile by mass spectrometry, renal function with the inulin clearance assay, the 3D morphology of the proximal convoluted tubule by two-photon microscopy and the ultrastructure of proximal convoluted tubule mitochondria by transmission electron microscopy. Paracetamol was metabolized by conjugation and oxidation with further detoxification with glutathione. Renal clearance was reduced with gentamicin and paracetamol. Proximal tubules were enlarged with paracetamol and tenofovir. All drugs induced mitochondrial alterations including

dysmorphic shapes ("donuts", "pancakes" and "rods"), mitochondrial swelling, cristae disruption and/or loss of matrix granules. These results are in agreement with the tubular effects of gentamicin, paracetamol and tenofovir in man and demonstrate that zebrafish larvae might be a good model to assess functional and structural damage associated with DIRI.

ATP prevents Woronin bodies from sealing septal pores in unwounded cells of the fungus Zymoseptoria tritici.
Septa of filamentous ascomycetes are perforated by septal pores that allow communication between individual hyphal compartments. Upon injury, septal pores are plugged rapidly by Woronin bodies (WBs), thereby preventing extensive cytoplasmic bleeding. The mechanism by which WBs translocate into the pore is not known, but it has been suggested that wound-induced cytoplasmic bleeding "flushes" WBs into the septal opening. Alternatively, contraction of septum-associated tethering proteins may pull WBs into the septal pore. Here, we investigate WB dynamics in the wheat pathogen Zymoseptoria tritici. Ultrastructural studies showed that 3.4 ± 0.2 WBs reside on each side of a septum and that single WBs of 128.5 ± 3.6 nm in diameter seal the septal pore (41 ± 1.5 nm). Live cell imaging of green fluorescent ZtHex1, a major protein in WBs, and the integral plasma membrane protein ZtSso1 confirms WB translocation into the septal pore. This was associated with the occasional formation of a plasma membrane "balloon," extruding into the dead cell, suggesting that the plasma membrane rapidly seals the wounded septal pore wound. Minor amounts of fluorescent ZtHex1-enhanced green fluorescent protein (eGFP) appeared associated with the "ballooning" plasma membrane, indicating that cytoplasmic ZtHex1-eGFP is recruited to the extending plasma membrane. Surprisingly, in ~15% of all cases, WBs moved from the ruptured cell into the septal pore. This translocation against the cytoplasmic flow suggests that an active mechanism drives WB plugging. Indeed, treatment of unwounded and intact cells with the respiration inhibitor carbonyl cyanide m-chlorophenyl hydrazone induced WB translocation into the pores. Moreover, carbonyl cyanide m-chlorophenyl hydrazone treatment recruited cytoplasmic ZtHex1-eGFP to the lateral plasma membrane of the cells. Thus, keeping the WBs out of the septal pores, in Z. tritici, is an ATP-dependent process.

Identification and Characterization of Highly Fluorescent Pigment Cells in Embryos of the Arabian Killifish ().
The Arabian killifish, , is a small tropical teleost fish living in wide range of habitats in sea water and fresh water in the Middle East. Here, we report extraordinary fluorescent pigment cells in the Arabian killifish embryo. These cells appear brown in transmitted light, yellowish white in reflected light, and as strong fluorescence in GFP and RFP filters. TEM and confocal microscopy analyses show the fluorescence emanates from leucosome-like pigment organelles. The cells express the gene encoding GTP cyclohydrolase (), a marker for leucophores and xanthophore. Gene knockdown and knockout of using morpholino or CRISPR-Cas9 induced loss of fluorescence in these embryos, indicating a crucial role of the enzyme and the associated pterine biosynthesis pathway in the generation of the fluorescence. We concluded that these cells are a highly fluorescent subtype of leucophores and have named them as fluoroleucophores.

PROFILING GANGLION CELL TYPES BASED ON VISUAL RESPONSES AND ELECTRICAL INPUT FILTERS IN WILD TYPE AND RD10 DEGENERATED MOUSE RETINA

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Zohreh Hosseinzadeh[1], Daniel Rathbun[2], Hamed Shabani[3]
[1]Leipzig University, Paul Flechsig Institute Of Brain Research, Leipzig, Germany, [2]Detroit Institute Ophthalmology, Bionics And Vision Lab, Detroit, United States of America, [3]University of Freiburg, Bernstein Center Freiburg, Freiburg, Germany

Retinal electronic devices make it possible to restore vision to patients with progressive retinal degenerative. However, current stimulation parameters cannot stimulate retinal pathways, leading to improper perception. Thus, We are exploring whether different Ganglion Cell types can be selectively activated using specific electrical input filters Microelectrode array (MEA) recording was used to record ganglion cells (GCs) from healthy and rd10 degenerated mouse. Firstly, visual stimuli were shone to retinas including moving bars, contrast and temporal frequency chirps, blue-green flashes for classifying different ganglion cell types. Then, we delivered Gaussian-distributed voltage pulses (mean -800 mV, sigma 280 mV) into the tissue and estimate the electrical input filter of each cell using electrical spike triggered averaging (eSTA). Finally, we applied noise-embedded, sine-wave, pulse train modulations to retina in order to selectively stimulate ON and OFF pathways. Based on GC light responses, 35 and 12 clusters were detected in wild-type and rd10 retinas. A hierarchical clustering of electrical input filters showed that ON GCs had upward eSTAs and OFF GCs had downward in both healthy and rd10 retinas. Noise-embedded, sine-wave, pulse train modulations were sufficient to elicit ON or OFF RGC-specific activation, depending on the direction of the modulation. GCs receiving ON pathway input responded more strongly to upward cathodic pulse train modulations, whereas GCs receiving OFF input responded more strongly to downward modulations. Deriving amplitude-modulated electrical pulse trains from the electrical input filter is a useful method to find out specific stimuli eliciting ON and OFF RGC pathway inputs.

A CERTAIN TYPE OF PHOTORECEPTOR CONTRIBUTES TO THE IMMEDIATE EFFECT OF LIGHT ON ECLOSION BEHAVIOUR

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Daniel Bidell[1], Tilman Triphan[2], Natalie-Danielle Feige[1], Claudia Müller[1], Charlotte Helfrich-Förster[3], Mareike Selcho[1]
[1]Biology, Animal Physiology, Leipzig, Germany, [2]Biology, Genetics, Leipzig, Germany, [3]Biology, Neurobiology And Genetics, Würzburg, Germany

For most organisms, adaption to altering external conditions is of critical importance. One of the most prominent external stimuli is light. While light has the ability to indirectly influence a wide variety of physiological processes and behaviours by entraining the circadian clock, it can also have a direct “masking” effect on circadian behaviour. In *Drosophila melanogaster*, light influences the emergence of the adult fly out of its puparium, called eclosion (Engelmann and Honegger, 1966). Eclosion is gated by the circadian clock to the morning to prevent desiccation and enhance survival rate. A light stimulus induces a rapid increase in eclosion rate, the so-called lights-on (LOn) effect that is eliminated in flies lacking eyes and ocelli (McNabb and Truman, 2008). Since eclosion is independent of the animal´s physiological state and motivation, we here use it as a readout to examine the immediate effects of light on eclosion behaviour. Light is perceived by the compound eyes, which consist of around 800 ommatidia, each equipped with six outer (R1-6) and two inner (R7, R8) photoreceptor cells. While the outer cells express Rhodopsin1, the inner ones express specific combinations of Rhodopsin3 and Rhodopsin4, Rhodopsin5 and Rhodopsin6 (Rister and Desplan, 2011). Besides the compound eyes, flies have three simple dorsal eyes called ocelli, which express Rhodopsin2 (Pollock and Benzer, 1988). Here we show that flies need the photoreceptors in the retina, but not the ocelli for the LOn response. Our results suggest that R8 photoreceptor cells appear to transmit the light signal that is responsible for the LOn response.

SOMATIC CONNEXIN PLAQUES ON AMACRINE CELLS OF THE MAMMALIAN RETINA

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Katalin Fusz[1,2], Péter Kóbor[1,2], Tamás Kovács-Öller[2,3], Béla Völgyi[2,3], Ildikó Telkes[1,2], Péter Buzás[1,2]

Aims: In the adult mammalian nervous system, gap junctions (GJs) are usually found on axon terminals and dendrites. Recently, we have also found plaques immunoreactive to the main neuronal GJ protein connexin-36 (Cx36) on certain amacrine cell bodies. Here, we aimed to characterize size and retinal distribution of these GJs as well as narrow down the cell types forming them. **Methods:** We used flat-mounted retinas of cats (n = 4), rats (n = 4) and mice (n = 5). Prox1 immunofluorescent labelling was used in combination with Cx36, calretinin (CaR) and parvalbumin (PV). The densities of labelled cells and Cx36 puncta were measured at several retinal locations. **Results:** Cx36 plaques were attached to about 8–10% of Prox1-positive amacrine cell somata. Co-expression patterns of CaR and PV showed that the majority of them are AII amacrine cells. The cross-sectional area of somatic plaques in the retina of cats (2.06±1.5µm^2), rats (1.40±0.6µm^2) and mice (0.81±0.39µm^2) was significantly larger than that of Cx36-plaques seen in the neuropil of the inner plexiform layer ($p < 0.001$). Somatic plaques were larger and their density was higher in the central areas of the retina in rats and mice. **Conclusions:** The presence of somatic plaques suggests strong coupling of pairs or small clusters of amacrine cell bodies via gap junctions. We hypothesize that these large gap junctions may enhance electrical synchronization or the exchange of signalling molecules between participating cells.

Regional Variation of Gap Junctional Connections in the Mammalian Inner Retina.
The retinas of many species show regional specialisations that are evident in the differences in the processing of visual input from different parts of the visual field. Regional specialisation is thought to reflect an adaptation to the natural visual environment, optical constraints, and lifestyle of the species. Yet, little is known about regional differences in synaptic circuitry. Here, we were interested in the topographical distribution of connexin-36 (Cx36), the major constituent of electrical synapses in the retina. We compared the retinas of mice, rats, and cats to include species with different patterns of regional specialisations in the analysis. First, we used the density of Prox1-immunoreactive amacrine cells as a marker of any regional specialisation, with higher cell density signifying more central regions. Double-labelling experiments showed that Prox1 is expressed in AII amacrine cells in all three species. Interestingly, large Cx36 plaques were attached to about 8-10% of Prox1-positive amacrine cell somata, suggesting the strong electrical coupling of pairs or small clusters of cell bodies. When analysing the regional changes in the volumetric density of Cx36-immunoreactive plaques, we found a tight correlation with the density of Prox1-expressing amacrine cells in the ON, but not in the OFF sublamina in all three species. The results suggest that the relative contribution of electrical synapses to the ON- and OFF-pathways of the retina changes with retinal location, which may contribute to functional ON/OFF asymmetries across the visual field.

A COMPLEXIN-TRANSDUCIN-COMPLEX IN LIGHT ADAPTATION IN MAMMALIAN RETINA

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Uwe Thorsten Lux[1], Anna Wartenberg[1], Jutta Meyer[2], Andreas Gießl[3], Olaf Jahn[2], Kerstin Reim[2], Johann Helmut Brandstätter[1]
[1]Friedrich-Alexander-Universität Erlangen-Nürnberg, Animal Physiology, Department Of Biology, Erlangen, Germany, [2]Max Planck Institute for Multidisciplinary Sciences, Department Of Molecular Neurobiology, Göttingen, Germany, [3]Universitätsklinikum Erlangen, Friedrich-Alexander-Universität Erlangen-Nürnberg, Department Of Ophthalmology, Erlangen, Germany

Complexins (Cplxs) are SNARE complex regulating proteins which control the speed and Ca^{2+} sensitivity of vesicle fusion at chemical synapses. In mammalian retina, all four known Cplx isoforms are present: Cplxs 1/2 at conventional synapses and Cplxs 3/4 primarily at the highly specialized ribbon synapses. The aim of our study was to decipher the synaptic function of Cplxs 3/4 to better understand tonic release at photoreceptor ribbon synapses. Previous results suggest that in addition to the role of Cplxs 3/4 in vesicle release, they may also be involved in light-regulated vesicle loading of the synaptic ribbon. Here we focused on the role of Cplx 4 in light adaptation at rod photoreceptor ribbon synapses. Electron microscopic analysis revealed that light-regulated vesicle loading of rod photoreceptor ribbons occurs on a timescale of minutes and that this process is compromised in Cplx 4 knockout mice. In affinity purification experiments with peptides representing the SNARE-binding domain of Cplx, we found the rod-specific alpha-subunit of the G-protein Transducin as a putative interactor of the Cplx 4-SNARE complex. Transducin, a key protein of the phototransduction process in the photoreceptor outer segments, is translocated to the rod photoreceptor synaptic terminals in light. Here its function is enigmatic. With *in situ* proximity ligation assays, we found a putative interaction between Cplx 4/Transducin, Cplx 4/Syt1, and Syt1/Transducin. In conclusion, our data suggest that the light-regulated function of Cplx 4 in vesicle loading of the synaptic ribbon is controlled by Transducin.

Cell Types and Synapses Expressing the SNARE Complex Regulating Proteins Complexin 1 and Complexin 2 in Mammalian Retina.
Complexins (Cplxs) 1 to 4 are components of the presynaptic compartment of chemical synapses where they regulate important steps in synaptic vesicle exocytosis. In the retina, all four Cplxs are present, and while we know a lot about Cplxs 3 and 4, little is known about Cplxs 1 and 2. Here, we performed in situ hybridization experiments and bioinformatics and exploited Cplx 1 and Cplx 2 single-knockout mice combined with immunocytochemistry and light microscopy to characterize in detail the cell type and synapse-specific distribution of Cplx 1 and Cplx 2. We found that Cplx 2 and not Cplx 1 is the main isoform expressed in normal and displaced amacrine cells and ganglion cells in mouse retinae and that amacrine cells seem to operate with a single Cplx isoform at their conventional chemical synapses. Surprising was the finding that retinal function, determined with electroretinographic recordings, was altered in Cplx 1 but not Cplx 2 single-knockout mice. In summary, the results provide an important basis for future studies on the function of Cplxs 1 and 2 in the processing of visual signals in the mammalian retina.

Siglec-15 on Osteoclasts Is Crucial for Bone Erosion in Serum-Transfer Arthritis.
Siglec-15 is a conserved sialic acid-binding Ig-like lectin, which is expressed on osteoclasts. Deficiency of Siglec-15 leads to an impaired osteoclast development, resulting in a mild osteopetrotic phenotype. The role of Siglec-15 in arthritis is still largely unclear. To address this, we generated Siglec-15 knockout mice and analyzed them in a mouse arthritis model. We could show that Siglec-15 is directly involved in pathologic bone erosion in the K/BxN serum-transfer arthritis model. Histological analyses of joint destruction provided evidence for a significant reduction in bone erosion area and osteoclast numbers in Siglec-15 mice, whereas the inflammation area and cartilage destruction was comparable to wild-type mice. Thus, Siglec-15 on osteoclasts has a crucial function for bone erosion during arthritis. In addition, we generated a new monoclonal

anti-Siglec-15 Ab to clarify its expression pattern on immune cells. Whereas this Ab demonstrated an almost exclusive Siglec-15 expression on murine osteoclasts and hardly any other expression on various other immune cell types, human Siglec-15 was more broadly expressed on human myeloid cells, including human osteoclasts. Taken together, our findings show a role of Siglec-15 as a regulator of pathologic bone resorption in arthritis and highlight its potential as a target for future therapies, as Siglec-15 blocking Abs are available.

Lack of a Retinal Phenotype in a Syne-2/Nesprin-2 Knockout Mouse Model.
Syne-2 (also known as Nesprin-2) is a member of a family of proteins that are found primarily in the outer nuclear membrane, as well as other subcellular compartments. Syne-2 contains a C-terminal KASH transmembrane domain and is part of a protein network that associates the nuclear envelope to the cytoskeleton via the binding to actin filaments. Syne-2 plays a role in nuclear migration, nuclear positioning during retinal development, and in ciliogenesis. In a previous study, we showed a connection between Syne-2 and the multifunctional scaffold protein Pericentrin (Pcnt). The elimination of the interaction of Syne-2 and Pcnt showed defects in nuclear migration and the formation of outer segments during retinal development, as well as disturbances in centrosomal migration at the beginning of ciliogenesis in general. In this study, the Syne-2 KO mouse model Nesprin-2△ABD (Syne-2, MGI) with special attention to Pcnt and ciliogenesis was analyzed. We show reduced expression of Syne-2 in the retina of the Syne-2 KO mouse but found no significant structural-and only a minor functional-phenotype. For the first time, detailed expression analyses showed an expression of a Syne-2 protein larger than 400 kDa (~750 kDa) in the Syne2/Nesprin-2 KO mouse. In conclusion, the lack of an overt phenotype in Syne-2/Nesprin-2 KO mice suggests the usage of alternative translational start sites, producing Syne-2 splice variants with an intact Pcnt interaction site. Nevertheless, deletion of the actin-binding site in the Syne-2/Nesprin-2 KO mouse revealed a high variability in scotopic oscillatory potentials assuming a novel function of Syne-2 in synchronizing inner retinal processes.

GLUCAGON AS A NOVEL NEUROMODULATOR OF RETINAL ROD BIPOLAR CELL INHIBITORY ACTIVITY, POSSIBLE IMPLICATIONS IN MYOPIA PATHOGENESIS

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Oliver Schmachtenberg[1], Felipe Tapia[2]
[1]CINV, Universidad de Valparaiso, Biology, Valparaiso, Chile, [2]CINV, Universidad de Valparaiso, Doctorado En Neurociencia, Valparaiso, Chile

Aims: Myopia incidence is steadily increasing worldwide, but the underlying pathophysiologic mechanisms are still only partially understood. Glucagon is a peptide thought to signal image defocus in the eye, which is considered the first step in myopia induction, and dopamine is known for its key role in myopia, being proposed as the main signaling molecule linked to its pathogenesis. The aim of this study was to corroborate glucagon signaling in the mammalian retina and find a possible link with dopaminergic signaling. **Methods:** Whole-cell patch-clamp was used to study the inhibitory activity of rod bipolar cells (RBCs), as this activity is known to be regulated by dopamine and RBCs have been implicated in glucagon-related activity. Inhibitory post-synaptic currents (IPSC) were measured in RBCs from wild-type and lens-induced myopia model mice. **Results:** Glucagon produced a dose-dependent and glucagon receptor-dependent increase in RBC glycinergic IPSC frequency. This effect was also dependent on dopaminergic activity as it was abolished by dopamine type 1 receptor (D1R) antagonism and in scotopic conditions. The effect was also abolished in the myopia murine model but could be recovered using D1R agonism. **Conclusions:** Glucagon is a novel retinal neuromodulator in mammals, regulating the glycinergic inhibitory activity acting on RBCs in a D1R-dependent manner. Its effects are abolished in a myopia model, suggesting it is one of the pathways affected in this condition. More research will be required to determine whether this pathway could be a target for myopia prevention or treatment.

SYNAPTIC DEGENERATION IN RETINAL ROD BIPOLAR CELLS IS A CAUSE OF AGE-RELATED LOSS IN VISUAL SENSITIVITY IN CHRONICALLY HYPOGLYCEMIC MICE

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Fuminobu Tamalu[1], Yumiko Umino[2], Eduardo Solessio[2], Naofumi Miwa[1]
[1]Saitama Medical University, Physiology, Saitama, Japan, [2]SUNY Upstate Medical University, Ophthalmology, Syracuse, United States of America

Aims Mice rendered chronically hypoglycemic by a null mutation of the glucagon receptor gene (Gcgr) experience an age-related loss in retinal and visual sensitivity along with a loss of synaptic contacts in the outer retina. Acuity and contrast sensitivity begin to decline at 9 to 13 months. Retinal function decreases more than 100-fold in the same period. Because the ERG b-wave is the first signal to decrease in amplitude, we investigated the response of rod bipolar cells (RBCs) in $Gcgr^{-/-}$ mice. **Methods** We performed whole-cell patch-clamp recoding from RBCs. To mimic a dark-adapted condition we included L-AP4 (an agonist at the mGluR6 receptor) in the external solution. We applied CPPG using a puffer pipette positioned near the dendrites of RBCs to simulate light responses. CPPG antagonizes L-AP4 at the mGluR6 receptors in RB dendrites, resembling the decrease in glutamate release that follows photoreceptor light activation. **Results** We found that the responses of RBCs in $Gcgr^{-/-}$ mice are smaller than in control $Gcgr^{+/-}$ mice. In voltage-clamp mode, CPPG evoked maximal inward currents of 6.8 ± 4.7 pA and 18 ± 14 pA in $Gcgr^{-/-}$ and $Gcgr^{+/-}$ mice, respectively. In current-clamp mode the voltage responses peaked at 18 ± 14 mV and 31 ± 18 mV in $Gcgr^{-/-}$ and $Gcgr^{+/-}$ mice, respectively. Dendrites of RBCs appeared to be shorter in $Gcgr^{-/-}$ mice than in control animals. **Conclusions** These results suggest that chronic hypoglycemia causes postsynaptic alterations in the photoreceptor to RB synapse in agreement with observed losses in visual and retinal sensitivity.

THE SELECTIVITY OF RETINAL GANGLION CELLS DYNAMICALLY CHANGES WHEN STIMULATED WITH A MOVING OBJECT

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Thomas Buffet, Samuele Virgili, Olivier Marre
Sorbonne Université, Institut De La Vision, Paris, France

Some ganglion cells have been shown to compensate for delays in information transmission and anticipate motion. Yet, fundamental characteristics of retinal ganglion cells selectivity such as their receptive field polarity, i.e. sensitivity to local light increase (ON) and/or decrease (OFF), are usually assessed using static stimuli like flashed images. Here we developed a new approach to characterize the ganglion cell selectivity when the retina processes motion. We recorded the responses of mouse ganglion cells to stimuli composed of moving bars slightly perturbed by patterns of random noise. We repeated the same moving stimulus many times, but always changing the random noise patterns. We then estimated how these random noise patterns change the response of each ganglion cell to the moving bar, and measured a dynamical receptive field for each ganglion cell, for each position of the bar. Our preliminary results show that the polarity of ganglion cell receptive fields can be dynamically modulated as a function of the position of the moving bar. A ganglion cell that initially responds to a light increase can respond to a light decrease when stimulated by a moving object. The selectivity of RGCs has previously been shown to depend on image statistics such as background luminance and local content of static images. Here we show that it can also change in time. The perturbative approach proposed here is therefore able to provide insight on how ganglion cells integrate the visual stimuli information in time.

A NOVEL MEMBRANE-TARGETED PHOTOSWITCH RESTORES PHYSIOLOGICAL LIGHT-RESPONSES IN THE DEGENERATED RD10 MOUSE RETINA

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Gaia Ziraldo[1,2], Stefano Di Marco[1,2], Elisabetta Colombo[1], Fabio Benfenati[2,3]
[1]Istituto Italiano di Tecnologia, Center For Synaptic Neuroscience And Technology, Genova, Italy, [2]IRCCS, Ospedale Policlinico San Martino, Genova, Italy, [3]Istituto Italiano Di Tecnologia, Center For Synaptic Neuroscience And Technology, Genova, Italy

Age-related macular degeneration (AMD) and retinitis pigmentosa (RP) are the principal pathologies leading to photoreceptor degeneration and blindness in humans. Unfortunately, no definitive cure exists, and the substitutive strategies currently available rely on prosthetic devices, whose application is strongly hampered by their poor sensitivity, low spatio-temporal resolution, wiring and size. In this context, we engineered a novel and injectable membrane-targeted photoswitchable molecule named Ziapin2, which can modulate membrane capacitance and trigger action potential firing. This work aims to investigate the capability of Ziapin2 to restore physiological responses to light and visual functions in blind retinas of Rd10 mice, a model of RP. We performed ex-vivo electrophysiological recordings on retinal explants freshly isolated from blind Rd10 mice: we assessed light-evoked response to light stimulation by combining patch-clamp experiments in current- and voltage-clamp configuration and high-density Multi-Electrode Array (HD-MEA) measurements. This work demonstrated that Ziapin2 could trigger light-evoked action potentials in RGCs of blind retinal explants at low luminance levels. Strikingly, the ability of Ziapin2 to increase membrane capacitance in the darkness and suddenly decrease it under light stimulation allows for restoration of both the ON- and OFF-response pathways, resembling the neuronal circuitry of a regular sighted retinal network. This work highlights the potential of Ziapin2 as a highly biocompatible, non-invasive injectable therapeutic tool to treat retinal dystrophies at single-cell resolution, paving the way to the development of novel therapeutic strategies that would finally overcome the significant obstacles currently existing to therapeutic intervention.

A NEW EXPERIMENTAL GLAUCOMA MODEL WITH CHRONIC OCULAR HYPERTENSION

POSTER SESSION 01 - SECTION: RETINAL CIRCUITRY AND FUNCTION

Qianbin Wang
University of Massachusetts Amherst Amherst, MA · Public · 4-year, Biomedical Engineering Department, Amherst, United States of America

Progress in understanding the glaucomatous pathogenesis is greatly hampered by the lack of a reliable animal model. Experimental animal models that can mimic the retinal ganglion cells (RGC) and optic nerve pathology in human disease are of crucial importance in uncovering the mechanisms of the disease and developing therapies. Therefore, developing a reliable and controllable experimental glaucoma model to induce chronic and sustained intraocular pressure (IOP) elevation and glaucomatous neurodegeneration would be extremely useful. Here, we developed a novel technique to induce chronic ocular hypertension using size distributed polymeric viscobeads. These viscobeads can partially degrade into viscoelastic material to completely block the aqueous drainage and obtained a sustained IOP elevation, and their diameters that match the pores in the trabecular meshwork nets have facilitated the generation of sustained ocular hypertension. ODOR CUES MAY BIAS HIPPOCAMPAL REACTIVATIONS DURING SPATIAL GOAL LEARNING

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Pascal Ravassard, Lisa Roux
IINS, UMR 5297 CNRS, Centre Broca Nouvelle-aquitaine, Bordeaux, France

In the hippocampus, neuronal sequences encoding past experience reactivate during sharp wave ripple events. Sharp wave ripples during waking immobility (wSPW-Rs) have recently been associated with memory consolidation, but also with future trajectory planning and hippocampal map stabilization. These observations raise the exciting possibility that enhancing reactivations through wSPW-Rs could improve memory performance. Previous studies showed that presenting a sensory cue associated with a past experience can bias the content of neuronal reactivations occurring during sleep SPW-Rs. Similarly, we used olfactory cues in an attempt to bias wSPW-R content and probe their function in spatial learning. We recorded neurons from the dorsal hippocampus of mice trained to locate fixed hidden goal locations in two environments. During learning, an odor was added in the water rewards of one environment while a second odor was used on the other environment. Both environments were visited in a pseudo-random fashion. In order to manipulate wSPW-Rs, one of the two odors (designed as a 'reinforcing' cue) was dispensed during the inter-trial intervals. A retrieval test was then conducted in the absence of odors. Preliminary results suggest that, despite having little influence on the behavioral performance, the rate of reward-associated ripples was enhanced on the non-reinforced environment during learning. During the retrieval test, place cell representations did not significantly differ in quality between reinforced and non-reinforced environments. Altogether these data suggest that wSPW-Rs occurrence are subject to task-demand and sensory priming that could favor a homogeneous representation of different environments for optimal memory performance and retrieval.

AN EXAMINATION OF THE BEHAVIOURAL AND NEURAL CORRELATES OF HUMAN NAVIGATION AND SPATIAL MEMORY.

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Conor Thornberry, Seán Commins
Maynooth University, Dept. Of Psychology, Kildare, Ireland

Learning how to navigate our environment and recall important locations is an vital subconscious cognitive task we perform every day. Navigation, along with the required learning and memory, has been examined extensively in animals using the Morris water maze (Morris, 1981). In this task animals are required to find a platform, hidden somewhere in a large circular pool of water (below surface level). As animals cannot see the goal directly, they must use various cues in the environment to locate it and escape. With the advancements in virtual reality technologies, navigation can now be directly examined in humans using a virtual version of the task. For this project, we have used our open-source virtual water maze software NavWell (Commins et al., 2020) to record real-time navigation learning and recall in human participants. We have also simultaneously recorded the neural activity using Electroencephalography (EEG) with the BioSemi Active 32 system. Here, we examine 25 adult participants (mean age = 22.5 years). All participants showed good learning across 12 trials of the navigation task. Furthermore, we examine frequency-band power changes in both theta (4 - 8Hz) and alpha (8 - 12Hz) that correlate with learning. Results are discussed in terms of the interaction between the two bands and their possible role in place learning and recall. We aim to examine learning and neural differences across age.

EFFECTS OF TRANSCRANIAL MAGNETIC STIMULATION ON SPATIAL MEMORY AND RELATED BRAIN OXIDATIVE METABOLISM

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Candela Zorzo Vallina, Marta Méndez, Jorge Arias
University of Oviedo, Psychology, Oviedo, Spain

Repetitive transcranial magnetic stimulation (rTMS) is a non-invasive neuromodulation technique that allows modifying brain excitability outside the skull. The use of rTMS is promising to treat several disorders that affect our nervous system, however, there are still many unknowns about its mechanism of action, as well as in the modulation of memory processes. Our objective was to determine its effects on the nervous system of healthy rodents, taking into account brain oxidative metabolism, neuronal activation and the study of glial cells, the latter being indicators of possible inflammatory effects. We apply rTMS with different stimulation protocols, modifying the number of trials, pulses and days of administration and we study the oxidative metabolism through the histochemistry of cytochrome c oxidase (CCO), the neuronal activation through the immunohistochemistry of c -Fos, and the study of glial cells through the immunohistochemistry of GFAP and Iba1, selective markers of astrocytes and immunoreactive microglia, respectively. Regarding possible impact on spatial memory, we used the Morris water maze. The results showed that rTMS is able to modify CCO activity in cortical and hippocampal regions, produces an increase in neuronal activation, and does not lead to changes in glial cell density. We also observe that, although it does not lead to facilitation of spatial memory, it is capable of achieving a more efficient use of the brain networks that support it. In conclusion, these experiments add information about the mechanism of action of rTMS, and its potential use in the modulation of cognitive functions.

Experience such as learning enhances adult hippocampal neurogenesis in the dentate gyrus, a brain region essential for learning and memory, by promoting newborn neurons development into the dentate network. In return, adult-born neurons play an important role in the encoding of new spatial memories. Yet, it is still unknown if spatial learning influences the connectome of adult-born neurons. Here, using an approach allowing the visualization of the glutamatergic post-synaptic densities and a retroviral retrograde monosynaptic tracing method, we characterized the connectome of adult-born neurons following spatial learning at different time points of their maturation. First, we showed that the glutamatergic post-synaptic density on adult-born neurons immature at the time of learning is increased following spatial learning, suggesting an enhanced excitatory innervation. We evidenced that this enhancement corresponds to a transient increase in the innervation from other mature granule cells during the first days of life of newborn neurons. Once adult-born neurons reach full maturity, we showed that spatial learning similarly increased their total glutamatergic post-synaptic density and also their innervation from the hilus. The analyses of their intrinsic properties by patch clamp confirm that spatial learning increase the presence of glutamatergic receptors. All together our results indicated a crucial role of glutamatergic transmission in learning–induced modulation of adult-born neurons.

COMMUNICATION BETWEEN THE HIPPOCAMPUS, NUCLEUS ACCUMBENS AND VENTRAL TEGMENTAL AREA DURING LEARNING AND MEMROY

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Raphael Brito, Linda Kokou, Maxime Linard, Anna Aldanondo, Ralitsa Todorova, Marco Pompili, Michaël Zugaro
Collège de France, Cirb, Paris, France

The hippocampus is thought to form the brain substrate of a cognitive map. While the spatial component of this map involves hippocampal ‘place’ cells, non-spatial features may require coupling with other brain areas. This could involve ‘hippocampal sequences’, endogenous activations of successive place cells representing entire trajectories at a highly accelerated rate. These sequences are paced by theta or ripple oscillations, and could participate in learning and memory, as well as goal-directed decision making. However, the association between hippocampal sequences and reward- and goal-related signals remains poorly understood. The ventral tegmental area (VTA) and nucleus accumbens (Nacc) are involved in reward coding and goal-directed action selection, and have both been independently reported to activate during hippocampal ripples. These co-activations could be part of a broader mechanism, whereby the three structures coordinate at a precise timescale during hippocampal oscillations, with different characteristics depending on cognitive function. To explore these questions, we perform electrophysiological recordings from dozens of single units in the dorsal hippocampus, NAcc and VTA simultaneously, in rats trained to learn a complex spatial memory task : the ‘Hippodamos maze’. This novel task features a daily-changing set of reward and error zones, requiring the rats to learn elaborate spatial configurations, to flexibly adapt to changes in these configurations, and every day learn and remember trajectories never experienced before. We investigate how the hippocampus, NAcc and VTA coordinate during various cognitive functions (learning, recall, planning, long-term storage, etc.) and relate to the performance of the animals in the task.

THE RAT HEXMAZE: A STUDY INTO HOW PREVIOUS KNOWLEDGE AFFECTS LEARNING

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Jacqueline Van Der Meij, Adrian Aleman-Zapata, Alejandra Alonso, Liz Van Den Brand, Abdel Rayan, Anumita Samanta, Irene Navarro-Lobato, Lisa Genzel
Donders Institute for Brain, Cognition and Behaviour, Radboud University, Neuroinformatics, Nijmegen, Netherlands

How does sleep influence memory processing and which factors such as previous knowledge can influence this? To examine this, we developed a new behavioral task called the HexMaze, a large (9x5m) maze for rats. This task allows us to study how quickly rats build a knowledge network (i.e. cognitive map) of the environment, how they update this map with new information (i.e. goal location change) and paves the way for examination of neural correlates for these behavioral measures. The use of pharmacological manipulations additionally allows us to evaluate the role of different brain regions, such as the hippocampus, during different phases of the task. In the current study, we used cyanquixaline (CNQX) to temporarily inhibit the CA1 region of the hippocampus in rats during the different phases of the task (i.e. build-up and update phase), either while learning a new goal location or while retrieving a previously learned location. We show that rats are able to perform direct runs between start and goal location already in the first training sessions. Moreover, they show expedited long-term memory after updating approximately twelve weeks into training. Through inhibition of CA1 during retrieval in both the build-up and update phase, we additionally show that the lack of a fully working hippocampus does not seem to negatively affect the rats' performance in the HexMaze task. These results seem to hint to less of a role of the hippocampus already during the formation of a cognitive map.

Disrupting ripples: Methods, results, and caveats in closed-loop approaches in rodents.
Hippocampal ripple oscillations have been associated with memory reactivations during wake and sleep. These reactivations should contribute to working memory and memory consolidation respectively. In the past decade studies have moved from being observational to actively disrupting ripple-related activity in closed-loop approaches to enable causal investigations into their function. All together these studies have been able to provide evidence that wake, task-related ripple activity is important for working memory and planning but less important for stabilisation of spatial representations. Rest and sleep-related ripple activity, in contrast, is important for long-term memory performance and thus memory consolidation. In this review, we summarise results from different closed-loop approaches in rodents. Further, we highlight differences in detection and stimulation methods as well as controls and discuss how these differences could influence outcomes.

The HexMaze: A Previous Knowledge Task on Map Learning for Mice.
New information is rarely learned in isolation; instead, most of what we experience can be incorporated into or uses previous knowledge networks in some form. Previous knowledge in form of a cognitive map can facilitate knowledge acquisition and will influence how we learn new spatial information. Here, we developed a new spatial navigation task where food locations are learned in a large, gangway maze to test how mice learn a large spatial map over a longer time period-the HexMaze. Analyzing performance across sessions as well as on specific trials, we can show simple memory effects as well as multiple effects of previous knowledge of the map accelerating both online learning and performance increases over offline periods when incorporating new information. We could identify the following three main phases: (1) learning the initial goal location; (2) faster learning after 2 weeks when learning a new goal location; and then (3) the ability to express one-session learning, leading to long-term memory effect after 12 weeks. Importantly, we are the first to show that buildup of a spatial map is dependent on how much time passes, not how often the animal is trained.

32954007: Alonso A, van der Meij J, Tse D, Genzel L
Naïve to expert: Considering the role of previous knowledge in memory.
In humans, most of our new memories are in some way or another related to what we have already experienced. However, in

memory research, especially in non-human animal research, subjects are often mostly naïve to the world. But we know that previous knowledge will change how memories are processed and which brain areas are critical at which time point. Each process from encoding, consolidation, to memory retrieval will be affected. Here, we summarise previous knowledge effects on the neurobiology of memory in both humans and non-human animals, with a special focus on schemas - associative network structures. Furthermore, we propose a new theory on how there may be a continuous gradient from naïve to expert, which would modulate the importance and role of brain areas, such as the hippocampus and prefrontal cortex.
Brain Neurosci Adv, 2020 Jan-Dec; 4

Divergent neuronal activity patterns in the avian hippocampus and nidopallium.
Sleep-related brain activity occurring during non-rapid eye-movement (NREM) sleep is proposed to play a role in processing information acquired during wakefulness. During mammalian NREM sleep, the transfer of information from the hippocampus to the neocortex is thought to be mediated by neocortical slow-waves and their interaction with thalamocortical spindles and hippocampal sharp-wave ripples (SWRs). In birds, brain regions composed of pallial neurons homologous to neocortical (pallial) neurons also generate slow-waves during NREM sleep, but little is known about sleep-related activity in the hippocampus and its possible relationship to activity in other pallial regions. We recorded local field potentials (LFP) and analogue multiunit activity (AMUA) using a 64-channel silicon multi-electrode probe simultaneously inserted into the hippocampus and medial part of the nidopallium (i.e., caudal medial nidopallium; NCM) or separately into the caudolateral nidopallium (NCL) of adult female zebra finches (Taeniopygia guttata) anesthetized with isoflurane, an anesthetic known to induce NREM sleep-like slow-waves. We show that slow-waves in NCM and NCL propagate as waves of neuronal activity. In contrast, the hippocampus does not show slow-waves, nor sharp-wave ripples, but instead displays localized gamma activity. In conclusion, neuronal activity in the avian hippocampus differs from that described in mammals during NREM sleep, suggesting that hippocampal memories are processed differently during sleep in birds and mammals.

Local Aspects of Avian Non-REM and REM Sleep.
Birds exhibit two types of sleep that are in many respects similar to mammalian rapid eye movement (REM) and non-REM (NREM) sleep. As in mammals, several aspects of avian sleep can occur in a local manner within the brain. Electrophysiological evidence of NREM sleep occurring more deeply in one hemisphere, or only in one hemisphere - the latter being a phenomenon most pronounced in dolphins - was actually first described in birds. Such asymmetric or unihemispheric NREM sleep occurs with one eye open, enabling birds to visually monitor their environment for predators. Frigatebirds primarily engage in this form of sleep in flight, perhaps to avoid collisions with other birds. In addition to interhemispheric differences in NREM sleep intensity, the intensity of NREM sleep is homeostatically regulated in a local, use-depended manner within each hemisphere. Furthermore, the intensity and temporo-spatial distribution of NREM sleep-related slow waves varies across layers of the avian hyperpallium - a primary visual area - with the slow waves occurring first in, and propagating through and outward from, thalamic input layers. Slow waves also have the greatest amplitude in these layers. Although most research has focused on NREM sleep, there are also local aspects to avian REM sleep. REM sleep-related reductions in skeletal muscle tone appear largely restricted to muscles involved in maintaining head posture. Other local aspects of sleep manifest as a mixture of features of NREM and REM sleep occurring simultaneously in different parts of the neuroaxis. Like monotreme mammals, ostriches often exhibit brainstem-mediated features of REM sleep (muscle atonia and REMs) while the hyperpallium shows EEG slow waves typical of NREM sleep. Finally, although mice show slow waves in thalamic input layers of primary sensory cortices during REM sleep, this is not the case in the hyperpallium of pigeons, suggesting that this phenomenon is not a universal feature of REM sleep. Collectively, the local aspects of sleep described in birds and mammals reveal that wakefulness, NREM sleep, and REM sleep are not always discrete states.
Front Neurosci, 2019; 13
30983954: van der Meij J, Martinez-Gonzalez D, Beckers GJL, Rattenborg NC
Neurophysiology of Avian Sleep: Comparing Natural Sleep and Isoflurane Anesthesia.
Propagating slow-waves in electroencephalogram (EEG) or local field potential (LFP) recordings occur during non-rapid eye-movement (NREM) sleep in both mammals and birds. Moreover, in both, input from the thalamus is thought to contribute to the genesis of NREM sleep slow-waves. Interestingly, the general features of slow-waves are also found under isoflurane anesthesia. However, it is unclear to what extent these slow-waves reflect the same processes as those giving rise to NREM sleep slow-waves. Similar slow-wave spatio-temporal properties during NREM sleep and isoflurane anesthesia would suggest that both types of slow-waves are based on related processes. We used a 32-channel silicon probe connected to a transmitter to make intra-cortical recordings of the visual hyperpallium in naturally sleeping and isoflurane anesthetized pigeons () using a within-bird design. Under anesthesia, the amplitude of LFP slow-waves was higher when compared to NREM sleep. Spectral power density across all frequencies (1.5-100 Hz) was also elevated. In addition, slow-wave

coherence between electrode sites was higher under anesthesia, indicating higher synchrony when compared to NREM sleep. Nonetheless, the spatial distribution of slow-waves under anesthesia was more comparable to NREM sleep than to wake or REM sleep. Similar to NREM sleep, slow-wave propagation under anesthesia mainly occurred in the thalamic input layers of the hyperpallium, regions which also showed the greatest slow-wave power during both recording conditions. This suggests that the thalamus could be involved in the genesis of slow-waves under both conditions. Taken together, although slow-waves under isoflurane anesthesia are stronger, they share spatio-temporal activity characteristics with slow-waves during NREM sleep.

Intra-"cortical" activity during avian non-REM and REM sleep: variant and invariant traits between birds and mammals.
Several mammalian-based theories propose that the varying patterns of neuronal activity occurring in wakefulness and sleep reflect different modes of information processing. Neocortical slow-waves, hippocampal sharp-wave ripples, and thalamocortical spindles occurring during mammalian non-rapid eye-movement (NREM) sleep are proposed to play a role in systems-level memory consolidation. Birds show similar NREM and REM (rapid eye-movement) sleep stages to mammals; however, it is unclear whether all neurophysiological rhythms implicated in mammalian memory consolidation are also present. Moreover, it is unknown whether the propagation of slow-waves described in the mammalian neocortex occurs in the avian "cortex" during natural NREM sleep. We used a 32-channel silicon probe connected to a transmitter to make intracerebral recordings of the visual hyperpallium and thalamus in naturally sleeping pigeons (Columba livia). As in the mammalian neocortex, slow-waves during NREM sleep propagated through the hyperpallium. Propagation primarily occurred in the thalamic input layers of the hyperpallium, regions that also showed the greatest slow-wave activity (SWA). Spindles were not detected in both the visual hyperpallium, including regions receiving thalamic input, and thalamus, using a recording method that readily detects spindles in mammals. Interestingly, during REM sleep fast gamma bursts in the hyperpallium (when present) were restricted to the thalamic input layers. In addition, unlike mice, the decrease in SWA from NREM to REM sleep was the greatest in these layers. Taken together, these variant and invariant neurophysiological aspects of avian and mammalian sleep suggest that there may be associated mechanistic and functional similarities and differences between avian and mammalian sleep.
Sleep, 2019; 42
24580797: Beckers GJ, van der Meij J, Lesku JA, Rattenborg NC
Plumes of neuronal activity propagate in three dimensions through the nuclear avian brain.
In mammals, the slow-oscillations of neuronal membrane potentials (reflected in the electroencephalogram as high-amplitude, slow-waves), which occur during non-rapid eye movement sleep and anesthesia, propagate across the neocortex largely as two-dimensional traveling waves. However, it remains unknown if the traveling nature of slow-waves is unique to the laminar cytoarchitecture and associated computational properties of the neocortex.

SUB-CHRONIC PCP TREATMENT IN RATS DOES NOT IMPAIR HIPPOCAMPAL RAPID PLACE LEARNING ON THE WATERMAZE DELAYED-MATCHING-TO-PLACE TASK

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Charlotte Taylor[1], Jacco Renstrom[1], Joanna Loayza[1], Paula Moran[1], Jo Neill[2], John Gigg[3], Mike Harte[2], Tobias Bast[1]
[1]University of Nottingham, School Of Psychology, Nottingham, United Kingdom, [2]University of Manchester, Division Of Pharmacy And Optometry, Manchester, United Kingdom, [3]University of Manchester, Division Of Neuroscience And Experimental Psychology, Manchester, United Kingdom

NMDA receptor hypofunction caused by sub-chronic treatment with phencyclidine (scPCP) has been reported to cause impairments in GABAergic interneurons, including in the hippocampus (Neill et al.,2010,*Pharmacol.Ther.*). However, it is unclear how this impairment may contribute to cognitive deficits in the scPCP model. The watermaze delayed-matching-to-place (DMP) task requires hippocampal GABAergic inhibition, with hippocampal neural disinhibition markedly impairing task performance (McGarrity et al.,2017,*Cereb.Cortex*). Therefore, we investigated whether scPCP treatment would cause watermaze-DMP deficits, similar to those produced by hippocampal neural disinhibition. Young adult male and female Lister-hooded rats were tested on the watermaze DMP task at 1, 3 and 5 weeks following scPCP (males: 5 mg/kg; females: 2 mg/kg, bi-daily for 7 days). Rats also underwent testing of novel object recognition (NOR), locomotor activity (LMA), startle reactivity and prepulse inhibition (PPI). Sub-chronic PCP did not impair watermaze-DMP performance. In addition, sensorimotor processes measured using LMA, startle and PPI were unaffected by scPCP treatment. NOR testing at week 1 revealed a deficit in the scPCP group ($F_{(1, 28)}$=10.5, p<0.01), which was not significant at later time points. This is consistent with previous studies, although many previous studies reported a long-lasting NOR deficit (Rajagopal et al.,2014,*Curr.Pharm.Des.*). We hypothesise that handling and/or exercise during watermaze testing may have rescued later NOR deficits, as both handling and exercise were reported to improve scPCP-induced NOR impairments (Mitsadali et al.,2020,*J.Psychopharmacol.*; Watson et al.,2019,*J.Psychopharmacol.*). Overall, scPCP treatment did not disrupt hippocampal rapid place learning performance. This contrasts with the marked impairments observed following acute pharmacological hippocampal disinhibition.

Hippocampal Disinhibition Reduces Contextual and Elemental Fear Conditioning While Sparing the Acquisition of Latent Inhibition.
Hippocampal neural disinhibition, i.e., reduced GABAergic inhibition, is a key feature of schizophrenia pathophysiology. The hippocampus is an important part of the neural circuitry that controls fear conditioning and can also modulate prefrontal and striatal mechanisms, including dopamine signaling, which play a role in salience modulation. Consequently, hippocampal neural disinhibition may contribute to impairments in fear conditioning and salience modulation reported in schizophrenia. Therefore, we examined the effect of ventral hippocampus (VH) disinhibition in male rats on fear conditioning and salience modulation, as reflected by latent inhibition (LI), in a conditioned emotional response (CER) procedure. A flashing light was used as the conditioned stimulus (CS), and conditioned suppression was used to index conditioned fear. In experiment 1, VH disinhibition via infusion of the GABA-A receptor antagonist picrotoxin before CS pre-exposure and conditioning markedly reduced fear conditioning to both the CS and context; LI was evident in saline-infused controls but could not be detected in picrotoxin-infused rats because of the low level of fear conditioning to the CS. In experiment 2, VH picrotoxin infusions only before CS pre-exposure did not affect the acquisition of fear conditioning or LI. Together, these findings indicate that VH neural disinhibition disrupts contextual and elemental fear conditioning, without affecting the acquisition of LI. The disruption of fear conditioning resembles aversive conditioning deficits reported in schizophrenia and may reflect a disruption of neural processing both within the hippocampus and in projection sites of the hippocampus.

The Pituitary Adenylate Cyclase-Activating Peptide 38 more commonly known as PACAP-38 (P38) is an endogenous human neuropeptide. In order to efficiently use its neuroprotective (Deguil *et al.,* 2010), vasodilatory (Tlili *et al.,* 2015) and antioxidant (Masmoudi-Kouki *et al.,* 2011) properties for potential therapeutical purposes, an analog (P38-alg), chemically more stable than P38 was synthesized by Bourgault *et al.,* in 2008. We studied the effects of a single intravenous injection of P38 (30 µg/kg), P38-alg (30 µg/kg) and NaCl 0.9% (SAL) on spatial memory in male Wistar rats and measured BDNF levels in the hippocampus. A fourth group received also an injection of NaCl (0.9%) but rats were neither trained nor tested (SALNT). Using a weak massed-learning procedure, we trained P38, P38-alg and SAL groups in a reference memory version of the navigation task in the Morris Water Maze. The 3 groups showed similar acquisition of the task but the P38 group displayed enhanced memory of the platform location in the probe trial with respect to both P38-alg and SAL groups. Training reduced BDNF expression in the hippocampus in SAL relative to SALNT rats. In contrast, P38 administration increased BDNF content that was restored to its basal level. BDNF in P38-alg group was similar to SAL group. Thus, the results suggest that P38 exerts a promnesic effect in rats that is mediated by hippocampal BDNF. In contrast, P38-alg did not mimick the effects of P38 on both spatial memory and BDNF.

EARLY EXPOSURE TO WESTERN-TYPE DIET AND STRESS BY MATERNAL SEPARATION PROGRAM BRAIN METABOLIC CAPACITY AND COGNITION IN ADULT RATS

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Saúl Sal Sarria, Isabel López Taboada, Nélida Conejo Jiménez, Héctor González Pardo
University Of Oviedo/INEUROPA, Department Of Psychology, Oviedo, Spain

Exposure to early-life stress and consumption of high-fat and high-sugar diets (HFS) [similar to Western-type diets] represent two of the most frequent and ubiquitous adverse environmental factors influencing neurodevelopment nowadays. Both factors have been widely associated with all kinds of problems, including learning or memory deficits and impaired cognitive flexibility. **Methods:** The combined effects after lifelong exposure to an HFS diet and early-life stress by maternal separation were evaluated in adult Wistar rats. Specifically, possible long-term effects on spatial memory and cognitive flexibility were evaluated in the Morris Water Maze. Regional brain metabolic capacity using quantitative cytochrome oxidase histochemistry was measured in selected key brain regions related to spatial memory and behavioral flexibility. **Results:** Significant effects of both factors were found for spatial learning and memory abilities, associated with changes in the metabolic capacity of the prefrontal cortex, the cingulate cortex and the dorsal hippocampus. **Conclusion:** Prolonged consumption of HFS diet impaired spatial memory, but particularly behavioral flexibility. Furthermore, these effects were accompanied by increased brain metabolic capacity in the previously mentioned regions, probably related with increased neuroinflammatory mechanisms. In summary, the study shows the relevance of the sensitive developmental periods of exposure to important environmental factors for brain development and adult cognition. Finally, our results suggests that the specific combination of particular environmental factors can program adult behavior and brain metabolic capacity.

THE ROLE OF MPFC SPATIAL CODING IN SUPPORTING A CONTEXTUAL ASSOCIATION TASK

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Andrea Cumpelik, Jozsef Csicsvari
Institute of Science and Technology Austria, Systems Neuroscience, Klosterneuburg, Austria

The medial prefrontal cortex (mPFC) has a broad role in decision making and executive functions, as well as consolidation of long-term memories. These distinct functions are reconciled by the mPFC's role in context-dependent decision making, which requires the evaluation and selection of representations that are relevant for a particular task or goal. Moreover, the mPFC has recently been shown to encode spatial information in well-trained animals during tasks that rely on spatial information for correct decisions. Importantly, this spatial encoding may not be present during purely exploratory behavior. Instead, it may arise as a result of coordination between the hippocampus and mPFC while animals engage in specific spatial tasks. Our work aims to identify at what point in the learning process these spatial representations appear in the mPFC. We use 32-tetrode microdrives to record from the hippocampus and mPFC while rats learn to associate a particular food cue with a specific reward location in an 8-arm maze. Two paired cue-location associations are learned in parallel. To find the reward, the rats must flexibly adapt their behavior based on which cue is presented, i.e. which "context" they find themselves in. During the acquisition of the behavioral data, we observed a sudden jump in performance after 6-7 days of training. This shift may coincide with the appearance of spatial representations in the mPFC. Determining when mPFC spatial representations first appear during context-dependent decision making will provide insight into how behavioral demands may drive the appearance of task-relevant information in the mPFC.

Cocaine Place Conditioning Strengthens Location-Specific Hippocampal Coupling to the Nucleus Accumbens.
Conditioned place preference (CPP) is a widely used model of addiction-related behavior whose underlying mechanisms are not understood. In this study, we used dual site silicon probe recordings in freely moving mice to examine interactions between the hippocampus and nucleus accumbens in cocaine CPP. We found that CPP was associated with recruitment of D2-positive nucleus accumbens medium spiny neurons to fire in the cocaine-paired location, and this recruitment was driven predominantly by selective strengthening of coupling with hippocampal place cells that encode the cocaine-paired location. These findings provide in vivo evidence suggesting that the synaptic potentiation in the accumbens caused by repeated cocaine administration preferentially affects inputs that were active at the time of drug exposure. This provides a potential physiological mechanism by which drug use becomes associated with specific environmental contexts.

CORTICO-STRIATAL NETWORK GUIDING STRATEGY DEPLOYMENT IN A TRIAL AND ERROR NAVIGATION TASK

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Martina Parrini, Guillaume Tricot, Pico Caroni, Maria Spolidoro
Friedrich Miescher Institute for Biomedical Research, Neurobiology, Basel, Switzerland

Unsupervised spatial navigation tasks involve deployment of search strategies, which are increasingly refined presumably as a function of action-outcome learning sessions. The brain mechanisms allowing this balance between flexibility and efficiency are poorly understood, but dorsal striatum is likely implicated, possibly under the direction of cortical areas related to the hippocampus. One of these areas, the retrosplenial cortex (RSC) has been shown to have a role in spatial learning and navigation in rodents and humans. In this study we show that RSC and dorsomedial striatum (DMS) have both an essential, although different role in implementing the deployment of search strategies in the Morris Water Maze. In particular, we demonstrate that RSC acts upstream of DMS to provide an instructive signal directing the relative use of different strategies in response to the goal and the knowledge of the task. On the other hand, activity in DMS is necessary for a fast learning progression and is more directly linked to the action. Moreover, the function of DMS is strongly dependent on validation, thus providing a fundamental feedback mechanism that helps promoting the gradual refinement of search strategies.

Restoring neuronal chloride homeostasis with anti-NKCC1 gene therapy rescues cognitive deficits in a mouse model of Down syndrome.
A common feature of diverse brain disorders is the alteration of GABA-mediated inhibition because of aberrant, intracellular chloride homeostasis induced by changes in the expression and/or function of chloride transporters. Notably, pharmacological inhibition of the chloride importer NKCC1 is able to rescue brain-related core deficits in animal models of these pathologies and in some human clinical studies. Here, we show that reducing NKCC1 expression by RNA interference in the Ts65Dn mouse model of Down syndrome (DS) restores intracellular chloride concentration, efficacy of gamma-aminobutyric acid (GABA)-mediated inhibition, and neuronal network dynamics in vitro and ex vivo. Importantly, adeno-associated virus (AAV)-mediated, neuron-specific NKCC1 knockdown in vivo rescues cognitive deficits in diverse behavioral tasks in Ts65Dn animals. Our results highlight a mechanistic link between NKCC1 expression and behavioral abnormalities in DS mice and establish a molecular target for new therapeutic approaches, including gene therapy, to treat brain disorders characterized by neuronal chloride imbalance.

Gene Editing Preserves Visual Functions in a Mouse Model of Retinal Degeneration.
Inherited retinal dystrophies (IRDs) are a large and heterogeneous group of degenerative diseases caused by mutations in various genes. Given the favorable anatomical and immunological characteristics of the eye, gene therapy holds great potential for their treatment. Our goal is to validate the preservation of visual functions by viral-free homology directed repair (HDR) in an autosomal recessive loss of function mutation. We used a tailored gene editing system based on clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated protein 9 (Cas9) to prevent retinal photoreceptor death in the retinal degeneration 10 (Rd10) mouse model of retinitis pigmentosa. We tested the gene editing tool and then used subretinal electroporation to deliver it to one of the retinas of mouse pups at different stages of photoreceptor differentiation. Three months after gene editing, the treated eye exhibited a higher visual acuity compared to the untreated eye. Moreover, we observed preservation of light-evoked responses both in explanted retinas and in the visual cortex of treated animals. Our study validates a CRISPR/Cas9-based therapy as a valuable new approach for the treatment of retinitis pigmentosa caused by autosomal recessive loss-of-function point mutations.

Aerobic exercise and a BDNF-mimetic therapy rescue learning and memory in a mouse model of Down syndrome.

Down syndrome (DS) is caused by the triplication of human chromosome 21 and represents the most frequent genetic cause of intellectual disability. The trisomic Ts65Dn mouse model of DS shows synaptic deficits and reproduces the essential cognitive disabilities of the human syndrome. Aerobic exercise improved various neurophysiological dysfunctions in Ts65Dn mice, including hippocampal synaptic deficits, by promoting synaptogenesis and neurotransmission at glutamatergic terminals. Most importantly, the same intervention also prompted the recovery of hippocampal adult neurogenesis and synaptic plasticity and restored cognitive performance in trisomic mice. Additionally, the expression of brain-derived neurotrophic factor (BDNF) was markedly decreased in the hippocampus of patients with DS. Since the positive effect of exercise was paralleled by increased BDNF expression in trisomic mice, we investigated the effectiveness of a BDNF-mimetic treatment with 7,8-dihydroxyflavone at alleviating intellectual disabilities in the DS model. Pharmacological stimulation of BDNF signaling rescued synaptic plasticity and memory deficits in Ts65Dn mice. Based on our findings, Ts65Dn mice benefit from interventions aimed at promoting brain plasticity, and we provide evidence that BDNF signaling represents a potentially new pharmacological target for treatments aimed at rescuing cognitive disabilities in patients with DS.

Reversing excitatory GABAAR signaling restores synaptic plasticity and memory in a mouse model of Down syndrome.
Down syndrome (DS) is the most frequent genetic cause of intellectual disability, and altered GABAergic transmission through Cl(-)-permeable GABAA receptors (GABAARs) contributes considerably to learning and memory deficits in DS mouse models. However, the efficacy of GABAergic transmission has never been directly assessed in DS. Here GABAAR signaling was found to be excitatory rather than inhibitory, and the reversal potential for GABAAR-driven Cl(-) currents (ECl) was shifted toward more positive potentials in the hippocampi of adult DS mice. Accordingly, hippocampal expression of the cation Cl(-) cotransporter NKCC1 was increased in both trisomic mice and individuals with DS. Notably, NKCC1 inhibition by the FDA-approved drug bumetanide restored ECl, synaptic plasticity and hippocampus-dependent memory in adult DS mice. Our findings demonstrate that GABA is excitatory in adult DS mice and identify a new therapeutic approach for the potential rescue of cognitive disabilities in individuals with DS.

Which brain regions play a key role in updating previous knowledge in a large navigational task? We studied the immediate early gene (IEG) expression of *c-Fos* and *Arc* in rodents trained in a large hexagonal maze (HexMaze, 2mX2m) for three months. We studied the IEG expression in medial prefrontal cortex, hippocampal structures, posterior parietal and retrosplenial cortex of mice and rats and compared the expression of IEGs during the first and fourth session of an update of a goal location after the animals were trained for three months on the maze and compared this to early training (2nd day on the maze) as well as a homecage control. We set up a double-labeling immunohistochemistry protocol and used widefield microscope and image data analysis with FIJI/ImageJ and Ilastik to count *Arc*+ and *c-Fos*+ cells. Our result indicate different brain regions show varying *Arc* and *cFOS* expression the different conditions. Overall, this effect of condition was especially pronounced in hippocampal regions as well as prelimbic and parietal cortex. In sum, we could show that previous knowledge will influence where in the brain memories are being consolidated.

CHOOSING MEMORY RETRIEVAL STRATEGIES: A CRITICAL ROLE FOR INHIBITION IN THE DENTATE GYRUS

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Alice Weiglein[1], Iris Müller[2], Gürsel Çalışkan[2], Oliver Stork[2], Anne Albrecht[1]

Remembering the location of a worthwhile food source is not only crucial for survival but also a major faculty of neural networks. Humans and rodents alike exert two distinct strategies to learn and retrieve reward-featuring locations. The cue response strategy is based on striatal stimulus-response, while the spatial strategy depends on the hippocampus. Especially rodents appear to prefer a spatial strategy. When being stressed, however, a shift to the stimulus-response strategy is observed. Using transgenic mice susceptible to stress due to a lack of the GABA-synthesizing enzyme GAD65, we investigated whether a reduction of spatial learning preference could be validated. The respective mice were assessed for their memory performance in a dual solution task for which they could learn the location of a food reward in an open field setup utilizing either one of the above-described strategies via proximal or distal cues, respectively. Interestingly, GAD65 knock out mice lacked a spatial preference during retrieval, but showed undisrupted spatial retrieval when no proximal cue was provided. Regarding the neural activation marker cFos, a shift in the co-activation of the hippocampal dentate gyrus (DG) with frontal cortical brain areas was demonstrated. Further, a shRNA-mediated local knock down of GAD65 within the DG replicated the behavioral effect, thus pinpointing a central role of the dorsal DG for retrieval strategies, particularly modulating strategy choices.

DEGREE OF CONTEXTUAL MEMORY IS ENCODED BY PLACE CELLS REMAPPING

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Azul Silva[1], Pedro Bekinschtein[2], Mariano Belluscio[1]
[1]University of Buenos Aires, Ifibio, Capital Federal, Argentina, [2]CONICET, Incyt, Buenos Aires, Argentina

Place cells (PC) are hippocampal neurons that are tuned to spatial location and are able to change their tuning when sensory inputs change (remapping). As a population, PCs are thought to form a cognitive map of events, providing the spatial dimension of episodic memory. Moreover, it has been suggested that the hippocampal ability of storing and distinguishing between different situations and contexts can be related with PC's remapping. Several studies have shown how PC can either remap or not as a consequence of changes in the environment. However, it is still unclear the role that PC have in episodic memory. The aim of this project is to understand how the PC activity of hippocampal's CA3 region correlates with the evocation of contextual memories. To tackle this question we performed electrophysiological recordings in CA3 while the animal was performing a task that allows us to discriminate if it recognizes a context as new, or as one it already knows. We found a significant correlation between CA3 PC activity and the memory that the animal is recalling. In particular the amount of remapping and the spatial correlation of PC activity between contexts is related with the animal's behavioral output. These results suggest that PC activity not only is important for spatial navigation but also for evocation of contextual memories.

NEURAL MECHANISMS OF SPATIAL MEMORY DEVELOPMENT

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Juraj Bevandić[1], Federico Stella[2], Freyja Ólafsdóttir[1]
[1]Donders Institute for brain, cognition & behaviour. Radboud University, Neurophysiology, Donders Centre For Neuroscience, Nijmegen, Netherlands, [2]Radboud University, Donders Institute, Nijmegen, Netherlands

Although as adults we can recall decades-old episodic/spatial memories with high precision this ability is not mature at birth; a phenomenon known as infantile amnesia. IA is thought to reflect the protracted development of the neuronal networks supporting memory recall and/or consolidation. Hippocampal replay – time-compressed reactivation of hippocampal cell sequences reflecting wakeful experiences – is a mechanism thought to support both these memory functions. Thus, we asked whether the delayed development of memory reflects the delayed maturation of replay. To this end, we recorded from large (~20-50) ensembles of hippocampal principal cells from developing (2-4weeks) rat pups while the pups engaged in a hippocampal-dependent working memory (WM) task and during rest. We observed the pups' performance on the task improved with age, reaching above-chance levels by P22. However, although the average performance improved gradually, individual pups displayed abrupt, over-night improvements in performance at different ages; showing the timing of WM emergence does not purely depend on learning time. Thus, we sought to investigate if the development of hippocampal reactivations mirrors these individual WM development profiles. *Preliminary* results show that although *candidate* hippocampal replay events become gradually more adult-like with age they also display a sharp transition in maturity at the time WM abruptly emerges. Further analyses are underway to elucidate the relationship between WM and replay development further. These results suggest the emergence of (working) memory may rely on the late development of replay and these findings indicate hippocampal replay as a prerequisite for different memory types and for planning.

INTERPLAY BETWEEN SLEEP AND NOVELTY IN SEMANTIC-LIKE MEMORY PROCESSING

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Anumita Samanta, Liz Van Den Brand, Jonna Spellmeyer, Laura Martinez, Irene Navarro-Lobato, Alejandra Alonso, Adrian Aleman-Zapata, Jacqueline Van Der Meij, Abdel Rayan, Lisa Genzel

Memories are thought to be initially encoded in the hippocampus and then integrated into the neocortex for long term storage. Sleep has been shown to play a crucial role in this consolidation process. However, the consolidation of one of a kind, novel memories (i.e. flashbulb memories) might be differently regulated. Novel experiences are known to strengthen memories encoded surrounding the event. We hypothesize that memories tagged with a novel experience get retained in the hippocampus with all the episodic details for the long-term, in contrast sleep following learning should lead to more cortical memory consolidation. Rats and mice were trained in the Object Space Task to evaluate their performance on cumulative memory expression (i.e. semantic-like memory). In addition, they were trained in an adapted version of the task wherein an interference trial was included 24 hours after training followed by novelty and/or sleep deprivation. Memory retrieval was then tested at 24/72 hours. Finally, they were sacrificed at different timepoints and brain samples were collected for IEG expression analyses Both rats and mice showed cumulative memory expression and remembered the original location configuration if they were allowed to sleep after training. However, when interference was followed by a novelty exposure, the animals remembered the interference trial and not the previous cumulative memory.. Our results validate the notion that novelty exposure strengthens event memories while sleep is important for cumulative memory processing.

Sleep Leads to Brain-Wide Neural Changes Independent of Allocentric and Egocentric Spatial Training in Humans and Rats.
Sleep is important for memory consolidation and systems consolidation in particular, which is thought to occur during sleep. While there has been a significant amount of research regarding the effect of sleep on behavior and certain mechanisms during sleep, evidence that sleep leads to consolidation across the system has been lacking until now. We investigated the role of sleep in the consolidation of spatial memory in both rats and humans using a watermaze task involving allocentric- and egocentric-based training. Analysis of immediate early gene expression in rodents, combined with functional magnetic resonance imaging in humans, elucidated similar behavioral and neural effects in both species. Sleep had a beneficial effect on behavior in rats and a marginally significant effect in humans. Interestingly, sleep led to changes across multiple brain regions at the time of retrieval in both species and in both training conditions. In rats, sleep led to increased gene expression in the hippocampus, striatum, and prefrontal cortex. In the humans, sleep led to an activity increase in brain regions belonging to the executive control network and a decrease in activity in regions belonging to the default mode network. Thus, we provide cross-species evidence for system-level memory consolidation occurring during sleep.

The HexMaze: A Previous Knowledge Task on Map Learning for Mice.
New information is rarely learned in isolation; instead, most of what we experience can be incorporated into or uses previous knowledge networks in some form. Previous knowledge in form of a cognitive map can facilitate knowledge acquisition and will influence how we learn new spatial information. Here, we developed a new spatial navigation task where food locations are learned in a large, gangway maze to test how mice learn a large spatial map over a longer time period-the HexMaze. Analyzing performance across sessions as well as on specific trials, we can show simple memory effects as well as multiple effects of previous knowledge of the map accelerating both online learning and performance increases over offline periods when incorporating new information. We could identify the following three main phases: (1) learning the initial goal location; (2) faster learning after 2 weeks when learning a new goal location; and then (3) the ability to express one-session learning, leading to long-term memory effect after 12 weeks. Importantly, we are the first to show that buildup of a spatial map is dependent on how much time passes, not how often the animal is trained.

The Object Space Task reveals increased expression of cumulative memory in a mouse model of Kleefstra syndrome.
Kleefstra syndrome is a disorder caused by a mutation in the EHMT1 gene characterized in humans by general developmental delay, mild to severe intellectual disability and autism. Here, we characterized cumulative memory in the Ehmt1 mouse model using the Object Space Task. We combined conventional behavioral analysis with automated analysis by deep-learning networks, a session-based computational learning model, and a trial-based classifier. Ehmt1 mice showed more anxiety-like features and generally explored objects less, but the difference decreased over time. Interestingly, when analyzing memory-specific exploration, Ehmt1 show increased expression of cumulative memory, but a deficit in a more simple, control memory condition. Using our automatic classifier to differentiate between genotypes, we found that cumulative memory features are better suited for classification than general exploration differences. Thus, detailed behavioral classification with the Object Space Task produced a more detailed behavioral phenotype of the Ehmt1 mouse model.

A novel natural product inspired scaffold with robust neurotrophic, neurogenic and neuroprotective action.
In search for drugs to treat neuropsychiatric disorders wherein neurotrophic and neurogenic properties are affected, two neurotrophically active small molecules specially crafted following natural product leads based on 2-oxa-spiro[5.5]-undecane scaffold, have been thoroughly evaluated for their neurotrophic, neurogenic and neuroprotective potential in ex vivo primary culture and in vivo zebrafish and mouse models. The outcome of in vivo investigations suggest that one of these molecules is more neurotrophic than neurogenic while the other one is more neurogenic than neurotrophic and the former exhibits remarkable neuroprotection in a mouse acute ischemic stroke model. The molecular mechanisms of action of these compounds appear to be through the TrkB-MEK-ERK-CREB-BDNF pathway as pre-treatment with neurotrophin receptor TrkB inhibitor ANA-12 and MEK inhibitor PD98059 attenuates the neurotrophic action of compounds.

Previous knowledge in the form of a cognitive map can facilitate knowledge acquisition and will influence how we learn new spatial information. Previous rat studies have shown that when memories fit to previous knowledge networks, consolidation can be very rapid, and memories can become hippocampal independent in a window of 48 hrs. However, which brain regions facilitate this effect in spatial memory is not clear yet. In the present study we perform pharmacological interventions of different brain regions at different stages of learning in a previous knowledge-based task. The mouse HexMaze is a large (2m x 2m) spatial environment, where animals learn to efficiently reach a reward location from different points of the maze. An initial 3 month build up period is followed by weekly changes to the maze, such as food location and introduction of barriers, and pharmacological inhibition takes place either during the initial build up period or during the stage of weekly updates. During weekly updates, inhibition took place either on the day of encoding, or 48 hrs later during retrieval. We replicated previous schema-effects and could show that the hippocampus was necessary for encoding of new information once the animals have extensive knowledge of the environment, but not necessary for retrieval. With this task we aim to disentangle current theories of memory consolidation taking into consideration the presence of previous knowledge.

Learning-Induced Shifts in Mice Navigational Strategies Are Unveiled by a Minimal Behavioral Model of Spatial Exploration.
Shifts in spatial patterns produced during the execution of a navigational task can be used to track the effects of the accumulation of knowledge and the acquisition of structured information about the environment. Here, we provide a quantitative analysis of mice behavior while performing a novel goal localization task in a large, modular arena, the HexMaze. To demonstrate the effects of different forms of previous knowledge we first obtain a precise statistical characterization of animals' paths with sub-trial resolution and over different phases of learning. The emergence of a flexible representation of the task is accompanied by a progressive improvement of performance, mediated by multiple, multiplexed time scales. We then use a generative mathematical model of the animal behavior to isolate the specific contributions to the final navigational strategy. We find that animal behavior can be accurately reproduced by the combined effect of a goal-oriented component, becoming stronger with the progression of learning, and of a random walk component, producing choices unrelated to the task and only partially weakened in time.

The HexMaze: A Previous Knowledge Task on Map Learning for Mice.
New information is rarely learned in isolation; instead, most of what we experience can be incorporated into or uses previous knowledge networks in some form. Previous knowledge in form of a cognitive map can facilitate knowledge acquisition and will influence how we learn new spatial information. Here, we developed a new spatial navigation task where food locations are learned in a large, gangway maze to test how mice learn a large spatial map over a longer time period-the HexMaze. Analyzing performance across sessions as well as on specific trials, we can show simple memory effects as well as multiple effects of previous knowledge of the map accelerating both online learning and performance increases over offline periods when incorporating new information. We could identify the following three main phases: (1) learning the initial goal location; (2) faster learning after 2 weeks when learning a new goal location; and then (3) the ability to express one-session learning, leading to long-term memory effect after 12 weeks. Importantly, we are the first to show that buildup of a spatial map is dependent on how much time passes, not how often the animal is trained.

Naïve to expert: Considering the role of previous knowledge in memory.

In humans, most of our new memories are in some way or another related to what we have already experienced. However, in memory research, especially in non-human animal research, subjects are often mostly naïve to the world. But we know that previous knowledge will change how memories are processed and which brain areas are critical at which time point. Each process from encoding, consolidation, to memory retrieval will be affected. Here, we summarise previous knowledge effects on the neurobiology of memory in both humans and non-human animals, with a special focus on schemas - associative network structures. Furthermore, we propose a new theory on how there may be a continuous gradient from naïve to expert, which would modulate the importance and role of brain areas, such as the hippocampus and prefrontal cortex.

The Object Space Task reveals increased expression of cumulative memory in a mouse model of Kleefstra syndrome.
Kleefstra syndrome is a disorder caused by a mutation in the EHMT1 gene characterized in humans by general developmental delay, mild to severe intellectual disability and autism. Here, we characterized cumulative memory in the Ehmt1 mouse model using the Object Space Task. We combined conventional behavioral analysis with automated analysis by deep-learning networks, a session-based computational learning model, and a trial-based classifier. Ehmt1 mice showed more anxiety-like features and generally explored objects less, but the difference decreased over time. Interestingly, when analyzing memory-specific exploration, Ehmt1 show increased expression of cumulative memory, but a deficit in a more simple, control memory condition. Using our automatic classifier to differentiate between genotypes, we found that cumulative memory features are better suited for classification than general exploration differences. Thus, detailed behavioral classification with the Object Space Task produced a more detailed behavioral phenotype of the Ehmt1 mouse model.

Basal forebrain somatostatin cells differentially regulate local gamma oscillations and functionally segregate motor and cognitive circuits.
The basal forebrain delivers extensive axonal projections to the cortical mantle regulating brain states and cognitive processing. Recent evidence has established the basal forebrain as a subcortical node of the default mode network that directionally influences cortical dynamics trough gamma oscillations, yet their synaptic origin has not been established. Here, we used optogenetic stimulation and in vivo recordings of transgenic mice to show that somatostatin neurons exert an anatomically specialized role in the coordination of subcortical gamma oscillations of the rostral basal forebrain. Indeed, the spike timing of somatostatin cells was tightly correlated with gamma oscillations in the ventral pallidum, but not in the medial septum. Consequently, optogenetic inactivation of somatostatin neurons selectively disrupted the amplitude and coupling of gamma oscillations only in the ventral pallidum. Moreover, photosupression of somatostatin cells produced specific behavioral interferences, with the ventral pallidum regulating locomotor speed and the medial septum modulating spatial working memory. Altogether, these data suggest that basal forebrain somatostatin cells can selectively synchronize local neuronal networks in the gamma band directly impinging on cortical dynamics and behavioral performance. This further supports the role of the basal forebrain as a subcortical switch commanding transitions between internally and externally oriented brain states.

Basal Forebrain Gating by Somatostatin Neurons Drives Prefrontal Cortical Activity.
The basal forebrain provides modulatory input to the cortex regulating brain states and cognitive processing. Somatostatin-expressing neurons constitute a heterogeneous GABAergic population known to functionally inhibit basal forebrain cortically projecting cells thus favoring sleep and cortical synchronization. However, it remains unclear if somatostatin cells can regulate population activity patterns in the basal forebrain and modulate cortical dynamics. Here, we demonstrate that somatostatin neurons regulate the corticopetal synaptic output of the basal forebrain impinging on cortical activity and behavior. Optogenetic inactivation of somatostatin neurons in vivo rapidly modified neural activity in the basal forebrain, with the consequent enhancement and desynchronization of activity in the prefrontal cortex, reflected in both neuronal spiking and network oscillations. Cortical activation was partially dependent on cholinergic transmission, suppressing slow waves and potentiating gamma oscillations. In addition, recruitment dynamics was cell type-specific, with interneurons showing similar temporal profiles, but stronger responses than pyramidal cells. Finally, optogenetic stimulation of quiescent animals during resting periods prompted locomotor activity, suggesting generalized cortical activation and increased arousal. Altogether, we provide physiological and behavioral evidence indicating that somatostatin neurons are pivotal in gating the synaptic output of the basal forebrain, thus indirectly controlling cortical operations via both cholinergic and non-cholinergic mechanisms.

During acquisition of spatial memory, subjects optimize the path to the goal across training, process supported by the prefrontal cortex (PFC). Theta oscillations (6-12 Hz) emerge in the PFC during spatial navigation, likely supporting large-scale neural communication during learning. Importantly, theta activity displays dynamical fluctuations along the behavioral task, which may represent different states of synchronization and desynchronization of neural populations as required for cortical computations. However, it is not known if this oscillatory dynamics in the PFC is necessary for spatial learning. To test this possibility, we perturbed prefrontal oscillatory dynamics during learning. Accordingly, we induced optogenetic continual entrainment of prefrontal activity at theta frequency band during training in the Barnes maze task in freely behaving mice expressing ChR2 in layer V cortical pyramidal neurons. Optogenetic stimulation at theta frequency reliably entrained neural firing and oscillatory activity in the PFC in opsin-expressing mice, but not in controls. Several measurements of oscillatory dynamics, as spectral power variation, incidence of phase resetting, theta-gamma cross-frequency coupling and multiscale entropy were significatively perturbed by optogenetic entrainment in opsin-expressing animals. Importantly, optogenetic entrainment during training sessions impaired learning performance parameters in opsin-expressing mice, as escape and nose-poke goal latency, as well as path optimization and navigation strategy progression across training. Similar behavioral impairments were observed in probe trials after training, when no optogenetic entrainment was delivered, suggesting an effect on memory formation. Altogether, our data revealed that entrainment of prefrontal activity during spatial training perturbed oscillatory dynamics and impaired memory formation.

HIPPOCAMPAL ASTROCYTES ENCODE REWARD LOCATION

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Adi Doron[1], Alon Rubin[2], Aviya Benmelech-Chovav[1], Netai Benaim[1], Tom Carmi[1], Ron Refaeli[1], Nechama Novick[1], Tirzah Kreisel[1], Yaniv Ziv[2], Inbal Goshen[1]

Astrocytic calcium dynamics are involved in sensory information encoding, and modulating them was shown to impact behavior. Recent studies have implicated hippocampal astrocytes in memory processes, but their real-time calcium activity in awake mice has not been investigated as of yet. We chronically imaged dozens of CA1 astrocytes using 2-photon microscopy when head-fixed mice performed a spatial task. Specifically, we trained mice to run on a linear treadmill and proceed in a virtual environment to obtain water rewards. We find that astrocytic activity persistently ramps towards the reward location in a familiar environment. When the reward location was changed in the same familiar environment or when mice were introduced to a novel context, the ramping was not apparent. Accordingly, using linear decoders we reconstructed mice location trajectories in a familiar environment from astrocyte activity alone, but could not do the same in the novel environment. Following additional training, as the mice were familiarized with the new reward location or novel context, the ramping was reestablished, suggesting that the astrocytic activity is experience dependent. This is the first indication that astrocytes are involved in spatial learning and can encode position related information in familiar contexts, thus implicating them as part of the neural computation involved in spatial processing.

Astrocytic Activation Generates De Novo Neuronal Potentiation and Memory Enhancement.
Astrocytes respond to neuronal activity and were shown to be necessary for plasticity and memory. To test whether astrocytic activity is also sufficient to generate synaptic potentiation and enhance memory, we expressed the Gq-coupled receptor hM3Dq in CA1 astrocytes, allowing their activation by a designer drug. We discovered that astrocytic activation is not only necessary for synaptic plasticity, but also sufficient to induce NMDA-dependent de novo long-term potentiation in the hippocampus that persisted after astrocytic activation ceased. In vivo, astrocytic activation enhanced memory allocation; i.e., it increased neuronal activity in a task-specific way only when coupled with learning, but not in home-caged mice. Furthermore, astrocytic activation using either a chemogenetic or an optogenetic tool during acquisition resulted in memory recall enhancement on the following day. Conversely, directly increasing neuronal activity resulted in dramatic memory impairment. Our findings that astrocytes induce plasticity and enhance memory may have important clinical implications for cognitive augmentation treatments.

Investigating the transition from recent to remote memory using advanced tools.
Remote memories, weeks to decades long, are usually the ones most important to the organism, as the longevity of a memory is tightly connected to its significance. Retrograde amnesia studies in human patients as well as lesions and immediate early gene expression investigation in animal models, suggested that the hippocampus has a time dependent role in memory consolidation. Namely, that as a memory matures it becomes independent of the hippocampus and instead depends on extra-hippocampal areas. However, accumulating evidence implies that this temporal segregation is not as rigid

as originally proposed. In this review we will focus on the integration of new methods, such as chemogenetics, optogenetics and calcium imaging, which enable genetic specificity as well as high temporal and spatial resolution. Using these methods, recent studies have started to resolve the inconsistencies of past findings by observing and manipulating neural ensembles in different brain regions. We then discuss how these techniques can be applied to investigate the cellular underpinnings of memory across multiple time points, and employed to study the contribution of various cell types to remote memory.

Features of hippocampal astrocytic domains and their spatial relation to excitatory and inhibitory neurons.
The mounting evidence for the involvement of astrocytes in neuronal circuits function and behavior stands in stark contrast to the lack of detailed anatomical description of these cells and the neurons in their domains. To fill this void, we imaged >30,000 astrocytes in hippocampi made transparent by CLARITY, and determined the elaborate structure, distribution, and neuronal content of astrocytic domains. First, we characterized the spatial distribution of >19,000 astrocytes across CA1 lamina, and analyzed the morphology of thousands of reconstructed domains. We then determined the excitatory somatic content of CA1 astrocytes, and measured the distance between inhibitory neuronal somata to the nearest astrocyte soma. We find that on average, there are almost 14 pyramidal neurons per domain in the CA1, increasing toward the pyramidal layer midline, compared to only five excitatory neurons per domain in the amygdala. Finally, we discovered that somatostatin neurons are found in close proximity to astrocytes, compared to parvalbumin and VIP inhibitory neurons. This work provides a comprehensive large-scale quantitative foundation for studying neuron-astrocyte interactions.

Intact crowding and temporal masking in dyslexia.
Phonological deficits in dyslexia are well documented. However, there is an ongoing discussion about whether visual deficits limit the reading skills of people with dyslexia. Here, we investigated visual crowding and backward masking. We presented a Vernier (i.e., two vertical bars slightly offset to the left or right) and asked observers to indicate the offset direction. Vernier stimuli are visually similar to letters and are strongly affected by crowding, even in the fovea. To increase task difficulty, Verniers are often followed by a mask (i.e., backward masking). We measured Vernier offset discrimination thresholds for the basic Vernier task, under crowding, and under backward masking, in students with dyslexia (n = 19) and age and intelligence matched students (n = 27). We found no group differences in any of these conditions. Controls with fast visual processing (good backward masking performance), were faster readers. By contrast, no such correlation was found among the students with dyslexia, suggesting that backward masking does not limit their reading efficiency. These findings indicate that neither elevated crowding nor elevated backward masking pose a bottleneck to reading skills of people with dyslexia.

DISTINCT ROLES OF THE DORSAL AND VENTRAL HIPPOCAMPUS IN SPATIAL WORKING MEMORY AND IN SIGNALING SPATIAL INFORMATION TO THE MEDIAL PREFRONTAL CORTEX

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Susanne Babl[1,2], Torfi Sigurdsson[1]
[1]Goethe University Frankfurt, Institute Of Neurophysiology, Frankfurt am Main, Germany, [2]Max Planck Institute for Brain Research, Imprs For Neural Circuits, Frankfurt am Main, Germany

The cognitive process of spatial working memory (SWM) engages both the medial prefrontal cortex (mPFC) and the hippocampus. The interaction of the dorsal and ventral hippocampus (dHPC, vHPC) with the mPFC can be observed on the level of single cells and as local field potentials. But it is not clear in which phases of SWM - encoding, maintenance and retrieval - the two hippocampal poles are involved and which task-relevant information they transmit to the mPFC. To address these questions, we infused mice with the viral construct AAV5-CamKII-ArchT-GFP in dHPC or vHPC and trained them to perform a delayed non-match-to-sample T-maze task. Pyramidal neurons in either dHPC or vHPC were optogenetically inhibited during the different phases of SWM while simultaneously recording neuronal activity in the mPFC. Our results indicate a complementary function of the two hippocampal poles. dHPC inhibition during encoding and retrieval, but not during maintenance, strongly impaired behavioral performance. The vHPC on the other hand was only critically involved in encoding, but not in maintenance or retrieval. In the mPFC, a subpopulation of neurons was modulated both by dHPC or vHPC inhibition. Goal-selective firing of mPFC neurons was however only disrupted by vHPC inhibition during the encoding phase, and unaffected by dHPC inhibition. In contrast, mPFC neuronal encoding of the linearized position between start and goal of the maze was modified both by dHPC and vHPC inhibition. These findings indicate distinct roles of the dorsal and ventral hippocampal poles in signaling task-related spatial information to the mPFC.

The Spatial Extent of Optogenetic Silencing in Transgenic Mice Expressing Channelrhodopsin in Inhibitory Interneurons.
Optogenetic stimulation of inhibitory interneurons has become a commonly used strategy for silencing neuronal activity. This is typically achieved using transgenic mice expressing excitatory opsins in inhibitory interneurons throughout the brain, raising the question of how spatially extensive the resulting inhibition is. Here, we characterize neuronal silencing in VGAT-ChR2 mice, which express channelrhodopsin-2 in inhibitory interneurons, as a function of light intensity and distance from the light source in several cortical and subcortical regions. We show that light stimulation, even at relatively low intensities, causes inhibition not only in brain regions targeted for silencing but also in their subjacent areas. In contrast, virus-mediated expression of an inhibitory opsin enables robust silencing that is restricted to the region of opsin expression. Our results reveal important constraints on using inhibitory interneuron activation to silence neuronal activity and emphasize the necessity of carefully controlling light stimulation parameters when using this silencing strategy.

Entorhinal-retrosplenial circuits for allocentric-egocentric transformation of boundary coding.
Spatial navigation requires landmark coding from two perspectives, relying on viewpoint-invariant and self-referenced representations. The brain encodes information within each reference frame but their interactions and functional dependency remains unclear. Here we investigate the relationship between neurons in the rat's retrosplenial cortex (RSC) and entorhinal cortex (MEC) that increase firing near boundaries of space. Border cells in RSC specifically encode walls, but not objects, and are sensitive to the animal's direction to nearby borders. These egocentric representations are generated independent of visual or whisker sensation but are affected by inputs from MEC that contains allocentric spatial cells. Pharmaco- and optogenetic inhibition of MEC led to a disruption of border coding in RSC, but not vice versa, indicating allocentric-to-egocentric transformation. Finally, RSC border cells fire prospective to the animal's next motion, unlike those in MEC, revealing the MEC-RSC pathway as an extended border coding circuit that implements coordinate transformation to guide navigation behavior.

EVENT STRUCTURE SCULPTS LATERAL ENTORHINAL DYNAMICS

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Benjamin Kanter, Christine Lykken, May-Britt Moser, Edvard Moser
NTNU, Kavli Institute For Systems Neuroscience And Centre For Neural Computation, Trondheim, Norway

The lateral entorhinal cortex (LEC) is a multisensory hub that processes information about objects and events which is formed into episodic memories in the hippocampus. How the moment-to-moment changes in an animal's experience are represented by LEC neural activity has remained elusive, in part because its anatomical position makes it difficult to access with high-density recording methods. In addition, many LEC neurons do not exhibit clear functional correlates in standard foraging experiments, as they do in the medial entorhinal cortex (MEC) and hippocampus. To overcome these challenges, we implanted newly developed multi-shank Neuropixels probes in rats to simultaneously record hundreds to thousands of units in LEC during various free behaviors and reward-based tasks. We simultaneously recorded from other areas including MEC and hippocampus for direct comparison. First, we found robust temporal coding in the dynamics of LEC activity that arose instantaneously during novel experience to support one-shot memory formation. Second, multiple behavioral timescales were encoded without interference to serve memories with different temporal resolutions. Third, temporal coding evolved relative to event structure, with salient events causing large changes in the population activity. Finally, such temporal coding was not observed in MEC and hippocampus. In ongoing work, we systematically manipulate event structure to test how these changes are reflected in LEC. Together, our results suggest that LEC may uniquely support episodic memory through one-shot encoding of experience at multiple behaviorally relevant timescales. In addition, these findings provide insight into how a continuous stream of multisensory information is processed into discrete events.

NEURONAL DISCRIMINATION OF VISUAL ENVIRONMENTS DIFFERENTIALLY DEPENDS ON BEHAVIOURAL CONTEXT IN THE HIPPOCAMPUS AND THE NEOCORTEX

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Cantin Ortiz[1], Manuela Allegra[2], Christoph Schmidt-Hieber[1]
[1]Institut Pasteur, Université de Paris, Neuroscience Department, Paris, France, [2]National Research Council, Neuroscience Institute, Padua, Italy

To guide memory-based behavioural decisions, the hippocampus needs to discriminate between distinct sensory environments. Before reaching the hippocampus, sensory information is initially processed in sensory cortices. We hypothesised that primary sensory cortices provide a faithful representation of the sensory environment to distributed brain regions, whereas the hippocampus produces a cognitive map that is weighted according to the behavioural relevance of the sensory inputs. To test this hypothesis, we aimed to determine how complex sensory stimuli differentially depend on the behavioural context in the primary visual cortex (V1), CA1 and the dentate gyrus (DG). We performed two-photon calcium imaging of head-fixed mice navigating in a virtual-reality linear tract. Mice were exposed to alternating environments by changing visual textures along the virtual corridor. During active navigation, movements in the virtual environment were controlled by the animal motion on a running wheel. By contrast, in a passive open-loop condition, the visual scene was completely uncoupled from animal locomotion. We found that a binary probabilistic decoder could predict the environment being explored based on the neuronal activity in all regions during active navigation. During passive exposure, decoding accuracy remained high in the visual cortex while it decreased to chance level in the hippocampus (accuracy [active-passive] in V1: 92-77%; DG: 65-51%, CA1: 61-52%). Task engagement is therefore necessary for neuronal discrimination in the hippocampus but not in the visual cortex, suggesting that primary sensory cortices serve as robust general-purpose discriminators of sensory inputs, while the hippocampus selectively discriminates behaviourally relevant inputs.

NEURAL SIGNATURES OF CONTEXTUAL LEARNING STRATEGIES

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Heloisa S. C. Chiossi, Jozsef Csicsvari
Institute of Science and Technology Austria, Systems Neuroscience, Klosterneuburg, Austria

Like humans and primates, rats can employ various learning strategies to meet the demands of a task, depending on its complexity. It is still unclear, however, how memory representations evolve in different individuals throughout learning. Here we used in vivo electrophysiological recordings in rats, in the CA1 area of the hippocampus, to monitor the formation of representations related to context and reward-position associations. We recorded local field potentials, cell activity, and the animal's position during a spatial memory task, in which performance was assessed by animals 'digging' at correct reward locations. Contextual cues determined one reward location, whilst a second reward was context-independent. Context-reward associations were learned by all animals in 3-4 days, yet individual learning curves differed considerably. Whilst some animals improved performance in all contextual categories simultaneously over days, others initially learned a single association and only later learned the remaining ones. We then investigated whether the hippocampal representation of context differed between animals. At the neural population level, by day four, all animals showed a small but significant decorrelation between contexts around context-dependent reward positions. This was not observed in other maze positions, including the context-independent reward location. However, in earlier learning, the representation similarity was less homogenous between individuals. Our data demonstrate that individual animals can exhibit different learning strategies, yet ultimately, the hippocampal cognitive map can reliably code for both contextual-dependent representations and context-independent ones.

INCREASED CORTICAL PLASTICITY ENHANCES ONE-TRIAL MEMORY BUT LEADS TO INCREASED INTERFERENCE OF SEMANTIC-LIKE MEMORY AND CHANGES IN NONREM SLEEP OSCILLATIONS IN RATS.

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Adrian Aleman-Zapata, Irene Navarro-Lobato, Shekhar Narayanan, Milan Bogers, Kopal Agarwal, Pelin Özsezer, Anumita Samanta, Alejandra Alonso, Lisa Genzel
Donders Institute for Brain, Cognition and Behaviour, Radboud University, Neuroinformatics, Nijmegen, Netherlands

AIM: To investigate the effects of increased cortical plasticity on one-trial and semantic memories respectively, as well as to describe its effect on the cortical and hippocampal mechanisms involved in memory consolidation during NonREM sleep. **METHODS:** Cortical plasticity was increased by overexpressing the $RGS14_{414}$ gene in the prelimbic cortex of rats. The rodents were trained to perform the Object Space task to evaluate their performance for one-trial and semantic memories. Tetrodes were implanted in the medial prefrontal cortex and the hippocampus to record local field potentials and spiking activity. Sleep stages, sleep oscillations and the spiking activity of cortical pyramidal neurons during sleep were quantified and analyzed. **RESULTS:** $RGS14_{414}$ rats showed a significantly higher discrimination index compared to the control rats during the one-trial memory condition. In contrast, $RGS14_{414}$ rats had increased interference effect in the semantic-like memory condition. $RGS14_{414}$ rats displayed a decrease of NonREM sleep, accompanied by significant changes in sleep oscillations, as well as a shift in the phase-coupling of spindles and ripples with slow oscillations. $RGS14_{414}$ cortical pyramidal neurons exhibited significantly lower firing rates and less phase-locking to slow oscillations. **CONCLUSION:** These results confirm and have implications in multiple theories and hypotheses on sleep, memory and plasticity. The complementary learning-systems theory is confirmed with the interference of semantic-like memory in $RGS14_{414}$. Changes in delta waves correspond to the synaptic homeostasis hypothesis. Finally, our results replicate the finding that high-plasticity neurons show slower firing rates (Grosmark & Buzsáki, Science, 2016).

Disrupting ripples: Methods, results, and caveats in closed-loop approaches in rodents.
Hippocampal ripple oscillations have been associated with memory reactivations during wake and sleep. These reactivations should contribute to working memory and memory consolidation respectively. In the past decade studies have moved from being observational to actively disrupting ripple-related activity in closed-loop approaches to enable causal investigations into their function. All together these studies have been able to provide evidence that wake, task-related ripple activity is important for working memory and planning but less important for stabilisation of spatial representations. Rest and sleep-related ripple activity, in contrast, is important for long-term memory performance and thus memory consolidation. In this review, we summarise results from different closed-loop approaches in rodents. Further, we highlight differences in detection and stimulation methods as well as controls and discuss how these differences could influence outcomes.

Do Cost Functions for Tracking Error Generalize across Tasks with Different Noise Levels?
Control of human-machine interfaces are well modeled by computational control models, which take into account the behavioral decisions people make in estimating task dynamics and state for a given control law. This control law is optimized according to a cost function, which for the sake of mathematical tractability is typically represented as a series of quadratic terms. Recent studies have found that people actually use cost functions for reaching tasks that are slightly different than a quadratic function, but it is unclear which of several cost functions best explain human behavior and if these cost functions generalize across tasks of similar nature but different scale. In this study, we used an inverse-decision-theory technique to reconstruct the cost function from empirical data collected on 24 able-bodied subjects controlling a myoelectric interface. Compared with previous studies, this experimental paradigm involved a different control source (myoelectric control, which has inherently large multiplicative noise), a different control interface (control signal was mapped to cursor velocity), and a different task (the tracking position dynamically moved on the screen throughout each trial). Several cost functions, including a linear-quadratic; an inverted Gaussian, and a power function, accurately described the behavior of subjects throughout this

experiment better than a quadratic cost function or other explored candidate cost functions ($p<0.05$). Importantly, despite the differences in the experimental paradigm and a substantially larger scale of error, we found only one candidate cost function whose parameter was consistent with the previous studies: a power function (cost $\propto$ error$^{\alpha}$) with a parameter value of α = 1.69 (1.53-1.78 interquartile range). This result suggests that a power-function is a representative function of user's error cost over a range of noise amplitudes for pointing and tracking tasks.

Learning-Induced Shifts in Mice Navigational Strategies Are Unveiled by a Minimal Behavioral Model of Spatial Exploration. Shifts in spatial patterns produced during the execution of a navigational task can be used to track the effects of the accumulation of knowledge and the acquisition of structured information about the environment. Here, we provide a quantitative analysis of mice behavior while performing a novel goal localization task in a large, modular arena, the HexMaze. To demonstrate the effects of different forms of previous knowledge we first obtain a precise statistical characterization of animals' paths with sub-trial resolution and over different phases of learning. The emergence of a flexible representation of the task is accompanied by a progressive improvement of performance, mediated by multiple, multiplexed time scales. We then use a generative mathematical model of the animal behavior to isolate the specific contributions to the final navigational strategy. We find that animal behavior can be accurately reproduced by the combined effect of a goal-oriented component, becoming stronger with the progression of learning, and of a random walk component, producing choices unrelated to the task and only partially weakened in time.

INHIBITING THE DIRECT INPUTS FROM THE DORSAL SUBICULUM TO THE RETROSPLENIAL CORTEX IMPAIRS SPATIAL MEMORY IN THE RAT

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Steliana Yanakieva, Bethany Frost, Andrew Nelson, John Aggleton
Cardiff University, Department Of Psychology, Cardiff, United Kingdom

Background and Aims: The dorsal subiculum is the primary source of hippocampal projections to the granular retrosplenial cortex. Although, both regions have been repeatedly implicated in spatial memory and navigation, it remains unclear how the regions interact or if functional control is from the hippocampus to the retrosplenial cortex. The aim of the present experiment was to address this issue and to investigate the functional consequences of selectively inhibiting these projections in the rat. **Methods:** To address the issue, adeno-associated virus encoding either inhibitory designer-receptor exclusively activated by designer drugs (iDREADDs) or GFP control, was injected in the dorsal subiculum in two separate groups of adult male rats. These preparations were combined with intracerebral infusions of clozapine or saline within the retrosplenial cortex. Animals were tested on the reinforced T-maze alternation task, using five experimental manipulations that differently taxed the use of intra-maze, extra-maze, and egocentric cues. **Results and Conclusions:** iDREADDs mediated disruption of these efferent projections seemed sufficient to impair spatial working memory, particularly when intra-maze and extra-maze cues were incongruent or when animals were required to switch between different strategies to solve the mazes. Cumulatively, these findings suggest that the direct projections from the dorsal subiculum to the granular retrosplenial cortex, may be key for successful integration of visual spatial cues.

AWAKE HIPPOCAMPAL REPLAY IS NOT REQUIRED FOR SHORT-TERM MEMORY

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Lies Deceuninck[1,2], Fabian Kloosterman[2,3,4,5]
[1]KU Leuven, Department Of Physics And Astronomy, Soft Matter And Biophysics, heverlee, Belgium, [2]NERF-NeuroElectronics Research Flanders, Kloosterman Lab, Heverlee, Belgium, [3]KU Leuven, Faculty Of Psychology & Educational Sciences, Leuven, Belgium, [4]VIB, Kloosterman Lab, Gent, Belgium, [5]Imec, Kloosterman Lab, Heverlee, Belgium

Short-term memory (STM) on a time scale of seconds to minutes is required to successfully perform day-to-day tasks, for example when engaging in a meaningful conversation. Previous studies in both rodents and primates have correlated hippocampal cellular activity and behavioural expression of STM. This research has led to models describing the putative neural mechanism in the hippocampus that mediate STM. In these models, a key role has been given to hippocampal replay – reactivation of neurons representing a trajectory through space– but definitive causal evidence that can challenge or confirm the model is missing. In this study, we aimed to address the uncertainty around the role of awake replay in STM by collecting direct causal evidence from behaving rats. Signatures of replay events were detected in the hippocampus and disrupted using electrical stimulation of the ventral hippocampal commissure in rats that were trained on three different spatial memory tasks in a multi-arm radial maze. All tasks required memory of the recent past, but varied in the time scale over which information needed to be retained: (1) a multiple trial match-to sample task, (2) a single trial non-match to sample task and (3) a spatial sequence memory paradigm. Rats readily learned the task rules, but disruption of awake replay did not affect task performance or other behavioural measures in any of the task. Altogether, our results show for the first time with definitive causal evidence that awake replay is not involved in STM of events or of their temporal order.

A SYNAPTIC SIGNAL FOR NOVELTY PROCESSING IN THE HIPPOCAMPUS

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Ruy Gómez-Ocádiz[1], Massimiliano Trippa[2], Chun-Lei Zhang[3], Lorenzo Posani[4], Simona Cocco[2], Remi Monasson[2], Christoph Schmidt-Hieber[3]
[1]Karolinska Institutet, Neuroscience, Stockholm, Sweden, [2]Ecole Normale Superieure, Physics, PARIS, France, [3]Institut Pasteur, Université de Paris, Neuroscience Department, Paris, France, [4]Columbia University, Center For Theoretical Neuroscience, new york, United States of America

Episodic memory formation and recall are complementary processes that put conflicting requirements on neuronal computations in the hippocampus. How this challenge is resolved in hippocampal circuits is unclear. To address this question, we obtained in vivo whole-cell patch-clamp recordings from dentate gyrus granule cells in head-fixed mice trained to explore and distinguish between familiar and novel virtual environments. We find that granule cells consistently show a small transient depolarization of their membrane potential upon transition to a novel environment. A computational model suggests that the observed transient synaptic response to novel environments may lead to a bias in the granule cell population activity, which can, in turn, drive the downstream attractor networks to a new state, thereby favoring the switch from generalization to discrimination when faced with novelty. Such a novelty-driven switch may enable flexible encoding of new memories while preserving stable retrieval of familiar ones.

SPATIAL AND REWARD CODING OF DORSAL HIPPOCAMPUS PROJECTION NEURONS TO THE NUCLEUS ACCUMBENS

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Oliver Barnstedt[1,2], Stefan Remy[1,2]
[1]German Center for Neurodegenerative Diseases, Neuronal Networks Group, Bonn, Germany, [2]Leibniz Institute for Neurobiology, Cellular Neuroscience, Magdeburg, Germany

The hippocampal formation is a brain structure crucial for spatial navigation. Many neurons in the dorsal hippocampus (dHPC) show position-selective tuning characteristics. These place cells are thought to be part of a ‘cognitive map’ that animals can use to navigate their environment. How such a hippocampal map is used by downstream regions to drive goal-directed navigation behaviour, however, remains unclear. The hippocampus sends extensive projections to the nucleus accumbens (NAc), a basal ganglia structure involved in reward-related behaviours. Indeed, dHPC shows functional coupling to NAc in reward contexts, and dHPC>NAc projection neurons are required for conditioned place preference. Yet, it is unknown which information is conveyed by individual dHPC>NAc projection neurons. To visualise hippocampal neuronal activity in behaving animals, we used mice expressing the calcium indicator GCaMP6s pan-neuronally, and implanted a hippocampal window for optical access. To visualise and compare the activity of dHPC>NAc projection neurons with the general dHPC population, we used a retro-Cre/mCherry intersectional approach. Head-fixed food-restricted mice were trained to run on a textured belt to receive milk in a fixed reward zone. Dual-colour two-photon calcium imaging of hippocampal neurons in trained animals shows that, while dHPC>NAc projection neurons showed similar reward-related tuning characteristics, their spatial tuning was enhanced compared to the rest of the dHPC population. dHPC>NAc projection neurons contained a higher proportion of place cells that showed greater reliability and a higher density of spatial information content. These results suggest that dHPC conveys a robust and dense spatial code to the NAc.

THE MORE THE MERRIER: IS MORE THAN ONE TRIAL NECESSARY FOR ACCURATE NAVIGATIONAL STRATEGY ASSESSMENT IN A DUAL-SOLUTION PLUS MAZE?

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Lorena Andreoli, Kazumasa Tanaka
OIST - Okinawa Institute of Science and Technology, Memory Research Unit, Okinawa, Japan

Rodents navigate using different strategies. The dual-solution plus maze is designed to assess whether an animal is using place (following a flexible representation or a cognitive map of the space) or response (following a sequence of actions to go to a specific place) strategy. This is done by training the animal in a plus-shaped maze with one of the arms blocked (turning it into a T-maze) and probing which navigational strategy the animal is using when releasing it from the opposite previously blocked arm to the start. Animals have been classified as place or response learners in this task based on a single probe trial. This work aims to investigate whether classifying the navigation strategy based on one probe trial is representative of the strategy the animal uses for most trials. For this we trained BL6 mice (n=7) in a plus maze with one of the arms blocked for 6 days (10 correct trials per day) and probed them on the opposite arm for ten trials. We compared the number of total place and response trials with the first trial. All animals showed more response than place trials. The two animals that showed place strategy on the first trial had the lowest response trials number. Since most protocols for this test base the classification of place/response strategy from one single probe trial, we wonder from our results whether the animals demonstrating “place strategy” isn’t simply a byproduct of their error rate on the task rather than their actual navigation strategy.

CLAUSTRUM LESIONS LEAD TO CHANGES IN BEHAVIOURAL STRATEGY DURING REVERSAL LEARNING IN A SPATIAL MEMORY TASK

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Vanessa Cattaud[1], Romain Goutagny[2], Jesse Jackson[1]
[1]University of Alberta, Physiology, Edmonton, Canada, [2]Université de Strasbourg / CNRS, Lnca, Strasbourg, France

The Claustrum (CLA) is a small subcortical region located between the insula and the putamen. Even though it has been shown that the CLA is directly connected to key structures that regulate memory processing such as prefrontal (PFC), anterior cingulate (ACC), retrosplenial (RSC) and entorinal (MEC) cortex, its potential role in memory-related mechanisms has yet to be explored. Thus, we aim to investigate whether the CLA is involved in memory processes by focusing on spatial memory. To test this, we specifically lesioned CLA cells projecting to PFC, ACC, RSC and MEC via stereotaxic injections an of apoptosis-inducing virus. Two weeks later, lesioned and control mice were placed on a modified Barnes maze. Our 10-day protocol included 4 days of training, 3 days reversal training and ending with a probe trial 24h following the end of each training sessions. Control and lesioned mice exhibited similar behavior and were capable of spatial learning and spatial memory during the training phase and the probe test, respectively. However, during the reversal training phase, lesioned mice favoured spatial strategy, whereas control mice used preferentially serial strategy. Nevertheless, during the reversal probe trial, there was no significant difference in spatial memory between both groups. To conclude, lesioning the CLA seems to affect behavioural strategy choice while not having a direct impact on spatial memory.

Early disruption of parvalbumin expression and perineuronal nets in the hippocampus of the Tg2576 mouse model of Alzheimer's disease can be rescued by enriched environment.
Recent findings show that parvalbumin (PV) interneuron function is impaired in Alzheimer's disease (AD), and that this impairment in PV function can be linked to network dysfunction and memory deficits. PV cells are often associated with a specific extracellular matrix, the perineuronal net (PNN). PNNs are believed to protect PV cell integrity, and whether the amyloidopathy affects PNNs remains unclear. Here, we evaluated the number of PV cells with and without PNNs in the hippocampus of the Tg2576 mouse model of AD at different stages of the disease. We show a deficit of PV+ and/or PV+/PNN+ cells in the areas CA1, CA2, and CA3 in Tg2576 as young as 3 months of age. Importantly, transient exposure to an enriched environment, which has proven long-lasting beneficial effects on memory in AD subjects, rescues the PV/PNN cell number deficits. We conclude that cognitive improvements induced by enriched environment in AD mouse models could be supported by a remodeling of hippocampal PV cell network and their PNNs.

TEMPORAL INSTABILITY OF CFOS EXPRESSION IN THE DENTATE GYRUS AS A MECHANISM FOR PATTERN SEPARATION

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Paul Lamothe-Molina[1], Andreas Franzelin[1], Lennart Beck[1], Fabio Morellini[2], Thomas Oertner[1]

The use of TetTag mice has advanced the understanding of memory acquisition and recall over the last 10 years. These mice allow for identification and control of specific ensembles that express plasticity-related transcription factors involved in memory formation (i.e. cFos) in several brain regions including the hippocampus. The dentate gyrus (DG) of the hippocampus is crucial for spatial memory tasks like the Morris water maze (WM). It is not clear, however, how a subset of $cFos^+$ neurons (engram cells) integrate the spatial information over the course of WM training. We found that despite the increase in spatial memory precision, cFos expression patterns were temporally unstable in granule cells (GCs). Optogenetic inhibition $cFos^+$ GCsof the first training day, impaired memory recall on subsequent days even though these cells did not express cFos again. Using CaMPARI, we identified that $cFos^+$ GCs were active when mice re-visit the WM tank but not a novel environment. These data challenge the notion that cFos re-expression in the same neuronal ensemble is a readout of memory recall. Additionally, we found that the observed cFos temporal instability is mediated via a different transcription factor (FosB/ΔFosB) in an inhibitory feedback loop fashion. Altogether, our results suggest that the temporal shift of cFos expression in GCs is a mechanism of temporal discrimination of past experiences

INVOLVEMENT OF THE CEREBELLAR MOLECULAR LAYER INTERNEURONS IN SEQUENCE-BASED NAVIGATION: DEVELOPMENT OF A COMPLEX NAVIGATION BEHAVIORAL TASK

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Charlotte Lehericy[1], Ludivine Therreau[2], Aurélie Watilliaux[1], Isabel Llano[3], Céline Auger[3], Laure Rondi-Reig[1]

Learning and execution of sequence-based navigation involves activation of the posterior cerebellum, in particular lobule VI in mice. In a simple Y-maze paradigm, where animals need to remember the location of a reward, the chemogenetic inactivation of Molecular Layer Interneurons (MLIs) in lobule VI delayed the acquisition of the task. However, the role of MLIs in a more complex sequence-based navigation has not been addressed yet. The purpose of this work is to understand how cerebellar MLIs in Lobule VI contribute to the learning of complex sequence-based navigation. To answer this question, we developed a behavioral task in which mice learn a sequence of three successive turns to obtain a stimulation of the Medial Forebrain Bundle as a reward. Mice are first evaluated in a place preference task to determine the optimal intensity of the reward, then trained every day for seven days, 4 sessions a day. Our preliminary results show that control mice properly acquire the task, achieving more than 75% success within 7 days. To evaluate the role of MLIs in cerebellar lobule VI, we performed specific chemogenetic inhibition of MLIs in this region during learning. Sensorimotor abilities (e.g. locomotor skills, movement coordination and balance) and level of anxiety of mice, assessed through a battery of tasks, suggest no obvious abnormalities. Performances in the sequence-based navigation task are currently under evaluation. We also plan to investigate the consequence of MLI inhibition on the cerebellum, performing cerebellar recordings during this sequence-based navigation.

LEARNING FAST AND SLOW: THE EFFECT OF INCREASED CORTICAL PLASTICITY ON THE PREFRONTAL-HIPPOCAMPAL COMMUNICATION DURING WAKE AND REM SLEEP STATES

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Abdel Rayan[1], Irene Navarro-Lobato[1], Adrian Aleman-Zapata[1], Anumita Samanta[1], Liz Van Den Brand[2], Jacqueline Van Der Meij[1], Alejandra Alonso[1], Lisa Genzel[1]
[1]Donders Institute for Brain, Cognition and Behaviour, Radboud University, Neuroinformatics, Nijmegen, Netherlands, [2]Donders Institute, Neuro-informatics, Nijmegen, Netherlands

Aims: In the contemporary view of memories' organization, the hippocampus is proposed to be involved initially in the rapid encoding of different events and their temporary storage (fast learning), while the neocortical system is critical for extracting information from several events and long-term storage of information (slow learning). Such differences between the two systems would protect our long-term memories from interference effects. Although the previous proposal is the basis of our current understanding of memory formation, it was not tested experimentally. **Methods**: We increased the cortical plasticity by overexpressing the RGS_{414} protein in the prelimbic prefrontal cortex (PFC). We then obtained simultaneous local field potential recording from the PFC and the HPC while rodents performed the object-space task (OST). The coherence between both regions and the theta-gamma dynamics were examined during wake and REM sleep states. **Results**: The sleep structure was altered in the RGS_{414} group showing shorter NREM and more prolonged REM bouts. Interestingly, during wake the theta coherence between the PFC and the HPC was higher in the RGS_{414} relative to the control group. Furthermore, the theta-gamma dynamics during wake and sleep states showed distinctive activity patterns in both groups. **Conclusion**: Our current results support the complementary learning system theory proposed by McClelland et al. (1995), emphasizing the role of synaptic plasticity in learning and memory consolidation and the possible top-down control of the neocortical system. Furthermore, they elucidate the underlying theta dynamics during wake and sleep states.

Experience-Dependency of Reliance on Local Visual and Idiothetic Cues for Spatial Representations Created in the Absence of Distal Information.
Spatial encoding in the hippocampus is based on a range of different input sources. To generate spatial representations, reliable sensory cues from the external environment are integrated with idiothetic cues, derived from self-movement, that enable path integration and directional perception. In this study, we examined to what extent idiothetic cues significantly contribute to spatial representations and navigation: we recorded place cells while rodents navigated towards two visually identical chambers in 180° orientation via two different paths in darkness and in the absence of reliable auditory or olfactory cues. Our goal was to generate a conflict between local visual and direction-specific information, and then to assess which strategy was prioritized in different learning phases. We observed that, in the absence of distal cues, place fields are initially controlled by local visual cues that override idiothetic cues, but that with multiple exposures to the paradigm, spaced at intervals of days, idiothetic cues become increasingly implemented in generating an accurate spatial representation. Taken together, these data support that, in the absence of distal cues, local visual cues are prioritized in the generation of context-specific spatial representations through place cells, whereby idiothetic cues are deemed unreliable. With cumulative exposures to the environments, the animal learns to attend to subtle idiothetic cues to resolve the conflict between visual and direction-specific information.

Activity-dependent switch of GABAergic inhibition into glutamatergic excitation in astrocyte-neuron networks.
Interneurons are critical for proper neural network function and can activate Ca signaling in astrocytes. However, the impact of the interneuron-astrocyte signaling into neuronal network operation remains unknown. Using the simplest hippocampal Astrocyte-Neuron network, i.e., GABAergic interneuron, pyramidal neuron, single CA3-CA1 glutamatergic synapse, and

astrocytes, we found that interneuron-astrocyte signaling dynamically affected excitatory neurotransmission in an activity- and time-dependent manner, and determined the sign (inhibition potentiation) of the GABA-mediated effects. While synaptic inhibition was mediated by GABA receptors, potentiation involved astrocyte GABA receptors, astrocytic glutamate release, and presynaptic metabotropic glutamate receptors. Using conditional astrocyte-specific GABA receptor () knockout mice, we confirmed the glial source of the interneuron-induced potentiation, and demonstrated the involvement of astrocytes in hippocampal theta and gamma oscillations in vivo. Therefore, astrocytes decode interneuron activity and transform inhibitory into excitatory signals, contributing to the emergence of novel network properties resulting from the interneuron-astrocyte interplay.

THE GENERALIZED SPATIAL REPRESENTATION IN THE PREFRONTAL CORTEX IS INHERITED FROM THE HIPPOCAMPUS

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Michele Nardin[1], Karola Kaefer[2], Jozsef Csicsvari[1]
[1]Institute of Science and Technology Austria, Systems Neuroscience, Klosterneuburg, Austria, [2]Radboud University, Neuroinformatics, Nijmegen, Netherlands

Hippocampal and neocortical neural activity is modulated by the position of the individual in space. While hippocampal neurons provide the basis for a spatial map, prefrontal cortical neurons generalize over environmental features. Whether these generalized representations result from a bidirectional interaction with, or are mainly derived from hippocampal spatial representations is not known. By examining simultaneously recorded hippocampal and medial prefrontal neurons, we observed that prefrontal spatial representations show a delayed coherence with hippocampal ones. We also identified subpopulations of cells in the hippocampus and medial prefrontal cortex that formed functional cross-area couplings; these resembled the optimal connections predicted by a probabilistic model of spatial information transfer and generalization. Moreover, cross-area couplings were strongest and had the shortest delay preceding spatial decision-making. Our results suggest that generalized spatial coding in the medial prefrontal cortex is inherited from spatial representations in the hippocampus and that the routing of information can change dynamically with behavioral demands.

Sleep's fundamental role for the processing of memory and its consolidation has now received large experimental support. Nevertheless, sleep actually consists of multiple stages that can be broadly classified in the two main categories of REM and non-REM (nREM) sleep, which display very different characteristics. Importantly, their relative contribution to memory function is largely unknown and questions about their interaction during offline processing of newly acquired information have remained mostly untapped. In this study, we addressed these issues by combining a goal-directed learning task with long-term wireless electrophysiological recordings in the hippocampus of rats. After the acquisition of a novel episodic-like memory, place cells were continuously tracked for an extended period of time (>20hrs) while animals rested. We then combined multiple decoding approaches to obtain a time-resolved characterization of the evolution during sleep of a newly established memory representation. This innovative approach allowed us to identify a continuous drift in the reactivated activity patterns: the firing rate of multiple coexisting place cell populations was progressively and differentially modulated in time, resulting in a multiplexed cell code combining change with representational stability. Intriguingly, the direction of this drift was not constant: a closer inspection revealed opposing effects of REM and nREM phases. While nREM sleep 'pushed' the representation towards novel configurations, REM sleep coincided with enhanced reactivation of the recent memory and therefore partially resetted the ongoing drift. The emerging picture is thus one of a complex interplay between sleep dynamics, the age of memories and differential coding properties across cells.

Down syndrome (DS), caused by trisomy of human chromosome 21, is the most common genetic cause of intellectual disability with an incidence of 1 in 1000 worldwide. Using a mouse model of DS - Dp(10)2Yey - with only 37 out of a possible 234 protein coding genes implicated in DS expressed in three copies, we investigated how these genes modulate cognitive function and cellular biology in brain regions typically associated with spatial cognition. Depth recording electrodes were implanted in the medial prefrontal cortex (mPFC) and hippocampus of Dp(10)2Yey mice performing open field and T-maze alternation paradigms. Histological techniques, including optical clearing and immunohistochemistry, were conducted to examine changes in cell density of three common interneuron markers - calretinin, parvalbumin, and neuropeptide-Y (NPY) - within mPFC and hippocampus, as well as spine density on hippocampal pyramidal cells, and whole-brain volumetric changes. Dp(10)2Yey mice showed reduced mean running speed and an increase in time spent at the edge of the arena in the open field, indicative of anxiety-like behaviour; and impaired spatial memory in the T-maze alternation task. Both paradigms were associated with altered neural dynamics in the mPFC and hippocampus and, in addition, we observed increased NPY+ interneuron densities within the same cortical regions. DS genes expressed in three copies in Dp(10)2Yey mice are associated with impairments in spatial cognition, altered neural dynamics and the increased expression of interneurons in mPFC and hippocampus. The Dp(10)2Yey mouse is therefore a tractable model to investigate the genetic mechanisms of cognitive impairment in DS.

APOE Genotype Specific Effects on the Early Neurodegenerative Sequelae Following Chronic Repeated Mild Traumatic Brain Injury.
Repeated mild traumatic brain injury (r-mTBI) can potentially manifest into chronic traumatic encephalopathy (CTE). The apolipoprotein E (APOE4) genotype, a well-recognized potent genetic risk factor in age-related neurodegenerative diseases such as Alzheimer's disease, has been linked to worse outcome after TBI in individuals who carry this allele. The underlying molecular modifications triggered by APOE genotype following r-mTBI remain elusive. We addressed the influence of APOE genotype on TBI dependent tau pathology in middle-aged mice. Using a previously established experimental mTBI protocol in a new repetitive injury paradigm, we report the pathological changes that occurred following one-month of repetitive injuries in APOE3/4 gene targeted mice. Firstly, pathological assessment demonstrated evidence of microgliosis and astrogliosis in the corpus callosum of injured animals, but there was no APOE dependent genotype effect on injury. However, in the parietal cortex Iba1-immunoreactivity was significantly increased in injured versus sham APOE3 mice, but not in APOE4 mice. No effects were observed in soluble amyloid levels with injury or interaction with genotype. APOE4 mice showed significant increases in the tau conformational marker MC1, neurofilament H, brain phospholipids, and endothelial specific oxidized low density lipoprotein receptor in cortical homogenates obtained from injured mice compared to sham counterparts. This pilot work suggests APOE3 and APOE4 specific effects following injury in a mouse model of r-mTBI. These changes may underlie the molecular changes that trigger the vulnerability and increased risk of developing neurodegenerative diseases in aged individuals exposed to repetitive mTBI.

Chronic Hippocampal Abnormalities and Blunted HPA Axis in an Animal Model of Repeated Unpredictable Stress.
Incidence of post-traumatic stress disorder (PTSD) ranges from 3 to 30% in individuals exposed to traumatic events, with the highest prevalence in groups exposed to combat, torture, or rape. To date, only a few FDA approved drugs are available to treat PTSD, which only offer symptomatic relief and variable efficacy. There is, therefore, an urgent need to explore new concepts regarding the biological responses causing PTSD. Animal models are an appropriate platform for conducting such studies. Herein, we examined the chronic behavioral and neurobiological effects of repeated unpredictable stress (RUS) in a mouse model. 12 weeks-old C57BL/6J male mice were exposed to a 21-day RUS paradigm consisting of exposures to a predator odor (TMT) whilst under restraint, unstable social housing, inescapable footshocks and social isolation. Validity of the model was assessed by comprehensive examination of behavioral outcomes at an acute timepoint, 3 and 6 months post-RUS; and molecular profiling was also conducted on brain and plasma samples at the acute and 6 months timepoints. Stressed mice demonstrated recall of traumatic memories, passive stress coping behavior, acute anxiety, and weight gain deficits when compared to control mice. Immunoblotting of amygdala lysates showed a dysregulation in the p75NTR/ProBDNF, and glutamatergic signaling in stressed mice at the acute timepoint. At 6 months after RUS, stressed mice had lower plasma corticosterone, reduced hippocampal CA1 volume and reduced brain-derived neurotrophic factor levels. In addition, glucocorticoid regulatory protein FKBP5 was downregulated in the hypothalamus of stressed mice at the same timepoint, together implicating an impaired hypothalamus-pituitary-adrenal-axis. Our model demonstrates chronic behavioral and neurobiological outcomes consistent with those reported in human PTSD cases and thus presents a platform through which to understand the neurobiology of stress and explore new therapeutic interventions.

EXERCISE INCREASES INFORMATION CONTENT AND PARADOXICALLY AFFECTS LONG-TERM STABILITY OF HIPPOCAMPAL PLACE CODES

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Alon Rubin[1], Yoav Rechavi[1], Yaniv Ziv[1,2]
[1]Weizmann Institute of Science, Department Of Brain Sciences, Rehovot, Israel, [2]Weizmann Institute of Science, Department Of Neurobiology, Rehovot, Israel

Physical exercise augments brain functioning, improving memory and cognition. While some of the physiological effects of physical activity on the brain are known (e.g., increased hippocampal neurogenesis), little is known about its effects on the neural code. Using Ca^{2+} imaging in freely behaving mice, we studied how voluntary exercise affects the quality and long-term stability of hippocampal place codes. In addition to increasing neurogenesis, we found that running accelerated the emergence of a more informative spatial code in novel environments and increased code stability over timescales of days to weeks. Paradoxically, although running mice demonstrated an overall more stable place code than their sedentary peers, their place code exhibited a higher degree of representational drift when controlling for code quality level. A model-based simulation showed that the combination of both improved code quality and faster representational drift in runners, but neither of these effects alone could account for our results. Thus, exercise may enhance hippocampal function via a more informative and dynamic place code.

EFFECTS OF REPRODUCTIVE STATUS ON COGNITIVE FUNCTION AND BEHAVIORAL FLEXIBILITY OF FEMALE MICE IN THE INTELLICAGE HOME CAGE ENVIRONMENT

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Melinda Cservenák[1], László Détári[2], Árpád Dobolyi[1]
[1]Laboratory of Molecular and Systems Neurobiology, Eötvös Loránd Research Network and Eötvös Loránd University, Department Of Physiology And Neurobiology, Budapest, Hungary, [2]Institute of Biology, Department Of Physiology And Neurobiology, Budapest, Hungary

The impact of pregnancy and motherhood on the physiology and behavior of the mother is dramatic. Dynamic fluctuations in steroid and peptide hormones during pregnancy and lactation and also sensory inputs from the pups induce the adaptations by acting on neural circuits in the brain. Although research has investigated the hormonal, neural and behavioral alterations related to maternal behaviors, it is not established how pregnancy and motherhood affect hippocampus-dependent spatial learning and memory and prefrontal-cortex dependent cognitive flexibility. Our purpose was to study the exploratory behavior, water consumption, spatial learning and cognitive flexibility of female mice throughout the reproductive cycle using automatic monitoring IntelliCage system. The present study is the first to determine that motherhood improves spatial learning performance and cognitive flexibility using IntelliCage. Previously, standard behavioral tests were used to examine these phenomenons in connection with different reproductive stages, but the findings were inconclusive. Our results demonstrate that compared to control/pregnant females, cognitive flexibility is enhanced in mothers tested by reversed place learning and fixed schedule drinking task in IntelliCage. Alterations of the executive functions, such as attention and cognitive flexibility, are likely critical for maternal responsiveness and parenting quality not just in rodents but in humans as well. INTERFERENCE-BASED FORGETTING IN A GOAL-DIRECTED SPATIAL NAVIGATION TASK FOR RODENTS.

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Paula Peixoto Moledo[1], Josep Dalmau[2], Pablo Jercog[3]
[1]August Pi i Sunyer Biomedical Research Institute (IDIBAPS), Neuroimmunology Program, Barcelona, Spain, [2]Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Hospital Clínic, Universitat de Barcelona, 1. neuroimmunology Program, Barcelona, Spain, [3]August Pi i Sunyer Biomedical Research Institute (IDIBAPS), Neuroimmunology Programm, Barcelona, Spain

The number of memories that can be stored in the brain is limited. Active forgetting is one possible mechanism by which the brain can decide which information to store in long-term memory. Interference-based forgetting occurs when information acquired before or after a learning event attenuates memory strength. In our daily lives, we are constantly exposed to new associations, each with its own value and volatility, limiting the interpretation of results obtained under lab conditions using only a few associations. For this reason, we developed a novel task that allows us to observe memory interference under more ethological conditions. We used our high-throughput behavioral task where animals learn the location of the reward among 8 positions that changes randomly over days. We test the memory recall of the reward position 2hrs after the training session and we observe how memories from previous sessions (i.e. days) interfere with the latest acquired memory. To dissect the interference between previously learned memories, we infused highly-specific human N-Methyl-D-aspartic receptor antibodies into animals' brain ventricles to mimic an anterograde amnesic state. We confirmed that the memory strength of new associations is weaker due to interference with previous memories. We found that antibody-mediated amnesia significantly reduces interference ($p<0.01$) by enhancing recent memories at the expense of a substantial reduction (~40%) in the strength of old ones. Our results support the theory of retroactive interference as a mechanism for eliminating memories of associations with high volatility.

Fluorescent BODIPY-Anionic Boron Cluster Conjugates as Potential Agents for Cell Tracking.
A series of novel fluorescent BODIPY-anionic boron cluster conjugates bearing [BH] (5, 6), [3,3'-Co(1,2-CBH)] (7, 8), and [3,3'-Fe(1,2-CBH)] (9) anions have been readily synthesized from meso-(4-hydroxyphenyl)-4,4-difluoro-4-bora-3 a,4 a-diaza-s-indacene (BODIPY 4), and their structure and photoluminescence properties have been assessed. Linking anionic boron clusters to the BODIPY (4) does not alter significantly the luminescent properties of the final fluorophores, showing all of them similar emission fluorescent quantum yields (3-6%). Moreover, the cytotoxicity and cellular uptake of compounds 5-9 have been analyzed in vitro at different concentrations of B (5, 50, and 100 μg B/mL) using HeLa cells. At the lowest concentration, none of the compounds shows cytotoxicity and they are successfully internalized by the cells, especially compounds 7 and 8, which exhibit a strong cytoplasmic stain indicating an excellent internalization efficiency. To the best of our knowledge, these are the first BODIPY-anionic boron cluster conjugates developed as fluorescent dyes aiming at prospective biomedical applications. Furthermore, the cellular permeability of the starting BODIPY (4) was improved after the functionalization with boron clusters. The exceptional cellular uptake and intracellular boron release, together with the fluorescent and biocompatibility properties, make compounds 7 and 8 good candidates for in vitro cell tracking.

LEC MODULATION OF CA1 ENSEMBLE DYNAMICS DURING MEMORY-GUIDED BEHAVIORS

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Maya Hopkins
New York University, Neuroscience, New York, United States of America

The ability to form and store memories is crucial for daily human functioning. It allows us to form appropriate relationships with others and our ever-changing environments. Without new memories we become unable to adapt and progress through space and time. In Alzheimer's Disease (AD), patients are robbed of this ability and experience severe cognitive deficits in spatial navigation and memory formation. Hippocampal output region, area CA1, receives inputs directly from the entorhinal cortex (EC). EC serves as an integrative hub for different sensory modalities, allowing a multisensory environment to be encoded within CA1. The lateral subdivision of EC (LEC) shows early dysfunction in both human AD patients and mouse models. Therefore, in early-stage AD, CA1 begins to receive corrupted inputs. But, how this translates into CA1's representation of environment or an animal's cognitive performance is unknown. To identify LEC-CA1 as a circuit underlying AD impairments, we determine if loss of LEC activity produces AD-like deficits. We performed *in vivo* imaging of CA1 neurons with chemogenetic silencing of LEC-CA1 long-range projections and found a decrease in ensemble stability while performance on a spatial task was spared. Ongoing imaging experiments are being conducted with multisensory spatial tasks in wild type and AD model mice to further dissect the contribution of LEC to CA1 ensemble activity. These experiments will contribute to our understanding of (1) basic memory processing and hippocampal circuits, as well as (2) early degradation of the cortico-hippocampal circuit in AD.

IN SEARCH FOR THE AVIAN TRIGEMINAL MAGNETIC SENSOR: ORGANIZATION OF THE OPHTHALMIC SENSORY COMPLEX IN THE NIGHT-MIGRATORY EURASIAN BLACKCAP (SYLVIA ATRICAPILLA)

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Katrin Haase[1], Isabelle Musielak[1], Leonie Warmuth-Moles[1], Bo Leberecht[1], Anna Zolotareva[2], Henrik Mouritsen[1,3], Dominik Heyers[1,3]

Night-migratory songbirds can use the Earth's magnetic field to navigate between their breeding and wintering grounds. Neurobiological and behavioral evidence suggests the existence of a magnetic sense associated with the ophthalmic branch of the trigeminal nerve (V1), located in the bird's upper beak. Curiously, neither the unequivocal existence, structural nature, nor the exact location of any sensory structure has been revealed to date. To narrow in on the putative location of any magnetic sensor, we used neuronal tract tracing to map both the innervation fields in the upper beak and the detailed trigeminal brainstem terminations of the medial and lateral V1 subbranches in the night-migratory Eurasian Blackcap (*Sylvia atricapilla*). The medial V1 subbranch takes its course along the ventral part of the upper beak to innervate subepidermal layers and the mucosa of the nasal cavity, while the lateral V1 subbranch runs along dorsolateral levels until the nostrils to innervate mainly the skin of the upper beak. In the trigeminal brainstem, medial V1 terminals innervate both the dorsal part and the ventral, magnetically activated part of the principle sensory trigeminal brainstem nuclei (PrV). In contrast, the lateral V1 subbranch innervates only a small part of the ventral PrV. The spinal sensory trigeminal brainstem nuclei receive topographically ordered projections from both medial and lateral subbranches. The present findings provide valuable information for further analysis of the trigeminal magnetic sense of birds and indicate that both the medial as well as the lateral V1 subbranch could be involved in mediating magnetic information.

CIRCUIT LOGIC OF DESCENDING INTERNEURONS CONTROLLING STEERING IN DROSOPHILA

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Tomke Stürner[1], Katharina Eichler[1], Paul Brooks[1], Han Cheong[2], Gwyneth Card[2], Elizabeth Marin[1], Marta Costa[1], Gregory Jefferis[3]
[1]University Cambridge, Department Of Zoology, Cambridge, United Kingdom, [2]HHMI's Janelia Research Campus, Neuroscience, Virginia, United States of America, [3]MRC Laboratory of Molecular Biology, Neurobiology Division, Cambridge, United Kingdom

Behavioural decisions result from a complex interplay between evolutionary predisposition and individual experience. In most animals a small set of descending interneurons (DNs) connect higher brain centres to the nerve cord to control a variety of complex behaviours. With the emergence of whole brain electron microscopy (EM) datasets for both the whole brain and Ventral Nerve Cord (VNC) of the fly, a systematic description of the DN population is now possible. In this project we identify and describe the entire set of 660 pairs of DNs that transfer pre-processed sensory information to motor centres in the VNC. This approach includes a comprehensive reconstruction of all DNs connecting brain and VNC and connectomics circuit reconstructions of VNC neurons involved in sensory-motor processing. Here, I present our collaborative work that has identified organisational principles across the DN population and their connections in the male VNC. Many DNs that relay information from the Lateral Accessory Lobes (LAL), a multimodal pre-motor integration centre in the brain, converge onto specific leg circuits involved in steering towards or away from a stimulus. Therefore a special focus of this project is the circuit logic of VNC local interneurons involved in steering during walking. The specific example of turning in response to learned or innately aversive stimuli gives us a general understanding of how the VNC executes a decision made in a higher brain centre.

MULTIMODAL REPRESENTATIONS OF CONTEXT IN GRADIENT NAVIGATION IN LARVAL ZEBRAFISH

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Virginia Palieri[1], Emanuele Paoli[1], Ilona Grunwald Kadow[2], Ruben Portugues[1]
[1]Technical University of Munich, Institute Of Neuroscience, München, Germany, [2]University of Bonn, Faculty Of Medicine, Bonn, Germany

Animals use a plethora of sensory systems and behavioral strategies to navigate where conditions for survival are maximized. It has been extensively shown that a temporal sampling strategy (i.e. detecting changes in stimulus intensity over time) will lead to an increase in turning rate when a worsening of conditions is detected. Conversely, animals will continue performing forward motion if the conditions are improving. Since the majority of existing studies on gradient navigation focus on single sensory modalities it is difficult to disentangle whether the aforementioned action selection processes are driven by the sensory modality itself or by a shared representation. In the present study, we took advantage of the optical accessibility and well-defined behavior of larval zebrafish to first confirm fish perform chemotaxis and thermotaxis in a freely swimming setup. Then, we identified the experienced rate of change of the gradient as the sole information sufficient for navigation. Finally, to find brain areas detecting an improvement or worsening of conditions we developed an open-loop virtual gradient navigation assay in head-restrained larvae used in combination with lightsheet microscopy. Notably, we found the habenular-interpeduncular pathway to be tuned to the rate of change of the stimulus while the serotoninergic superior raphe showed context-dependent representations of movements. The importance of the habenular-interpeduncular pathway and the involvement of the superior raphe in gradient navigation was further verified through chemical treatments. Taken together our results uncovered a pathway processing relevant sensory and motor variables for successful gradient navigation irrespective of sensory modality identity.

To track and control self-location, animals integrate their movements through space. While self-location is represented in the hippocampal formation, it is unknown how such representations arise from integrated self-motion, whether they exist in more ancient brain regions, and by what pathways they control locomotion. Fish can be carried by water currents to potentially dangerous areas; here we report that larval zebrafish track their displacements to later return to previous locations. Whole-brain functional imaging revealed the circuit enabling this 'positional homeostasis'. A newly identified brainstem positional integrator stores a memory of past displacements and induces an error signal in the inferior olive, which controls future corrective swimming. Optogenetically manipulating functionally-identified integrator cells evokes displacement-memory behavior; ablating them, or downstream olivary cells, abolishes positional homeostasis. These results reveal a multiregional hindbrain circuit in vertebrates for integration of self-motion, memory of self-location, and control of locomotor behavior.

SPINDLE–SLOW OSCILLATION COUPLING CORRELATES WITH MEMORY PERFORMANCE AND CONNECTIVITY CHANGES IN A HIPPOCAMPAL NETWORK AFTER SLEEP

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Lisa-Marie Bastian[1], Anumita Samanta[1], Demetrius Ribeiro De Paula[2], Frederik Weber[2], Robby Schoenfeld[3], Martin Dresler[2], Lisa Genzel[1]
[1]Donders Institute for Brain, Cognition and Behaviour, Radboud University, Neuroinformatics, Nijmegen, Netherlands, [2]Donders Institute for Brain Cognition and Behavior, Radboud University Medical Centre, Nijmegen, Netherlands, [3]University of Halle, Institute For Psychology, Halle, Germany

After experiences are encoded, post-encoding reactivations during sleep have been proposed to mediate long-term memory consolidation. Spindle–slow oscillation coupling during NREM sleep is a candidate mechanism through which a hippocampal-cortical dialogue may strengthen a newly formed memory engram. Here, we investigated the role of fast spindle- and slow spindle–slow oscillation coupling in the consolidation of spatial memory in humans with a virtual watermaze task involving allocentric and egocentric learning strategies. Furthermore, we analyzed how resting-state functional connectivity evolved across learning, consolidation, and retrieval of this task using a data-driven approach. Our results show task-related connectivity changes in the executive control network, the default mode network, and the hippocampal network at post-task rest. The hippocampal network could further be divided into two subnetworks of which only one showed modulation by sleep. Decreased functional connectivity in this subnetwork was associated with higher spindle–slow oscillation coupling power, which was also related to better memory performance at test. Overall, this study contributes to a more holistic understanding of the functional resting-state networks and the mechanisms during sleep associated to spatial memory

consolidation.

MEMORY IS REGULATED BY ASTROCYTIC RECEPTORS IN A SEX-SPECIFIC MANNER

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Samantha Meadows[1,2,3], Fernando Palaguachi[1,3], Avital Licht-Murava[1,3], Till Zimmer[1,3], Daniel Barnett[1,2,3], Adam Orr[1,3], Anna Orr[1,3]
[1]Weill Cornell Medicine, Feil Family Brain And Mind Research Institute, New York, United States of America, [2]Weill Cornell Medicine, Neuroscience Graduate Program, New York, United States of America, [3]Weill Cornell Medicine, Appel Alzheimer's Disease Research Institute, New York, United States of America

Aims: Astrocytes regulate cognition and behavior, but the precise mechanisms are unclear. Previous studies have shown that astrocytic G protein-coupled receptors (GPCRs) are key regulators of astrocytic-neuronal interactions and cognitive function. However, these studies did not account for sex as a biological variable. Here, we tested whether astrocytic glutamate receptors and other GPCRs have sex-specific effects on spatial learning and memory. **Methods:** We interrogated the effects of astrocytic GPCRs in the hippocampus using complementary transgenic and chemogenetic approaches. CRISPR-Cas9 was used to selectively knock down astrocytic metabotropic glutamate receptor 3 (mGluR3), a $G_{i/o}$-coupled receptor that is highly enriched in astrocytes and implicated in various cognitive disorders. To complement this approach, we employed a Cre-dependent viral vector to selectively enhance astrocytic mGluR3 expression. Additionally, we used chemogenetics to activate either $G_{i/o}$- or G_s-coupled receptor signaling in astrocytes during spatial learning. **Results:** We found that knocking down astrocytic mGluR3 impaired memory in females, but improved memory in males. Conversely, increasing astrocytic mGluR3 expression improved memory in females, but not males. Analogous to the sexually dimorphic effects of manipulating astrocytic mGluR3, activating astrocytic $G_{i/o}$-coupled signaling improved memory in females, but impaired memory in males. Moreover, activating astrocytic G_s-coupled signaling impaired memory in females but not males. **Conclusions:** Thus, astrocytic glutamate receptor mGluR3 and related GPCR signaling regulate spatial memory in a sex-specific manner. Given that alterations in mGluR3 and astrocytic receptor signaling are linked to various neurological and neuropsychiatric disorders, our findings suggest that astrocytes may promote sex differences in disease-associated cognitive impairments.

SPATIAL REASONING VIA RECURRENT NEURAL DYNAMICS IN MOUSE RETROSPLENIAL CORTEX

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Jakob Voigts[1], Ingmar Kanitscheider[2], Nicholas Miller[1], Enrique Toloza[1], Jonathan Newman[1], Ila Fiete[3], Mark Harnett[1]
[1]MIT, Brain And Cognitive Sciences, cambridge, United States of America, [2]openAI, Openai, San Francisco, United States of America, [3]Massachussets Institute of Technology, Department Of Brain And Cognitive Sciences, Cambridge, United States of America

From visual perception to language, sensory stimuli change their meaning depending on prior experience. Recurrent neural dynamics can interpret stimuli based on externally cued context, but it is unknown whether similar dynamics can compute and employ internal hypotheses to resolve ambiguities. Here, we show that mouse retrosplenial cortex (RSC) can form hypotheses over time and perform spatial reasoning through recurrent dynamics. In our task, mice navigated using ambiguous landmarks that are identified through their mutual spatial relationship, requiring sequential refinement of hypotheses. Neurons in RSC and in artificial neural networks encoded mixtures of hypotheses, location, and sensory information, and were constrained by robust low dimensional dynamics. RSC encoded hypotheses as locations in activity space with divergent trajectories for identical sensory inputs, enabling their correct interpretation. Our results indicate that interactions between internal hypotheses and external sensory data in recurrent circuits can provide a substrate for complex sequential cognitive reasoning.

HIPPOCAMPAL REPRESENTATIONS OF HOMING BASED ON PATH INTEGRATION

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Maryam Najafian Jazi, Adrian Tymorek, Ting-Yun Yen, Moritz Stingl, Benay Baskurt, Celia García Vilela, Kevin Allen
University of Heidelberg and DKFZ, Dkfz, Clinical Neurobiology A230, Heidelberg, Germany

Homing based on path integration (H/PI) is a form of navigation in which an animal processes self-motion cues to keep track of its location in order to return to a starting point. The neuronal representations supporting H/PI have remained largely unexplored because of a lack of H/PI tasks suitable for recordings of spatially selective neurons. Here we overcame this problem by developing an automated H/PI task for rodents. The task required a mouse to find a variably placed lever on a circular arena, before heading back to their home base. H/PI was assessed in complete darkness, where performance depended on path integration. Recordings from CA1 pyramidal neurons in mice performing the H/PI task showed that several firing fields were anchored to the lever position. The spatial selectivity of these fields was reduced during trials with lower homing accuracy. In a subset of lever-anchored neurons, the field position around the lever predicted the homing direction of the mouse. These results demonstrate how object-anchored firing fields convey behaviourally relevant information for homing and navigation beyond the object vicinity.

THALAMIC HEAD-DIRECTION CELLS ARE ORGANIZED IRRESPECTIVE OF THEIR INPUTS

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Guillaume Viejo, Adrien Peyrache
McGill University, Mni, Montreal, Canada

The thalamus relays sensory signals to the cortex and understanding its role in sensory processing is a central question. Thalamic head-directions (HD) neurons of the anterodorsal nucleus (ADN) increase their firing rates as a function of the direction of the head of the animal in the horizontal plane. ADN-HD cells maintain their mutual coordination during sleep, when sensory inputs are virtually absent, supporting the view that the HD signal arises from attractor dynamics. It has been proposed that the upstream structure, the lateral mammillary nucleus (LMN), is a central component of the HD signal generator circuit. Yet, whether the ADN passively relays LMN inputs or actively processes its inputs remains unclear. We investigated the organization of LMN activity across brain states in mice, and its relationship to ADN activity. While, during non-REM sleep, ADN-HD neurons maintained the same level of mutual coherence as during wake, LMN-HD cells showed reduced coordination. The decreased level of correlation in the LMN resulted, at least in part, by neurons co-firing irrespectively of their mutual preferred direction. Spike train dynamics were also strikingly different between structures. When the animal's HD was around a cell's preferred direction, the rate of LMN neurons varied linearly. ADN-HD neurons showed sharp transitions from low to high activity states. A model of nonlinear integration of LMN inputs accounts for the coordination of ADN-HD cell activity irrespective of the organization of the inputs. This suggests that intrinsic properties of thalamic cells are essential in shaping representation in thalamocortical networks.

CAN EPILEPTIC RODENTS CREATE A REPRESENTATION OF SPACE THROUGH OBSERVATION ONLY?

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Thomas Doublet, Antoine Ghestem, Christophe Bernard
Aix-Marseille Université, Institut De Neurosciences Des Systèmes, Marseille, France

In humans and many animals, new behaviors may be learned through observation of conspecific's experience. Patients with epilepsy and experimental models show memory deficits, but whether observational learning is affected is not known. We studied whether epileptic rats show cognitive deficit in learning by observation in a spatial task. We developed a new behavior task in an environment containing both directly experienced and purely observed areas. In this task a demonstrator animal performs a task under observation of a naïve animal which never physically experience the space where the task is occurring. After sufficient observational sessions, the observer animal is free to explore the observed space and perform the task. In control rats, we found that this observation led to highly significant improvements in both accuracy and latency towards the goal as compared to naïve animals. By contrast, epileptic animals failed to learn by observation. However, they were able to successfully complete the task through their own experience. This new behavior task allows us to confirm that rodents can create representations of a space they observed but never physically explored and that epileptic animals show a clear cognitive deficit in learning by observation.

THE EFFECT OF PROBLEM CONTEXTUALIZATION IN PHYSICS : A NEUROPHYSIOLOGICAL APPROACH TOWARDS A BETTER UNDERSTANDING OF PROBLEM SOLVING

POSTER SESSION 02 - SECTION: SPATIAL MEMORY, NAVIGATION & COGNITION

Patrick Charland[1], Pierre-Majorique Léger[2], Hugo Lapierre[1], Mohamed Amine Mahhou[1], Yannick Skelling[1], Patrice Potvin[1], Steve Masson[1], Martin Riopel[1]
[1]Université du Québec à Montréal, Didactique, Montreal, Canada, [2]HEC-Montréal, Information Technology, Montreal, Canada

In their critical review of available studies related to contextualization of physics, Taasoobshirazi, & Carr (2008) showed a certain lack of quality in available empirical studies and called for more rigorous research on the topic. Considering the work of Haussler et al. (1998), who observed that certain types of contexts (technical or humanistic) do promote girls' or boys' engagement, the overall goal of the present project is to evaluate the extent to which contextualization of mechanical physics instruction can influence student's engagement and performance. The study was conducted on 65 university students (32 females/33 males) who were given a task consisting of 18 mechanical physics problems (6 technical; 6 humanistic contextualized; 6 decontextualized) on a computer. Drawing on neurophysiological methods, cognitive (electroencephalography, pupillometry), affective (electrodermal activity and facial recognition of emotions) and behavioral (traces, responses to questionnaires) engagement data was collected during the task. The data are now being analyzed and will be available for the presentation. These results may possibly provide support (or otherwise) for the relevance of contextualizing physics instruction.

INVESTIGATING THE FUNCTIONAL SPECIALIZATION OF HUMAN DECLARATIVE MEMORY SUBSYSTEMS

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Svenja Klinkowski[1], Anna Seewald[1], Björn Fath[1], Panagiotis Iliopoulos[1], Silke Schmidt[1], Franziska Voss[1], Michael Erb[2], Klaus Scheffler[2], Steffen Gais[1], Svenja Brodt[1]
[1]University of Tuebingen, Institute Of Medical Psychology And Behavioral Neurobiology, Tübingen, Germany, [2]MPI for Biological Cybernetics, High Field Magnetic Resonance, Tuebingen, Germany

Aims. While traditional models of systems memory consolidation postulate the reliance of freshly encoded memories on the hippocampus, recent evidence in humans and animals has shown that there are conditions under which the neocortex can rapidly acquire genuine memory engrams. The current study investigates the idea of concurrent memory encoding in the entire network, and specialized subsystems coding for different aspects of the memory. **Methods**. 80 participants encoded the same abstract visual stimuli during fMRI scanning and were instructed to either remember the detailed item-context combinations (DET) or to identify conceptual categories (CEP). 24h later, performance was tested in a categorization and an item-context recognition task. **Results**. CEP performed better in categorizing novel stimuli (t_{78}=-6.91*; p*<0.001), whereas DET had better memory for item-context combinations (t_{78}=6.31*; p*<0.001). In both groups, repetitions activated the precuneus, for exact items (p_{FWE}<0.05) as well as conceptual repetitions (p_{FWE}<0.05). Contrasting the two groups, exact item repetition elicited higher bilateral activation of the superior frontal gyrus (t=7.03; p_{FWE}<0.05), caudate and thalamus in DET (t=5.88; p_{FWE}<0.05), and higher activation in visual cortex extending towards precuneus and fusiform gyrus (t=7.51; p_{FWE}<0.05) in CEP. Comparing CEP with DET, activation in medial occipital cortex (t=6.83, p_{FWE}<0.05) increased over category repetitions only in CEP. **Discussion**. Our data suggest the precuneus as a hub for detailed as well as conceptual memory representations. Additionally, differences in memory performance and neural differences between the two groups indicate a functional specialization of neocortical and subcortical areas during prioritized encoding of similar vs. differential features.

Higher Social Rejection Sensitivity in Opioid-Dependent Patients Is Related to Smaller Insula Gray Matter Volume: A Voxel-Based Morphometric Study.
Opioid-dependent patients are highly sensitized to negative social feedback, and increased social rejection sensitivity was linked to adverse treatment outcome, but its neurobiological underpinnings have not been understood yet. The present study investigated gray matter (GM) volume differences between 19 opioid maintenance treatment (OMT) patients and 20 healthy controls using magnetic resonance imaging and voxel-based morphometry. Associations of GM volumes with subjective feelings of exclusion and inclusion during a social ostracism (Cyberball) paradigm, with rejection sensitivity, social interaction anxiety and social phobia were explored. OMT patients displayed smaller GM volume in the bilateral insula and inferior frontal gyri. Psychometric and task data showed that patients reported significantly higher rejection sensitivity, social anxiety and social phobia scores and felt more excluded and less included during the social ostracism paradigm. Smaller GM volume in the insula was associated with higher subjective exclusion, lower subjective inclusion and higher rejection sensitivity, social anxiety and social phobia scores. Findings indicate that structural deficits in emotion- and anxiety-processing brain regions in OMT patients are associated with increased social rejection sensitivity. As social rejection is a potential trigger for relapse, patients might benefit from therapeutic strategies that promote social integration.

THE ROLES OF THE HUMAN ORBITOFRONTAL CORTEX, VMPFC, AND ANTERIOR CINGULATE CORTEX CONNECTOME IN EMOTION AND MEMORY

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Edmund Rolls
University of Warwick, Computer Science, CV AL, United Kingdom

The human orbitofrontal cortex, ventromedial prefrontal cortex (vmPFC) and anterior cingulate cortex are implicated in reward and emotion, but also in memory. Analysis of the effective connectivity of these regions in humans using Human Connectome Project data and the HCPex brain atlas (Huang et al 2021) shows how the human orbitofrontal cortex connecting with the vmPFC and anterior cingulate provide a route to the hippocampus for reward and emotional value to be incorporated in episodic memory, enabling memory of where a reward was seen (Rolls et al 2022a,b). It is proposed that this value component results in primarily episodic memories with some value component to be repeatedly recalled from the hippocampus so that they are more likely to become incorporated into neocortical semantic and autobiographical memories. The same orbitofrontal and anterior cingulate regions also connect in humans to the septal and basal forebrain cholinergic nuclei, thereby helping to consolidate memory, and helping to account for why damage to the vMPFC impairs memory (Rolls et al 2022a,b). The human hippocampus and vmPFC thus contribute in complementary ways to forming episodic and semantic memories. Rolls,E.T., Deco,G., Huang,C-C. and Feng,J. P300 LATENCY DEPEND ON WORKING MEMORY CAPACITY IN THE ELDERLY

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Joaquín Castillo Escamilla, Isabel Carmona Lorente, María Del Mar Salvador Viñas, José Manuel Cimadevilla Redondo
University of Almería, Department Of Psychology, Almería, Spain

The present study explored modulations of the event-related brain potentials (ERPs) in young and elder adults during a modified version of the ASMRT (Almeria Spatial Memory Recognition Test) modulated by working memory capacity. Forty adults (20 young) performed this task. As we expected, young adults showed better performance in the task. ERP results revealed significant differences in the P300 latency between groups. Latency was greater in the elderly. In addition, the P300 latency decreased with working memory capacity, only in this group. This results support previous research that suggest the relationship between age and latency in this ERP component.

IS THERE EVIDENCE FOR REWARD-CONDITIONING INDUCED RETROSPECTIVE AND PROSPECTIVE MEMORY ENHANCEMENT EFFECTS?

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Priyanka Sukumaran[1], Conor Houghton[2], Nina Kazanina[1,3]
[1]University of Bristol, School Of Psychological Sciences, Bristol, United Kingdom, [2]University of Bristol, Department Of Computer Science, Bristol, United Kingdom, [3]National Research University Higher School of Economics, Institute Of Cognitive Neuroscience, Moscow, Russian Federation

The neurobiological synaptic tagging mechanism allows the brain to temporarily store episodic events which seem insignificant at encoding but are subsequently enhanced in memory by acquiring salience. Human behavioural studies have found evidence for retrospective memory enhancement of initially neutral stimuli from a semantic category when images from that category were later paired with a salient event, e.g. monetary reward [Patil et al., 2017]. Although this phenomenon has important implications for adaptive memory and reward-memory literature, the generalisability of these findings remains unexplored. Our initial aims to find the same effects in different learning and reward paradigms were inconclusive, leading us to conduct four experiments to (1) replicate category-specific retrospective memory enhancement through reward conditioning using the same approach as [Patil et al., 2017], and (2) investigate the possibility of prospective memory effects. None of our experiments provided reliable evidence for effect of reward-conditioning on recognition memory. Our findings were analysed with frequentist statistics, linear mixed-effects models and further supported by Bayesian hypothesis testing, indicating substantial evidence for the null hypothesis of no effect of reward category. Critically, we also did not find any evidence for category-specific retrospective or prospective enhancement effects. Overall, our results cast doubt on the robustness of the reward-conditioning paradigm used to probe retrospective enhancement of memory, and thus on the underlying reward-induced adaptive memory phenomenon itself. Patil, A., Murty, V. P., Dunsmoor, J. E., Phelps, E. A., and Davachi, L. (2017). Reward retroactively enhances memory consolidation for related items. Learning and Memory, 24(1):65–69

FILTERING EFFICIENCY AS AN UNDERLYING MECHANISM OF MODEL-BASED WORKING MEMORY TRAINING IN HEALTHY OLD ADULTS

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Priska Zuber[1], Emanuel Geiter[2], Gresa Mazreku[1], Martina Foresti[1], Stefano Magon[3], Dominique De Quervain[1]
[1]University of Basel, Division Of Cognitive Neuroscience, Basel, Switzerland, [2]MIAC AG, Medical Image Analysis Center, Basel, Switzerland, [3]F. Hoffmann-La Roche Ltd., Roche Pharma Research And Early Development, Basel, Switzerland

Background: Working memory (WM) is crucial for cognitive functioning and amongst the first abilities to decline with age. It has been shown that older adults have difficulties to suppress distracting information during WM encoding, termed as filtering efficiency (FE). Own results revealed improved WM capacity in healthy older adults following combined training of WM and FE. Research is needed to establish how WM and FE interact in order to reach maximal improvement in WM functioning. **Aims:** To study FE as an underlying mechanism of WM capacity improvement in healthy older adults when trained in combination with WM by altering FE or WM load to a training version with high WM and low FE (MB+), high FE and high WM (MB++), and high FE but low WM (MB+-) load. **Methods**: This online, randomized, double-blind, parallel group study aims at including 171 healthy adults aged ≥ 50 years, 57 in each training condition (MB+, MB+-, MB++). Participants perform twelve 40-min training sessions during three weeks using the in-house developed application *SmartBrain* for smartphones and three web-based cognitive assessments, each assessing WM capacity by three complex span tasks and FE by a change detection task. The first two assessments serve as double-baseline to investigate practice effects. **Results:** The results will yield novel insights on underlying mechanisms of WM training in healthy elderly adults. These insights will allow to help elderly people overcome difficulties in daily life tasks due to their age-related cognitive decline and may be translated in rehabilitative strategies for clinical conditions.

Additive and interaction effects of working memory and motor sequence training on brain functional connectivity.
Although shared behavioral and neural mechanisms between working memory (WM) and motor sequence learning (MSL) have been suggested, the additive and interactive effects of training have not been studied. This study aimed at investigating changes in brain functional connectivity (FC) induced by sequential (WM + MSL and MSL + WM) and combined (WM × MSL) training programs. 54 healthy subjects (27 women; mean age: 30.2 ± 8.6 years) allocated to three training groups underwent twenty-four 40-min training sessions over 6 weeks and four cognitive assessments including functional MRI. A double-baseline approach was applied to account for practice effects. Test performances were compared using linear mixed-effects models and t-tests. Resting state fMRI data were analysed using FSL. Processing speed, verbal WM and manual dexterity increased following training in all groups. MSL + WM training led to additive effects in processing speed and verbal WM. Increased FC was found after training in a network including the right angular gyrus, left superior temporal sulcus, right superior parietal gyrus, bilateral middle temporal gyri and left precentral gyrus. No difference in FC was found between double baselines. Results indicate distinct patterns of resting state FC modulation related to sequential and combined WM and MSL training suggesting a relevance of the order of training performance. These observations could provide new insight for the planning of effective training/rehabilitation.

Investigation of a Model-Based Working Memory Training With and Without Distractor Inhibition and Its Comparative Efficacy: A Randomized Controlled Trial on Healthy Old Adults.
: Various working memory (WM) trainings have been tested, but differences in experimental designs, the lack of theoretical background, and the need of identifying task-related processes such as filtering efficiency limit conclusions about their comparative efficacy. : In this study, we compared the efficacy of a model-based WM training with (MB) and without (MB) distractor inhibition on improving WM capacity to a dual and active control condition. : This randomized clinical trial included 123 healthy elderly adults (78 women, 45 men; aged 64.1 ± 8.3 years). All groups underwent 12 40-min training sessions

over 3 weeks and four cognitive testing sessions. The first two sessions served as double baseline to account for practice effects. Primary outcome was WM capacity post-training measured by complex span tasks. Near and far transfer was assessed by simple span, n-back, visuospatial and verbal learning, processing speed, and reasoning tasks. : Due to preliminary termination (COVID-19), 93 subjects completed the post-training and 60 subjects the follow-up session. On a whole group level, practice effects occurred from prebaseline to baseline in WM capacity (= 4.85, = 4.01, < 0.001, = 0.37). Linear mixed-effects models revealed a difference in WM capacity post-training between MB and MB (= -9.62, = -2.52, = 0.014, = 0.27) and a trend difference between MB and dual (= -7.59, = -1.87, = 0.065, = 0.20) and control training (= -7.08, = -1.86, = 0.067, = 0.20). Univariate analyses showed an increase between pre- and post-training for WM capacity within MB (= -3.34, < 0.05) only. There was no difference between groups pre- and post-training regarding near and far transfer. Univariate analyses showed improved visuospatial learning within MB (= -3.8, < 0.05), improved processing speed (= 2.19, < 0.05) and -back performance (= 2.12, < 0.05) in MB, and improved -back performance (= 3.83, < 0.001) in the dual -back training. : A model-based WM training including filtering efficacy may be a promising approach to increase WM capacity and needs further investigation in randomized controlled studies.

BORDERS BETWEEN DOMAIN-GENERAL AND TASK-SPECIFIC BRAIN REGIONS ARE CRITICAL FOR EXECUTIVE FUNCTIONS

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Moataz Assem[1], Sneha Shashidhara[1,2], Matthew Glasser[3], John Duncan[1]
[1]University of Cambridge, Mrc Cognition And Brain Sciences Unit, Cambridge, United Kingdom, [2]Ashoka University, Psychology Department, Sonipat, India, [3]Washington University in St. Louis, Departments Of Neuroscience And Radiology, St Louis, United States of America

Executive functions are associated with fMRI activations that overlap with fronto-parieto-temporal domain-general or multiple-demand (MD) cortex. Mechanistic insight into how MD cortex supports executive functions remains lacking as the limited spatial resolution of traditional imaging methods obscured overlapping and segregated activations for different executive components. Here we used multimodal MRI techniques of the Human Connectome Project (HCP) to scan subjects performing three kinds of executive tasks: working memory, set shifting and inhibition, each contrasted with a matched baseline task. In line with a “common” executive function component, the three executive>baseline contrasts showed robust overlaps in MD cortex at the single subject level. Each executive demand, however, showed unique activations that overlapped with adjacent regions belonging to different networks. Strikingly, activation peaks clustered at the borders between MD and adjacent regions. Inhibition showed relatively right lateralized activations lying between MD and cingulo-opercular networks, working memory showed overlaps between MD and default-mode networks, while for set shifting, activations were relatively left lateralized lying between MD and dorsal attention networks. Using an independent HCP resting-state dataset, we found that seed regions within MD cortex show differential connectivity patterns that closely predict each task’s precise topography. These results bring a new level of precision to understanding how executive functions are assembled in the brain. Each task demand displays a unique intersection between the domain-general MD network and adjacent, more specialised networks. In this intersection, the strongest activity arises at network borders, where information may be most intensively
exchanged.

Aims
Working memory is an essential cognitive system involved in retaining and manipulating information. Mental workload describes the relationship between working memory capacity and task demand. Despite its importance, the relationship between working memory load and neural activity remains unclear. **Methods**
We aimed to decode task difficulty, a proxy for working memory load, from frontoparietal electrocorticography data collected from three subjects during an n-back memory task using regularized logistic regression. We fitted generalised models (using data from all subjects) and individualised models. We selected electrodes using either the average difference in amplitude between conditions or in common cortical regions across participants. Decoder performance was assessed by measuring the accuracy for classifying task type, i.e., 1-back, 2-back, or 3-back. **Results**
Working memory load can be decoded from neural activity in frontoparietal cortex with a mean accuracy of 57.23% (61.7%, 71.7%, and 38.3% individually). We show that individualised models produce greater decoding accuracy than generalised models (58.33% vs. 42%). Further, accuracy is not strongly influenced by the electrodes used for training, with 58.33% accuracy for electrodes chosen based on amplitude-differences and 57.23% accuracy for electrodes in common regions. **Conclusions**
Our results suggest that the neural signature of working memory load varies between participants, but some cross-participant features appear to be conserved. These results also suggest that working memory is not strongly localised to a specific cortical region, but is widely distributed in the frontoparietal cortex.

Sergievsky Center, New York, United States of America

Aims: Several reports have demonstrated cognitive impairment in patients who have recovered from COVID-19. We conducted an objective screening of maternal cognitive functioning at 8-11 months postpartum in women with and without history of SARS-CoV-2 infection during pregnancy. **Methods:** We assessed cognition in 131 women (60 SARS-CoV-2 infected, 71 uninfected) who gave birth at Columbia University Irving Medical Center and enrolled in the COVID-19 Mother Baby Outcomes (COMBO) Study. Over Zoom, we administered the American National Adult Reading Test (AmNART) as an estimate of Full-Scale IQ (FSIQ), the Blind Montreal Cognitive Assessment (MoCA) screen for cognitive impairment, and the Trail Making Test A and B to assess processing speed and executive function. **Results:** Analysis of covariance (ANCOVA) models adjusting for maternal age, years of education, language of administration (English or Spanish), AmNART FSIQ, ethnicity, and race demonstrated that women infected with SARS-CoV-2 during pregnancy scored significantly lower on the global Blind MoCA cognitive screen (23.34±4.68 infected vs. 25.33±3.13 uninfected; $F(1,115)=10.56$; $p=0.002$), due primarily to reduced working memory performance (serial 7s: 2.50±0.87 infected vs. 2.82±0.52 uninfected [$F(1,115)=7.98$; $p=0.006$]; sentence repetition: 1.08±0.79 infected vs. 1.52±0.61 uninfected [$F(1,115)=21.27$; $p<0.001$]). No significant differences were observed in Trail Making. **Conclusions:** Women in our cohort who were infected with SARS-CoV-2 during pregnancy scored significantly lower than uninfected women on the global Blind MoCA screen administered more than 8 months after infection. More specifically, previously infected women exhibited impairment in tasks assessing working memory.

Human memory is prone to errors, that is why the neural correlates of true and false recognition have been investigated for years. Meanwhile, the influence of time-of-day on cognitive functions has been confirmed by numerous previous research. The aim of this study was to determine the effects of diurnal factors on true and false recognition in short-term memory with the use of a non-linear correlation analysis, originally designed for resting-state fMRI data (known as "resting BOLD event triggered averages"). Fifty-four young and healthy participants (32 females, mean age: 24.17 ± 3.56 y.o.) performed a task in an MR scanner twice, once in the morning and once in the evening. The task was based on the Deese-Roediger-McDermott paradigm adjusted to investigate the short-term memory and required global visual information processing. The regional BOLD activity was non-linearly correlated with the stimuli, separately for the encoding and retrieval phases of the task. The results of a model predicting true and false recognitions demonstrated that the correlations between the stimuli and BOLD interact with the time-of-day and the type of the probe (a previously seen versus a misleadingly similar one). Moreover, the interactions depended on the brain regions, with particular differences in correlations for the two types of probe within hippocampal areas. The study sheds new light on the influence of diurnal factors on memory functioning, on the neural correlates and predictive measures of memory distortions as well as it confirms the effectiveness of the non-linear correlation analysis method for the task fMRI paradigm.

INFORMATION FLOWS FROM HIPPOCAMPUS TO AUDITORY CORTEX DURING REPLAY OF VERBAL WORKING MEMORY ITEMS.

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Vasileios Dimakopoulos[1], Piere Megevand[2,3], Lennart Stieglitz[4], Lucas Imbach[5], Johannes Sarnthein[4]
[1]University Hospital Zurich, Neurosurgery, Zurich, Switzerland, [2]Faculté de médecine, Université de Genève, Geneva, Switzerland, Département Des Neurosciences Fondamentales, F, Geneva, Switzerland, [3]Hôpitaux Universitaires de Genève, Service De Neurologie, Geneva, Switzerland, [4]University Hospital Zurich, Neurosurgery, Zürich, Switzerland, [5]Schweizerisches Epilepsie Zentrum, Klinik Lengg, Zurich, Switzerland

The maintenance of items in working memory relies on a widespread network of cortical areas and hippocampus where synchronization between electrophysiological recordings reflects functional coupling. We investigated the direction of information flow between auditory cortex and hippocampus while participants heard and then mentally replayed strings of letters in working memory by activating their phonological loop. We recorded LFP from the hippocampus, reconstructed beamforming sources of scalp EEG, and - additionally in 3 participants – recorded from subdural cortical electrodes. When analyzing Granger causality, the information flow was from auditory cortex to hippocampus with a peak in the 4-8 Hz range while participants heard the letters. This flow was subsequently reversed during maintenance while participants maintained the letters in memory. The functional interaction between hippocampus and the cortex and the reversal of information flow provide a physiological basis for the encoding of memory items and their active replay during maintenance.

UPPER ALPHA OSCILLATORY ACTIVITY REFLECTS SUB-PROCESSES OF CREATING, BUT NOT SOLVING GEOMETRIC MATRICES

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Vera Eymann, Ann-Kathrin Beck, Saskia Jaarsveld, Thomas Lachmann, Daniela Czernochowski
TU Kaiserslautern, Center For Cognitive Science, Kaiserslautern, Germany

Although the relationship between fluid intelligence and creativity has been studied for many years, the underlying neural mechanisms of this relationship are still under debate. Typically, fluid intelligence is measured using convergent thinking tasks, whereas creativity is measured using divergent thinking tasks. Both fluid intelligence and creativity have been associated with working memory abilities (especially working memory capacity). In our study, we investigated how divergent and convergent thinking (as proxy for fluid intelligence and creativity) are related above and beyond activity related to working memory. We collected EEG data while 17 participants performed the Creative Reasoning Task (CRT) and the Raven's Advanced Matrices (APM), in which participants are asked to either create or solve geometric matrices, respectively. Furthermore, we measured working memory within the same knowledge domain and by using highly comparable stimulus material. We analyzed upper alpha (10-12 Hz) oscillatory activity in both CRT and APM while subtracting working memory related activity. To account for the temporal variability associated with the different cognitive stages in convergent and divergent thinking, we investigated early, intermediate and late stages of the self-paced trials in CRT and APM. In addition, we separated the CRT into phases according to predominantly divergent and convergent thinking processes. Beyond activity related to working memory, we observed differences in upper alpha synchronization in divergent thinking phases which were not found in convergent thinking phases. This implies that increased activity in the upper alpha band reflects sub-processes of creating - but not solving - geometrical matrices.

SHORT-TERM MEMORY CAPACITY IS DETERMINED BY LONG-TERM MEMORY REPRESENTATIONS

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Thomas Alrik Sørensen
Aalborg University, Department Of Communication And Psychology, Aalborg, Denmark

Several studies have described the attentional bottleneck and tried to explore the nature of the limitation in short-term memory (e.g., Luck & Vogel, 1997). Most notably whether short-term memory limitations are feature- or object-based, and while alternate models add to the debate, most seem to omit the possible role of familiarity and expertise. In a range of behavioral studies, we investigate how attentional selection and encoding into short-term memory are modulated by prior expertise and the degree of familiarity. Sørensen & Kyllingsbæk (2012) demonstrate that memory capacity is modulated by expertise in a change detection design of various age groups ranging from children to adults, this is later replicated by Dall, Watanabe, & Sørensen (2016) in three groups of adults with varying degrees of knowledge to Japanese, and finally processing of Chinese characters are explored in a whole-report design revealing that familiarity solely drives processing over character complexity (Dall, Wang, Cai, Chan, & Sørensen, 2021). Across several studies we demonstrate the dynamics of how familiarity and expertise gradually tune mental representations involved in perceptual processing and attentional selection (see also Brogaard & Sørensen, *in press*), suggesting that long-term memory representations play a pivotal role in both attentional selection and the encoding into short-term memory.

MISMATCH NEGATIVITY, A NEURAL MARKER OF PLASTICITY IN UNILATERAL HEARING LOSS PATIENTS

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Mariam Alzaher[1], Strelnikov Kuzma[2], Pascal Barone[3], Mathieu Marx[2]
[1]Centre de Recherche Cerveau et Cognition, Cnrs, Toulouse, France, [2]CHU Purpan, Ent, Toulouse, France, [3]CNRS UMR5549, Cerveau & Cognition, Toulouse, France

Objectives: Unilateral Hearing Loss (UHL) possess detrimental consequences on horizontal sound localization. However, some patients might present near-normal localization accuracies that could be related to spatial induced plasticity due to monaural spatial adaptation. In order to assess the neural mechanisms underlying auditory spatial adaptation in UHL, we used the Mismatch Negativity (MMN) as a neural marker of plasticity, combined with a behavioural evaluation of sound localization and speech recognition. **Methods:** Twenty-one UHL were assigned into three groups based on their behavioural performances using K-mean cluster analysis: better performers group (BPG n=6), moderate (MPG n=9) and poor (PPG n=6), and 20 normal hearing subjects (NHS) took part in the study. Participants underwent behavioural evaluations of sound localization and speech segregation, followed by a passive oddball paradigm to record the MMN as a response to 3 spatial deviations placed at 10°, 20° and 100° of deviation from the standard (50°). NHS underwent binaural (NHS_bin) and monaural (NH_mon) stimulation in both behavioural and neural investigations. **Results:** BPG showed normal localization performances, reflected by significant MMN at small spatial disparities of 10° similarly to NH_bin. In addition, despite their hearing loss, MPG had better spatial sensitivity than NH_mon with significant MMN starting from 20° of deviation. PPG and NH_mon had the highest localization errors, with an MMN response only at 100° of deviation. **Conclusion:** Our results suggest that some UHL patients are able to adapt to monaural hearing, and that MMN can be used as a neural marker to reflect this adaptation.

Brain plasticity and hearing disorders.
Permanently changed sensory stimulation can modify functional connectivity patterns in the healthy brain and in pathology. In the pathology case, these adaptive modifications of the brain are referred to as compensation, and the subsequent configurations of functional connectivity are called compensatory plasticity. The variability and extent of auditory deficits due to the impairments in the hearing system determine the related brain reorganization and rehabilitation. In this review, we consider cross-modal and intra-modal brain plasticity related to bilateral and unilateral hearing loss and their restoration using cochlear implantation. Cross-modal brain plasticity may have both beneficial and detrimental effects on hearing disorders. It has a beneficial effect when it serves to improve a patient's adaptation to the visuo-auditory environment. However, the occupation of the auditory cortex by visual functions may be a negative factor for the restoration of hearing with cochlear implants. In what concerns intra-modal plasticity, the loss of interhemispheric asymmetry in asymmetric hearing loss is deleterious for the auditory spatial localization. Research on brain plasticity in hearing disorders can advance our understanding of brain plasticity and improve the rehabilitation of the patients using prognostic, evidence-based approaches from cognitive neuroscience combined with post-rehabilitation objective biomarkers of this plasticity utilizing neuroimaging.

Aims: Resective surgery for mesial temporal lobe epilepsy carries the potential risk of memory decline. Although neurofeedback (NF) is thought to be a promising solution for preserving memory function, there have been no studies on its application to preserve memory function. Thus, we aimed to develop an NF system for memory function and investigate the changes in neural activity and memory task scores in the hippocampal area through NF training. ***Methods:*** We constructed a memory NF system that uses intracranial electrodes to acquire and visualize brain activity near the hippocampus while memorizing words. Twenty trials of tug-of-war per session were used for NF, and the game was designed so that the tug was pulled to the right (red team side) when brain activity increased and to the left (white team side) when brain activity decreased. Two patients participated in this NF training, and they were told which team to root for before the start of each session and were instructed to try to win (red team/white team root condition). ***Results:*** The difference in NF signal (hippocampal low-theta power ratio for the first trial) between the two conditions became larger as the number of sessions increased. On the other hand, there was no correlation between the hippocampal activity change and the memory task performance change. ***Conclusions:*** Our results indicated that NF could change hippocampal activity related to memorization. We plan to improve the NF system further and verify its effects on memory functions for future study.

Effects of Transcranial Direct Current Stimulation on Brain Networks Related to Creative Thinking.
Human creative thinking is unique and capable of generating novel and valuable ideas. Recent research has clarified the contribution of different brain networks (default mode network, DN; executive control network; salience network) to creative thinking. However, the effects of brain stimulation on brain networks during creative thinking and on creative performance have not been clarified. The present study was designed to examine the changes in functional connectivity (FC) and effective connectivity (EC) of the large-scale brain network, and the ensuing changes in creative performance, induced by transcranial direct current stimulation (tDCS). Fourteen healthy male students underwent two tDCS sessions, one with actual stimulation and one with sham stimulation, on two separate days. Participants underwent tDCS (anode over the left dorsolateral prefrontal cortex, DLPFC; cathode over the right inferior parietal lobule, IPL) for 20 min. Before and after the tDCS session, electroencephalography signals were acquired from 32 electrodes over the whole head during the creative thinking task. On FC analysis, the delta band FC between the posterior cingulate cortex and IPL significantly increased only after real stimulation. We also found that the change of flexibility score was significantly correlated with the change in: (i) delta band FC between mPFC and left lateral temporal cortex (LTC) and (ii) alpha band FC between IPL and right LTC. On EC analysis, decreased flow within the DN (from left LTC to right IPL) was observed. Our results reveal that tDCS could affect brain networks, particularly the DN, during creative thinking and modulate key FC in the generation of flexible creative ideas.

Development of a Cognitive Brain-Machine Interface Based on a Visual Imagery Method.
In the field of brain-machine interface (BMI) research, the development of cognitive BMI is a hot topic because it may lead to more intuitive and goal-directed findings than existing BMI technology. In this study, we devised a "visual-imagery method," which enables visual imaging of the operation of a target. We also investigated an "inner-speech method," which comprised internal pronunciation of words without emitting sounds, and an "inner-speech + visual-imagery method," which combined the two methods. When only the high γ band (60-120 Hz) power in the prefrontal cortex was used, the average accuracy of the 15 participants, with 20-fold crossvalidation, was 81.3% in inner speech, 84.6% in visual imagery, and 83.2% in inner speech + visual imagery. This study also found that the frontal pole was the most useful region in the prefrontal

cortex.

GRID-LIKE CODES IN THE HUMAN ENTORHINAL CORTEX MAP VISUAL SPACE DURING MEMORY FORMATION

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Luise Graichen, Magdalena Linder, Lars Keuter, Claus Lamm, Isabella Wagner
University of Vienna, Faculty Of Psychology, Vienna, Austria

Whether we will remember or forget is partly determined by the processes engaged upon the initial encounter of new information. For instance, when presented with visual input, we tend to actively sample information with saccadic eye movements to visually explore and extract relevant image features which can support recognition memory thereafter. Grid cells in the entorhinal cortex of animals and humans were recently shown to map visual space, similar to their role in navigating physical space. Here, we asked whether grid-like coding of visual space supported memory formation. Fifty human participants studied face and scene images while undergoing functional magnetic resonance imaging (fMRI) and continuous eye tracking. To determine memory performance, participants completed a recognition memory test immediately after studying as well as one week later. Results revealed significantly increased activation in the medial temporal lobe (including the hippocampus, parahippocampal and entorhinal cortices), the ventromedial prefrontal cortex and occipital regions when studying later remembered compared to later forgotten images. Focusing on eye movement-related activity, we found significantly increased grid-like codes in the entorhinal cortex when participants performed saccades to study later remembered images, but not when they studied later forgotten images. We provide first evidence that entorhinal grid-like coding of visual space supports memory formation.

[1]University Hospital Bonn, Department Of Neurodegenerative Diseases And Geriatric Psychiatry, Bonn, Germany, [2]German Center for Neurodegenerative Diseases, German Center For Neurodegenerative Diseases, Bonn, Germany, [3]The University of Sydney, School Of Psychology, Sydney, Australia, [4]University of Bonn, Department Of Physics And Astronomy, Bonn, Germany

Re-living autobiographical memories (AM) is one of our most valued cognitive abilities and it is impaired in a broad range of psychiatric and neurological disorders with devastating effects for patients and caregivers. The hippocampus (HC) plays a key role in vivid AM retrieval. However, the HC comprises several subfields and it remains unclear how HC subfields differentially contribute to AM. Furthermore, while the HC is part of a distributed brain network supporting AM, due to technical limitations inherent to 3T fMRI, how HC subfields interact with this network is unknown. A novel 7T fMRI sequence covering the whole-brain at submillimeter resolution was employed using customized 3D Echo Planar Imaging (EPI). This sequence enabled us to examine both detailed HC subfield activity and whole-brain functional connectivity during AM retrieval. While scanning, 24 healthy participants were instructed to relive detail rich AM relevant to specific word cues or solve simple math problems as a control condition. HC subfields were manually segmented, and fMRI signals extracted for each subfield and condition in all participants. Our results suggest that, while all HC subfields were engaged during AM retrieval, the pre/parasubiculum contributed more so than other subfields. Subsequent, functional connectivity analyses also revealed that the pre/parasubiculum was strongly connected to neocortical regions typically associated with AM. Together, these technically innovative results indicate functional differentiation amongst HC subfields and their neocortical connectivity pattern, highlighting a crucial role of the pre/parasubiculum in AM retrieval.

MetaSleepLearner: A Pilot Study on Fast Adaptation of Bio-Signals-Based Sleep Stage Classifier to New Individual Subject Using Meta-Learning.
Identifying bio-signals based-sleep stages requires time-consuming and tedious labor of skilled clinicians. Deep learning approaches have been introduced in order to challenge the automatic sleep stage classification conundrum. However, the difficulties can be posed in replacing the clinicians with the automatic system due to the differences in many aspects found in individual bio-signals, causing the inconsistency in the performance of the model on every incoming individual. Thus, we aim to explore the feasibility of using a novel approach, capable of assisting the clinicians and lessening the workload. We propose the transfer learning framework, entitled MetaSleepLearner, based on Model Agnostic Meta-Learning (MAML), in order to transfer the acquired sleep staging knowledge from a large dataset to new individual subjects (source code is available at https://github.com/IoBT-VISTEC/MetaSleepLearner). The framework was demonstrated to require the labelling of only a few sleep epochs by the clinicians and allow the remainder to be handled by the system. Layer-wise Relevance Propagation (LRP) was also applied to understand the learning course of our approach. In all acquired datasets, in comparison to the conventional approach, MetaSleepLearner achieved a range of 5.4% to 17.7% improvement with statistical difference in the mean of both approaches. The illustration of the model interpretation after the adaptation to each subject also confirmed that the performance was directed towards reasonable learning. MetaSleepLearner outperformed the conventional approaches as a result from the fine-tuning using the recordings of both healthy subjects and patients. This is the first work that investigated a non-conventional pre-training method, MAML, resulting in a possibility for human-machine collaboration in sleep stage classification and easing the burden of the clinicians in labelling the sleep stages through only several epochs rather than an entire recording.

SleepPoseNet: Multi-View Learning for Sleep Postural Transition Recognition Using UWB.
Recognizing movements during sleep is crucial for the monitoring of patients with sleep disorders, and the utilization of ultra-wideband (UWB) radar for the classification of human sleep postures has not been explored widely. This study investigates the performance of an off-the-shelf single antenna UWB in a novel application of sleep postural transition (SPT) recognition. The proposed Multi-View Learning, entitled SleepPoseNet or SPN, with time series data augmentation aims to classify four standard SPTs. SPN exhibits an ability to capture both time and frequency features, including the movement and direction of sleeping positions. The data recorded from 38 volunteers displayed that SPN with a mean accuracy of 73.7 ±0.8 % significantly outperformed the mean accuracy of 59.9 ±0.7 % obtained from deep convolution neural network (DCNN) in recent state-of-the-art work on human activity recognition using UWB. Apart from UWB system, SPN with the data augmentation can ultimately be adopted to learn and classify time series data in various applications.

Specific B- and T-cell populations are associated with cognition in patients with epilepsy and antibody positive and negative suspected limbic encephalitis.
Neuropsychological impairments are major symptoms of autoimmune limbic encephalitis (LE) epilepsy patients. In LE epilepsy patients with an autoimmune response against intracellular antigens as well as in antibody-negative patients, the antibody findings and magnetic resonance imaging pathology correspond poorly to the clinical features. Here, we evaluated whether T- and B-cells are linked to cognitive impairment in these groups.

MEMORY SUPPRESSION RELIES ON TARGETED REPRESENTATIONAL CONTROL OF INDIVIDUAL MEMORIES

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Frederik Bergmann, Michael Anderson
University of Cambridge, Mrc Cognition And Brain Sciences Unit, Cambridge, United Kingdom

Some memories haunt us. However, prior research has shown that the human brain can learn to control intrusive memories even when faced with reminders. By deliberately suppressing their retrieval, unwanted memories become less frequent, less vivid and can even be forgotten. This suggests that memory control depends on the targeted weakening of individual representations of unwanted memories. Here we tracked this gradual decrease in mnemonic strength of intrusive memories in the ventral visual stream and the hippocampus using fMRI. To isolate instances of involuntary recall, we used the Think/No-Think task in which people are asked to suppress retrieval of a memory, given a reminder to it. By introducing subjective reports after each reminder, we identified trials in which a memory came to mind, despite attempts to suppress it, indicating involuntary retrieval. We then correlated activation patterns of each suppression trial with patterns from a separate visual task that belonged to the same item. This allowed us to quantify the degree to which an individual memory was reinstated on each suppression trial. We hypothesized that reported intrusions will be accompanied by more reinstatement than trials without memory intrusions. However, irrespective of intrusion reports, reinstatement of memory specific activation should decline over suppression attempts. This reduction in reinstatement should be related to the decrease in the frequency of involuntary recalls and memory deficits on a later test. Hence, each time we push an intrusive memory out of awareness, its mnemonic strength weakens until its memory trace no longer supports effective remembering.

Introduction
The hippocampus is an essential hub for episodic memory processing. However, how human hippocampal single neurons code multi-feature associations remains unknown. Some argue that each hippocampal neuron codes for an invariant element within an episode (Quiroga, 2012). Instead, others have proposed that hippocampal neurons bind together all features present in a discrete episodic memory (Teyler and DiScenna, 1986). Methods
In search of an answer to this issue, we have recorded the activity of 585 single neurons in the hippocampus of human epileptic patients (N = 16). During a self-paced memory association task patients formed unique episodic memories comprising an animal cue and two associate images (places or faces). Results
We contrasted the empirical firing reinstatement (firing rate at encoding multiplied with retrieval) of every single unit during every episode with a shuffled distribution. Next, we excluded potential concept neurons that showed increased firing to the animal cue at encoding. In a second level shuffling procedure we show that a significant number (N = 144/585; $p < 0.001$) of single units showed a memory specific reinstatement of neural firing during individual episodes. We termed these single units Episode Specific Neurons (ESNs).

Conclusions
In conclusion, we provide evidence that individual neurons code discrete episodes via an increased firing rate during encoding and retrieval. We demonstrate that these Episode Specific Neurons do not reflect the coding of a particular feature in the episode (i.e., concept or time). Instead, they code for the conjunction of the different elements that make up the episode.

POST-STIMULUS INACTIVATION OF THE MAMMILLARY BODIES IMPAIRS PERFORMANCE ON SPATIAL RECOGNITION TASKS.

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

James Perry, Michal Milczarek, Christopher Dillingham, Eman Amin, Seralynne Vann
Cardiff University, School Of Psychology, Cardiff, United Kingdom

The mammillary bodies, and their connections to the anterior thalamic nuclei, are important for memory. Damage to the mammillary bodies can result in diencephalic amnesia in humans and spatial memory impairments in rodents. Previous studies have typically used permanent lesions to determine the contribution of the mammillary bodies making it difficult to differentiate specific roles during stimulus processing, post-stimulus encoding and retrieval. To address this, we used a temporary inactivation approach by infusing the Group II metabotropic glutamate receptor specific agonist, APDC, into the mammillary bodies of rats. Saline infusions were used as a control. Rats were tested on two spatial memory tasks: a place discrimination task in the Y maze and an object-in-place task. Both tasks involved a sample phase, followed by a 6h delay, then a test session. The extent to which animals spent exploring the novel place (Y-maze) or novel place-object combination during the test phase was taken as a measure of “memory” of the sample phase. When rats were infused with APDC immediately after the sample phase, their performance was impaired on both spatial tasks, compared to performance following saline infusions. In contrast, infusions of APDC 15 minutes before the test phase resulted in similar performance to that seen following saline infusions. This highlights a specific involvement of the mammillary bodies in post-stimulus processing.

INTERMITTENT WORKING MEMORY TRAINING PROTECTS FROM AGE-RELATED DECLINE OF SPATIAL MEMORY IN RATS.

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Alexandra Barbelivien, Laura Durieux, Eliabel Seys, Monique Majchrzak
Université de Strasbourg-CNRS, Laboratoire De Neurosciences Cognitives Et Adaptatives, Strasbourg, France

Engagement in cognitive activity in adulthood is one of the factors that enable successful cognitive aging, both in humans and rodents. However, some studies emphasize that the beneficial effect on cognition of such an activity may reflect carry over from one test situation to another, including memory for procedural aspects of the behavioral tasks, and thus question whether this effect can be limited to the trained cognitive domain or whether it can be transfer to an untrained one's. In the current study, we assessed whether adulthood intermittent working memory training has beneficial effect on long-term memory of aged rats using two very different test situations. To this aim, rats trained in a delayed non-matching to position task in operant box at 3 and 15 months of age were tested in a place learning task in water maze when they were 24 months. The two tasks differ with regard to the cognitive domain but also in their spatial ability requirement and the nature of the reinforcer used. During the memory tests, accuracy of the platform search indicated age-related impairment only in the aged-untrained group. In contrast to aged untrained rats, aged trained rats performed as young ones: they showed a specific search in the target quadrant. Thus, intermittent training during adult life in a task involving working memory protects against the effects of aging on spatial memory abilities. Working memory training has beneficial effect on an untrained cognitive domain in older animals.

In decision-making tasks, animal responses must sometimes be maintained in short-term memory before their execution, a period during which they are presumably prepared but they can also undergo alterations. NMDA receptors have been linked to such mnemonic maintenance. Aiming to better understand neural mechanisms of action selection, maintenance in short-term memory and execution, we developed a visuospatial delayed response task in mice. Subjects were trained to look at a visual stimulus briefly displayed on a touchscreen, maintain its position during a short mnemonic delay, and execute a response by touching at the remembered position. We found that animals' errors increased as a function of delay showing that, at least partially, mice made memory maintenance errors. Forgetting errors were idiosyncratically biased, suggesting that memory stability is not homogenous across possible responses but mice exhibit side preferences for one of the memorized choices which increases with delay. Responses in memory trials were also biased by subjects' tendency to repeat the previous choice, however, its magnitude did not vary with delay length. This means that, in some trials, animals use their previous choices instead of a stimulus-guided strategy to resolve the task. Finally, we pharmacologically blocked NMDA receptors systemically and found that animals increased their repeating bias, although their memory stability and overall accuracy were not affected. Our results suggest that mice accuracy is limited by biases in the stability of the different responses and that NMDA receptors might impact how often responses are memory-guided rather than memory stability.

Introduction: A growing body of research indicates that regular exercise has a significant impact on cognitive function. The structural changes associated with exercise are reflected in improvements in synaptic plasticity. In addition, it appears that physical activity exerts neuroregenerative and neuroprotective influences. Exercise has been found to benefit working memory in late life, but its effects in young adults are less clear. **The Aim:** The aim is to investigate the effect of subchronic aerobic exercise on spatial memory, neurogenesis, and oxidative stress in young adult female rats. **Methods:** Adult female Wistar rats were divided into two groups: sedentary control (C) and exercise (E). E group ran 30 min/day on a treadmill for 15 consecutive days. The parameters of spatial memory: total number of errors, working, and reference memory errors were tested in the radial arm maze. The number of Ki67+ and NeuN+ cells in the dentate gyrus was determined immunohistochemically. Levels of proBDNF, mBDNF, and markers of oxidative stress have been determined in the hippocampus and the cortex. **Results:** Subchronic exercise increased the total number of errors and working memory errors. Exercise did not change the number of Ki67+ and NeuN+ cells. The expression of BDNF was significantly increased in the cortex of the E group. Exercise significantly decreased the activity of superoxide dismutase and glutathione peroxidase in the hippocampus and the cortex, respectively. **Conclusion:** Subchronic exercise impairs working memory in healthy female rats, which correlates with increased oxidative stress.

INACTIVATION OF THE VENTRAL MIDLINE THALAMUS DOES NOT ALTER ENCODING, HOLDING OR RESTITUTION OF A SPATIAL WORKING MEMORY IN RATS.

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Laurine Boch, Thomas Morvan, Thibaut Neige, Nina Kobakhidze, Brigitte Cosquer, Elodie Panzer, Aline Stephan, Anne Pereira De Vasconcelos, Jean-Christophe Cassel
Université de Strasbourg, Cnrs Umr 7364 Lnca, Strasbourg, France

Tasks assessing spatial working memory (SWM) in animals encompass 3 phases: 1) a first trial allowing animals to encode information, 2) a holding time with various delays (from seconds to hours), and 3) an evaluation trial to test the restitution capabilities. In a delayed SWM water-escape task, we previously showed that activity of the reuniens nucleus (Re) positively correlated with performance on the evaluation trial (Morvan et al. 2021). Here, we used the same protocol in the Double-H maze: rats had to localize a platform submerged in water during the first trial (encoding) and after a 6-h delay, an evaluation trial was performed. Ventral midline thalamic nuclei (Re, Rhomboid, Rh) were inactivated using muscimol (0,26 and 0,70 nmol, 0,3 µL) or DREADD-inhibition (2 X 0.4 µL of 7.3 X 10^9 genomic copies /µL, AAV8-Camk2α-hM4Di-mCherry, Vigene, Biosciences) either during or right after the first trial, or before the second trial. With both amounts of muscimol, inhibition of the ReRh nuclei, be it during or after encoding, or during evaluation, did not alter performance. CNO administered before encoding in rats with DREADD-expressing neurons in ReRh was also ineffective. These findings are the first to challenge previous data showing an implication of ReRh nuclei in SWM. The main difference between our task and other standard SWM tasks, (usually in a T-maze), is the lower risk for proactive interference, especially due to the longer delay we used between encoding and restitution. The discrepancy calls for further investigation.

NMDAR BLOCKING BY MK801 ALTERS HIPPOCAMPAL AND PREFRONTAL CORTEX OSCILLATIONS AND IMPAIRS SPATIAL WORKING MEMORY IN MICE

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Pablo Abad Perez[1,2], Luis Martinez Otero[2], Roger Redondo[3], Victor Borrell[2], Jorge Brotons Mas[1,2]
[1]Universidad Cardenal Herrera, Medicine Department, Alicante, Spain, [2]Instituto de Neurociencias UMH-CSIC, Neurosciences, San Juan de Alicante, Spain, [3]Roche Innovation Center Basel, Neuroscience And Rare Diseases, Basel, Switzerland

Abnormal NMDAr function has been linked to rhythmopathies, psychosis, and cognitive dysfunction in schizophrenia (SCZ). Here, we investigate the role of NMDAr hypofunction in pathological oscillations and behavior. We implanted mice with tetrodes in the dorsal hippocampus and medial prefrontal cortex (mPFC), administered the NMDAr antagonist MK801, and recorded oscillations during spontaneous exploration in an open field and in the y-maze spatial working memory test. Our results show that NMDAr blockade increased locomotor activity, impaired spatial working memory, and disrupted the correlation between oscillations and speed of movement, crucial for internal representations of distance. In the hippocampus, MK801 increased gamma oscillations and theta/gamma coupling, while in the mPFC, it increased the power of theta, gamma, and generated high-frequency oscillations (HFO 155-185 Hz). Spatial working memory tests in the y-maze revealed that theta/gamma coupling was consistently higher in correct trials after MK801 administration but lower in the baseline condition. Theta/gamma co-modulation mediated by NMDAr function might be essential to explaining several of SCZ's cognitive symptoms.

IN VIVO TWO-PHOTON IMAGING OF HIPPOCAMPAL NEURONS DURING THE FORCED ALTERNATION WORKING MEMORY TASK IN 5XFAD ALZHEIMER MOUSE MODEL

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Yimei Li, Mary Ann Go, Seigfred Prado, Simon Schultz
Imperial College London, Bioengineering, London, United Kingdom

Alzheimer's disease (AD) is associated with progressive memory decline and cognitive impairments. Spatial memory decline in transgenic mouse models of AD is believed to reflect neuropathological processing in the hippocampus. Here we present that two-photon imaging of hippocampal CA1 neurons in the 5xFAD model of AD during the performance of a spatial working memory task in an air-lifted T maze. 5xFAD and WT control mice were divided into two age groups: young (2-4 months) and old (7-9 months). AAV-jGCaMP7s were injected into the pyramidal cell body layer of the hippocampal CA1 subregion, then implanted a glass craniotomy imaging window by aspirating the cortex above the injection site and a metal head-plate. Water-restricted animals were trained using 1% sucrose water rewards under head-fixation in the air-lifted T maze cage for two sessions daily. We recorded hippocampal neural activity using two-photon calcium imaging in both 5xFAD and WT mice during both learning and testing. Our results demonstrate deficits in 5xFAD mice in the forced alternation working memory task in both age groups. Hippocampal CA1 neurons show neuronal hyperactivity in 5xFAD mice. Also, place cells are hyperactive only in animals with working memory deficits. Place cell quality is correlated to performance level in the air-lifted T maze alternation task. In this work, we have validated a new working memory task compatible with in vivo head-fixed two-photon calcium imaging, enabling quantitative assessment of deficits in and recovery of neural circuit function underpinning cognitive behaviour in mouse models of AD.

Chronic stress causes memory deficits, together with impairments in structural plasticity in the hippocampus. The mechanisms underlying these deleterious effects remain to be fully understood. Beside classical mediators such as corticosterone (CORT), stress induces the release of an opioid-related neuropeptide named Nociceptin/OrphaninFQ (N/OFQ) which acts on a G protein-coupled receptors called NOP. Since this peptide has deleterious effects on memory when injected into the brain, we hypothesized that it could be a mediator of the negative effects of stress on memory and plasticity. In order to establish a causal link between stress-induced impairments in memory and structural plasticity and the dysregulation of the N/OFQ system, we performed systemic and local blockade of the nociceptin system *via* pharmacological and genetic tools in mice exposed to chronic CORT administration. We show that acute NOP receptor blockade restores long-term memory performance in the object location and recognition tasks. Our results also suggest a protective effect of the NOP antagonist against the hippocampus structural defects induced by stress. More specifically co-treatment with the antagonist prevents the deficits in spinogenesis observed in adult-born neurons following chronic CORT exposure. The region-specific knockout of NOP receptors in the hippocampus is in progress. Preliminary data suggest that this local knockout mimics the effect of systemic antagonist treatment. Our data demonstrate that blocking the N/OFQ system can be beneficial for hippocampus plasticity and memory in a pharmacological model of chronic stress. We therefore suggest that NOP antagonists could be useful for the treatment of memory deficits in stress-related disorders.

INTERNALLY ORGANIZED TASK MAPS IN THE MOUSE MEDIAL FRONTAL CORTEX

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Mohamady El-Gaby[1], Adam Harris[1], James Whittington[2], Mark Walton[3], Thomas Akam[3], Timothy Behrens[1]
[1]University of Oxford, Nuffield Department Of Clinical Neurosciences, Oxford, United Kingdom, [2]Stanford University, James H. Clark Center, Stanford, United States of America, [3]University of Oxford, Experimental Psychology, Oxford, United Kingdom

New tasks are often similar in structure to old ones. Animals that take advantage of such conserved or “abstract” task structures can master new tasks with minimal training. To understand the neural basis of this abstraction, we developed a novel behavioural paradigm for mice and recorded from their medial frontal neurons as they learned. Freely moving mice learned multiple tasks where they had to visit 4 rewarded locations in sequence (ABCD) on a 3x3 spatial maze. Tasks within this "ABCD paradigm" shared the same circular transition structure (… ABCDABCD …) but differed in the locations and geometric arrangement of rewards. As well as improving across tasks, mice inferred that A followed D (i.e. completed the loop) on the very first trial of a new task. This “zero-shot inference” is only possible if animals had learned the abstract structure of the task. Medial frontal cortex (mFC) neurons were tuned to task space in a hierarchical manner. Moreover, this tuning showed multiple signatures of internal organization, including offline replay. These findings point to separable neuronal substrates for internally organised representations of task structure that may guide abstraction in the mammalian brain

THE ROLE OF TRANSIENT RECEPTOR POTENTIAL CHANNELS IN MEMORY CONSOLIDATION IN THE PASSIVE AVOIDANCE TASK LEARNING MODEL IN ONE-DAY OLD CHICKS

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Elżbieta Salinska[1], Andrzej Krolik[1], Agnieszka Bronisz[2]
[1]Mirosław Mossakowski Research Institute Polish Academy of Sciences, Department Of Neurochemistry, Warsaw, Poland, [2]Mossakowski Medical Research Institute, PAS, 2tumor Microenvironment Laboratory, Warsaw, Poland

Introduction An increase in intracellular Ca^{2+} concentration is an important step in memory consolidation processes that stabilize a memory trace after its initial acquisition. Stimulation of mGluR1 and mGluR5 leads to an increase in intracellular Ca^{2+} by stimulation of IP3 receptors and Ca^{2+} release from intracellular stores and by activation transient receptor potential (TRP) channels. Ca^{2+} fluxes tie mGluR1/5 and TRP channels with the effector kinase cascade (CaMKII) indicating that their activation affects memory formation. Thus, disclosure of the potential of each of these Ca^{2+} signals in memory formation may establish the premise for innovative strategy and treatment of memory impairment. **Methods** We used the passive avoidance task in one-day chicks. Animals trained to avoid pecking metal bead covered with bitter-tasting substance (methylanthranilate) were tested 2 h after training. The non-specific TRP channels antagonist or agonist, and specific mGluR1 mGluR5 antagonists or agonists were injected immediately after training into intermediate medial mesopallium, the chick brain region responsible for early stages of memory formation. **Results** Inhibition of mGluR1/5 or TRP channels resulted in significant memory impairment. Inhibition of TRP channels in the presence of mGluR1/5 agonist also disrupted memory formation. However, inhibition of mGluR1/5 in the presence of TRP channels agonist did not result in amnesia. TRP channels agonist prevented amnesia even though Ca^{2+} release from an intracellular store was inhibited due to IP3 agonist administration. **Conclusion** Our results show that the memory formation process can bypass the mGluR1/5 channels pathway, using the Ca^{2+} signal generated by TRP channels.

DISTRACTION AND PROACTIVE INTERFERENCE FOR OBJECT MEMORY IN THE SUB-CHRONIC PHENCYCLIDINE (SCPCP) MODEL OF SCHIZOPHRENIA; A COMPARISON OF RAT AND MOUSE BEHAVIOUR

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Katie Landreth[1], Jacob Juty[2], Mike Harte[3], John Gigg[2]
[1]The University of Manchester, Pharmacy And Optometry, Manchester, United Kingdom, [2]University of Manchester, Division Of Neuroscience And Experimental Psychology, Manchester, United Kingdom, [3]University of Manchester, Division Of Pharmacy And Optometry, Manchester, United Kingdom

Introduction Cognitive deficits are a key, treatment-resistant symptom of schizophrenia. The rodent sub-chronic phencyclidine (scPCP) model of schizophrenia exhibits robust amnesia in the novel object recognition (NOR) task, which can be improved in both scPCP rats and mice by minimising distraction during the task inter-trial interval (Grayson *et al.,* 2014; Gigg *et al*., 2020). Minimising distraction allows the study of disease-relevant proactive interference via multiple consecutive NOR trials in scPCP rats using the continuous NOR (cNOR) task (Landreth et al. 2021). However, whether scPCP mice are also sensitive to proactive interference in this task is unknown. **Aims** To run the cNOR task with scPCP mice to determine if there are species-specific differences in task performance. **Methods** Female c57 mice (c. 12 weeks old) were dosed sub-chronically with phencyclidine (2mg/kg daily for 10 days) before undergoing standard NOR testing. Under mild food restriction, mice were then trained to perform 11 consecutive NOR trials using a continuous testing design (cNOR). Exploration of the novel versus familiar object was measured for each trial. **Results and Conclusions** Preliminary results indicate that scPCP mice are unable to identify object novelty in the standard NOR task, as expected, but their performance is rescued in trial one of the cNOR. Interestingly, initial analyses suggest that the effect of proactive interference on object memory is weaker in mice compared to rats for both scPCP and control groups. A full analysis of these data will be presented.

Memory storage is distributed in large brain territories. However, distributed information storage imposes the need for coordination to link the activated experience-relevant neurons into comprehensive memory engrams. Here we are concern with the mechanisms of activity coordination during contextual memory encoding and hypothesize that the dentate gyrus (DG) plays a critical role. Synaptic potentiation in the DG has been shown to enhance the functional coupling of a network of mesolimbic neocortical and subcortical structures important for memory formation. Furthermore, optogenetic activation of granule cells in the DG, tagged via c-Fos-dependent expression of channelrhodopsin, has been shown to recall complete contextual fear memories. We combined pharmacogenetic tools to bidirectionally modulate granule cells activity through the regulation of parvalbumin (PV) cell activity, while mice encoded spatial information in the Novel Object Location task. Disinhibition of DG enhanced the encoding of novel object-location associations whereas increased inhibition blocked it. Correlations between the number of c-Fos+ neurons in a network composed by different hippocampal structures, the prefrontal cortex and the nucleus accumbens, demonstrates that DG disinhibition enhances the functional coupling between these regions, while increased inhibition decorrelates cell assemblies in the network. We will further present our latest graph theory analysis on an extended brain network composed of more than 200 brain areas. Our results attribute a pivotal role to the DG in coordinating brain-wide functional connectivity and help explain why reactivation of engrams in the DG can efficiently induce recall of artificial memories.

Chronic alcohol consumption alters extracellular space geometry and transmitter diffusion in the brain.
Already moderate alcohol consumption has detrimental long-term effects on brain function. However, how alcohol produces its potent addictive effects despite being a weak reinforcer is a poorly understood conundrum that likely hampers the development of successful interventions to limit heavy drinking. In this translational study, we demonstrate widespread increased mean diffusivity in the brain gray matter of chronically drinking humans and rats. These alterations appear soon after drinking initiation in rats, persist into early abstinence in both species, and are associated with a robust decrease in extracellular space tortuosity explained by a microglial reaction. Mathematical modeling of the diffusivity changes unveils an increased spatial reach of extrasynaptically released transmitters like dopamine that may contribute to alcohol's progressively enhanced addictive potency.

Cognitive deficits caused by ageing, neurodegenerative diseases or brain injury are associated with a disruption of neural oscillations in large-scale brain networks, but the exact signatures of physiological and impaired cognitive processes are unclear. Here, we propose a methodological framework for studying these oscillations in distributed brain networks and for applying neurostimulation protocols during cognitive tasks in non-human primates. We first trained 2 macaque monkeys to perform a memory task called “paired associates learning” on an instrumented touchscreen (MonkeyCANTAB, >100 sessions each). Animals were trained to select a stimulus presented at one among 1-4 possible locations. Task difficulty was further increased by presenting 2 consecutive stimuli, followed by two choice phases containing 2-3 distractors each. Preliminary results indicate that both monkeys perform well above chance level, and increasing task difficulty results in lower performance. This task, used to probe episodic memory, is known to rely on the hippocampal formation and the prefrontal cortex. To study neuronal oscillations across this network, we next designed a novel brain implant to record field potentials and apply electrical stimulation in three disctinct areas: the hippocampus and entorhinal cortex using two depth macroelectrodes, and the prefrontal cortex using a custom electrocorticographic (ECoG) grid. We performed a preliminary validation of the surgical procedures and neurophysiological recordings during an acute surgery in one anesthetized macaque monkey. These experiments lay the ground for future work that will involve neuronal recording and electrical stimulation in the large-scale memory network during an episodic memory task in non-human primates.

Memory is known to be supported by periods of offline consolidation, most significantly during sleep. For episodic memories, reactivation of previously active ensembles (replay) is thought to be the substrate of this consolidation. Like episodic, procedural memory is also improved by sleep but the offline dynamics that support consolidation are not known. Here we use unsupervised analysis methods of recordings from a multi-step sequence task to show that replay of procedural information occurs in the dorsolateral striatum during offline consolidation. Mapping dopamine-dependent transcriptional activation markers revealed that this region of dorsolateral striatum was engaged during the task. Lesion to this area impaired both sequence learning and execution, while pharmacologically blocking plasticity post task revealed that offline consolidation in this region was required for procedural memory. Neuropixel probe recordings revealed that, during the task, activity in the dorsolateral striatum tiles sequence execution with individual neuronal activity locked to distinct postural movements. Recordings were extended to include post-task sleep bouts and linear decoding of online activity, in parallel with novel application of an unsupervised point process model (PP-Seq), revealed multiple instances of replay. These instances were compressed in time and included both partial and full recapitulation of the sequential extent of task related activity. Consequently, our results provide evidence that procedural replay occurs in the striatum during offline consolidation of a motor sequence. These replay instances may represent a mechanism for procedural memory consolidation akin to but independent from those found for consolidation of episodic memory.

NAVIGATION TO A VIRTUAL PLATFORM TO EVALUATE ENCODING AND RETRIEVAL OF "EVERYDAY MEMORIES"

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Andrés Pérez-Segura, Antonio Cerdán-Cerdá, Cristina Sánchez-Ferri, Santiago Canals

The study of behaviour allows us to contextualize and provide biological meaning to experimentally acquired physiological and molecular data. In the study of memory formation, often, loss- and gain-of-function experiments to investigate the mechanisms underlying specific memory processes, focus on misleading learning curves during manipulations. They commonly reflect their effect on encoding, storage, consolidation, and/or retrieval of memories, without discriminating relative contributions, nor identifying possible confounding factors due to performance alterations (i.e., attention and motor effects). Here we present a modification of the delayed-matching to place protocol of the water maze [1] to investigate “everyday memory” formation. The test is based on spatial navigation in a large arena and the finding of a virtual (invisible) “platform”. Online video tracking of the animals is used to operate the maze, regulting light intensity and opening the access door to a home location when the animal crosses the target virtual platform location. The task requires remembering the location of the previous day platform and encoding the current location, to be tested on the next day. The implementation in a “dry maze”, facilitates concomitant electrophysiological recordings and brain network manipulations based on deep brain electric or optogenetic stimulation (DBS). We show that, in a 3-day protocol with experimental pharmacological or DBS interventions in the second day, this procedure allows dissociation between memory encoding, retrieval and consolidation, measured in the behavioural performance. MULTISENSORY LEARNING EXPANDS A MEMORY ENGRAM

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Zeynep Okray
University of Oxford, Centre For Neural Circuits And Behaviour, Oxford, United Kingdom

Life is a multisensory experience for most animals. Learning to associate and bind different sensory features into a scene is a fundamental process of the brain, which improves subsequent memory performance. However, neural mechanisms that bind sensory features during learning remain to be explained. We developed new multisensory aversive and appetitive memory paradigms in *Drosophila* which combine visual and olfactory cues. Flies trained with combinations of both modalities show improved memory performance, even when the sensory cues are presented separately during testing. We used temporal control of neuronal function to define the components of the mushroom body memory network that are required for multisensory learning and performance enhancement. Calcium imaging in head-fixed flies revealed that dopaminergic reinforcement during multisensory learning binds activity in streams of modality-specific Kenyon Cells. After learning, a unimodal sensory input generates a multimodal neuronal response. This cross-modal binding and expansion of the memory engram underlies improved memory performance.

Prior experience conditionally inhibits the expression of new learning in Drosophila.
Prior experience of a stimulus can inhibit subsequent acquisition or expression of a learned association of that stimulus. However, the neuronal manifestations of this learning effect, named latent inhibition (LI), are poorly understood. Here, we show that prior odor exposure can produce context-dependent LI of later appetitive olfactory memory performance in Drosophila. Odor pre-exposure forms a short-lived aversive memory whose lone expression lacks context-dependence. Acquisition of odor pre-exposure memory requires aversively reinforcing dopaminergic neurons that innervate two mushroom body compartments-one group of which exhibits increasing activity with successive odor experience. Odor-specific responses of the corresponding mushroom body output neurons are suppressed, and their output is necessary for expression of both pre-exposure memory and LI of appetitive memory. Therefore, odor pre-exposure attaches negative valence to the odor itself, and LI of appetitive memory results from a temporary and context-dependent retrieval deficit imposed by competition with the parallel short-lived aversive memory.

The impact of the gut microbiome on memory and sleep in .
The gut microbiome has been proposed to influence diverse behavioral traits of animals, although the experimental evidence is limited and often contradictory. Here, we made use of the tractability of for both behavioral analyses and microbiome studies to test how elimination of microorganisms affects a number of behavioral traits. Relative to conventional flies (i.e. with unaltered microbiome), microbiologically sterile (axenic) flies displayed a moderate reduction in memory performance in olfactory appetitive conditioning and courtship assays. The microbiological status of the flies had a small or no effect on anxiety-like behavior (centrophobism) or circadian rhythmicity of locomotor activity, but axenic flies tended to sleep for longer and displayed reduced sleep rebound after sleep deprivation. These last two effects were robust for most tests conducted on both wild-type Canton S and strains, as well for tests using an isogenized panel of flies with mutations in the gene, which causes altered circadian rhythmicity. Interestingly, the effect of absence of microbiota on a few behavioral features, most notably instantaneous locomotor activity speed, varied among wild-type strains. Taken together, our findings demonstrate that the microbiome can have subtle but significant effects on specific aspects of behavior, some of which are dependent on genetic background.

Reduced Lateral Inhibition Impairs Olfactory Computations and Behaviors in a Drosophila Model of Fragile X Syndrome.
Fragile X syndrome (FXS) patients present neuronal alterations that lead to severe intellectual disability, but the underlying

neuronal circuit mechanisms are poorly understood. An emerging hypothesis postulates that reduced GABAergic inhibition of excitatory neurons is a key component in the pathophysiology of FXS. Here, we directly test this idea in a FXS Drosophila model. We show that FXS flies exhibit strongly impaired olfactory behaviors. In line with this, olfactory representations are less odor specific due to broader response tuning of excitatory projection neurons. We find that impaired inhibitory interactions underlie reduced specificity in olfactory computations. Finally, we show that defective lateral inhibition across projection neurons is caused by weaker inhibition from GABAergic interneurons. We provide direct evidence that deficient inhibition impairs sensory computations and behavior in an in vivo model of FXS. Together with evidence of impaired inhibition in autism and Rett syndrome, these findings suggest a potentially general mechanism for intellectual disability.

The Drosophila neurogenin Tap functionally interacts with the Wnt-PCP pathway to regulate neuronal extension and guidance.
The neurogenin (Ngn) transcription factors control early neurogenesis and neurite outgrowth in mammalian cortex. In contrast to their proneural activity, their function in neurite growth is poorly understood. Drosophila has a single predicted Ngn homolog, Tap, of unknown function. Here we show that Tap is not a proneural protein in Drosophila but is required for proper axonal growth and guidance of neurons of the mushroom body, a neuropile required for associative learning and memory. Genetic and expression analyses suggest that Tap inhibits excessive axonal growth by fine regulation of the levels of the Wnt signaling adaptor protein Dishevelled.

A novel fragile X syndrome mutation reveals a conserved role for the carboxy-terminus in FMRP localization and function.
Loss of function of the FMR1 gene leads to fragile X syndrome (FXS), the most common form of intellectual disability. The loss of FMR1 function is usually caused by epigenetic silencing of the FMR1 promoter leading to expansion and subsequent methylation of a CGG repeat in the 5' untranslated region. Very few coding sequence variations have been experimentally characterized and shown to be causal to the disease. Here, we describe a novel FMR1 mutation and reveal an unexpected nuclear export function for the C-terminus of FMRP. We screened a cohort of patients with typical FXS symptoms who tested negative for CGG repeat expansion in the FMR1 locus. In one patient, we identified a guanine insertion in FMR1 exon 15. This mutation alters the open reading frame creating a short novel C-terminal sequence, followed by a stop codon. We find that this novel peptide encodes a functional nuclear localization signal (NLS) targeting the patient FMRP to the nucleolus in human cells. We also reveal an evolutionarily conserved nuclear export function associated with the endogenous C-terminus of FMRP. In vivo analyses in Drosophila demonstrate that a patient-mimetic mutation alters the localization and function of Dfmrp in neurons, leading to neomorphic neuronal phenotypes.

The Drosophila homologue of the amyloid precursor protein is a conserved modulator of Wnt PCP signaling.
Wnt Planar Cell Polarity (PCP) signaling is a universal regulator of polarity in epithelial cells, but it regulates axon outgrowth in neurons, suggesting the existence of axonal modulators of Wnt-PCP activity. The Amyloid precursor proteins (APPs) are intensely investigated because of their link to Alzheimer's disease (AD). APP's in vivo function in the brain and the mechanisms underlying it remain unclear and controversial. Drosophila possesses a single APP homologue called APP Like, or APPL. APPL is expressed in all neurons throughout development, but has no established function in neuronal development. We therefore investigated the role of Drosophila APPL during brain development. We find that APPL is involved in the development of the Mushroom Body αβ neurons and, in particular, is required cell-autonomously for the β-axons and non-cell autonomously for the α-axons growth. Moreover, we find that APPL is a modulator of the Wnt-PCP pathway required for axonal outgrowth, but not cell polarity. Molecularly, both human APP and fly APPL form complexes with PCP receptors, thus suggesting that APPs are part of the membrane protein complex upstream of PCP signaling. Moreover, we show that APPL regulates PCP pathway activation by modulating the phosphorylation of the Wnt adaptor protein Dishevelled (Dsh) by Abelson kinase (Abl). Taken together our data suggest that APPL is the first example of a modulator of the Wnt-PCP pathway specifically required for axon outgrowth.

A LOCUS COERULEUS- DORSAL CA1 DOPAMINERGIC CIRCUIT MODULATES MEMORY LINKING

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Ananya Chowdhury[1], Alessandro Luchetti[1], Giselle Fernandes[1], Daniel Almeida[1], George Kastellakis[2], Alexandra Tzilivaki[2], Erica Ramirez[1], Mary Tran[1], Panayiota Poirazi[2], Alcino Silva[1]
[1]UCLA, Neurobiology, Los Angeles, United States of America, [2]FORTH, Imbb, Heraklion, Crete, Greece

Our brain not only encodes memories of individual events, it can also link memories encoded close in time, such that the recall of one memory triggers the recall of the other. For example, our lab showed that when two contextual memories are encoded close in time (e.g., 5 hours apart) the recall of one triggers the recall of the other. Neuromodulatory projections are thought to have a role in sending information about novelty to dCA1, including dopaminergic/noradrenergic projections from Locus Coeruleus (LC) and serotonergic projections from the Raphe Nucleus (RN). Although both the LC and RN are activated by contextual exploration, only inhibition of LC to CA1-projecting neurons disrupted contextual memory linking. Importantly, this same manipulation did not disrupt contextual learning and memory. Furthermore, pharmacological manipulations demonstrated that this effect was mediated by dopamine and not by noradrenaline. Studies with head mounted fluorescent microscopes (UCLA miniscopes) in dCA1 showed that the manipulations that disrupted contextual memory linking also impaired the overlap between dCA1 contextual memory ensembles. We found that the inhibition of LC to CA1-projecting neurons also affected the synchrony of firing between subpopulations of dCA1 neurons activated by both contextual memories, as well as their activity patterns within cell assemblies. This discovery of a neuromodulatory system that specifically affects memory linking without affecting memory formation reveals a fundamental separation between the brain mechanisms that modulate these two distinct processes, and highlights a new mechanism through which memories can be encoded together.

AUDITORY PRIMING IN FREELY-MOVING MICE

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Shir Sivroni[1,2,3], Hadas Sloin[1,4], Eran Stark[4,5]
[1]Tel Aviv University, Physiology And Pharmacology, Tel Aviv, Israel, [2]Afeka Tel Aviv Academic College of Engineering, Mathematics, Tel-Aviv, Israel, [3]The Open University of Israel, Mathematics, Raanana, Israel, [4]Tel Aviv University, Sagol School Of Neuroscience, tel aviv, Israel, [5]Tel Aviv University, Department Of Physiology And Pharmacology, Tel Aviv, Israel

Priming is a form of implicit short-term memory, defined as a change in the ability to process an object as a result of previously encountering that object. A key part of our daily life, priming has been studied extensively. However, no behavioral model of priming in lab animals has been established, precluding the study of the neuronal network basis of priming. Here, we developed a novel paradigm for studying priming in freely-moving mice, consisting of three stages. In the first stage, the mouse learns a discrimination task, associating a long 5 kHz auditory “target” stimulus with water reward in one port, and a 10 kHz stimulus with reward in another port. In the third stage, a “prime” stimulus, namely a short tone, precedes the target stimulus. Two types of prime stimuli are used: congruent, at the same frequency as the target; and non-congruent. In an intermediate stage, the mouse learns to ignore prime stimuli that are not followed by target stimuli. Four mice were trained on the paradigm. The mice learned the discrimination task within two weeks, achieving 90-95% success. Within two additional weeks, animals learned to ignore isolated prime stimuli, with false alarm under 15%. Finally, we found a consistent prime effect: success rates in congruent trials were 5%-10% higher than in non-congruent trials. Detecting priming behavior in mice implies that priming is not limited to humans or primates. The novel mouse task can be combined with electrophysiological recordings for deciphering the network basis of priming. Funding: ERC #679253

UNRAVELLING THE ROLE OF HISTAMINE NEURONS IN MEMORY PROCESSES THROUGH CHEMOGENETICS SILENCING : POTENTIAL SEX DIFFERENCES

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Lola Hardt[1], Eva-Gunnel Ducourneau[1,2], Ioannis Bakoyiannis[1], Gustavo Provensi[3], Essi Biyong[1], Maria Beatrice Passani[3], Pierre Trifilieff[1], Guillaume Ferreira[1]
[1]INRAE, Umr 1286 - Nutrineuro, Bordeaux, France, [2]INRAE, Nutrineuro Laboratory, Bordeaux CEDEX, France, [3]University of Florence, Dipartimento Di Scienze Della Salute, Florence, Italy

Histamine is a known modulator of memory processes, however its implication in consolidation and/or retrieval phases remains poorly understood. This is particularly worrisome because anti-histaminergic drugs are among the most commonly used drugs worldwide and display unwanted mnemonic side effects. **Aims:** Previous studies were based on histamine receptors pharmacology or histamine depletion which have inherent limitations, restricting the ability to clearly separate the implication of histamine transmission between different memory phases e.g., consolidation or retrieval. **Methods:** Our study used a chemogenetic approach in order to specifically silence histaminergic neurons during either memory formation/consolidation or retrieval in three different long-term memory tasks, i.e. Object Recognition Memory (ORM), Inhibitory Avoidance (IA) and Social Recognition Memory (SRM), in both male and female mice. **Results:** Chemogenetic histamine modulation specifically during training (*not* retreival) impairs ORM at 48h but not 24h, independently of sex. Similar manipulations during IA training *or* retrieval have an opposite effect in both sexes at 7 days but not 48h, impairing IA memory in males but enhancing it in females. Finally, histaminergic neurons silencing had no impact on SRM assessed at 24h in males (we observed sex differences with SRM protocol not being efficient in females). **Conclusions:** Our results confirm the implication of histamine in memory consolidation and further indicate an additional role in later consolidation phases necessary for long-term memory persistence. Furthermore, our results stress the complexity of histamine implication in memory processes through the discovery of opposite sex effects of histamine neuron inhibition in the aversive IA memory task.

THE DEVELOPMENT OF THE RELAXIN3 INNERVATION OF THE MEDIAL SEPTUM

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Francisco Olucha-Bordonau, Jorge Lucerón-Morales, Mónica Navarro Sánchez, Isis Gil-Miravet, Aroa Mañas-Ojeda, Clara García Mompó, Francisco Ros-Bernal
Universitat Jaume I, Unitat Predepartamental De Medicina, Castelló de la Plana, Spain

The hippocampal theta rhythm is a key element associated with the spatial navigation and memory. It depends on driving connections arising from the medial septum. Both the medial septum and the hippocampus are targeted by relaxin3 projections coming from the medial septum and these projections also contribute to the hippocampal theta rhythm. Thus, its development is important in understanding the emergence of these functions. In this work we have analyzed the postnatal development of the relaxin3 innervation of the medial septum. We have studied the relaxin3 fibers at postnatal (PN) days 3, 10, 15, 17, 20, 30 and 3 months. Along PN3 to PN15 there is a plateau with a scattered number of fibers dispersed along the medial septum. At these times, the different neuronal types progressively gain complexity in their dendritic trees. A few of these fibers contain some synaptic markers like synaptophysin and homer. At P17 there is a huge emergence of the RLN3 innervation of the entire complex. Also at this time, the neuronal types look to be fully configured. After P17, the innervation of the area declines smoothly. Thus, the RLN3 innervation of the medial septum is produced at two stages, the first comes before the birth and the second abruptly emerges at P17. It is worth to highlight that the appearance of these fibers comes just before weaning when the animal starts a free autonomous life. TEMPORAL COORDINATION BETWEEN SLEEP SLOW OSCILLATIONS, SPINDLES, AND RIPPLES IS ASSOCIATED WITH SPATIAL MEMORY FORMATION IN DEVELOPING RATS.

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Marion Inostroza, María Contreras, Jan Born
University of Tübingen, Institute Of Medical Psychology And Behavioral Neurobiology, Tübingen, Germany

Memory formation is a major function of sleep. Infant rats can form spatial memory representations from early life; however, the role of sleep oscillation coordination during brain maturation and memory formation is unknown. In this study, we used rats as a developmental model to investigate the association between the maturation of spatial memory capabilities and the temporal coordination between slow oscillation (SO), spindles, and hippocampal ripples. We compared rats which upon prior experience exposures, can express adult-like spatial memory. Starting on PD25, the Spatial experience group performed three exposures to the object-place recognition (OPR) task on subsequent days. The Control group performed three exposures to a pseudo-OPR task where the objects remained stationary. At the test phase on PD31, both groups were subjected to a classical OPR task, including a 3-hours consolidation period during which frontal and parietal EEGs and hippocampal LFP recordings were acquired. Behavioral results showed that only rats with prior spatial experiences formed a persistent spatial memory. Further, sleep analyses revealed an increase in the percentage of ripples that co-occurred with spindles nested in a SO in the Spatial experience group. Interestingly, this increase in the triple-coupling was restricted to the parietal SO-spindle events. Rats of the Spatial experience group also showed a significant ripple-spindle phase-locking and an increase in both the ripple activity and the ripple band's power after the parietal spindle onset. Overall, we demonstrated that the temporal association between the three major cardinal sleep oscillations is associated with the maturation of spatial memory in developing rats.

THE ROLE OF NORADRENALINE IN SLEEP-DEPENDENT MEMORY CONSOLIDATION

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Yaroslav Sych[1,2], Tiago Campelo[2,3], Carolina Gutierrez Herrera[2], Thomas Rusterholz[2], Fritjof Helmchen[1,4], Antoine Adamantidis[2,3]

Molecular and cellular mechanisms contribute to memory consolidation. Noradrenaline release controlled by the midbrain neurons of the locus coeruleus (LC) can modulate learning and memory. Here we investigate the role of noradrenaline in sleep-dependent memory consolidation. We used the genetically encoded fluorescent noradrenaline sensor $GRAB_{NE}$ and multi-fiber photometry to examine how salient experiences during wakefulness, such as learning a reward-based auditory discrimination task, relate to noradrenergic modulation of frontal cortical circuits. We identified region-specific noradrenaline changes on the short time scale of behavioral trials during task engagement, corresponding to memory encoding, as well as on the longer time scale of task learning, corresponding to memory consolidation. During task execution, sustained elevated levels of noradrenaline were present in lateral orbitofrontal cortex (lOFC) and anterolateral motor cortex (ALM). During the first episodes of NREM sleep, after reaching the expert criterion of task proficiency, noradrenaline levels in ALM increased as compared to the NREM sleep in the pre-learning phase. Conversely, noradrenaline levels decreased during NREM sleep for lOFC and prefrontal cortex as compared to the pre-learning state. Furthermore, we identified a fraction of sleep spindles that was coupled to the noradrenaline dynamics during NREM sleep. This coupling of sleep spindles and noradrenaline was also strengthened by task learning in the medial orbitofrontal cortex and ALM. Bilateral optogenetic silencing of LC neurons with ArchT slowed task learning and decreased the coupling between sleep spindles and noradrenaline. Our results underscore the region-specific role of noradrenaline at multiple time-scales for memory encoding and consolidation.

FUNCTIONAL IMAGING MEMORIES OF A MOTHER DURING FILIAL IMPRINTING IN AWAKE DOMESTIC CHICK NEWBORNS

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Mehdi Behroozi[1], Elena Lorenzi[2], Sepideh Tabrik[3], Martin Tegenthoff[3], Alessandro Gozzi[4], Onur Güntürkün[1], Giorgio Vallortigara[2]
[1]Ruhr University Bochum, Psychology, Bochum, Germany, [2]University of Trento, Cimec - Center For Mind/brain Sciences, Rovereto, Italy, [3]Ruhr-University Bochum, Department Of Neurology, Bg-university Hospital Bergmannsheil, Bochum, Germany, [4]Italian Institute of Technology, Functional Neuroimaging Laboratory,cncs@unitn, Rovereto, Trento, Italy

Filial imprinting has been used as a powerful ethological paradigm to investigate the neurobiology of early learning that affects lifelong behaviors. When a visually naïve chick is exposed to one of a wide range of conspicuous objects, it may learn its characteristics and subsequently recognizes and selectively approaches this stimulus (usually the mother hen). While the initial phases of memory acquisition have been unravelled, the long-term storage and retrieval components of imprinting memories are still unknown. Here, we established an fMRI protocol to study awake brain activity in newborn chicks. We identified a neural network involved in the acquisition and long-term storage of imprinting memory, providing the first example of imaging in vivo memory formation, storage, and retrieval during imprinting. Our findings unveiled a prosencephalic neural network that, among others, comprises the Social Behavior Network, the Mesolimbic Reward System, and the medial meso-/nidopallium for long-term storage and retrieval of filial imprinting memory. As expected, the networks of memory formation and retrieval partially overlapped. Network activity was more pronounced during memory retrieval and further involved the avian analogue to the mammalian prefrontal cortex. Thus, consolidation of imprinting memory results in strengthening and expanding the neural system encoding the original engram, but in a more distributed manner. From this perspective, the storage of the imprinting memory is likely to comprise this wide and distributed network within which the “prefrontal” NCL could be a central hub. These results provide the first example of non-invasive imaging of the brain in a newborn vertebrate.

Gradual Restraint Habituation for Awake Functional Magnetic Resonance Imaging Combined With a Sparse Imaging Paradigm Reduces Motion Artifacts and Stress Levels in Rodents.
Functional magnetic resonance imaging, as a non-invasive technique, offers unique opportunities to assess brain function and connectivity under a broad range of applications, ranging from passive sensory stimulation to high-level cognitive abilities, in awake animals. This approach is confounded, however, by the fact that physical restraint and loud unpredictable acoustic noise must inevitably accompany fMRI recordings. These factors induce marked stress in rodents, and stress-related elevations of corticosterone levels are known to alter information processing and cognition in the rodent. Here, we propose a habituation strategy that spans specific stages of adaptation to restraint, MRI noise, and confinement stress in awake rats and circumvents the need for surgical head restraint. This habituation protocol results in stress levels during awake fMRI that do not differ from pre-handling levels and enables stable image acquisition with very low motion artifacts. For this, rats were gradually trained over a period of three weeks and eighteen training sessions. Stress levels were assessed by analysis of fecal corticosterone metabolite levels and breathing rates. We observed significant drops in stress levels to below pre-handling levels at the end of the habituation procedure. During fMRI in awake rats, after the conclusion of habituation and using a non-invasive head-fixation device, breathing was stable and head motion artifacts were minimal. A task-based fMRI experiment, using acoustic stimulation, conducted 2 days after the end of habituation, resulted in precise whole brain mapping of BOLD signals in the brain, with clear delineation of the expected auditory-related structures. The active discrimination by the animals of the acoustic stimuli from the backdrop of scanner noise was corroborated by significant increases in BOLD signals in the thalamus and reticular formation. Taken together, these data show that effective habituation to awake fMRI can be achieved by gradual and incremental acclimatization to the experimental conditions. Subsequent BOLD recordings, even during superimposed acoustic stimulation, reflect low stress-levels, low motion and a corresponding high-quality image acquisition. Furthermore, BOLD signals obtained during fMRI indicate that effective habituation facilitates selective attention to sensory stimuli that can in turn support the discrimination of cognitive processes in the absence of

stress confounds.

Unihemispheric evidence accumulation in pigeons.
Perceptual decision making involves choices between alternatives based on sensory information. Studies in primates and rodents revealed a stochastic perceptual evidence accumulation process that, after reaching threshold, results in action execution. Birds represent a cognitively highly successful vertebrate class that has been evolving independent from mammals for more than 300 million years. The present study investigated whether perceptual decision making in pigeons shows behavioral and computational dynamics comparable to those in mammals and rodents. Using a novel "pigeon helmet" with liquid shutter displays that controls visual input to individual eyes/hemispheres with precise timing, we indeed revealed highly similar dynamics of perceptual decision making. Thus, both mammals and birds seem to share this core cognitive process that possibly represents a fundamental constituent of decision making throughout vertebrates. Interestingly, in our experiments we additionally discovered that both avian hemispheres start independent sensory accumulation processes without any major interhemispheric exchange. Because birds lack a corpus callosum and have only a small anterior commissure, they seem to be forced to decide on motor responses based on unihemispheric decisions under conditions of time pressure. Visual and Tactile Sensory Systems Share Common Features in Object Recognition.
Although we use our visual and tactile sensory systems interchangeably for object recognition on a daily basis, little is known about the mechanism underlying this ability. This study examined how 3D shape features of objects form two congruent and interchangeable visual and tactile perceptual spaces in healthy male and female participants. Since active exploration plays an important role in shape processing, a virtual reality environment was used to visually explore 3D objects called digital embryos without using the tactile sense. In addition, during the tactile procedure, blindfolded participants actively palpated a 3D-printed version of the same objects with both hands. We first demonstrated that the visual and tactile perceptual spaces were highly similar. We then extracted a series of 3D shape features to investigate how visual and tactile exploration can lead to the correct identification of the relationships between objects. The results indicate that both modalities share the same shape features to form highly similar veridical spaces. This finding suggests that visual and tactile systems might apply similar cognitive processes to sensory inputs that enable humans to rely merely on one modality in the absence of another to recognize surrounding objects.

Event-related functional MRI of awake behaving pigeons at 7T.
Animal-fMRI is a powerful method to understand neural mechanisms of cognition, but it remains a major challenge to scan actively participating small animals under low-stress conditions. Here, we present an event-related functional MRI platform in awake pigeons using single-shot RARE fMRI to investigate the neural fundaments for visually-guided decision making. We established a head-fixated Go/NoGo paradigm, which the animals quickly learned under low-stress conditions. The animals were motivated by water reward and behavior was assessed by logging mandibulations during the fMRI experiment with close to zero motion artifacts over hundreds of repeats. To achieve optimal results, we characterized the species-specific hemodynamic response function. As a proof-of-principle, we run a color discrimination task and discovered differential neural networks for Go-, NoGo-, and response execution-phases. Our findings open the door to visualize the neural fundaments of perceptual and cognitive functions in birds-a vertebrate class of which some clades are cognitively on par with primates.

A three-dimensional digital atlas of the Nile crocodile (Crocodylus niloticus) forebrain.
The phylogenetic position of crocodilians in relation to birds and mammals makes them an interesting animal model for investigating the evolution of the nervous system in amniote vertebrates. A few neuroanatomical atlases are available for reptiles, but with a growing interest in these animals within the comparative neurosciences, a need for these anatomical reference templates is becoming apparent. With the advent of MRI being used more frequently in comparative neuroscience, the aim of this study was to create a three-dimensional MRI-based atlas of the Nile crocodile (Crocodylus niloticus) brain to provide a common reference template for the interpretation of the crocodilian, and more broadly reptilian, brain. Ex vivo MRI acquisitions in combination with histological data were used to delineate crocodilian brain areas at telencephalic, diencephalic, mesencephalic, and rhombencephalic levels. A total of 50 anatomical structures were successfully identified

and outlined to create a 3-D model of the Nile crocodile brain. The majority of structures were more readily discerned within the forebrain of the crocodile with the methods used to produce this atlas. The anatomy outlined herein corresponds with both classical and recent crocodilian anatomical analyses, barring a few areas of contention predominantly related to a lack of functional data and conflicting nomenclature.

Functional MRI in the Nile crocodile: a new avenue for evolutionary neurobiology.
Crocodilians are important for understanding the evolutionary history of amniote neural systems as they are the nearest extant relatives of modern birds and share a stem amniote ancestor with mammals. Although the crocodilian brain has been investigated anatomically, functional studies are rare. Here, we employed functional magnetic resonance imaging (fMRI), never tested in poikilotherms, to investigate crocodilian telencephalic sensory processing. Juvenile were placed in a 7 T MRI scanner to record blood oxygenation level-dependent (BOLD) signal changes during the presentation of visual and auditory stimuli. Visual stimulation increased BOLD signals in rostral to mid-caudal portions of the dorso-lateral anterior dorsal ventricular ridge (ADVR). Simple auditory stimuli led to signal increase in the rostromedial and caudocentral ADVR. These activation patterns are in line with previously described projection fields of diencephalic sensory fibres. Furthermore, complex auditory stimuli activated additional regions of the caudomedial ADVR. The recruitment of these additional, presumably higher-order, sensory areas reflects observations made in birds and mammals. Our results indicate that structural and functional aspects of sensory processing have been likely conserved during the evolution of sauropsids. In addition, our study shows that fMRI can be used to investigate neural processing in poikilotherms, providing a new avenue for neurobiological research in these critical species.

Decoding the different states of visual attention using functional and effective connectivity features in fMRI data.
The present paper concentrates on the impact of visual attention task on structure of the brain functional and effective connectivity networks using coherence and Granger causality methods. Since most studies used correlation method and resting-state functional connectivity, the task-based approach was selected for this experiment to boost our knowledge of spatial and feature-based attention. In the present study, the whole brain was divided into 82 sub-regions based on Brodmann areas. The coherence and Granger causality were applied to construct functional and effective connectivity matrices. These matrices were converted into graphs using a threshold, and the graph theory measures were calculated from it including degree and characteristic path length. Visual attention was found to reveal more information during the spatial-based task. The degree was higher while performing a spatial-based task, whereas characteristic path length was lower in the spatial-based task in both functional and effective connectivity. Primary and secondary visual cortex (17 and 18 Brodmann areas) were highly connected to parietal and prefrontal cortex while doing visual attention task. Whole brain connectivity was also calculated in both functional and effective connectivity. Our results reveal that Brodmann areas of 17, 18, 19, 46, 3 and 4 had a significant role proving that somatosensory, parietal and prefrontal regions along with visual cortex were highly connected to other parts of the cortex during the visual attention task. Characteristic path length results indicated an increase in functional connectivity and more functional integration in spatial-based attention compared with feature-based attention. The results of this work can provide useful information about the mechanism of visual attention at the network level.

Functional Connectivity Pattern of the Internal Hippocampal Network in Awake Pigeons: A Resting-State fMRI Study.
In the last two decades, the avian hippocampus has been repeatedly studied with respect to its architecture, neurochemistry, and connectivity pattern. We review these insights and conclude that we unfortunately still lack proper knowledge on the interaction between the different hippocampal subregions. To fill this gap, we need information on the functional connectivity pattern of the hippocampal network. These data could complement our structural connectivity knowledge. To this end, we conducted a resting-state fMRI experiment in awake pigeons in a 7-T MR scanner. A voxel-wise regression analysis of blood oxygenation level-dependent (BOLD) fluctuations was performed in 6 distinct areas, dorsomedial (DM), dorsolateral (DL), triangular shaped (Tr), dorsolateral corticoid (CDL), temporo-parieto-occipital (TPO), and lateral septum regions (SL), to establish a functional connectivity map of the avian hippocampal network. Our study reveals that the system of connectivities between CDL, DL, DM, and Tr is the functional backbone of the pigeon hippocampal system. Within this network, DM is the central hub and is strongly associated with DL and CDL BOLD signal fluctuations. DM is also the only hippocampal region to which large Tr areas are functionally connected. In contrast to published tracing data, TPO and SL are only weakly integrated in this network. In summary, our findings uncovered a structurally otherwise invisible architecture of the avian hippocampal formation by revealing the dynamic blueprints of this network.

EEG phase patterns reflect the representation of semantic categories of objects.
Oscillations of electroencephalographic signals represent the cognitive processes arose from the behavioral task and sensory representations across the mental state activity. Previous studies have shown the relation between event-related EEG and sensory-cognitive representation and revealed that categorization of presented object can be successfully recognized using recorded EEG signals when subjects view objects. Here, EEG signals in conjunction with a multivariate pattern recognition technique were used for investigating the possibility to identify conceptual representation based on the presentation of 12 semantic categories of objects (5 exemplars per category). Using multivariate stimulus decoding methods, surprisingly, we demonstrate that how objects are discriminated from phase pattern of EEG signals across the time in low-frequency band (1-4 Hz), but not from power of oscillatory brain signals in the same frequency band. In contrast, discrimination accuracy from the power of EEG signals has significantly higher than the performance from phase of EEG signal in the high-frequency band (20-30 Hz). Moreover, our results indicate that how the accuracy of prediction changes between various areas of brain continuously across the time. In particular, we find that, during the object categorization task, the inter-trial phase coherence in low-frequency band is significantly higher than other frequency in various regions of interests. This measure is associated with decoding pattern across the time. These results suggest that the mechanism underlying conceptual representation can be mediated by the phase of oscillatory neural activity.

FROM RECENCY EFFECTS TO CONTRACTION BIAS - A NEURAL NETWORK MODEL FOR HISTORY EFFECTS IN PARAMETRIC WORKING MEMORY TASKS

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Vezha Boboeva[1], Alberto Pezzotta[2], Athena Akrami[1], Claudia Clopath[3]
[1]University College London, Sainsbury Wellcome Centre, London, United Kingdom, [2]The Francis Crick Institute, Developmental Dynamics Laboratory, London, United Kingdom, [3]Imperial College London, Bioengineering, London, United Kingdom

Contraction bias is a phenomenon where the judgment of the magnitude of items held in working memory (WM) is biased towards the average of past observations. This phenomenon has been first described more than a century ago and has been replicated in various decision making tasks in humans and rodents. Contraction bias is assumed to be an optimal strategy by the brain, given the noisy nature of WM. In proposed Bayesian frameworks, the progressive shift of the memory towards the mean of a prior distribution built from past sensory experience helps with more accurate estimates of it. We propose an alternative mechanism, via short-term sensory history biases. Our model is motivated by recent results from a delayed-discrimination task in rats, where the posterior parietal cortex (PPC) has been shown to be critical to these memory effects. In our model, a circuit with a WM function receives inputs from another network (PPC). Both modules are continuous 1D attractor networks that differ in the timescales over which they integrate external inputs; the neurons in the PPC are additionally equipped with neuronal adaptation. As a result, contraction bias emerges as a result of a volatile WM content which makes it susceptible to shifting towards the previous sensory experience. This can result in errors that are sampled from the full distribution of the stimuli, and not simply its mean. Our results are consistent with the role of the PPC in encoding such sensory history biases, and provide predictions of performance across different stimulus distributions.

UNSUPERVISED, FREQUENT AND REMOTE: A NOVEL PLATFORM FOR PERSONALISED DIGITAL PHENOTYPING OF SPATIAL WORKING MEMORY AND IMAGE RECOGNITION IN HUMANS.

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Marino Krstulovic[1], Marius Bauza[2], Julija Krupic[1]
[1]University of Cambridge, Physiology, Development And Neuroscience, Cambridge, United Kingdom, [2]University College London, Sainsbury Wellcome Centre, London, United Kingdom

AIMS: Spatial working memory and image recognition tests are commonly used to facilitate the diagnosis of hippocampal-related neurological disorders such as Alzheimer's disease. Hence, there is an urgent need to implement them at scale and frequency. **METHODS:** We developed a novel digital platform, hAge ('healthy Age'), which integrates spatial alternation (SA), image recognition (IR) and visuospatial task (VS) for the frequent remote and unsupervised assessment of spatial and non-spatial working memory. **RESULTS:** We tested 191 healthy adults who continuously engaged with the hAge ~10 times/day for >eight weeks. Consistent with findings from analogous standard laboratory-based tests, we showed that Participants found VS task to be more challenging than IR and that performance on SA task negatively correlated with inter-trial periods. Importantly, we demonstrated that frequent engagement with the double SA task in older age groups (>50 years old) led to a strong practice effect. All of these measures were previously used to assess the cognitive decline and risks of developing AD in MCI patients. Unexpectedly, older Participants demonstrated higher absolute performance compared to the younger group. **CONCLUSIONS:** We demonstrated feasibility of our approach by showing good adherence levels. We also showed that the performance on hAge tasks is comparable to the performance observed in the analogous standard tests. Older participants performing better than younger ones, while unexpected, can be explained by unrelated confounds which could be addressed with some modifications to the current hAge.

Deep brain electrophysiology in freely moving sheep.
Although rodents are arguably the easiest animals to use for studying brain function, relying on them as model species for translational research comes with its own set of limitations. Here, we propose sheep as a practical large animal species to use for in vivo brain function studies performed in naturalistic settings. We conducted proof-of-principle deep brain electrophysiological recording experiments using unrestrained sheep during behavioral testing. Recordings were made from cortex and hippocampus, both while sheep performed goal-directed behaviors (two-choice discrimination tasks) and across states of vigilance, including sleep. Hippocampal and cortical oscillatory rhythms were consistent with those seen in rodents and non-human primates, and included cortical alpha oscillations and hippocampal sharp wave ripple oscillations (~150 Hz) during immobility and hippocampal theta oscillations (5-6 Hz) during locomotion. Recordings were conducted over a period of many months during which time the animals participated willingly in the experiments. Over 3,000 putative neurons were identified, including examples whose activity was modulated by task, speed of locomotion, spatial position, reward and vigilance states, and one whose firing rate was potentially modulated by the sight of the investigator. Together, these experiments demonstrate that sheep are excellent experimental animals to use for longitudinal studies requiring a large-brained mammal and/or large-scale recordings across distributed neuronal networks. Sheep could be used safely for studying not only neural encoding of decision-making and spatial-mapping in naturalistic environments outside the confines of the traditional laboratory but also the neural basis of both intra- and inter-species social interactions.

MOUSE MATERNAL LOW PROTEIN DIET AFFECTS WORKING MEMORY AND HIPPOCAMPAL GLIAL CELLS

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Joanna Gould[1], Emily Mort[1], Barira Islam[2], Eda Sezer[1], Jennifer Pearson-Farr[1], Patrick Mchugh[2], Tom Fleming[3], Sandrine Willaime-Morawek[1]
[1]University of Southampton, Medicine, yd, United Kingdom, [2]University of Huddersfield, Centre For Biomarker Research, dh, United Kingdom, [3]University of Southampton, Centre For Biological Sciences, Southampton, United Kingdom

Brain development in late gestation and after birth are affected by poor maternal nutrition, influencing structural, biochemical and pathway dynamics for motor and cognitive function. However, the importance of nutrition during early embryogenesis for brain development is less known. We have previously shown mouse maternal low protein diet (LPD) confined to the preimplantation period (Emb-LPD) with normal nutrition thereafter is sufficient to alter brain neuron proportion and adult short-term memory in adult offspring (doi/10.1073/pnas.1721876115). Aim: Here, we explore mechanisms of offspring memory change related to maternal LPD. Methods: Female mice were fed from mating to term normal protein diet (NPD), LPD or Emb-LPD (LPD up to E3.5, NPD thereafter). T-Maze tested working memory at 14 weeks. Hippocampus were analysed at 14 weeks, using immunohistochemistry and RNAseq. Results: LPD and Emb-LPD offspring exhibited memory deficit in the T-Maze, except for LPD females. While radial glia were not affected in the dentate gyrus, astrocyte density increased in LPD females compared to NDP and Emb-LPD females. Microglia density decreased in Emb-LPD and LPD, males and females, likely excluding an inflammatory role of these cells. RNAseq analysis revealed minimal pathway modulation in LPD females, whereas several metabolism pathways were altered in Emb-LPD females, compared to NPD females. Conclusions: Transient Emb-LPD around conception was sufficient to induce adult memory defects and altered glial metabolism and density. LPD females' memory rescue may be linked to dentate gyrus astrocyte density increase, which may lead to normalisation of metabolism pathways. TARGETED MEMORY REACTIVATION DURING POST-LEARNING SLEEP AFFECTS MEMORY CONSOLIDATION WITHIN CHANGES OF DENDRITIC SPINE PLASTICITY

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Qiyu Zheng[1], Xiaoqing Hu[2], Cora Sau Wan Lai[1]
[1]University of Hong Kong, School Of Biomedical Sciences, Hong Kong, Hong Kong PRC, [2]University of Hong Kong, Department Of Psychology, Hong Kong, Hong Kong PRC

Post-learning sleep is thought to be the critical period for the memory consolidation, during which the newly encoding memory is also susceptible to the external stimulus. Targeted memory reactivation (TMR), a procedure presenting the conditioned cues during sleep, has shown be able to trigger the replay of internal memory in recent studies. However, studies applying TMR in different sleep substages presented divergent outcomes, and the mechanism underlying TMR in memory consolidation is still unclear. Here we aim to investigate the effects of TMR at different sleep stages after fear conditioning in the frontal association cortex. We found that mice received TMR during the non-slow wave phases of non-rapid eye movement sleep (nS-NREM) significantly reduced the freezing rate in the recall test and inhibited the increased dendritic spine elimination in the frontal association cortex induced by fear conditioning when compared with controls. In contrast, mice subjected to TMR during slow wave sleep (SWS) showed enhanced fear memory with a stronger resistance to the later extinction trainings. In addition, the increased spine formation was also inhibited in SWS-TMR group when compared to normal extinction group. Furthermore, optogenetic inhibition in the frontal association cortex simultaneously with TMR cueing abolished the effects of TMR on animal behaviour. Our results indicated that synaptic plasticity and neuronal activity in the frontal association cortex at different sleep stages played an indispensable role in TMR.

PATTERN SEPARATION DEFICITS IN THE 3XTG MOUSE MODEL OF ALZHEIMER'S DISEASE.

POSTER SESSION 02 - SECTION: WORKING MEMORY AND MEMORY CONSOLIDATION

Haady Hajar[1], John Gigg[2]
[1]The University of Manchester, School Of Biological Sciences, Manchester, United Kingdom, [2]The University of Manchester, Division Of Neuroscience And Experimental Psychology, Manchester, United Kingdom

3xTgAD mice exhibit pronounced deficits in episodic-like memory encoding, akin to Alzheimer's disease patients. Pattern separation (PS) is required to encode similar episodic memories as distinct representations in the brain. This study aimed to determine whether impaired PS underlies episodic-like memory deficits in 3xTgAD. To achieve this, control and 3xTgAD mice performed a four-trial continuous novel object recognition task that individually familiarised them to a sample object before exposing them to the sample object and a novel object of either high or low similarity to that sample object. There was a significant effect of group but not trial on the novelty discrimination ratio (D2) for high similarity objects, with control mice D2s being significantly greater than those of 3xTgAD mice at trial four. There was no significant effect of group or trial on D2s for low similarity objects. Furthermore, proactive interference did not significantly affect D2s across trials for both groups and object types. Overall, these findings indicate that 3xTgAD mice had a moderate PS deficit; such that they preferentially explored low similarity object novel objects (which requires less PS) but only control mice had the PS capacity to detect novelty in high similarity objects.

CONTEXTUAL MODULATION OF REWARD SIGNALS ACROSS OBJECT AND SPATIAL REVERSAL LEARNING TASKS IN THE RHESUS MACAQUE BRAIN

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Jerome Sallet[1], Mathilde Lojkiewiez[2], Elsa Fouragnan[2], Bolton Chau[3], Poullias Claire[4], Urs Schuffelgen[5], Maryann Noonan[6], Matthew Rushworth[5]
[1]SBRI Inserm U1208, Neurobiology Of Executive Functions, Bron, France, [2]University of Plymouth, School Of Psychology, Plymouth, United Kingdom, [3]The Hong Kong Polytechnic University, Department Of Rehabilitation Sciences, Hong Kong, China, [4]Otto-von-Guericke- University Magdeburg, Department In Sensory Physiology, Magdeburg, Germany, [5]University of Oxford, Department Of Experimental Psychology, Oxford, United Kingdom, [6]University of Oxford, Experimental Psychology, Oxford, United Kingdom

Aims. Decision-making situations could differ along many dimensions such the nature of the action to take, or the identity of the option to choose from. To make such decisions in a changing environment, the brain needs to assign a value to each option, compare them to make a choice and update them based on the obtained outcome. We investigated how learning about spatial position or object identity are represented in specific brain areas and rely on similar computational principles. **Methods.** We used fMRI data from rhesus macaque performing deterministic reversal discrimination tasks in which they had to choose between stimuli with either different identities or target locations. **Results**. In previous studies, we linked an area located on the lateral part of the orbital surface (area 47/12o) to win-stay-lose-shift behaviours in object learning. In a spatial context, this region is important during the learning stage but did not show the same functional role in trained animals. We further investigated the fundamental difference between the two task contexts and found that a different pattern of activation in the ventromedial prefrontal cortex in processing reward information seems to originate an adaptive coding across contexts. While this region was functionally connected with the putamen in the two tasks, its activity was only correlated with activity in area 47/12o in the object context. **Conclusion.** Our findings reveal different recruitments of areas of the prefrontal cortex in object and spatial learning contexts and suggest that reward encoding is a main driver of these different network activities.

ACTIVITY IN DISTINCT NEURAL CIRCUITS PREDICTS RISK-SEEKING VERSUS RISK-AVERSE CHOICES

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Elnaz Ghasemi, Leili Mortazavi, Charlene Wu, Brian Knutson
Stanford University, Department Of Psychology, Stanford, United States of America

Previous findings on risky decision-making have raised the question of whether a single system or distinct circuits contribute to risky choice. In this study, we investigated brain activation preceding risky choice using Functional Magnetic Resonance Imaging (FMRI) in three independent samples with two different gambling tasks and analysis methods. In original (n=20) and validation (n=48) datasets, participants were scanned as they chose between a safe and a risky gamble, all of which had equal expected value and variance but which differed in skewness. Consistent with the Affect-Integration-Motivation framework (Samanez-Larkin & Knutson, 2015), pre-choice activity in the Nucleus Accumbens (NAcc) and Medial Prefrontal Cortex (MPFC) predicted risk seeking, whereas activity in the Anterior Insula (AIns) predicted risk averse choices. This pattern of results replicated in an independent sample using univariate and multivariate methods, and generalized to data acquired with a different gambling task (i.e., the Mixed Gambles Task; Tom et al. (2007)). Results also provided convergent evidence that distinct neural predictors of trial-by-trial risky choice could be dissociated from activity in sensory and motor cortices associated with gamble perception and choice. Findings therefore indicated that risky choice may be controlled in opposite directions by two distinct circuits, rather than a single circuit.

ECONOMIC VALUE IN THE BRAIN: AN ACTIVATION LIKELIHOOD ESTIMATION META-ANALYSIS OF WILLINGNESS-TO-PAY

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Alice Newton-Fenner[1,2], Danielle Hewitt[1], Jessica Henderson[1], Hannah Roberts[1], Tyler Mari[1], Yiquan Gu[3], Olga Gorelkina[3], Timo Giesbrecht[4], Nick Fallon[1], Carl Roberts[1], Andrej Stancak[1,2]

Forming and comparing subjective values of choice options is a critical stage of decision making. Previous literature has highlighted a complex network of brain regions involved in this process by utilising a wide variety of tasks and stimuli, varying in economic, hedonic and sensory qualities. To identify the core brain valuation system that processes economic value, we conducted a coordinate-based activation likelihood estimation meta-analysis of fMRI studies that employed the Becker-DeGroot-Marshack (BDM) auction, an incentivised demand-revealing mechanism which quantifies economic value of stimuli as willingness-to-pay (WTP). The systematic review revealed twenty-two studies (703 participants; 164 foci). Using two additional contrast analyses, we also investigated whether this encoding of subjective value would be invariant to the synchrony of auction task and fMRI recordings, and types of stimuli (food vs. non-food). WTP positively correlated with fMRI-BOLD activations in the bilateral ventral striatum and left ventromedial prefrontal cortex, with a sub-cluster reaching into the anterior cingulate cortex. Contrast analysis revealed no difference in brain activation patterns between outside versus inside scanner BDMs, or between food vs non-food stimuli. Our findings offer succinct empirical support for the ventral striatum and vmPFC as the core structures responsible for the formation of economic value, irrespective of the type, quality or quantity of item. The results also suggest that economic valuation is an automatic process, as the activation patterns were not affected by when and where the BDM was completed and are therefore unaffected by task relevancy.

Aims: A hallmark of our survival in the real world is our ability to show behavioural adaptation (BA). BA is a challenging process that requires to know whether to link our failures to our own actions (i.e. our actions' feedback -FB-) or to unexpected changes in our environment (i.e. when facing Action-Independent Events -AIDEs-, e.g. rules changed). The aim of this study is to identify how the functional interplay in the network formed by the midcingulate cortex (MCC) and the amygdala (AMG) is modulated by BA. **Methods:** We scanned 20 human subjects with fMRI while they were performing a new behavioral task in which they had to learn by trial and error how to adapt when facing both FB and AiDEs, AiDEs influencing or not the meaning of the FB. **Results:** Results show that the functional interplay between the AMG and MCC changes during the learning process: 1) the AMG is activated and the MCC deactivated at the first occurrence of AiDEs (i.e. when subjects do not know yet the meaning of the AiDEs), 2) then the MCC becomes activated and the AMG deactivated when subjects understood that an AiDE signal a need to adapt. **Conclusions:** This study suggests the AMG detects salient information from the environment and constantly informs the MCC through a bottom-up pathway. When the MCC identifies a particular event that requires BA, it exerts a top-down control onto AMG to optimize behavioral adaptation.

Frontal Cortical Functional Connectivity Is Impacted by Anaesthesia in Macaques.
A critical aspect of neuroscience is to establish whether and how brain networks evolved across primates. To date, most comparative studies have used resting-state functional magnetic resonance imaging (rs-fMRI) in anaesthetized nonhuman primates and in awake humans. However, anaesthesia strongly affects rs-fMRI signals. The present study investigated the impact of the awareness state (anaesthesia vs. awake) within the same group of macaque monkeys on the rs-fMRI functional connectivity organization of a well-characterized network in the human brain, the cingulo-frontal lateral network. Results in awake macaques show that rostral seeds in the cingulate sulcus exhibited stronger correlation strength with rostral compared to caudal lateral frontal cortical areas, while more caudal seeds displayed stronger correlation strength with caudal compared to anterior lateral frontal cortical areas. Critically, this inverse rostro-caudal functional gradient was abolished under anaesthesia. This study demonstrated a similar functional connectivity (FC) organization of the cingulo-frontal cortical network in awake macaque to that previously uncovered in the human brain pointing toward a preserved FC organization from macaque to human. However, it can only be observed in awake state suggesting that this network is sensitive to anaesthesia and warranting significant caution when comparing FC patterns across species under different states.

THE ROAD NOT TAKEN: INVESTIGATING THE BEHAVIOURAL AND NEURAL CORRELATES OF CHANGING ONE'S MIND

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Katharina Zuhlsdorff[1], Jeffrey Dalley[1], Trevor Robbins[1], Sharon Morein-Zamir[2]
[1]University of Cambridge, Department Of Psychology, Cambridge, United Kingdom, [2]Anglia Ruskin University, Psychology And Sport Science, Cambridge, United Kingdom

Cognitive flexibility is the ability to adapt to our constantly changing environment. Reduced flexibility can lead to worse life outcomes and heightened cognitive decline with age. However, a full picture of the behavioural and neural underpinnings of cognitive flexibility has not yet been established, as it is a multifaceted construct. Paradigms commonly used to study flexibility include task-switching, attentional set-shifting and reversal learning. In daily life, flexibility often involves a shift in behaviour being elicited volitionally. Individuals often choose to change behaviours based on environmental signals, but these are frequently accompanied by noise. We report results from a novel 'change your mind' task, which assesses proactive switching under uncertainty, without the need for ongoing rule-based learning. Participants completed a two-alternative choice task and following spurious feedback, were presented with the same stimulus again. They could repeat their previous response or change it, acting of their own volition. To our knowledge, no existing task provides participants with the opportunity to repeat their choice and assess whether they subsequently choose the 'road not taken'. We report findings from forty healthy participants who completed the task whilst undergoing a functional MRI scan. Behavioural findings indicate that participants predominantly repeat their choice but do change their response when the first response was incorrect, or feedback was negative. Brain circuitry including the anterior insula, anterior cingulate cortex and dorsolateral prefrontal cortex were found to be more active on change than repeat trials. The importance of the circuitry including anterior insula and occipital cortex was highlighted.

THE NEURAL NETWORK FOR SOCIAL DECISION-MAKING DEPENDENT ON A MULTI-CONTEXT ENVIRONMENT

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Jingkang Zhao[1,2,3], Shingo Tanaka[2], Tetsuya Matsuda[4], Keisuke Kawasaki[2], Atsuhiko Iijima[1,5], Isao Hsegawa[2]
[1]Niigata University, Department Of Electrical And Information Engineering, Graduate School Of Science And Technology, Niigata, Japan, [2]Niigata University, Department Of Physiology, Niigata, Japan, [3]Technical University of Munich, Department Of Electrical And Computer Engineering, Munich, Germany, [4]Tamagawa University, Brain Science Institute, Tokyo, Japan, [5]Niigata University, School Of Health Sciences, Faculty Of Medicine, Niigata, Japan

We optimize our behaviors in social situations where we constantly interact with other individuals in various contexts. Social decisions can be affected by multi-social contexts such as others' intentions, our position, and interest. In this study, we aim to reveal the neural mechanism of social decision-making considering the above-mentioned contexts. We developed a modified Old-Maid card game experiment that enables us to parametrically control the computer opponents' honesty. The participants' roles were randomly assigned on each trial, and interests between subjects and the computer opponent occasionally changed. In the experiment, fifty-one subjects performed the task in an fMRI scanner and we acquired BOLD signals in the task. To explain the subjects' behaviors, we introduce a novel computational model, which integrates several internal parameters related to the opponents' intentions and other social contexts. Then, we performed the GLM analysis to identify the brain activity correlated to these parameters. We found that 1) Activities in the temporoparietal junction (TPJ) and the dorsomedial prefrontal cortex (dmPFC), which are implicated by the theory of mind function, were correlated with the subjects' estimation of the opponent's honesty; 2) Multiple prefrontal regions, especially the ventromedial prefrontal cortex (vmPFC) and TPJ were related to the changing of interests; and 3) The right anterior insula and the left temporal pole had a close correlation with the subject's honesty parameter. Based on these observations, we suggest the existence of a network including the above-mentioned brain regions would play an important role in social decision-making.

Whether it be in front of a restaurant menu or a library shelf, humans make decisions on a constant basis, shifting their gaze between stimuli of interest, evaluating, and integrating values before reaching a decision. Despite visual attention being a well-established component of the value-based decision-making process, little is known about the role fixations may play on underlying neural mechanisms. In the present study, we recorded neural activity from 38 patients with refractory epilepsy using stereoencephalography (sEEG) while they performed an economics choice task in which they were asked to integrate prospective gains and losses before accepting or declining a sensori-motor challenge. Behavioral results showed that the duration and pattern of visual fixations to gains and losses biased choices made. Neural results revealed that the ventromedial prefrontal cortex (vmPFC) and anterior insula (aINS) respectively encoded fixation-dependent gain and loss magnitudes, and that this gaze-related activity mediated the effect of prospective gains and losses on choices. These results offer novel evidence for a guiding role of visual fixations on the neural mechanisms underlying the biasing effects of gaze on choices.

This study aimed to investigate the effect of different sport categories (open- and closed skills) on proactive and reactive inhibitory processes as two distinct components of motor inhibition. A mouse tracking procedure was employed to compare behavioural performance among three groups of participants (tennis players, swimmers and non-athletes) in non-sport-specific cued Go/No-Go (GNG) and Stop Signal Task (SST), which mainly engage proactive and reactive inhibitory control, respectively. Reaction times (RTs), inhibitory failures, and Stop Signal Reaction Times (SSRTs) were measured. To investigate dynamic aspects of inhibitory control, one-shot and non-one-shot movement profiles were analysed and compared among groups. Results showed no group differences in RTs in Go/No-Go and Stop conditions. SSRTs were significant shorter for the athletes than non-athletes in SST, but no differences emerged for inhibitory failures in cued GNG. During inhibitory failures athletes showed higher proportion of non-one-shot movements than non-athletes in both tasks. Higher proportion of non-one-shot profiles was observed in cued GNG compared to SST. Finally, no differences between two sport categories were found in both tasks. Our findings suggest that both proactive and reactive inhibitory controls do benefit from sport practice, but open- and closed-skills sports do not differ in influencing inhibitory processes. Movement profile analysis could be a promising, complementary behavioral analysis to integrate for more fine-grained evaluation and differentiation of inhibitory motor control in athletes, specifically when using GNG tasks.

Individual differences in delay discounting—how much we discount future compared to immediate rewards—are associated with general life outcomes, psychopathology, and obesity. Here, we use machine-learning on fMRI activity during an intertemporal choice task to develop a brain marker of these individual differences. Training the marker in one dataset (N = 110) resulted in a significant cross-validated prediction-outcome correlation (r = 0.49), and accuracy of the marker was replicated in an independent data set (N = 145, r = 0.45). Significant predictive weights were found in cingulate, insula, and frontoparietal areas, suggesting an interplay between regions associated with valuation and cognitive control. Responses of the marker also predicted discounting several weeks later, differed between overweight and lean individuals, and predicted blood markers related to glucose metabolism. This pattern (termed k-marker) is a step towards a generalizable brain model of delay discounting that can be tested as a potentially transdiagnostic phenotype in future studies.

NOVEL CONTINUOUS SENSORY PROCESSING AND DECISION-MAKING PARADIGM EXHIBITS HIGH TEST-RETEST RELIABILITY ACROSS NEURAL AND BEHAVIOURAL MEASURES

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Layla Stahr, Lilian Weber, Kaelyn Brown, Luca Mezossy-Dona, Cameron Hassall, Laurence Hunt
University of Oxford, Department Of Psychiatry, Oxford, United Kingdom

Aims: When conducting psychiatric research, we must balance the desire for high-quality data with the inherent attentional and time constraints of clinical populations. We have developed a novel paradigm that pairs a continuous random dot motion task with a roving auditory mismatch negativity (MMN) paradigm. By concurrently exposing participants to a continuous visual and auditory stimulus stream alongside electroencephalogram (EEG) recording, we can study both auditory processing and visual evidence accumulation. However, for this paradigm to be applicable in clinical and pharmacological settings, we must ensure that we can reliably measure the neural signatures of both task components within a single session and across multiple days. *Methods:* The present study examines the test-retest reliability of the MMN response, behavioural integration kernels, and neural responses in the visual task. Test-retest reliability was assessed both across continuous five-minute blocks within a single recording session and across separate recording days. *Results:* We found that our task elicited the expected neural responses for the visual and auditory paradigms. While participants' MMN waveforms were highly reliable even across separate recording days, significant between-subject variability emerged. Through our paradigm's blocked design, we were further able to classify the relationship between EEG recording length and signal reliability. Reliable behavioural integration kernels were also observed. *Conclusions:* These findings suggest that our combined task can successfully elicit the key neural and behavioural signatures of both the auditory and visual paradigms. This high reliability, paired with the between-subject heterogeneity, supports the suitability of our paradigm for clinical and pharmacological settings.

PUPILLOMETRY IN INSTRUMENTAL ACTION- AND VALENCE-BASED DECISION-MAKING

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Zahra Rezazadeh[1], Simone Schütz-Bosbach[2], Bahador Bahrami[2]
[1]Graduate School of Systematic Neuroscience, Faculty Of Biology, Ludwig Maximilian University, Munich, Germany, [2]Faculty of Psychology and Educational Sciences, Ludwig Maximilian University, Department Of Psychology, Munich, Germany

In decisions involving motor actions, we decide either to invigorate or to inhibit. This is the action (effect) axis of control over the decision. On the other hand, we make decisions based on whether the situation is rewarding or punishing, and this comprises the valence (affect) axis of decision. Although it seems like actions are instructed by valence, we can also decide on “no-go” to receive a reward, or on “go” to avoid a punishment. Therefore, conversely to what is suggested by the classical instrumental vs. Pavlovian learning framework, there should not be a deductive dependence between action and valence. Optimal decision-making also involves the ability to regulate between known sources of reward (exploitation) and new rewards (exploration). Brain’s locus coeruleus-noradrenergic (LC-NE) system, whose activity is tracked by pupil diameter, is thought to be critically involved in this regulation. The present study aims to investigate the role of the LC-NE system in valence-based decision-making by studying pupil diameter as an index of norepinephrine activity. To this end, a go/no-go task (as in Guitart-Massip et al., 2012) is used in which reaction times and accuracy rates for going and stopping are compared as a function of rewarding and punishing conditions. We hypothesize that “go to reward” and “no-go to avoid punishment” conditions result in less reaction times, higher accuracy rates and less task-evoked pupil dilation, compared to ”no-go to reward” and “go to avoid punishment” conditions. Our results may lead to a better understanding of neuromodulation processes involved in decision-making.

COORDINATED MULTI-REGION ACTIVITY DURING CHOICE BEHAVIOR REVEALED BY HUMAN INTRACRANIAL RECORDINGS

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Jacqueline Overton[1], Matthew Stickle[2], Karen Moxon[3], Ignacio Saez[1]
[1]Icahn School of Medicine at Mount Sinai, Neuroscience, Neurosurgery And Neurology, New York, United States of America, [2]University of California, San Diego, Data Science & Engineering, La Jolla, United States of America, [3]University of California, Davis, Biomedical Engineering, Davis, United States of America

Decision-making requires coordinated activity across multiple brain regions involved in evaluation, comparison, and choice. Understanding neural activations underlying choices therefore requires examination of distributed neural activity. Here, we probed activity across multiple brain regions involved in valuation and choice using intracranial electroencephalography (iEEG) in human neurosurgical patients (n=20) while they played a gambling game designed to probe value-based decisions. On each trial, participants chose between a certain reward and a risky gamble of varying win probability. We recorded iEEG activity from orbitofrontal cortex (OFC), lateral prefrontal cortex (LPFC), cingulate cortex (CC), amygdala, hippocampus, insula, parietal cortex, and pre- and post-central gyri. We analyzed iEEG local field potential data across six canonical frequency bands and nine regions during deliberation (1s prior to choice). By comparing pre-choice activity to a pre-stimulus baseline, we found significant widespread task-related power modulations across multiple power bands and regions. Specifically, lower frequency (<30Hz) activity increased in all regions except pre- and post-central gyri and parietal regions, whereas higher frequencies were more likely to decrease, particularly in LPFC, OFC and CC. Next, we examined power modulations related to patient choice (gamble or safe bet) and found that low (30 to 70 Hz) and high gamma (70 to 200 Hz) were associated with decisions taken, particularly in OFC, LPFC, and precentral gyrus. These results describe critical neural components underlying human decision-making and demonstrate that widespread and multi-frequency neural activity underlies human choices under uncertainty.

Improved methods for acrylic-free implants in nonhuman primates for neuroscience research.
Traditionally, head fixation devices and recording cylinders have been implanted in nonhuman primates (NHP) using dental acrylic despite several shortcomings associated with acrylic. The use of more biocompatible materials such as titanium and PEEK is becoming more prevalent in NHP research. We describe a cost-effective set of procedures that maximizes the integration of headposts and recording cylinders with the animal's tissues while reducing surgery time. Nine rhesus monkeys were implanted with titanium headposts, and one of these was also implanted with a recording chamber. In each case, a three-dimensional printed replica of the skull was created based on computerized tomography scans. The titanium feet of the headposts were shaped, and the skull thickness was measured preoperatively, reducing surgery time by up to 70%. The recording cylinder was manufactured to conform tightly to the skull, which was fastened to the skull with four screws and remained watertight for 8.5 mo. We quantified the amount of regression of the skin edge at the headpost. We found a large degree of variability in the timing and extent of skin regression that could not be explained by any single recorded factor. However, there was not a single case of bone exposure; although skin retracted from the titanium, skin also remained adhered to the skull adjacent to those regions. The headposts remained fully functional and free of complications for the experimental life of each animal, several of which are still participating in experiments more than 4 yr after implant. Cranial implants are often necessary for performing neurophysiology research with nonhuman primates. We present methods for using three-dimensional printed monkey skulls to form and fabricate acrylic-free implants preoperatively to decrease surgery times and the risk of complications and increase the functional life of the implant. We focused on reducing costs, creating a feasible timeline, and ensuring compatibility with existing laboratory systems. We discuss the importance of using more biocompatible materials and enhancing osseointegration.

Effects of aging on the response of single neurons to amplitude-modulated noise in primary auditory cortex of rhesus

macaque.
Temporal envelope processing is critical for speech comprehension, which is known to be affected by normal aging. Whereas the macaque is an excellent animal model for human cerebral cortical function, few studies have investigated neural processing in the auditory cortex of aged, nonhuman primates. Therefore, we investigated age-related changes in the spiking activity of neurons in primary auditory cortex (A1) of two aged macaque monkeys using amplitude-modulated (AM) noise and compared these responses with data from a similar study in young monkeys (Yin P, Johnson JS, O'Connor KN, Sutter ML. J Neurophysiol 105: 582-600, 2011). For each neuron, we calculated firing rate (rate code) and phase-locking using phase-projected vector strength (temporal code). We made several key findings where neurons in old monkeys differed from those in young monkeys. Old monkeys had higher spontaneous and driven firing rates, fewer neurons that synchronized with the AM stimulus, and fewer neurons that had differential responses to AM stimuli with both a rate and temporal code. Finally, whereas rate and temporal tuning functions were positively correlated in young monkeys, this relationship was lost in older monkeys at both the population and single neuron levels. These results are consistent with considerable evidence from rodents and primates of an age-related decrease in inhibition throughout the auditory pathway. Furthermore, this dual coding in A1 is thought to underlie the capacity to encode multiple features of an acoustic stimulus. The apparent loss of ability to encode AM with both rate and temporal codes may have consequences for stream segregation and effective speech comprehension in complex listening environments.

THE NEURAL CORRELATES OF EFFORT-REWARD DECISION-MAKING IN OLDER ADULTS

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Larissa Chiu
McGill University, Neurology And Neurosurgery, Montreal, Canada

BACKGROUND: Effort mobilization is critical for goal directed behaviour across the human lifespan. Effort discounting is the process of reducing the subjective value of a reward as increasing effort that is required to obtain that reward. However, the neurobehavioral substrates of effort discounting in older adults are poorly understood and identifying related brain regions can help us better understand factors affecting normal cognitive aging. **METHODS**: We examined the effect of effort discounting on functional brain connectivity in 19 cognitively normal older adults (10 males; mean age = 66±6 years). Participants completed a computerized cognitive task, the Effort Expenditure for Rewards Task, capturing decision making to expend effort for monetary rewards through binary choices between high-reward-high-effort or low-reward-low-effort options. We modelled subjective value to assess the *k* parameter, as a proxy of effort discounting, and then examined the association to brain functional connectivity. Regions associated to the salience network—right/left anterior insula (AI) and anterior cingulate cortex (ACC)—were selected in seed-to-voxel analyses with age, sex, and Bayesian information criterion as covariates. **RESULTS**: Increased willingness to exert effort for reward was associated with enhanced functional connectivity between ACC and right lateral occipital cortex, and between the left AI, cerebellum and precuneus cortex (voxel $p<0.001$, cluster $p<0.05$ FDR corrected). The effect size of effort discounting was greater for ACC ($r^2=0.737$ for ACC; $r^2=0.718$ for left AI). **CONCLUSIONS**: Effort discounting is associated with functional connectivity changes involving the anterior cingulate cortex and left anterior insula in cognitively healthy older adults.

The influence of an acute bout of moderate-intensity cycling exercise on sensorimotor integration.
Acute cycling exercise can modulate motor cortical circuitry in the non-exercised upper-limb. Within the primary motor cortex, measures of intracortical inhibition are reduced and intracortical facilitation is enhanced following acute exercise. Further, acute cycling exercise decreases interhemispheric inhibition between the motor cortices and lowers cerebellar-to-motor cortex inhibition. Yet, investigations into the effects of acute exercise on sensorimotor integration, referring to the transfer of incoming afferent information from the primary somatosensory cortex to motor cortex, are lacking. The current work addresses this gap in knowledge with two experimental sessions. In the first session, we tested the exercise-induced changes in somatosensory and motor excitability by assessing somatosensory (SEP) and motor evoked potentials (MEPs). In the second session, we explored the effects of acute cycling exercise on short- (SAI) and long-latency afferent inhibition (LAI), and afferent facilitation. In both experimental sessions, neurophysiological measures were obtained from the non-exercised upper-limb muscle, tested at two time points pre-exercise separated by a 25-min period of rest. Next, a 25-min bout of moderate-intensity lower-limb cycling was performed with measures assessed at two time points post-exercise. Acute lower-limb cycling increased LAI, without modulation of SAI or afferent facilitation. Further, there were no exercise-induced changes to SEP or MEP amplitudes. Together, these results suggest that acute exercise has unique effects on sensorimotor integration, which are not accompanied by concurrent changes in somatosensory or motor cortical excitability.

MCC-DLPFC NETWORK MODULATION BY PATHWAY-SPECIFIC DREADDS IN MACAQUE MONKEYS: BEHAVIORAL, RESTING-STATE FMRI AND HISTOLOGICAL VALIDATIONS.

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Clémence Gandaux[1], Charlie Wilson[1], Jerome Sallet[1], Céline Amiez[1], Eric Kremer[2], Marina Lavigne[2], Franck Lamberton[3], Emmanuel Procyk[1]
[1]SBRI Inserm U1208, Neurobiology Of Executive Functions, Bron, France, [2]Institut de Génétique Moléculaire de Montpellier, Cnrs, Montpellier, France, [3]CERMEP, Imagerie Du Vivant, Bron, France

Brain perturbation methods are essential to investigate causal inferences of behavioral and neural processes. We present the first stages in a project to use pathway-specific DREADDs (*Designer Receptor Exclusively Activated by Designer Drugs)* in macaque monkeys to target and reversibly modulate these neural networks. DREADDs are well established in rodents, but to date there has been little use of them in a pathway-specific manner in primate species, an essential step toward translation to clinical applications.
We assessed pathway-specific DREADD activation in macaques with a behavioral task and resting-state fMRI analysis, and validated transfection with histology. We targeted an anatomically defined pathway between midcingulate cortex (MCC) and dorsolateral prefrontal cortex (dlPFC) by injecting floxed hM3D(Gq) DREADD genetic material carried by AAV5 to MCC, and Cre-recombinase carried by retrograde CAV-2 vector to the dlPFC. Only neurons transfected by both AAV and CAV-2 would be able to express the DREADDs.
We present behavioural results from a search task, indicating an alteration of adaptive behaviour under DREADD activation with Deschloroclozapine (DCZ). We also present data showing whether resting-state fMRI networks are modified in the presence of DCZ in lightly anesthetized monkeys with and without DREADDs. Finally, we present histological validation of pathway-specific DREADDs in the MCC-DLPFC network. Our data provide a first step towards reversible pathway-specific interventions in primates.

THALAMOCORTICAL BASES OF THE EXPLOITATION/EXPLORATION TRADE-OFF

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Sarah Morceau[1,2], Margaux Giraudet[1,2], Angélique Faugère[1,2], Marie-Line Fournier[1,2], Alain R. Marchand[1,2], Etienne Coutureau[1,2], Mathieu Wolff[1,2]

In a constantly changing environment, deciding when to explore (to gain knowledge) instead of exploiting it (using available knowledge to secure a gain) is an essential aspect of adaptive decision-making. Recent studies have shown a crucial role of the orbitofrontal cortex (OFC) when arbitrating between exploitation and exploration is required. The OFC shares extensive reciprocal connections with various subcortical regions including the mediodorsal thalamus (MD), a thalamic nucleus previously demonstrated to be largely involved in higher-order cognitive functions. To probe the contribution of these cortical and thalamic regions in the rat, we developed a probabilistic three-armed bandit task, in which rats must identify the most valuable option among three possible choices. Three levers are differentially rewarded, defining a good (80% chance to get a reward) and two bad options (20%). Within a session, the contingencies are randomly shuffled once to prompt the animals to switch from exploitation to exploration. Post-training excitotoxic lesions of the OFC and the MD appear to selectively impair the transition between exploitation and exploration. Indeed, exploration strategies appear to be less efficient in these animals and OFC rats also exhibited perseverative responses indicating an impairment in flexible exploration. Further experiments are warranted to document the role of the reciprocal pathways connecting the OFC and the MD. Ongoing work relying on a fiber photometry approach suggests that calcic transients in the cortex and the thalamus are differentially associated with specific behavioral events as rats perform the three-armed bandit task.

VENTRAL HIPPOCAMPUS IS REQUIRED FOR UPDATING ACTION-OUTCOME ASSOCIATIONS THROUGH CONTEXT-OUTCOME LEARNING

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Robin Piquet, Léa Caverzan, Angélique Faugère, Shauna Parkes
Université de Bordeaux, Incia, Bordeaux, France

In a changing environment, the ability to update our representation of previously learnt information is essential. Such goal-directed behaviour requires individuals to constantly monitor their knowledge about the causal relationships between available actions and their specific outcomes, as well as the value of those outcomes. Interestingly, the influence of the environmental context on goal-directed action and specifically on the ability to adapt to any changes in action-outcome relationships remains poorly understood. Thus, here, we studied whether goal-directed behaviour relies on activity in the ventral hippocampus (vHPC), a structure involved in the contextual regulation of other associative learning processes. We first assessed the effect of pre-training vHPC lesions on outcome devaluation, a task designed to assess whether an action is sensitive to changes in outcome value. We found that inhibition of vHPC left devaluation intact. We then assessed the effect of vHPC inhibition on contingency degradation, which requires the animal to learn that the environmental context (and not the action) is now the best predictor of outcome delivery. We showed that rats with vHPC inhibition were unable to readily adapt their behaviour when the causal relationship between the action and the outcome was disrupted, and the context became the best predictor of reward. This suggests that the vHPC may be required to form context-outcome relationships to guide adaptive behaviour and appropriate action selection. Overall, our results show that goal-directed behaviour relies on activity in the vHPC only when learning about the environment is required.

NORADRENERGIC SIGNALING IN THE RODENT ORBITOFRONTAL CORTEX IS REQUIRED TO UPDATE GOAL-DIRECTED ACTIONS

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Alessandro Piccin[1], Juan-Carlos Cerpa[2], Margot Dehove[1], Mathieu Wolff[1], Shauna Parkes[1], Etienne Coutureau[1]
[1]INCIA, Cnrs Umr 5287, Bordeaux cedex, France, [2]University of Oxford, Department Of Experimental Psychology, Oxford, United Kingdom

Aims: In a constantly changing world, an organism must be able to assign specific outcomes to distinct actions in order to meet basic needs and desires. Such adaptive behaviour relies on circuits involving cortical and subcortical structures. For instance, recent data from our laboratory indicate that the ventral (VO) and lateral (LO) parts of the orbitofrontal cortex are required to integrate changes in the relationships between actions and their specific outcomes. Moreover, among all neuromodulatory agents involved in prefrontal functioning, it has been proposed that adaptive behavior might heavily depend upon the noradrenergic drive. Therefore, we assessed the intriguing possibility that noradrenergic innervation of the VO and the LO might play a role in updating action-outcome relationships. **Methods**: To do so, we tested Long-Evans rats in an identity-based reversal task, employed toxins selective for noradrenergic and dopaminergic neurons, and a retrograde virus carrying a noradrenergic-specific promoter and inhibitory DREADDs. **Results**: We found that either depletion or chemogenetic silencing of noradrenergic inputs within the VO and the LO impaired the update of action-outcome associations. Silencing of noradrenergic inputs in the medial prefrontal cortex or depletion of dopaminergic inputs in the VO and the LO did not reproduce this deficit. **Conclusions**: Altogether, our results indicate that noradrenergic projections to the ventral and lateral parts of the orbitofrontal cortex are cardinal for updating action-outcome associations, blending in and enriching our knowledge of neuroanatomical and neuromodulatory substrates of adaptive behavior.

INSULAR CORTEX IS REQUIRED TO GUIDE ACTION SELECTION IN OUTCOME-SPECIFIC DEVALUATION AND PAVLOVIAN-TO-INSTRUMENTAL TRANSFER

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Yacine Tensaouti, Shauna Parkes
Université de Bordeaux, Incia - Umr 5287- Cnrs, Bordeaux cedex, France

Aims: Appropriate decision making relies on our ability to recall the causal relationship between our actions and their consequences, as well as the value of expected outcomes. Cues associated with rewarding or aversive outcomes have been shown to influence such decisions, altering motivation and choice between competing actions. The phenomenon by which these mental representations or Pavlovian expectancies are able to bias choice selection is called Pavlovian-to-Instrumental transfer (PIT). Decades of research have identified two forms of PIT (General and Specific), distinct in terms of both behaviour and neural substrates. However, little is known about the involvement of cortical areas in such behaviors. Here, we investigated the potential role of the rodent gustatory insular cortex in specific PIT, as we have previously shown that this cortical region is required to guide action selection based on current outcome value. **Methods:** We used chemogenetics to temporally inactivate the insular cortex in adult Long-Evans male and female rats during a satiety-induced outcome-specific devaluation choice test and a specific PIT test. **Results:** We found that silencing the insular cortex during the test phase of both tasks impaired the rats' ability to bias their choice towards the appropriate action. **Conclusions:** These results indicate that the gustatory insular cortex is required to bias (1) choice selection towards the most desirable outcome and (2) operant behavior using predictive cues, by recalling associated mental representations.

Aims : The orbitofrontal cortex (OFC) is known to play a critical role in acquiring and updating outcomes to specific events in a changing environment. Specifically, it has been involved in updating pavlovian but not instrumental associations in contingency degradation experiments. Moreover, noradrenaline has been shown to play critical roles in adaptative behavior depending on prefrontal regions. As a result, we assessed the role of noradrenergic innervation onto the ventrolateral OFC (vlOFC) in updating stimulus and actions/outcomes associations. **Methods :** In order to adress these questions, we tested the ability of Long Evans rats to update stimulus-outcome and action-outcome contingency degradations using chemogenetical inhibition of noradrenergic fibers projecting to the vlOFC. To do so, retrograde viruses carrying inhibitory DREADDs were injected into the vlOFC targetting noradrenergic fibers using a specific promoter. **Results :** We found that selectively inhibiting noradrenergic fibers projecting to the vlOFC during contingency degradation specifically impaired the rats ability to update Pavlovian but not instrumental associations. **Conclusions :** Altogether, these results indicate that noradrenergic projections to the vlOFC are crucial to update stimulus-outcome but not actions-outcomes associations in a changing environment, thus further improving our understanding of the role of noradrenaline in flexible behavior.

MOUSE PREFRONTAL AREA MOS ENCODES TASK FEATURES AND BODY MOVEMENTS

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Lauren Wool[1], Matteo Carandini[2], Kenneth Harris[1]
[1]University College London, Institute Of Neurology, London, United Kingdom, [2]University College London, Ucl Institute Of Ophthalmology, London, United Kingdom

[Aims] Area MOs in the mouse prefrontal cortex is implicated in sensory-based decision-making, but it is not known if its neurons also carry signals related to value-based decisions, or how these neurons are affected by 'task-irrelevant' signals such as spontaneous body movements. **[Methods]** We used two-photon calcium imaging to measure the activity of L2/3 cortical excitatory neurons in area MOs while mice performed a visually guided decision task, in which the location of a visual stimulus was reported with a wheel movement. In addition to the changing stimulus location, the value of choices also differed, with reward volume for left versus right correct choices alternating over blocks (Lak et al. *Neuron*, 2020). We imaged the same field of view over multiple sessions, and simultaneously recorded eye, face and forepaw movements with an infrared video camera. **[Results]** MOs neurons heterogeneously encoded multiple task variables, such as contraversive or ipsiversive choice direction, contralateral visual stimulus, and the presence or absence of reward. Moreover, they encoded spontaneous movements of the eye, forepaws and/or snout that occurred on single trials. In some sessions, we observed neurons whose pretrial activity correlated with the reward block, but the strength and direction of this encoding changed over repeated sessions in the same population. **[Conclusions]** MOs neurons encode features of a decision-making task, such as stimulus, choice direction and reward outcome, but their value encoding varies across sessions. Additionally, MOs neurons encode 'task-irrelevant' spontaneous body movements.

TASK-EXPERIENCE-DEPENDENT STABILISATION OF OUTCOME-SELECTIVE NEURONS IN SENSORY CORTEX DURING REVERSAL LEARNING

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Jasper Teutsch, Rohan Rao, Anastasia Dimitriou, Abhishek Banerjee
Newcastle University, Adaptive Decisions Lab, Biosciences Institute, Newcastle upon Tyne, United Kingdom

Flexible behavioural adaptation relies on learning and adjusting complex 'rules' that link sensory experience to possible actions. While mechanisms of learning and generalising rules have been identified in the prefrontal cortex, their interactions with the primary sensory cortex remain unknown. We trained head-fixed mice on a 'Go/No-go' tactile serial reversal-learning task where the animal experienced two successive rule switches (R1 and R2, respectively). Functional responses were measured using two-photon Ca^{2+} imaging from excitatory layer 2/3 neurons in primary somatosensory cortex (S1) and lateral orbitofrontal cortex (lOFC). We used a receiver operating characteristic analysis to assess the selectivity of single-neuron activity for specific trial types and employed tensor decomposition to analyse inter-trial population dynamics across all task stages. Upon R1, S1 neurons lost outcome-selectivity acquired during initial learning, whereas lOFC neurons showed increased activity, signalling a feedback prediction error. Lateral OFC top-down feedback instructed S1 response-remapping, enabling neurons to slowly gain outcome-selectivity. Silencing lOFC-to-S1 projections following R1, but not R2, impaired behavioural performance (*d'*), indicating the involvement of lOFC when task demands are relatively high. Despite a comparable drop in *d'* across R1 and R2, lOFC and S1 showed distinct engagements. While lOFC showed no significant activity upon R2, a substantial fraction of S1 neurons retained outcome-selective and history-dependent responses during early R2. Our findings propose feedback-independent assignment of outcome values in S1 that switch between conserved states depending on task demand. This strengthens the emerging idea that local mechanisms in the primary sensory areas can crucially contribute to higher cognitive functions.

Value-guided remapping of sensory cortex by lateral orbitofrontal cortex.
Adaptive behaviour crucially depends on flexible decision-making, which in mammals relies on the frontal cortex, specifically the orbitofrontal cortex (OFC). How OFC encodes decision variables and instructs sensory areas to guide adaptive behaviour are key open questions. Here we developed a reversal learning task for head-fixed mice, monitored the activity of neurons of the lateral OFC using two-photon calcium imaging and investigated how OFC dynamically interacts with primary somatosensory cortex (S1). Mice learned to discriminate 'go' from 'no-go' tactile stimuli and adapt their behaviour upon reversal of stimulus-reward contingency ('rule switch'). Imaging individual neurons longitudinally across all behavioural phases revealed a distinct engagement of S1 and lateral OFC, with S1 neural activity reflecting initial task learning, whereas lateral OFC neurons responded saliently and transiently to the rule switch. We identified direct long-range projections from lateral OFC to S1 that can feed this activity back to S1 as value prediction error. This top-down signal updated sensory representations in S1 by functionally remapping responses in a subpopulation of neurons that was sensitive to reward history. Functional remapping crucially depended on top-down feedback as chemogenetic silencing of lateral OFC neurons disrupted reversal learning, as well as plasticity in S1. The dynamic interaction of lateral OFC with sensory cortex thus implements computations critical for value prediction that are history dependent and error based, providing plasticity essential for flexible decision-making.

Operant Assessment of DMTP Spatial Working Memory in Mice.
Working memory (WM) is required to bridge the time between the moment of sensory perception and the usage of the acquired information for subsequent actions. Its frequent and pharmacoresistent impairment in mental health disorders urges the development of rodent paradigms through back-translation of human WM tests, ideally avoiding the confounds of alternation-based assays. Here we show, that mice can acquire a delayed-matching-to-position (DMTP) operant spatial WM (SWM) paradigm that is akin to the (CAM) task previously developed for rats, and that relies on a 5-choice wall [5-CSWM, 5-

choice based operant testing of SWM (5-CSWM)]. Requiring ca. 3 months of daily training with a non-illuminated operant box in the default state, mice could attain a performance level of ≥70% choice accuracy with short (2 s) delays in the DMTP 5-CSWM task. Performance decreased with extended delays, as expected for WM processes. Modafinil (15 and 30 mg/kg) and guanfacine (0.3 and 1 mg/kg) showed no consistent efficacy in enhancing task performance. We also found, that mice did not improve beyond chance level, when trained in the DNMTP-version of the 5-CSWM. Our results outline the methodical possibility and constraints of assessing spatial WM in mice with an operant paradigm that provides high control over potentially confounding variables, such as cue-directed attention, motivation or mediating strategies like body-positioning.

Delayed-matching-to-position working memory in mice relies on NMDA-receptors in prefrontal pyramidal cells.
A hypofunction of N-methyl-D-aspartate glutamate receptors (NMDARs) has been implicated in the pathogenesis of schizophrenia by clinical and rodent studies. However, to what extent NMDAR-hypofunction in distinct cell-types across the brain causes different symptoms of this disease is largely unknown. One pharmaco-resistant core symptom of schizophrenia is impaired working memory (WM). NMDARs have been suggested to mediate sustained firing in excitatory neurons of the prefrontal cortex (PFC) that might underlie WM storage. However, if NMDAR-hypofunction in prefrontal excitatory neurons may indeed entail WM impairments is unknown. We here investigated this question in mice, in which NMDARs were genetically-ablated in PFC excitatory cells. This cell type-selective NMDAR-hypofunction caused a specific deficit in a delayed-matching-to-position (DMTP) 5-choice-based operant WM task. In contrast, T-maze rewarded alternation and several psychological functions including attention, spatial short-term habituation, novelty-processing, motivation, sociability, impulsivity, and hedonic valuation remained unimpaired at the level of GluN1-hypofunction caused by our manipulation. Our data suggest that a hypofunction of NMDARs in prefrontal excitatory neurons may indeed cause WM impairments, but are possibly not accounting for most other deficits in schizophrenia.

Region-Specific KCC2 Rescue by rhIGF-1 and Oxytocin in a Mouse Model of Rett Syndrome.
Rett syndrome (RTT) is characterized by dysfunction in neuronal excitation/inhibition (E/I) balance, potentially impacting seizure susceptibility via deficits in K+/Cl- cotransporter 2 (KCC2) function. Mice lacking the Methyl-CpG binding protein 2 (MeCP2) recapitulate many symptoms of RTT, and recombinant human insulin-like growth factor-1 (rhIGF-1) restores KCC2 expression and E/I balance in MeCP2 KO mice. However, clinical trial outcomes of rhIGF-1 in RTT have been variable, and increasing its therapeutic efficacy is highly desirable. To this end, the neuropeptide oxytocin (OXT) is promising, as it also critically modulates KCC2 function during early postnatal development. We measured basal KCC2 expression levels in MeCP2 KO mice and identified 3 key frontal brain regions showing KCC2 alterations in young adult mice, but not in postnatal P10 animals. We hypothesized that deficits in an IGF-1/OXT signaling crosstalk modulating KCC2 may occur in RTT during postnatal development. Consistently, we detected alterations of IGF-1 receptor and OXT receptor levels in those brain areas. rhIGF-1 and OXT treatments in KO mice rescued KCC2 expression in a region-specific and complementary manner. These results suggest that region-selective combinatorial pharmacotherapeutic strategies could be most effective at normalizing E/I balance in key brain regions subtending the RTT pathophysiology.

Schizophrenia-related cognitive dysfunction in the Cyclin-D2 knockout mouse model of ventral hippocampal hyperactivity.
Elevated activity at the output stage of the anterior hippocampus has been described as a physiological endophenotype of schizophrenia, and its development maps onto the transition from the prodromal to the psychotic state. Interventions that halt the spreading glutamatergic over-activity in this region and thereby the development of overt schizophrenia could be promising therapies. However, animal models with high construct validity to support such pre-clinical development are scarce. The Cyclin-D2 knockout (CD2-KO) mouse model shows a hippocampal parvalbumin-interneuron dysfunction, and its pattern of hippocampal over-activity shares similarities with that seen in prodromal patients. Conducting a comprehensive phenotyping of CD2-KO mice, we found that they displayed novelty-induced hyperlocomotion (a rodent correlate of positive symptoms of schizophrenia), that was largely resistant against D1- and D2-dopamine-receptor antagonism, but responsive to the mGluR2/3-agonist LY379268. In the negative symptom domain, CD2-KO mice showed transiently reduced sucrose-preference (anhedonia), but enhanced interaction with novel mice and objects, as well as normal nest building and incentive motivation. Also, unconditioned anxiety, perseveration, and motor-impulsivity were unaltered. However, in the cognitive domain, CD2-knockouts showed reduced executive function in assays of rule-shift and rule-reversal learning, and also an impairment in working memory, that was resistant against LY379268-treatment. In contrast, sustained attention and forms of spatial and object-related memory that are mediated by short-term habituation of stimulus-specific attention were intact. Our results suggest that CD2-KO mice are a valuable model in translational research targeted at the pharmacoresistant cognitive

symptom domain in causal relation to hippocampal over-activity in the prodrome-to-psychosis transition. Transl Psychiatry, 2018; 8

STATE REPRESENTATION OF NON-SENSORY NEURONS IN VISUAL CORTICAL AREAS TO VISUALLY GUIDED DECISIONS IN THE RAT

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Yuma Osako[1], Tomoya Ohnuki[1], Kazuki Shiotani[2], Yuta Tanisumi[3], Hiroyuki Manabe[1], Yoshio Sakurai[1], Junya Hirokawa[1]
[1]Doshisha University, Graduate School Of Brain Science, Kyoto, Japan, [2]College of Life Sciences, Ritsumeikan University, Laboratory Of Brain Network Information, Kusatsu, Shiga, Japan, [3]Graduate School of Brain Science, Doshisha University, Laboratory Of Neural Information, Kyotanabe, Kyoto, Japan

It is widely assumed that trial-by-trial variability in visual detection performance is explained by the fidelity of visual responses in visual cortical areas influenced by fluctuations of internal states, such as vigilance and behavioral history. However, which neuronal ensembles represent such different internal states remain unclear. In this study, we utilized a visual detection task, which distinguishes rats' internal states in response to identical stimuli, while recording neurons simultaneously from the primary visual cortex (V1) and the posterior parietal cortex (PPC). We found that rats often fail to respond to visual stimuli despite the robust presence of V1 responses. Our unsupervised analysis revealed distinct population dynamics segregating hit responses from misses, orthogonally embedded to visual response dynamics in both V1 and PPC. Heterogeneous non-sensory neurons in V1 and PPC significantly contributed to population-level encoding accompanied with the modulation of noise correlation only in V1. These results highlight the non-trivial contributions of non-sensory neurons in V1 and PPC for population-level computations that reflect the animals' internal states to drive behavioral responses to visual stimuli.

ALPHA 2-ADRENERGIC MECHANISM IN STRESS-INDUCED DECISION-MAKING

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Carleigh Turner, Vladimir Visockis, Yogita Chudasama
National Insitutes of Health, National Institute Of Mental Health, Bethesda, United States of America

The α2A-adrenergic receptor is closely associated with stress. Systemic administration of yohimbine, an α2A receptor antagonist increases stress and impulsivity in rats and humans. The stress response is associated with significant increases in noradrenaline in the hippocampus, and dopamine in the prefrontal cortex, which might stimulate the cortex to drive risky behaviors contributing to pathological tendencies towards gambling, substance abuse, and other high-risk behaviors. Here, we explored this possibility by combining a pharmacological stressor, FG7142 with adrenergic agonists and antagonists. We first trained rats on an operant touchscreen decision-making task in which rats chose between two visual stimuli. Responses to the 'safe' stimulus always resulted in the delivery of a certain reward (50µl sucrose). Responses to the 'risky' stimulus resulted in the delivery of an uncertain reward (10µl 75% of the time, and 170µl 25% of the time). When given a systemic 4 mg dose of FG7142, the rats shifted their baseline strategies by increasing their choice of the safe stimulus and hence the certain reward. In contrast, the co-administration of FG7142 and yohimbine made the rats riskier since these animals not only preferred the option that delivered the uncertain reward but also increased the speed of responding. The combination of FG7142 and guanfacine, an α2A receptor agonist had the opposite effect of making animals significantly slower in their choices especially following a loss. These data indicate that stress together with acute activation of the noradrenergic system may worsen or trigger risky behaviors observed in both clinical and non-clinical populations.

Adapting one's choices and learning from their outcomes is critical for survival in complex and changing environments. Exploring available options is a strategy to solve this problem that requires identifying when to explore to avoid forgo valuable rewards unnecessarily. Here we showed that monkeys (rhesus macaques) assess the need for exploration and its usefulness for future choices when making strategic exploratory decisions. Using fMRI, we showed that only when there was a need to explore through information sampling did the mid-cingulate cortex (MCC) and the dorsolateral prefrontal cortex (dlPFC) show increased activity with decreasing value of the chosen option. This suggests a role in counteracting expected value signals, when exploration away from value needs to be considered. At the heart of this strategic assessment, exploration and learning are intertwined. To optimize exploration based on the need for exploratory choices, one must be able to process the counterfactual information that is obtained without active sampling. We suggest that this occurs in medial orbito-frontal cortex (OFC), where we showed that monkeys represent chosen and unchosen reward prediction errors. Overall, our study shows how MCC-dlPFC and OFC circuits together could support exploitation of available information to the fullest and drive behavior towards finding more information when the need arises.

Knowing the difference between a choice that was taken with high confidence and one with low, can make the difference between life and death. Monitoring confidence allows a decision maker to adapt to variable uncertainty for any given decision. The firing rates of individual neurons within the orbitofrontal cortex (OFC) encode decision confidence, the probability of a decision being correct, given choice and evidence. Pharmacological inhibition of the OFC prevents rats from adjusting their time investment based on decision confidence. However, the cortical location and connectivity of functionally distinct neurons within the OFC microcircuit remains unknown. We trained rats to perform a previously described confidence reporting task in rats. Using the freely moving juxtaxellular labelling technique, we first recorded OFC neurons in rats performing this confidence task, then labelled them with neurobiotin. Neurons were selected for labelling on the basis of precisely timed fluctuations in firing rates relative to task events. We combined this technique with retrograde tracer injections, into candidate projection target areas, allowing us to identify the axon target of neurons with known activity. The post-hoc anatomical evaluation allowed us to determine soma position, dendritic arborisation and axonal projections of the recorded neurons. Our results indicate a correspondence between the behaviourally-related firing patterns of a neuron, and distinct dendritic and axonal connectivity. We expect that our approach will reveal how specific elements of OFC circuits compute confidence and contribute to neural machinery of a mysterious cognitive capacity.

REPRESENTATION OF ACTION VALUE AND UNCERTAINTY ACROSS DORSAL STRIATUM

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Juan Carlos Cerpa[1], Beren Millidge[2], Rafal Bogacz[2], Mark Walton[1]
[1]University of Oxford, Experimental Psychology, Oxford, United Kingdom, [2]University of Oxford, Mrc Brain Network Dynamics Unit, Oxford, United Kingdom

Aims The dorsal striatum plays a key role in reward-guided decision making. Its primary cell type, medium spiny neurons (MSNs), are largely segregated into a *direct* and an *indirect* pathway. However, it is still highly contentious *how* these coordinate their activity to allow beneficial decisions to be made. One recent theoretical idea is that the relative patterns of activity across these pathways encode the expected value *and* uncertainty of the options (Mikhael & Bogacz, 2016). We therefore aimed at testing this in a context where an agent chooses between options with different reward probabilities. **Methods** We trained D1- and A2a-*Cre* mice, to allow selective targeting of the direct or indirect pathways MSNs, respectively, in a 3-option probabilistic decision-making task. Mice were trained to initiate a trial and then choose between 3 spatially-distinct reward ports, each of which was associated with a specific reward probability (100%, 50% or 20%). We injected GCaMP6f into dorsomedial and dorsolateral striatum and recorded bulk signals from either the direct or indirect MSNs while mice performed the task. **Results** Our preliminary results confirm a strong movement- and outcome-driven activation of both pathways in both regions. Critically, we can observe that encoding of the value and uncertainty of the options might be reflected in the signals from both MSNs type when the animal selects an option, and as it waits for the outcome. **Conclusions** Our study is revealing how dorsal striatum MSNs in different regions reflect decision variables such as reward value and uncertainty associated with options.

Dopamine and noradrenaline modulation of goal-directed behavior in orbital and medial prefrontal cortex: Toward a division of labor?
The prefrontal cortex is considered to be at the core of goal-directed behaviors. Notably, the medial prefrontal cortex (mPFC) is known to play an important role in learning action-outcome (A-O) associations, as well as in detecting changes in this contingency. Previous studies have also highlighted a specific engagement of the dopaminergic pathway innervating the mPFC in adapting to changes in action causality. While previous research on goal-directed actions has primarily focused on the mPFC region, recent findings have revealed a distinct and specific role of the ventral and lateral orbitofrontal cortex (vlOFC). Indeed, vlOFC is not necessary to learn about A-O associations but appears specifically involved when outcome identity is unexpectedly changed. Unlike the mPFC, the vlOFC does not receive a strong dopaminergic innervation. However, it receives a dense noradrenergic innervation which might indicate a crucial role for this neuromodulator. In addition, several lines of evidence highlight a role for noradrenaline in adapting to changes in the environment. We, therefore, propose that the vlOFC's function in action control might be under the strong influence of the noradrenergic system. In the present article, we review anatomical and functional evidence consistent with this proposal and suggest a direction for future studies that aim to shed light on the orbitofrontal mechanisms for flexible action control. Specifically, we suggest that dopaminergic modulation in the mPFC and noradrenergic modulation in the vlOFC may underlie distinct processes related to updating one's actions. Insular and Ventrolateral Orbitofrontal Cortices Differentially Contribute to Goal-Directed Behavior in Rodents.
The medial prefrontal cortex (mPFC) has long been considered a critical site in action control. However, recent evidence indicates that the contribution of cortical areas to goal-directed behavior likely extends beyond mPFC. Here, we examine the function of both insular (IC) and ventrolateral orbitofrontal (vlOFC) cortices in action-dependent learning. We used chemogenetics to study the consequences of IC or vlOFC inhibition on acquisition and performance of instrumental actions using the outcome devaluation task. Rats first learned to associate actions with desirable outcomes. Then, one of these outcomes was devalued and we assessed the rats' choice between the 2 actions. Typically, rats will bias their selection

towards the action that delivers the still valued outcome. We show that chemogenetic-induced inhibition of IC during choice abolishes goal-directed control whereas inhibition during instrumental acquisition is without effect. IC is therefore necessary for action selection based on current outcome value. By contrast, vlOFC inhibition during acquisition or the choice test impaired goal-directed behavior but only following a shift in the instrumental contingencies. Our results provide clear evidence that vlOFC plays a critical role in action-dependent learning, which challenges the popular idea that this region of OFC is exclusively involved in stimulus-dependent behaviors.

Distinct regional patterns in noradrenergic innervation of the rat prefrontal cortex.
The anatomy and functions of the rodent prefrontal cortex (PFC) have been extensively studied. It is now clear that the PFC is at the core of various executive functions and that these functions depend on monoaminergic neuromodulation. The PFC receives extensive projections from monoaminergic nuclei and, in particular, from the locus cœruleus (LC) which is the major source of noradrenaline (NA) in the cortex. Projections of this nucleus have long been considered to act diffusely and uniformly throughout the entire brain. However, recent studies have revealed a separate innervation of prefrontal sub-regions by non-collateralizing LC neurons, suggesting a specific modulation of their functions. Following this idea, we aimed at describing more precisely the pattern of noradrenergic innervation into different orbital (OFC) and medial (mPFC) sub-regions of the PFC. We focused on the lateral (LO), ventral (VO) and medial (MO) portions of the OFC, and on areas 32d (A32d), 32v (A32v) and 25 (A25) in the mPFC. Using Dopamine-β-Hydroxylase as a specific noradrenergic marker, we performed an automatic quantification of noradrenergic fibers and varicosities in each of these sub-regions. The results indicate that noradrenergic innervation is heterogeneous in some prefrontal sub-regions along the rostro-caudal axis. Functional dissociations have been recently reported in prefrontal sub-regions along the rostro-caudal direction. Our findings add neuroanatomical support to this emergent idea.

Targeting Catecholaminergic Systems in Transgenic Rats With a CAV-2 Vector Harboring a Cre-Dependent DREADD Cassette.
Techniques that allow the manipulation of specific neural circuits have greatly increased in the past few years. DREADDs (Designer receptors exclusively activated by designer drugs) provide an elegant way to manipulate individual brain structures and/or neural circuits, including neuromodulatory pathways. Considerable efforts have been made to increase cell-type specificity of DREADD expression while decreasing possible limitations due to multiple viral vectors injections. In line with this, a retrograde canine adenovirus type 2 (CAV-2) vector carrying a Cre-dependent DREADD cassette has been recently developed. In combination with Cre-driver transgenic animals, the vector allows one to target neuromodulatory pathways with cell-type specificity. In the present study, we specifically targeted catecholaminergic pathways by injecting the vector in knock-in rat line containing Cre recombinase cassette under the control of the tyrosine hydroxylase promoter. We assessed the efficacy of infection of the nigrostriatal pathway and the catecholaminergic pathways ascending to the orbitofrontal cortex (OFC) and found cell-type-specific DREADD expression.

Corticosteroid-Binding Globulin Deficiency Specifically Impairs Contextual and Recognition Memory Consolidation in Male Mice.
Glucocorticoids are essential in modulating memory processes of emotionally arousing experiences and we have shown that corticosteroid-binding globulin (CBG) influences glucocorticoid delivery to the brain. Here, we investigated the role of CBG in contextual and recognition long-term memory according to stress intensity.

BILATERAL MAPPING OF ACTIONS IN THE SUPERIOR COLLICULUS

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Karolina Socha[1,2], Steven West[1,3], Rebecca Terry[1,2], The International Brain Laboratory[1], Kenneth Harris[1,4], Matteo Carandini[1,2]
[1]University College London, The International Brain Laboratory, London, United Kingdom, [2]University College London, Ucl Institute Of Ophthalmology, London, United Kingdom, [3]University College London, Sainsbury Wellcome Centre, London, United Kingdom, [4]University College London, Institute Of Neurology, London, United Kingdom

[Aims] Mouse superior colliculus (SC) plays a key role in selecting actions guided by sensory cues (e.g. Huda et al. 2020, Duan et al. 2021, Essig et al. 2021). SC neurons exhibit lateralized activity, responding after contralateral visual cues and before contraversive movements (Steinmetz et al. 2019). A common view therefore is that the two sides of the SC compete, each side promoting contralateral choices. [Methods] We inactivated the left SC in head-fixed mice trained to turn a steering wheel to indicate whether a stimulus appears on the left or right (Burgess et al. 2017, IBL et al. 2021), by expressing the inhibitory soma-targeting opsin stGtACR2 (Mahn et al. 2018) in deep and intermediate SC layers. [Results] Unilateral optogenetic manipulation had opposite effects depending on the region of SC that was inactivated. Inactivation of lateral SC suppressed contralateral choices (n=2 mice), whereas inactivation of medial SC promoted contralateral choices (n=3 mice). Inactivation of medial SC also markedly reduced the reaction times, possibly suggesting a different behavioral strategy. [Conclusions] These initial results reveal that each side of the SC contains regions that promote vs. suppress contralateral actions . This observation suggests that we need to revise the classical view of competition between two sides of the SC: for instance, competition may also take place within each side of the SC.

LIPOPOLYSACCHARIDE-INDUCED NEUROINFLAMMATION IN THE POSTERIOR DORSOMEDIAL STRIATUM FACILITATES GOAL-DIRECTED ACTION.

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Arvie Abiero
University of Technology Sydney, School Of Life Sciences, Faculty Of Science, Ultimo, Australia

Neuroinflammation has been identified in striatum of individuals with compulsive disorders. These individuals also display deficits in goal-directed action. Nevertheless, a direct, causal link between striatal neuroinflammation and impaired goal-directed action has yet to be established. In Experiment 1, rats received micro-injections in posterior dorsomedial striatum (pDMS) of either saline or lipopolysaccharide (LPS) (5mg/ml) to induce neuroinflammation. We then examined goal-directed decision-making performance using Pavlovian-instrumental transfer and outcome devaluation. In the Pavlovian phase, rats were trained to associate two unique auditory cues with pellets and sucrose (counterbalanced). In the instrumental phase, the same rats were trained to press left and right levers for pellet and sucrose outcomes respectively (counterbalanced). When animals were overfed and control effects were small, transfer and devaluation were comparatively enhanced in group LPS. During transfer testing, group LPS selectively responded on the lever associated with the same outcome (Same>Different) whereas group Sham did not. During devaluation testing, although both groups responded more on the lever that had earned the valued relative to the devalued outcome, this difference was larger in group LPS. Experiment 2 tested whether pDMS neuroinflammation increases motivation generally, or goal-directed action specifically. We trained sham and LPS pDMS animals to press a single lever for sucrose. When tested for progressive ratio performance, animals in group LPS reached consistently higher breakpoints than group Sham. Upon devaluation testing, group Sham demonstrated evidence of habits (Valued=Devalued) and group LPS demonstrated intact goal-directed actions (Valued>Devalued). These results suggest that LPS-induced neuroinflammation in pDMS increases both motivation and goal-directed action.

Outcome-selective reinstatement is predominantly context-independent, and associated with c-Fos activation in the posterior dorsomedial striatum.
Research from human and animal studies has found that after responding has been successfully reduced following treatment it can return upon exposure to certain contexts. An individual in recovery from alcohol use disorder, for example, might relapse to drinking upon visiting their favourite bar. However, most of these data have been derived from experiments involving a single (active) response, and the context-dependence of returned responding in situations involving choice between multiple actions and outcomes is less well-understood. We thus investigated how outcome-selective reinstatement - a procedure involving choice between two actions and outcomes - was affected by altering the physical context in rats. In Experiment 1, rats were trained over 6 days to press a left lever for one food outcome (pellets or sucrose) and a right lever for the other outcome. Then, rats received an extinction session in either the same context (A) as lever press training, or in a different context (B). Rats were tested immediately (5 min) after extinction in Context A or B such that there were four groups in total: AAA, ABB, ABA, and AAB. Reinstatement testing consisted of one food outcome being delivered 'freely' (i.e. unearned by lever pressing and unsignalled by cues) to the food magazine every 4 min in the following order: Sucrose, Pellet, Pellet, Sucrose. Selective reinstatement was considered intact if pellet delivery increased pressing selectively on the pellet lever, and sucrose delivery selectively increased pressing on the sucrose lever. This result (Reinstated > Nonreinstated) was observed for rats in group AAA and ABB, but not rats in groups ABA and AAB. Experiment 2 was conducted identically, except that rats received two extinction sessions over two days and tested one day later. This time, all groups demonstrated intact outcome-selective reinstatement regardless of context. Analysis of c-Fos expression in several brain regions revealed that only c-Fos expression in the posterior dorsomedial striatum (pDMS) was related to intact reinstatement performance. Overall, these results suggest that outcome-selective reinstatement is predominantly context-independent, and that intact reinstatement is related to neuronal activity in the pDMS.

1-Phenylcyclohexan-1-amine hydrochloride (PCA HCl) alters mesolimbic dopamine system accompanied by neuroplastic changes: A neuropsychopharmacological evaluation in rodents.
The recreational use of N-methyl-D-aspartate (NMDA) antagonist phencyclidine (PCP) and ketamine have grown rapidly due to their psychotomimetic properties. These compounds induce both non-fatal and fatal adverse effects and despite the enhanced regulation, they are continuously synthesized and are being sold in the illegal drug market, including 1-phenylcyclohexan-1-amine hydrochloride (PCA). Therefore, we evaluated its abuse potential through the conditioned-place preference (CPP), self-administration, and locomotor sensitization paradigms. Pretreatment with SCH 2 3390 and haloperidol was also performed during a CPP test. We used ELISA to measure dopamine (DA) levels and western blotting to determine effects on the DA-related proteins as well as on phosphorylated CREB, deltaFosB, and brain-derived neurotrophic factor (BDNF) in the ventral tegmental area (VTA) and nucleus accumbens (NAc). Finally, we examined the effects on brain wave activity using electroencephalography (EEG). PCA induced CPP in mice and was self-administered by rats, suggesting that PCA has rewarding and reinforcing properties. PCA increased locomotor of mice on the first treatment and challenge days. SCH 23390 and haloperidol blocked the CPP. PCA altered the DA, tyrosine hydroxylase, dopamine D1 and D2 receptors as well as p-CREB and deltaFosB. Also, PCA altered the delta and gamma waves in the brain, which were then normalized by SCH 2 3390 and haloperidol. The present findings indicate that PCA may induce abuse potential through the dopaminergic system and probably accompanied with alterations in brain wave activity which is similar to that of other psychotomimetic NMDA antagonists. We advocate thorough monitoring of PCP analogs as they pose potential harm to public health.

The dopaminergic alterations induced by 4-F-PCP and 4-Keto-PCP may enhance their drug-induced rewarding and reinforcing effects: Implications for abuse.
Novel psychoactive substances remain the popular recreational drugs of use over the years. They continue to bypass government restrictions due to their synthesis and modifications. Recent additions to the lists are the 4-F-PCP and 4-Keto-PCP, analogs of the drug phencyclidine (PCP) known to induce adverse effects and abuse potential. However, studies on the abuse potential of 4-F-PCP and 4-Keto-PCP remain scarce. The rewarding and reinforcing effects of the drugs were assessed using conditioned place preference (CPP), self-administration, and locomotor sensitization tests. Dopamine (DA) receptor antagonists (SCH23390 and haloperidol) were administered during CPP to evaluate the involvement of the mesolimbic dopaminergic system. DA-related protein expression in the nucleus accumbens (NAcc) and ventral tegmental area (VTA) was measured. Additionally, phosphorylated cyclic-adenosine monophosphate-activated protein (AMP) response element-binding (p-CREB) protein, deltaFosB (ΔFosB), and brain-derived neurotrophic factor (BDNF) protein levels in the NAcc were measured to assess the addiction neural plasticity effect of the drugs. Both 4-F-PCP and 4-Keto-PCP-induced CPP and self-administration; however, only 4-F-PCP elicited locomotor sensitization. Treatment with DA receptor antagonists (SH23390 and haloperidol) inhibited the 4-F- and 4-Keto-induced CPP. Both substances altered the levels of DA receptor D1 (DRD1), thyroxine hydroxylase (TH), DA receptor D2 (DRD2), p-CREB, ΔFosB, and BDNF. The results suggest that 4-F-PCP and 4-Keto-PCP may induce abuse potential in rodents via alterations in dopaminergic system accompanied by addiction neural plasticity.

Catalpol and Mannitol, Two Components of , Exhibit Anticonvulsant Effects Probably via GABA Receptor Regulation.
Epilepsy is a brain disorder that affects millions of people worldwide and is usually managed using currently available antiepileptic drugs, which result in adverse effects and are ineffective in approximately 20-25% of patients. Thus, there is growing interest in the development of new antiepileptic drugs with fewer side effects. In a previous study, we showed that a (RG) water extract has protective effects against electroshock- and pentylenetetrazol (PTZ)-induced seizures, with fewer side effects. In this study, the objective was to identify the RG components that are responsible for its anticonvulsant effects. Initially, a number of RG components (aucubin, acteoside, catalpol, and mannitol) were screened, and the anticonvulsant effects of different doses of catalpol, mannitol, and their combination on electroshock- and chemically (PTZ or strychnine)-

induced seizures in mice, were further assessed. Gamma-aminobutyric acid (GABA) receptor binding assay and electroencephalography (EEG) analysis were conducted to identify the potential underlying drug mechanism. Additionally, treated mice were tested using open-field and rotarod tests. Catalpol, mannitol, and their combination increased threshold against electroshock-induced seizures, and decreased the percentage of seizure responses induced by PTZ, a GABA antagonist. GABA receptor binding assay results revealed that catalpol and mannitol are associated with GABA receptor activity, and EEG analysis provided evidence that catalpol and mannitol have anticonvulsant effects against PTZ-induced seizures. In summary, our results indicate that catalpol and mannitol have anticonvulsant properties, and may mediate the protective effects of RG against seizures.

Four Novel Synthetic Tryptamine Analogs Induce Head-Twitch Responses and Increase 5-HTR2a in the Prefrontal Cortex in Mice.
Tryptamines are monoamine alkaloids with hallucinogenic properties and are widely abused worldwide. To hasten the regulations of novel substances and predict their abuse potential, we designed and synthesized four novel synthetic tryptamine analogs: Pyrrolidino tryptamine hydrochloride (PYT HCl), Piperidino tryptamine hydrochloride (PIT HCl), N,N-dibutyl tryptamine hydrochloride (DBT HCl), and 2-Methyl tryptamine hydrochloride (2-MT HCl). Then, we evaluated their rewarding and reinforcing effects using the conditioned place preference (CPP) and self-administration (SA) paradigms. We conducted an open field test (OFT) to determine the effects of the novel compounds on locomotor activity. A head-twitch response (HTR) was also performed to characterize their hallucinogenic properties. Lastly, we examined the effects of the compounds on 5-HTR1a and 5-HTR2a in the prefrontal cortex using a quantitative real-time polymerase chain reaction (qRT-PCR) assay. None of the compounds induced CPP in mice or initiated SA in rats. PYT HCl and PIT HCl reduced the locomotor activity and elevated the 5-HTR1a mRNA levels in mice. Acute and repeated treatment with the novel tryptamines elicited HTR in mice. Furthermore, a drug challenge involving a 7-day abstinence from drug use produced higher HTR than acute and repeated treatments. Both the acute treatment and drug challenge increased the 5-HTR2a mRNA levels. Ketanserin blocked the induced HTR. Taken together, the findings suggest that PYT HCl, PIT HCl, DBT HCl, and 2-MT HCl produce hallucinogenic effects via 5-HTR2a stimulation, but may have low abuse potential.

The circadian gene, Per2, influences methamphetamine sensitization and reward through the dopaminergic system in the striatum of mice.
Drug addiction is a chronic and relapsing brain disorder, influenced by complex interactions between endogenous and exogenous factors. Per2, a circadian gene, plays a role in drug addiction. Previous studies using Per2-knockout mice have shown a role for Per2 in cocaine, morphine and alcohol addiction. In the present study, we investigated the role of Per2 in methamphetamine (METH) addiction using Per2-overexpression and knockout mice. We observed locomotor sensitization responses to METH administration, and rewarding effects using a conditioned place preference test. In addition, we measured expression levels of dopamine and dopamine-related genes (monoamine oxidase A, DA receptor 1, DA receptor 2, DA active transporter, tyrosine hydroxylase and cAMP response element-binding protein 1) in the striatum of the mice after repeated METH treatments, using qRT-PCR. Per2-overexpressed mice showed decreased locomotor sensitization and rewarding effects of METH compared to the wildtype mice, whereas the opposite was observed in Per2 knockout mice. Both types of transgenic mice showed altered expression levels of dopamine-related genes after repeated METH administration. Specifically, we observed lower dopamine levels in Per2-overexpressed mice and higher levels in Per2-knockout mice. Taken together, Per2 expression levels may influence the addictive effects of METH through the dopaminergic system in the striatum of mice.

25B-NBOMe, a novel N-2-methoxybenzyl-phenethylamine (NBOMe) derivative, may induce rewarding and reinforcing effects via a dopaminergic mechanism: Evidence of abuse potential.
An increasing number of N-2-methoxybenzyl-phenethylamine (NBOMe) derivatives are being misused worldwide, including the potent hallucinogen 2-(4-bromo-2,5-dimethoxyphenyl)-N-(2-methoxybenzyl)ethanamine (25B-NBOMe). However, the number of studies characterizing the abuse potential and psychopharmacological properties of 25B-NBOMe is limited; thus, we examined its rewarding and reinforcing effects using conditioned place preference (CPP) and self-administration (SA) tests. Pretreatment with SCH23390 (SCH), Haloperidol (HAL), and ketanserin (KS), antagonists of dopamine D1 (DRD), dopamine D2 (DRD), and serotonin 2A (5-HT receptor) receptors, respectively, was utilized during a CPP test to investigate

the involvement of the dopaminergic and serotonergic systems in 25B-NBOMe-mediated effects. We also examined the effects of 25B-NBOMe on the expression of dopamine-related proteins in the nucleus accumbens (NAcc) and ventral tegmental area (VTA). Then, we measured the dopamine level, phosphorylated CREB (p-CREB), deltaFosB (ΔFosB), and brain-derived neurotrophic factor (BDNF) in the NAcc. In addition, we explored the involvement of 5-HT receptors in the 25B-NBOMe-induced head twitch response (HTR). We also examined the effects of 25B-NBOMe on brain wave activity using electroencephalography. 25B-NBOMe elicited CPP and SA. SCH and HAL blocked 25B-NBOMe-induced CPP, whereas KS did not. Moreover, 25B-NBOMe altered the DRD , DRD , and dopamine transporter expression and increased dopamine levels. It also induced changes in p-CREB, ΔFosB, and BDNF expression. 25B-NBOMe induced HTR and increased 5-HT receptor mRNA levels, effects inhibited by KS. Furthermore, 25B-NBOMe altered delta and gamma wave activity, which was normalized by SCH and HAL. These findings show that 25B-NBOMe may induce rewarding and reinforcing effects via a dopaminergic mechanism, suggesting its abuse potential.

5-Methoxy-α-methyltryptamine (5-MeO-AMT), a tryptamine derivative, induces head-twitch responses in mice through the activation of serotonin receptor 2a in the prefrontal cortex.
5-Methoxy-α-methyltryptamine (5-MeO-AMT) is a tryptamine derivative that is used recreationally because of its reported hallucinogenic and mood elevating effects. Studies suggest that the psychopharmacological effects of tryptamines involve serotonin receptor 2a (5-HTR2a) activation in the brain. The head-twitch response (HTR) is widely used as a behavioral correlate for assessing 5-HTR2a agonist activity of a drug. Thus, we investigated whether 5-MeO-AMT induces HTR in mice and explored its mechanism of action. 5-MeO-AMT (0.3, 1, 3, 10 mg/kg) was administered once a day for 7 days, and the HTR was measured after 1 day (acute) and 7 days (repeated) of administration. Another cohort of mice was treated with 5-HTR2a antagonist ketanserin (KS) before 5-MeO-AMT administration. We measured 5-HTR2a and 5-HTR2c mRNA levels in the prefrontal cortex of the mice treated acutely or repeatedly with 5-MeO-AMT. We performed western blotting to determine the effects of the drug on the expression of G protein (G), protein kinase C gamma (PKC-γ), and extracellular signal-regulated kinases 1/2 (ERK1/2), in addition to PKC-γ and ERK1/2 phosphorylation. Additionally, we evaluated potential rewarding and reinforcing effects of 5-MeO-AMT using locomotor sensitization, conditioned place preference (CPP), and self-administration (SA) paradigms. Acute 5-MeO-AMT administration elicited the HTR, while repeated administration resulted in tolerance. KS blocked the 5-MeO-AMT-induced HTR. 5-MeO-AMT increased 5-HTR2a mRNA levels and induced PKC-γ phosphorylation in the prefrontal cortex. 5-MeO-AMT did not induce locomotor sensitization, CPP, or SA. This study shows that 5-MeO-AMT induces HTR through 5-HTR2a activation in the prefrontal cortex, and may have low potential for abuse.

THE BASOLATERAL AMYGDALA TO NUCLEUS ACCUMBENS SHELL PATHWAY ENCODES, BUT DOESN'T RETRIEVE, OUTCOME-SPECIFIC PREDICTIONS TO GUIDE CHOICE BETWEEN ACTIONS

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Elise Pepin, Beatrice Leung, Billy Chieng, Bernard Balleine, Vincent Laurent
UNSW, School Of Psychology, Sydney, Australia

Aims: Outcome-specific predictions drive the accumulation of delta-opioid receptors (DOPR) on the membrane of cholinergic interneurons (CINs) in the nucleus accumbens shell (NAc-S) to promote choice between actions. Here, we aimed to provide decisive evidence that outcome-specific predictions control DOPR accumulation and to establish whether this control is mediated by projections from the basolateral amygdala (BLA) to the NAc-S. **Methods and Results:** We confirmed that outcome-specific predictions drive DOPR accumulation on NAc-S CINs and found that this accumulation can be removed by systemic administration of the DOPR agonist SNC80. Remarkably, DOPR accumulation was reinstated by a single session retraining the outcome-specific predictions, underscoring the causal relationship between these predictions and DOPR expression. To establish whether this relationship relies on the BLA→NAc-S pathway, we optically silenced this pathway during outcome-specific predictive learning and assessed the impact on subsequent choice between actions. BLA→NAc-S silencing abolished the traditional influence of outcome-specific predictions on choice between actions. In another experiment, we found that the same silencing had no effect when it was conducted at the time of choice. **Conclusions:** Taken together, these findings indicate that the BLA encodes outcome-specific predictions and drive DOPR accumulation on NAc-S CINs to guide choice between actions. However, they also show that the BLA does not control how this accumulation is then used to guide choice, suggesting that other brain regions may oversee this control

Basolateral Amygdala Drives a GPCR-Mediated Striatal Memory Necessary for Predictive Learning to Influence Choice.
Predictive learning exerts a powerful influence over choice between instrumental actions. Nevertheless, how this learning is encoded in a sufficiently stable manner to influence choices that can occur much later in time is unclear. Here, we report that the basolateral amygdala (BLA) encodes predictive learning and establishes the memory necessary for future choices by driving the accumulation of delta-opioid receptors (DOPRs) on the somatic membrane of cholinergic interneurons in the nucleus accumbens shell (NAc-S). We found that the BLA controls DOPR accumulation via its influence on substance P release in the NAc-S, and that although DOPR accumulation is not necessary for predictive learning per se, it is necessary for the influence of this learning on later choice between actions. This study uncovers, therefore, a novel GPCR-based form of memory that is established by predictive learning and is necessary for such learning to guide the selection and execution of specific actions.

Sphingosine-1-Phosphate Receptors Modulators Decrease Signs of Neuroinflammation and Prevent Parkinson's Disease Symptoms in the 1-Methyl-4-Phenyl-1,2,3,6-Tetrahydropyridine Mouse Model.
Sphingosine-1-phosphate (S1P) is a potent bioactive lipid mediator that acts as a natural ligand upon binding to five different receptors that are located in astrocytes, oligodendrocytes, microglial and neuronal cells. Recently, global activation of these receptors by FTY720 (fingolimod) has been suggested to provide neuroprotection in animal model of Parkinson's disease (PD). Among S1P receptors, the subtype 1 (S1P1R) has been linked to features of neuroprotection and, using the selective agonist SEW2871, the present investigation assessed potential benefits (and mechanisms) of this receptor subtype in an established animal model of PD. We demonstrated that oral treatments with SEW2871 are able to provide protection to the same levels as FTY720 against loss of dopaminergic neurons and motor deficits in the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) (30 mg/kg, i.p., 5 days) mouse model of PD. At the molecular level, we observed that the beneficial effects of both S1PR agonists were not associated with alterations in ERK and Akt levels, two markers of molecular adaptations in the striatum neurons. However, these compounds have the capacity to prevent signs of neuroinflammation such as the activation of astrocytes and glial cells, as well as MPTP-induced reduction of BDNF levels in key regions of the

brain implicated in motor functions. These findings suggest that selective S1P1R modulation has the ability to provide neuroprotection in response to MPTP neurotoxicity. Targeting S1P1R in PD therapy may represent a prominent candidate for treatment of this neurodegenerative conditions.

Motor learning deficits and striatal GSK-3 hyperactivity in Akt3 knockout mice.
Akt protein family (Akt1, Akt2 and Akt3) of serine/threonine kinases, also known as protein kinase B, are enzymes implicated in many physiological and pathological processes in the central nervous system. A striking feature of these enzymes is their ability to interact with several molecular targets such as the glycogen synthase kinase 3 (GSK-3). Among Akt isoforms, the Akt3 is significantly more expressed in the brain and the present investigation was designed to determine whether the Akt3/GSK-3 pathway plays a role in the learning of a complex motor skill. Using the accelerating rotarod task, known to reproduce different motor learning phases, we demonstrated in mouse models that genetic deletion of GSK-3α or GSK-3β had no effect on rotarod performances. However, Akt3 deletion robustly compromised rotarod learning when compared with wild-type animals. Biochemical analysis in the striatum revealed modifications in the levels of both phosphorylated GSK-3 and tau in Akt3-deficient mice, which are reminiscent of enhanced GSK-3 activity. In this line, we observed that both biochemical and motor learning impairments were prevented in Akt3-deficent mice by chronic treatments with lithium, a well-known GSK-3 inhibitor. Altogether, our findings raised the interesting possibility that interconnection between Akt3 and GSK-3 kinases is required in the learning of new complex motor tasks. GluN2B-containing NMDA receptors are upregulated in plasma membranes by the sphingosine-1-phosphate analog FTY720P.
Sphingosine-1-phosphate (S1P) is a ceramide derivative serving not only as a regulator of immune properties but also as a modulator of brain functions. To better understand the mechanism underlying the effects of S1P on brain functions, we investigated the potential impact of S1P receptor (S1PR) activation on NMDA receptor subunits. We used acute rat hippocampal slices as a model system, and determined the effects of the active phosphorylated S1P analog, fingolimod (FTY720P) on various NMDA receptors. Treatment with FTY720P significantly increased phosphorylation of GluN2B-containing NMDA receptors at Tyr1472. This effect appears rather specific, as treatment with FTY720P did not modify GluN2B-Tyr1336, GluN2B-Ser1480, GluN2A-Tyr1325 or GluN1-Ser897 phosphorylation. Pre-treatment of hippocampal slices with the compounds W146 and PP1 indicated that FTY720P-induced GluN2B phosphorylation at Tyr1472 epitopes was dependent on activation of S1PR subunit 1 (S1PR1) and Src/Fyn kinase, respectively. Cell surface biotinylation experiments indicated that FTY720P-induced GluN2B phosphorylation at Tyr1472 was also associated with increased levels of GluN1 and GluN2B subunits on membrane surface, whereas no change was observed for GluN2A subunits. We finally demonstrate that FTY720P is inclined to favor Tau and Fyn accumulation on plasma membranes. These results suggest that activation of S1PR1 by FTY720P enhances GluN2B receptor phosphorylation in rat hippocampal slices, resulting in increased levels of GluN1 and GluN2B receptor subunits in neuronal membranes through a mechanism probably involving Fyn and Tau.

CONTRIBUTIONS OF ORBITOFRONTAL CORTEX NEURONS TO CHOICE ABANDONMENT IN A DECISION CONFIDENCE TASK

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Paul Anderson[1], Michael Lagler[1], Ben-Orli Nathanson[1], Paul Masset[2], Torben Ott[3], Marta Solano Mateos[1], Romana Hauer[1], Adam Kepecs[4], Thomas Klausberger[1]
[1]Medical University of Vienna, Centre For Brain Research, Vienna, Austria, [2]Harvard University, Department Of Molecular And Cellular Biology & Center For Brain Science, Cambridge, United States of America, [3]Humboldt University of Berlin, Bernstein Centre For Computational Neuroscience, Berlin, Germany, [4]Washington University School of Medicine, Neuroscience & Psychiatry, St. Louis, United States of America

Effective decision-making requires not just resolving difficult choices but also knowing when to abandon a failed strategy. The orbitofrontal cortex (OFC) plays a key role in decision-making and has been shown to represent metacognitive computations such as post-decision confidence, i.e. the probability of being correct given the subjective evidence. How neural representations of decision confidence contribute to the determination to abandon or persevere with a choice is as yet unclear. Here we examined the activity of neurons in the OFC of rats, while they were performing an auditory choice task with a post-decision time investment option. After making their perceptual decision, animals had to wait for reward delivery delayed by a pseudo-random period. The time animals were willing to invest into waiting for an uncertain reward before abandoning their choice served as a post-decision measure of confidence We utilised high-density silicon probes to record cells throughout the deep layers of the OFC, using a function driven strategy to search for neurons that were specifically active during time investment periods. We coupled these recordings with an optogenetic tagging approach that allowed us to identify neurons that had specific distal projection targets. We recorded populations of OFC neurons with distinctive activity profiles that reflect different aspects of the waiting period commitment. The firing patterns of identified cells with projections to distal sub-cortical regions will be analysed to reveal how OFC neurons contribute to the decision to abandon a choice commitment.

Opposite effects of ketamine and deep brain stimulation on rat thalamocortical information processing.
Sensory and cognitive deficits are common in schizophrenia. They are associated with abnormal brain rhythms, including disturbances in γ frequency (30-80 Hz) oscillations (GFO) in cortex-related networks. However, the underlying anatomofunctional mechanisms remain elusive. Clinical and experimental evidence suggests that these deficits result from a hyporegulation of glutamate N-methyl-D-aspartate receptors. Here we modeled these deficits in rats with ketamine, a non-competitive N-methyl-D-aspartate receptor antagonist and a translational psychotomimetic substance at subanesthetic doses. We tested the hypothesis that ketamine-induced sensory deficits involve an impairment of the ability of the thalamocortical (TC) system to discriminate the relevant information from the baseline activity. Furthermore, we wanted to assess whether ketamine disrupts synaptic plasticity in TC systems. We conducted multisite network recordings in the rat somatosensory TC system, natural stimulation of the vibrissae and high-frequency electrical stimulation (HFS) of the thalamus. A single systemic injection of ketamine increased the amount of baseline GFO, reduced the amplitude of the sensory-evoked TC response and decreased the power of the sensory-evoked GFO. Furthermore, cortical application of ketamine elicited local and distant increases in baseline GFO. The ketamine effects were transient. Unexpectedly, HFS of the TC pathway had opposite actions. In conclusion, ketamine and thalamic HFS have opposite effects on the ability of the somatosensory TC system to discriminate the sensory-evoked response from the baseline GFO during information processing. Investigating the link between the state and function of the TC system may conceptually be a key strategy to design innovative therapies against neuropsychiatric disorders.

Acute administration of typical and atypical antipsychotics reduces EEG γ power, but only the preclinical compound LY379268 reduces the ketamine-induced rise in γ power.

A single non-anaesthetic dose of ketamine, a non-competitive NMDA receptor (NMDAR) antagonist with hallucinogenic properties, induces cognitive impairment and psychosis, and aggravates schizophrenia symptoms in patients. In conscious rats an equivalent dose of ketamine induces key features of animal models of acute psychosis, including hyperlocomotor activity, deficits in prepulse inhibition and gating of auditory evoked potentials, and concomitantly increases the power of ongoing spontaneously occurring gamma (30-80 Hz) oscillations in the neocortex. This study investigated whether NMDAR antagonist-induced aberrant gamma oscillations could be modulated by acute treatment with typical and atypical antipsychotic drugs. Extradural electrodes were surgically implanted into the skull of adult male Wistar rats. After recovery, rats were subcutaneously administered either clozapine (1-5 mg/kg, n=7), haloperidol (0.05-0.25 mg/kg; n=8), LY379268 (a preclinical agonist at mGluR2/3 receptors: 0.3-3 mg/kg; n=5) or the appropriate vehicles, and 30 min later received ketamine (5 mg/kg s.c.). Quantitative measures of EEG gamma power and locomotor activity were assessed throughout the experiment. All three drugs significantly reduced the power of baseline EEG gamma oscillations by 30-50%, an effect most prominent after LY379268, and all inhibited ketamine-induced hyperlocomotor activity. However, only pretreatment with LY379268 attenuated trough-to-peak ketamine-induced gamma hyperactivity. These results demonstrate that typical and atypical antipsychotic drugs acutely reduce cortical gamma oscillations, an effect that may be related to their clinical efficacy.

Effects of aberrant gamma frequency oscillations on prepulse inhibition.
Emerging literature implicates abnormalities in gamma frequency oscillations in the pathophysiology of schizophrenia, with hypofunction of N-methyl-D-aspartate (NMDA) receptors implicated as a key factor. Prepulse inhibition (PPI) is a behavioural measure of sensorimotor gating, which is disrupted in schizophrenia. We studied relationships between ongoing and sensory-evoked gamma oscillations and PPI using pharmacological interventions designed to increase gamma oscillations (ketamine, MK-801); reduce gamma oscillations (LY379268); or disrupt PPI (amphetamine). We predicted that elevating ongoing gamma power would lead to increased 'neural noise' in cortical circuits, dampened sensory-evoked gamma responses and disrupted behaviour. Wistar rats were implanted with EEG recording electrodes. They received ketamine (5 mg/kg), MK-801 (0.16 mg/kg), amphetamine (0.5 mg/kg), LY379268 (3 mg/kg) or vehicle and underwent PPI sessions with concurrent EEG recording. Ketamine and MK-801 increased the power of ongoing gamma oscillations and caused time-matched disruptions of PPI, while amphetamine marginally affected ongoing gamma power. In contrast, LY379268 reduced ongoing gamma power, but had no effect on PPI. The sensory gamma response evoked by the prepulse was reduced following treatment with all psychotomimetics, associating with disruptions in PPI. This was most noticeable following treatment with NMDA receptor antagonists. We found that ketamine and MK-801 increase ongoing gamma power and reduce evoked gamma power, both of which are related to disruptions in sensorimotor gating. This appears to be due to antagonism of NMDA receptors, since amphetamine and LY379268 differentially impacted these outcomes and possess different neuropharmacological substrates. Aberrant gamma frequency oscillations caused by NMDA receptor hypofunction may mediate the sensory processing deficits observed in schizophrenia.

Chronic administration of antipsychotics attenuates ongoing and ketamine-induced increases in cortical γ oscillations.
Noncompetitive N-methyl-d-aspartate receptor (NMDAr) antagonists can elicit many of the symptoms observed in schizophrenia in healthy humans, and induce a behavioural phenotype in animals relevant to psychosis. These compounds also elevate the power and synchrony of gamma (γ) frequency (30-80 Hz) neural oscillations. Acute doses of antipsychotic medications have been shown to reduce ongoing γ power and to inhibit NMDAr antagonist-mediated psychosis-like behaviour in rodents. This study aimed to investigate how a chronic antipsychotic dosing regimen affects ongoing cortical γ oscillations, and the electrophysiological and behavioural responses induced by the NMDAr antagonist ketamine. Male Wistar rats were chronically treated with haloperidol (0.25 mg/kg/d), clozapine (5 mg/kg/d), LY379268 (0.3 mg/kg/d) or vehicle for 28 d, delivered by subcutaneous (s.c.) osmotic pumps. Weekly electrocorticogram (ECoG) recordings were acquired. On day 26, ketamine (5 mg/kg, s.c.) was administered, and ECoG and locomotor activity were simultaneously measured. These results were compared with data generated previously following acute treatment with these antipsychotics. Sustained and significant decreases in ongoing γ power were observed during chronic administration of haloperidol (64%) or clozapine (43%), but not of LY379268 (2% increase), compared with vehicle. Acute ketamine injection concurrently increased γ power and locomotor activity in vehicle-treated rats, and these effects were attenuated in rats chronically treated with all three antipsychotics. The ability of haloperidol or clozapine to inhibit ketamine-induced elevation in γ power was not observed following acute administration of these drugs. These results indicate that modulation of γ power may be a useful biomarker of chronic antipsychotic efficacy.

Reduced susceptibility to induced seizures in the Neuroligin-3(R451C) mouse model of autism.
Epilepsy is a common comorbidity in patients with autism spectrum disorder (ASD) and several gene mutations are associated with both of these disorders. In order to determine whether a point mutation in the gene for the synaptic protein, Neuroligin-3 (Nlgn3, R451C), identified in patients with ASD alters seizure susceptibility, we administered the proconvulsant pentylenetetrazole (PTZ) to adult male Neuroligin-3(R451C) (NL3(R451C)) and wild type (WT) mice. It has previously been reported that NL3(R451C) mice show altered inhibitory GABAergic activity in brain regions relevant to epilepsy, including the hippocampus and somatosensory cortex. PTZ administration induces absence-seizures at low dose, and generalised convulsive seizures at higher dose. Susceptibility to absence seizures was examined by analysing the frequency and duration of spike-and-wave discharge (SWD) events and accompanying motor seizure activity induced by subcutaneous administration of low dosage (20 or 30mg/kg) PTZ. Susceptibility to generalised convulsive seizures was tested by measuring the response to high dosage (60mg/kg) PTZ using a modified Racine scale. There was no change in the number of SWD events exhibited by NL3(R451C) compared to WT mice following administration of both 20mg/kg PTZ (1.17±0.31 compared to 16.0±11.16 events/30min, NL3(R451C) versus WT, respectively) and 30mg/kg PTZ (7.5±6.54 compared with 27.8±19.9 events/30min, NL3(R451C) versus WT, respectively). NL3(R451C) mice were seizure resistant to generalised convulsive seizures induced by high dose PTZ compared to WT littermates (median latency to first >3s duration clonic seizure; 14.5min versus 7.25min, 95% CI: 1.625-2.375, p=0.0009, NL3(R451C) versus WT, respectively). These results indicate that the R451C mutation in the Nlgn3 gene, associated with ASD in humans, confers resistance to induced seizures, suggesting dysfunction of PTZ-sensitive GABAergic signalling in this mouse model of ASD.

Neuregulin 1 expression and electrophysiological abnormalities in the Neuregulin 1 transmembrane domain heterozygous mutant mouse.
The Neuregulin 1 transmembrane domain heterozygous mutant (Nrg1 TM HET) mouse is used to investigate the role of Nrg1 in brain function and schizophrenia-like behavioural phenotypes. However, the molecular alterations in brain Nrg1 expression that underpin the behavioural observations have been assumed, but not directly determined. Here we comprehensively characterise mRNA Nrg1 transcripts throughout development of the Nrg1 TM HET mouse. In addition, we investigate the regulation of high-frequency (gamma) electrophysiological oscillations in this mutant mouse to associate molecular changes in Nrg1 with a schizophrenia-relevant neurophysiological profile.

The N-Methyl d-Aspartate Glutamate Receptor Antagonist Ketamine Disrupts the Functional State of the Corticothalamic Pathway.
The non-competitive N-methyl d-aspartate glutamate receptor (NMDAR) antagonist ketamine elicits a brain state resembling high-risk states for developing psychosis and early stages of schizophrenia characterized by sensory and cognitive deficits and aberrant ongoing gamma (30-80 Hz) oscillations in cortical and subcortical structures, including the thalamus. The underlying mechanisms are unknown. The goal of the present study was to determine whether a ketamine-induced psychotic-relevant state disturbs the functional state of the corticothalamic (CT) pathway. Multisite field recordings were performed in the somatosensory CT system of the sedated rat. Baseline activity was challenged by activation of vibrissa-related prethalamic inputs. The sensory-evoked thalamic response was characterized by a short-latency (~4 ms) prethalamic-mediated negative sharp potential and a longer latency (~10 ms) CT-mediated negative potential. Following a single subcutaneous injection of ketamine (2.5 mg/kg), spontaneously occurring and sensory-evoked thalamic gamma oscillations increased and decreased in power, respectively. The power of the sensory-related gamma oscillations was positively correlated with both the amplitude and the area under the curve of the corresponding CT potential but not with the prethalamic potential. The present results show that the layer VI CT pathway significantly contributes in thalamic gamma oscillations, and they support the hypothesis that reduced NMDAR activation disturbs the functional state of CT and corticocortical networks.

Disentangling causal webs in the brain using functional magnetic resonance imaging: A review of current approaches.
In the past two decades, functional Magnetic Resonance Imaging (fMRI) has been used to relate neuronal network activity to cognitive processing and behavior. Recently this approach has been augmented by algorithms that allow us to infer causal links between component populations of neuronal networks. Multiple inference procedures have been proposed to approach this research question but so far, each method has limitations when it comes to establishing whole-brain connectivity patterns. In this paper, we discuss eight ways to infer causality in fMRI research: Bayesian Nets, Dynamical Causal

Modelling, Granger Causality, Likelihood Ratios, Linear Non-Gaussian Acyclic Models, Patel's Tau, Structural Equation Modelling, and Transfer Entropy. We finish with formulating some recommendations for the future directions in this area. Netw Neurosci, 2019; 3

Mesocorticolimbic dopamine transmission is believed to be a key modulator of goal-directed actions and reward processing through its action on dopaminoceptive neurons expressing either D1 (D1R) or D2 receptors (D2R) in the medial prefrontal cortex (mPFC) and the nucleus accumbens (NAc). Through chemogenetic approaches coupled with operant conditioning tasks, we demonstrated an implication of dopaminergic projections from the Ventral Tegmental Area together with a complex interplay between D1R- and D2R-expressing neurons of the mPFC and the NAc in the flexible expression of food-oriented action as well as in the motivation to obtain a palatable reward. In both structures, the activity of dopaminoceptive neurons is strongly regulated by the convergence of glutamatergic and dopaminergic inputs. Heteromers formed by dopaminergic and glutamatergic N-methyl-d-aspartate receptors (NMDAR) recently emerged as molecular coincidence detectors of these transmissions, notably in the context of psychostimulant-induced adaptations. We therefore asked whether these receptor complexes could play a role in physiological processing. Expression of heteromers was mapped in substructures of the striatum and mPFC with Proximity Ligation Assay. Blockade of D1R-NMDAR or D2R-NMDAR heteromerization in either the mPFC or the NAc through the local viral-mediated expression of interfering peptides induced alterations of discrete components of goal directed behaviors. These findings contribute to decipher the role of dopaminoceptive neurons in executive functions and support a key role of heteromers formed by dopamine and NMDA receptors in such processes.

[Aims] The medial prefrontal cortex is necessary for executing learned associations between visual stimuli and movement. This function is possibly supported by the presence of stimulus-driven activity specifically after learning, though it is unknown how this stimulus-driven activity develops across learning and what aspects of behavior it is linked to. [Methods] We performed longitudinal widefield calcium imaging of excitatory neurons across days while mice learned a visuomotor detection task. The task consisted of turning a wheel with the forelimbs in response to a single visual stimulus to receive a sucrose reward, which was successfully learned over the course of about one week. We monitored cortical responses to the task stimulus in both behavioral and passive contexts. [Results] We found that stimulus responses in the medial prefrontal cortex developed over the same time course as task learning. This stimulus activity was present during both the task and quiescent passive viewing, indicating that it was not tied to subsequent movement. Furthermore, both behavioral performance and medial prefrontal stimulus responses increased overnight rather than within training sessions, suggesting that training induces delayed plasticity. Neuropixels recordings revealed that the medial prefrontal stimulus response originates from both the secondary motor and anterior cingulate cortex, and the stimulus response was eliminated by visual cortical inactivation. [Conclusions] These results show that visual information is routed to the medial prefrontal cortex during visuomotor learning.

Striatal activity topographically reflects cortical activity.
The cortex projects to the dorsal striatum topographically to regulate behaviour, but spiking activity in the two structures has previously been reported to have markedly different relations to sensorimotor events. Here we show that the relationship between activity in the cortex and striatum is spatiotemporally precise, topographic, causal and invariant to behaviour. We simultaneously recorded activity across large regions of the cortex and across the width of the dorsal striatum in mice that performed a visually guided task. Striatal activity followed a mediolateral gradient in which behavioural correlates progressed from visual cue to response movement to reward licking. The summed activity in each part of the striatum closely and specifically mirrored activity in topographically associated cortical regions, regardless of task engagement. This relationship held for medium spiny neurons and fast-spiking interneurons, whereas the activity of tonically active neurons differed from cortical activity with stereotypical responses to sensory or reward events. Inactivation of the visual cortex abolished striatal responses to visual stimuli, supporting a causal role of cortical inputs in driving the striatum. Striatal visual responses were larger in trained mice than untrained mice, with no corresponding change in overall activity in the visual cortex. Striatal activity therefore reflects a consistent, causal and scalable topographical mapping of cortical activity.

Cortical State Fluctuations during Sensory Decision Making.
In many behavioral tasks, cortex enters a desynchronized state where low-frequency fluctuations in population activity are suppressed. The precise behavioral correlates of desynchronization and its global organization are unclear. One hypothesis holds that desynchronization enhances stimulus coding in the relevant sensory cortex. Another hypothesis holds that desynchronization reflects global arousal, such as task engagement. Here, we trained mice on tasks where task engagement could be distinguished from sensory accuracy. Using widefield calcium imaging, we found that performance-related desynchronization was global and correlated better with engagement than with accuracy. Consistent with this link between desynchronization and engagement, rewards had a long-lasting desynchronizing effect. To determine whether engagement-related state changes depended on the relevant sensory modality, we trained mice on visual and auditory tasks and found that in both cases desynchronization was global, including regions such as somatomotor cortex. We conclude that variations

in low-frequency fluctuations are predominately global and related to task engagement.

Aberrant Cortical Activity in Multiple GCaMP6-Expressing Transgenic Mouse Lines.
Transgenic mouse lines are invaluable tools for neuroscience but, as with any technique, care must be taken to ensure that the tool itself does not unduly affect the system under study. Here we report aberrant electrical activity, similar to interictal spikes, and accompanying fluorescence events in some genotypes of transgenic mice expressing GCaMP6 genetically encoded calcium sensors. These epileptiform events have been observed particularly, but not exclusively, in mice with Emx1-Cre and Ai93 transgenes, of either sex, across multiple laboratories. The events occur at >0.1 Hz, are very large in amplitude (>1.0 mV local field potentials, >10% df/f widefield imaging signals), and typically cover large regions of cortex. Many properties of neuronal responses and behavior seem normal despite these events, although rare subjects exhibit overt generalized seizures. The underlying mechanisms of this phenomenon remain unclear, but we speculate about possible causes on the basis of diverse observations. We encourage researchers to be aware of these activity patterns while interpreting neuronal recordings from affected mouse lines and when considering which lines to study.

Learning in the Rodent Motor Cortex.
The motor cortex is far from a stable conduit for motor commands and instead undergoes significant changes during learning. An understanding of motor cortex plasticity has been advanced greatly using rodents as experimental animals. Two major focuses of this research have been on the connectivity and activity of the motor cortex. The motor cortex exhibits structural changes in response to learning, and substantial evidence has implicated the local formation and maintenance of new synapses as crucial substrates of motor learning. This synaptic reorganization translates into changes in spiking activity, which appear to result in a modification and refinement of the relationship between motor cortical activity and movement. This review presents the progress that has been made using rodents to establish the motor cortex as an adaptive structure that supports motor learning.

Reorganization of corticospinal output during motor learning.
Motor learning is accompanied by widespread changes within the motor cortex, but it is unknown whether these changes are ultimately funneled through a stable corticospinal output channel or whether the corticospinal output itself is plastic. We investigated the consistency of the relationship between corticospinal neuron activity and movement through in vivo two-photon calcium imaging in mice learning a lever-press task. Corticospinal neurons exhibited heterogeneous correlations with movement, with the majority of movement-modulated neurons decreasing activity during movement. Individual cells changed their activity across days, which led to changed associations between corticospinal activity and movement. Unlike previous observations in layer 2/3, activity accompanying learned movements did not become more consistent with learning; instead, the activity of dissimilar movements became more decorrelated. These results indicate that the relationship between corticospinal activity and movement is dynamic and that the types of activity and plasticity are different from and possibly complementary to those in layer 2/3.

Parvalbumin-expressing interneurons linearly control olfactory bulb output.
In the olfactory bulb, odor representations by principal mitral cells are modulated by local inhibitory circuits. While dendrodendritic synapses between mitral and granule cells are typically thought to be a major source of this modulation, the contributions of other inhibitory neurons remain unclear. Here we demonstrate the functional properties of olfactory bulb parvalbumin-expressing interneurons (PV cells) and identify their important role in odor coding. Using paired recordings, we find that PV cells form reciprocal connections with the majority of nearby mitral cells, in contrast to the sparse connectivity between mitral and granule cells. In vivo calcium imaging in awake mice reveals that PV cells are broadly tuned to odors. Furthermore, selective PV cell inactivation enhances mitral cell responses in a linear fashion while maintaining mitral cell odor preferences. Thus, dense connections between mitral and PV cells underlie an inhibitory circuit poised to modulate the gain of olfactory bulb output.

Emergence of reproducible spatiotemporal activity during motor learning.
The motor cortex is capable of reliably driving complex movements yet exhibits considerable plasticity during motor learning. These observations suggest that the fundamental relationship between motor cortex activity and movement may not be fixed but is instead shaped by learning; however, to what extent and how motor learning shapes this relationship are not fully understood. Here we addressed this issue by using in vivo two-photon calcium imaging to monitor the activity of the same population of hundreds of layer 2/3 neurons while mice learned a forelimb lever-press task over two weeks. Excitatory and inhibitory neurons were identified by transgenic labelling. Inhibitory neuron activity was relatively stable and balanced local excitatory neuron activity on a movement-by-movement basis, whereas excitatory neuron activity showed higher dynamism during the initial phase of learning. The dynamics of excitatory neurons during the initial phase involved the expansion of the movement-related population which explored various activity patterns even during similar movements. This was followed by a refinement into a smaller population exhibiting reproducible spatiotemporal sequences of activity. This pattern of activity associated with the learned movement was unique to expert animals and not observed during similar movements made during the naive phase, and the relationship between neuronal activity and individual movements became more consistent with learning. These changes in population activity coincided with a transient increase in dendritic spine turnover in these neurons. Our results indicate that a novel and reproducible activity-movement relationship develops as a result of motor learning, and we speculate that synaptic plasticity within the motor cortex underlies the emergence of reproducible spatiotemporal activity patterns for learned movements. These results underscore the profound influence of learning on the way that the cortex produces movements.

Subtype-specific plasticity of inhibitory circuits in motor cortex during motor learning.
Motor skill learning induces long-lasting reorganization of dendritic spines, principal sites of excitatory synapses, in the motor cortex. However, mechanisms that regulate these excitatory synaptic changes remain poorly understood. Here, using in vivo two-photon imaging in awake mice, we found that learning-induced spine reorganization of layer (L) 2/3 excitatory neurons occurs in the distal branches of their apical dendrites in L1 but not in the perisomatic dendrites. This compartment-specific spine reorganization coincided with subtype-specific plasticity of local inhibitory circuits. Somatostatin-expressing inhibitory neurons (SOM-INs), which mainly inhibit distal dendrites of excitatory neurons, showed a decrease in axonal boutons immediately after the training began, whereas parvalbumin-expressing inhibitory neurons (PV-INs), which mainly inhibit perisomatic regions of excitatory neurons, exhibited a gradual increase in axonal boutons during training. Optogenetic enhancement and suppression of SOM-IN activity during training destabilized and hyperstabilized spines, respectively, and both manipulations impaired the learning of stereotyped movements. Our results identify SOM inhibition of distal dendrites as a key regulator of learning-related changes in excitatory synapses and the acquisition of motor skills.

PROBING PREFRONTAL CORTICAL SIGNALS DURING RISKY ECONOMIC DECISIONS IN MICE

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Antara Majumdar, Caitlin Ashcroft, Lauren Strickland, Anita Rominto, Simon Butt, Matthias Fritsche, Armin Lak

Economic decision making under risk – the process of selecting between options with different values and uncertain outcomes – concerns many aspects of our lives. Past studies have identified the prefrontal cortex (PFC) as one of the crucial brain regions for such decisions. These studies, however, could either record signals across the brain with coarse resolution (e.g. using fMRI) or acquire high-resolution readouts (e.g. using electrophysiology) but often only in select brain regions. Therefore, it is not known how the activity of neurons across different regions of PFC underlie risky economic decisions. To address this, we developed a novel two-alternative economic decision task in head-fixed mice, and employed high-density large-scale electrophysiological recordings to measure the activity of thousands of neurons across PFC during the task. In each trial, mice chose between visual stimuli associated with different size and probabilities of reward, akin to previous tasks in primates. We show that mice successfully perform the task, selecting stimuli with higher expected value. Moreover, we demonstrate that each mouse exhibits a consistent risk attitude; some showing strong risk-seeking while others exhibit risk-neutral behavior. Preliminary analyses of neural responses show rich neural representations across PFC during the task. In our ongoing analysis, we use regression models to examine the relationship between neuronal responses and key variables inferred from the behavioral data. Our work provides a platform for investigating neural bases of economic decision-making at a large scale and high spatial and temporal resolution.

A Conserved Requirement for During Male Germ Cell Cytoplasmic Remodeling.
Fbxo7 is the substrate-recognition subunit of an SCF-type ubiquitin E3 ligase complex. It has physiologically important functions in regulating mitophagy, proteasome activity and the cell cycle in multiple cell types, like neurons, lymphocytes and erythrocytes. Here, we show that in addition to the previously known Parkinsonian and hematopoietic phenotypes, male mice with reduced Fbxo7 expression are sterile. In these males, despite successful meiosis, nuclear elongation and eviction of histones from chromatin, the developing spermatids are phagocytosed by Sertoli cells during late spermiogenesis, as the spermatids undergo cytoplasmic remodeling. Surprisingly, despite the loss of all germ cells, there was no evidence of the symplast formation and cell sloughing that is typically associated with spermatid death in other mouse sterility models, suggesting that novel cell death and/or cell disposal mechanisms may be engaged in Fbxo7 mutant males. Mutation of the Fbxo7 ortholog, () also leads to sterility with germ cell death during cytoplasmic remodeling, indicating that the requirement for Fbxo7 at this stage is conserved. The phenotype was attributed to decreased levels of the proteasome regulator, DmPI31 and reduced proteasome activity. Consistent with the fly model, we observe a reduction in PI31 levels in mutant mice; however, there is no alteration in proteasome activity in whole mouse testes. Our results are consistent with findings that Fbxo7 regulates PI31 protein levels, and indicates that a defect at the late stages of spermiogenesis, possibly due to faulty spatial dynamics of proteasomes during cytoplasmic remodeling, may underlie the fertility phenotype in mice.

Noise-induced hearing loss alters hippocampal glucocorticoid receptor expression in rats.
Although the effects of intense noise exposure on the peripheral and central auditory pathway have been well characterized, its effects on non-classical auditory structures in the brain, such as the hippocampus, are less well understood. Previously, we demonstrated that noise-induced hearing loss causes a significant long-term reduction in hippocampal neurogenesis and cell proliferation. Given the known suppressive effects of stress hormones on neurogenesis, the goal of the present study was to determine if activation of the stress response is an underlying mechanism for the long-term reduction in hippocampal neurogenesis observed following noise trauma. To accomplish this, we monitored basal and reactive blood plasma levels of

the stress hormone corticosterone in rats for ten weeks following acoustic trauma, and quantified changes in hippocampal glucocorticoid and mineralocorticoid receptors. Our results indicate that long-term auditory deprivation does not cause a persistent increase in basal or reactive stress hormone levels in the weeks following noise exposure. Instead, we observed a greater decline in reactive corticosterone release in noise-exposed rats between the first and tenth week of sampling compared to control rats. We also observed a significant increase in hippocampal glucocorticoid receptor expression which may cause greater hippocampal sensitivity to circulating glucocorticoid levels and result in glucocorticoid-induced suppression of neurogenesis, as well as increased feedback inhibition on the HPA axis. No change in mineralocorticoid receptor expression was observed between control and noise exposed rats. These results highlight the adverse effect of intense noise exposure and auditory deprivation on the hippocampus.

DOPAMINERGIC COMPUTATIONS UNDERLYING LEARNING OF A PERCEPTUAL DECISION TASK FROM NAIVE TO EXPERT

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Dopamine signals across the striatum reflect a range of computations necessary for perceptual decision making. How these computations emerge when first learning to make perceptual decisions remains unclear. When training animals, experimenters typically start with an easy task and increase its difficulty as animals learn, making it hard to study longitudinal learning and its associated dopaminergic signatures. Here, we trained mice on a two-alternative visual decision making task that was difficult from the start and did not change across several weeks of experimentation. Throughout learning, we imaged dopamine release in three regions of dorsal striatum: anterior dorsomedial (aDMS), posterior dorsomedial (pDMS), and dorsolateral (DLS) striatum. In all these regions stimulus-locked dopamine release increased gradually over learning. The dopamine responses in both aDMS and pDMS developed over learning to scale by contralateral sensory evidence. However, aDMS and pDMS differed in that only pDMS dopamine release encoded contralateral sensory evidence in naive animals. DLS dopamine developed over learning to predominantly reflect expectation of reward irrespective of stimulus laterality. To formalize these findings, we are developing a computational framework that provides trial-by-trial trajectories of latent variables underlying the learning process (see Liebana Garcia et al. poster). By showing distinct signatures of learning in dopamine release across dorsal striatum, our findings reveal previously unknown diversity in dopaminergic computations during longitudinal learning under perceptual uncertainty.

Attentional modulation of neural entrainment to sound streams in children with and without ADHD.
To extract meaningful information from complex auditory scenes like a noisy playground, rock concert, or classroom, children can direct attention to different sound streams. One means of accomplishing this might be to align neural activity with the temporal structure of a target stream, such as a specific talker or melody. However, this may be more difficult for children with ADHD, who can struggle with accurately perceiving and producing temporal intervals. In this EEG study, we found that school-aged children's attention to one of two temporally-interleaved isochronous tone 'melodies' was linked to an increase in phase-locking at the melody's rate, and a shift in neural phase that aligned the neural responses with the attended tone stream. Children's attention task performance and neural phase alignment with the attended melody were linked to performance on temporal production tasks, suggesting that children with more robust control over motor timing were better able to direct attention to the time points associated with the target melody. Finally, we found that although children with ADHD performed less accurately on the tonal attention task than typically developing children, they showed the same degree of attentional modulation of phase locking and neural phase shifts, suggesting that children with ADHD may have difficulty with attentional engagement rather than attentional selection.

Apical length governs computational diversity of layer 5 pyramidal neurons.
Anatomical similarity across the neocortex has led to the common assumption that the circuitry is modular and performs stereotyped computations. Layer 5 pyramidal neurons (L5PNs) in particular are thought to be central to cortical computation because of their extensive arborisation and nonlinear dendritic operations. Here, we demonstrate that computations associated with dendritic Ca plateaus in mouse L5PNs vary substantially between the primary and secondary visual cortices. L5PNs in the secondary visual cortex show reduced dendritic excitability and smaller propensity for burst firing. This reduced excitability is correlated with shorter apical dendrites. Using numerical modelling, we uncover a universal principle underlying

the influence of apical length on dendritic backpropagation and excitability, based on a Na channel-dependent broadening of backpropagating action potentials. In summary, we provide new insights into the modulation of dendritic excitability by apical dendrite length and show that the operational repertoire of L5PNs is not universal throughout the brain.

Effects of auditory selective attention on neural phase: individual differences and short-term training.
How does the brain follow a sound that is mixed with others in a noisy environment? One possible strategy is to allocate attention to task-relevant time intervals. Prior work has linked auditory selective attention to alignment of neural modulations with stimulus temporal structure. However, since this prior research used relatively easy tasks and focused on analysis of main effects of attention across participants, relatively little is known about the neural foundations of individual differences in auditory selective attention. Here we investigated individual differences in auditory selective attention by asking participants to perform a 1-back task on a target auditory stream while ignoring a distractor auditory stream presented 180° out of phase. Neural entrainment to the attended auditory stream was strongly linked to individual differences in task performance. Some variability in performance was accounted for by degree of musical training, suggesting a link between long-term auditory experience and auditory selective attention. To investigate whether short-term improvements in auditory selective attention are possible, we gave participants 2 h of auditory selective attention training and found improvements in both task performance and enhancements of the effects of attention on neural phase angle. Our results suggest that although there exist large individual differences in auditory selective attention and attentional modulation of neural phase angle, this skill improves after a small amount of targeted training.

Dimension-selective attention as a possible driver of dynamic, context-dependent re-weighting in speech processing.
The contribution of acoustic dimensions to an auditory percept is dynamically adjusted and reweighted based on prior experience about how informative these dimensions are across the long-term and short-term environment. This is especially evident in speech perception, where listeners differentially weight information across multiple acoustic dimensions, and use this information selectively to update expectations about future sounds. The dynamic and selective adjustment of how acoustic input dimensions contribute to perception has made it tempting to conceive of this as a form of non-spatial auditory selective attention. Here, we review several human speech perception phenomena that might be consistent with auditory selective attention although, as of yet, the literature does not definitively support a mechanistic tie. We relate these human perceptual phenomena to illustrative nonhuman animal neurobiological findings that offer informative guideposts in how to test mechanistic connections. We next present a novel empirical approach that can serve as a methodological bridge from human research to animal neurobiological studies. Finally, we describe four preliminary results that demonstrate its utility in advancing understanding of human non-spatial dimension-based auditory selective attention.

NEURAL BASES OF DECISION MAKING: REINFORCEMENT, VARIABILITY AND EXPLORATION IN CHOICE BEHAVIOR

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Aims: Behaving in an unusual, variable, or unpredictable manner is a fundamental ability, observed even when animals repeatedly face the same situation, for instance in decision-making settings (exploration). Yet, the neural bases underlying such behavior are still poorly understood. The dopaminergic (DA) system encodes rewards value, reinforces the best options and makes us choose them more frequently (exploitation). This work aims to assess DA dynamics in exploratory goal-directed decisions. **Methods:** We designed a conditioning task where mice learn to perform sequences of binary choices to obtain rewards. Animals are rewarded for non-repetitive choice sequences (when they choose the target leading to higher sequence complexity). Neural correlates of choice strategy are assessed using tetrodes recordings in the Ventral Tegmental Area (VTA) and fiber photometry (DA sensor) in the Nucleus Accumbens (NAc) during the task. **Results:** We show that mice progressively increase their choice variability and use a random-like choice strategy (Belkaïd et al, 2020), which seems to rely on DA dynamics. Indeed, when rewards are certain (all choices are rewarded), VTA DA neurons activity encode next choice's value, but this encoding is impaired in our complexity rule. Moreover, electrophysiological recordings suggest an adaptive modulation of DA neurons activity during the task, while DA release in the NAc displays continuous computations of Reward Prediction Errors (RPE) to adapt choice strategy online. **Conclusions:** We show evidence of mice ability to generate and reinforce a random-like choice strategy. Preliminary results suggest the involvement of meso-limbic DA signaling in this exploratory strategy.

CONTEXTUAL MODULATION OF MESOSCALE FUNCTIONAL CONNECTIVITY

POSTER SESSION 02 - SECTION: THE NEURAL CIRCUITS OF DECISION-MAKING

Matthew Harvey, Adil Khan
King's College London, Mrc Centre For Developmental Neurobiology, London, United Kingdom

Cognitive flexibility involves rapidly modifying input-output mappings of brain-wide networks to achieve context-appropriate behaviour. While context-dependent changes in neural responses have been studied locally in various brain regions, it is not clear to what extent different contexts lead to changes in functional connectivity between brain regions. We sought to examine how functional connectivity between dorsal cortical regions was modulated while mice performed a context dependent decision making task. We imaged widefield calcium activity from the entire dorsal cortex of mice as they switched between two distinct contexts in an attention-switching task. Different task contexts were distinctly represented across multiple cortical areas with both increases and decreases in average activity levels, which could not be accounted for by overt movements. We obtained measures of cortex-wide functional connectivity from the correlations in neural activity across brain regions. Different task contexts were associated with widespread, systematic changes in functional connectivity patterns. While some regions showed uniform, cortex-wide changes in functional connectivity with changing context, the majority of regions showed a heterogenous distribution of increased and decreased functional connectivity distributed across different brain regions. During visual attention, visual and retrosplenial cortex showed the greatest increase in functional coupling to most other regions of the cortex. Finally, to validate correlation-based functional connectivity measures, we developed a causal approach using widefield calcium imaging during patterned optogenetic stimulation. Our results demonstrate that changes in mesoscale functional connectivity provide a substrate for flexibly rerouting information across brain-wide networks with changing contextual demands.

Reinforcement learning offers a conceptual framework of how agents can learn different tasks by promoting the actions that maximize expected reward. Learning, however, is often based on more abstract rules based on action or stimulus categories. Rules are thought to be represented in prefrontal circuits but the neural bases of rule learning are not well understood. Here, we developed a two-alternative auditory discrimination task in which rats had to categorize stimuli with various levels of evidence. The stimulus sequence included trial blocks generated with two different statistical rules: a tendency to repeat the previous stimulus category or a preference to alternate it. We fitted three reinforcement learning (RL) models based on (1) action values (Left versus Right), (2) sequence values (Left-Left vs Left-Right and Right-Right vs Right-Left) and (3) rule values (Repetition versus Alternation). Only the rule RL described behavior accurately. To assess the role of different brain areas in rule encoding, we photo-inhibited neural activity during the inter-trial-interval and found that inactivation of mPFC, the dorso medial striatum (DMS) and the auditory striatum tail decreased the impact of the rule value on the immediately subsequent choice while sparing the stimulus impact. Moreover, inactivation impaired the rule updating in illuminated trials affecting choices in several upcoming trials. Finally, DMS neural recordings showed that a significant fraction of neurons encoded the rule value provided by the RL model. Our results suggest that, similarly to model-free RL, rule reinforcement may involve reward-based strengthening of connections between the prefrontal cortex and the striatum.

Aims Inhibitory modulation of associative learning is crucial to healthy cognition. Impairment of inhibition can cause unchecked trains of associations to disturb thought processes, producing incoherence and impulsivity, as seen in various psychological disorders including schizophrenia and addiction. Neuromodulation in prelimbic (PL) versus infralimbic (IL) subregions of the medial prefrontal cortex has different effects in various cognitive tasks. We aim to investigate whether these subregions play dissociable roles in inhibitory learning. **Methods** We examined how bilateral PL or IL inactivation, using muscimol (GABA-A receptor agonist) micro-infusions compared to saline-controls, affected inhibitory learning in Wistar rats, using a within-subjects appetitive Pavlovian task (A+/AX-; Waite et al.,2021*,PhysiolBehav*). The task involved learning excitatory associations (rewarded presentations of stimulus A; micro-infusion-free), preceding inhibitory training (following micro-infusions) which introduced a non-rewarded compound of A with novel stimulus X (AX-). Learning required establishing X as a non-rewarded inhibitor of excitatory responding to A. Performance, measured by nose-pokes during stimulus presentation versus baseline responding, was analysed via mixed-factorial 2-Way-ANOVA (within-subjects factors: stimuli and task (1 session/day); between-subjects factor: micro-infusion group). **Results** Following excitatory training, the inhibitory discrimination was learned overall, with decreased responding to AX- vs A+. However, preliminary results (pre-histology) indicate that the IL group showed weaker discrimination than the PL and control groups. **Conclusions** PL and IL may contribute differently to inhibitory learning, as IL inactivation caused more impairment. Differences may reflect functionally dissociable components in cortico-striatal neurocircuitry, and the influence of dopaminergic modulation. Ongoing work is investigating effects of prefrontal D1-receptors on inhibitory learning.
