Electric stimulators with precise and reliable outputs are an indispensable part of electrophysiological research. From single cells to deep brain or neuromuscular tissue, there are diverse targets for electrical stimulation. Even though commercial systems are available, we state the need for a low-cost, high precision, functional, and modular (hardware, firmware, and software) current stimulation system with the capacity to generate stable and complex waveforms for pre-clinical research. The system presented in this study is a USB controlled 4-channel modular current stimulator that can be expanded and generate biphasic arbitrary waveforms with 16-bit resolution, high temporal precision (µs), and passive charge balancing: the

NES STiM (Neuro Electronic Systems Stimulator). We present a detailed description of the system's structural design, the controlling software, reliability test, and the pre-clinical studies [deep brain stimulation (DBS) in hemi-PD rat model] in which it was utilized. The NES STiM has been tested with MacOS and Windows operating systems. Interfaces to MATLAB source codes are provided. The system is inexpensive, relatively easy to build and can be assembled quickly. We hope that the NES STiM will be used in a wide variety of neurological applications such as Functional Electrical Stimulation (FES), DBS and closed loop neurophysiological research.

ENGAGEMENT AND STRATEGY: COMPLEMENTARY NEURAL CIRCUITS FOR SELF-DRIVEN SPEED AND ACCURACY CHANGES IN MACAQUES

POSTER SESSION 05 - SECTION: DECISION-MAKING

Alessandro Bongioanni[1], Nima Khalighinejad[1], Urs Schuffelgen[1], Nils Kolling[2], Matthew Rushworth[1]
[1]University of Oxford, Department Of Experimental Psychology, Oxford, United Kingdom, [2]University of Oxford, Department Of Psychiatry, Oxford, United Kingdom

Aims Quick decisions are prone to errors, leading to a trade-off between speed and accuracy. In different circumstances animals may chose a faster or more accurate approach; some strategies may be more adaptive depending on the value and difficulty of the current trial, and the richness of the environment. However, subjects may also break this trade-off and increase both speed and accuracy if they are highly motivated. Previous work identified the neural bases of instructed fast response preparation, but little is known about mechanisms influencing self-driven speed and accuracy adjustments. Methods Three macaques performed a binary decision task based on perceptual evidence accumulation with variable reward stakes and intertrial intervals, while in an MRI scanner. Each trial was characterised in a two-dimensional space: along the speed-accuracy trade-off (SAT) axis, trials went from fast-and-inaccurate to slow-and-accurate, and this captured most of the variance. On the perpendicular axis, trials varied from slow and inaccurate (low efficiency) to fast and accurate (high efficiency). We identified the neural correlates of future SAT and efficiency, measured several seconds before each trial. Results Activity in the macaque frontal pole predicted SAT changes, whereas activity in a network including habenula and thalamus predicted future efficiency. Moreover, the same areas mediated the effects of contextual factors such as reward received and reward at stake on self-driven behaviour changes. Conclusions We identified two dissociable neural circuits: a prefrontal one influencing cost-free strategic changes in speed-accuracy trade-off and a subcortical circuit driving costly variations in efficiency depending on animals' motivation.

ANTICIPATORY CODING OF ANXIETY IN THE VENTRAL HIPPOCAMPUS

POSTER SESSION 05 - SECTION: DECISION-MAKING

Konstantinos Koukoutselos, Stéphane Ciocchi
Universität Bern, Laboratory Of Systems Neuroscience, Department Of Physiology, Bern, Switzerland

Anxiety is an aversive mood reflecting the expectation of potential threats. The ventral hippocampus (vHip) is a key brain region for the genesis of anxiety responses. Recent studies have shown that anxiety is mediated by the recruitment of pyramidal neurons from the vHip (known as 'anxiety' neurons) targeting various limbic structures. Despite the function of the vHip in triggering emotional responses, whether the vHip also signals the anticipation of an anxiogenic experience remains elusive. We hypothesized that distinct vHip neuronal populations either reflect the direct experience of anxiety or its anticipation. To address this question, we developed a novel trial-based anxiety paradigm, the forced emotional shifting task (FEST), with sequential and separated exposure to an anxiogenic situation (an elevated, bright and open space) or a safe situation (closed and darker space). By performing *in vivo* single-unit recordings from the vHip of freely-moving mice during FEST, we identified both anxiety neurons as well as a distinct neuronal population with ramping activity in the safe configuration of FEST, suggestive of an anticipatory coding for anxiety. The activity of these anticipatory neurons intrinsically depended on the experience of anxiety, indicating that anticipatory neurons are not the mere result of novelty or time processing. Moreover, unpredictable time intervals impaired the formation of ramping/anticipatory neurons which associated with lower anxiety-related activity in vHip, suggestive of a functional interaction between anticipatory and anxiety neurons. Collectively, our results point to distinct neuronal populations within the vHip mediating anxiety or its anticipation.

RESOLVING DECISION-MAKING DURING EMOTIONAL CONFLICTS BY VENTRAL HIPPOCAMPAL CIRCUITS.

POSTER SESSION 05 - SECTION: DECISION-MAKING

Carlo Cerquetella, Stéphane Ciocchi
University of Bern, Laboratory Of Systems Neuroscience, Department Of Physiology, Bern, Switzerland

How the brain computes decisions to support adaptive behaviours under different demands is a long-standing question. Decision-making does not solely rely on cognitive judgements but is likewise influenced by internal states. The ventral hippocampus (vHip) is a higher-order cortical brain region critical for processing emotions such as anxiety. Here, we examined the influence of anxiety levels on decision-making while recording neuronal activity in the vHip and medial prefrontal cortex (mPFC) as mice performed decision-making tasks under emotional conflicts. We observed that the activity of vHip neurons was scaling according to anxiety levels with concomitant remapping of firing fields. This effect was modulated by trajectories with different anxiety levels but was not a mere reflection of novelty. We additionally identified vHip neurons with preferential ‘deliberating’ and ‘anxiety’ features as mice made decisions under emotional conflicts. Using selective optogenetic inhibition of vHip terminals in the mPFC, we showed that mice exhibited biased decision-making selectively during trials with higher emotional conflicts. Collectively, these results suggest that vHip circuits targeting mPFC mediate decision-making under emotional conflicts.

DIFFERENTIAL CODING OF ABSOLUTE AND RELATIVE VALUE IN THE DROSOPHILA BRAIN.

POSTER SESSION 05 - SECTION: DECISION-MAKING

Maria Villar[1], Miguel Pavao Delgado[2], Marie Amigo[1], Pedro Jacob[3], Nesrine Merabet[1], Anthony Pinot[4], Sophie Perry[3], Scott Waddell[3], Emmanuel Perisse[1]
[1]Institute of Functional Genomics, University of Montpellier, CNRS, Inserm, Neuroscience, Montpellier, France, [2]Friedrich Miescher Institute for Biomedical Research, Neuroscience, Basel, Switzerland, [3]Centre for Neural Circuits and Behaviour, University of Oxford, Dpag, Oxford, United Kingdom, [4]BioCampus Montpellier, University Of Montpellier, Cnrs, Inserm, Montpellier, France

Animals use prior experience to assign absolute (good or bad) and also relative (better or worse) value to new experience. These learned values guide appropriate later decision-making. While our understanding of how the dopaminergic system computes absolute value is relatively advanced, the mechanistic underpinnings of relative valuation are unclear. Here we reveal mechanisms of absolute and relative aversive valuation in *Drosophila*. Three types of punishment-sensitive dopaminergic neurons (DANs) drive intensity-scaled plasticity at their respective mushroom body output neuron (MBON) connections to code absolute aversive value. In contrast, by comparing current and previous aversive experiences the MBON-DAN network can code relative aversive value by recruiting a specific subtype of reward-coding DANs which assigns a ‘better than’ value to the lesser of two aversive experiences. This study therefore provides an important functional consequence of having opposing populations of DANs and illustrates how these can operate together as a system within the MB network to code and compare sequential aversive experience to learn relative aversive value.

MUSHROOM BODY OUTPUT NEURON 02 REGULATES THE TRANSITION FROM GOAL-DIRECTED ACTIONS TO HABITS IN DROSOPHILA

POSTER SESSION 05 - SECTION: DECISION-MAKING

Radostina Lyutova, Björn Brembs
University of Regensburg, Zoology - Neurogenetics, Regensburg, Germany

Goal-directed exploration of the environment allows an animal to learn about the relationships between stimuli and how the environment responds to its actions. In this goal-directed phase, animals can flexibly apply learned relationships to other contexts. However, flexibility usually implies a cost in time, together with higher cognitive and energetic costs. In contrast, the formation of habits ensures fast and efficient behaviors. The learning mechanisms that lead to flexible and efficient behaviors, respectively, interact with each other. During the early, goal-directed phase of such composite operant learning situations, the process that mediates learning about relations in the environment (world-learning) is known to inhibit the process that renders behaviors stereotypic and efficient (self-learning), presumably in order to prevent premature habit-formation. In humans, imbalance between flexible actions and habitual responses can be linked to neuropsychiatric diseases (OCD, drug addiction). We use the fruit fly *Drosophila* to study the interactions between world- and self-learning which mediate the transition mechanisms from goal-directed actions to habitual responses. In *Drosophila* goal-directed behavior inhibits habit formation at the level of the mushroom bodies (MB), such that inhibition of the MBs results in premature habit formation. Here, we present the identification of a single mushroom body output neuron responsible for mediating this highly adaptive interaction between the two learning systems.

Reward signaling in a recurrent circuit of dopaminergic neurons and peptidergic Kenyon cells.
Dopaminergic neurons in the brain of the Drosophila larva play a key role in mediating reward information to the mushroom bodies during appetitive olfactory learning and memory. Using optogenetic activation of Kenyon cells we provide evidence that recurrent signaling exists between Kenyon cells and dopaminergic neurons of the primary protocerebral anterior (pPAM) cluster. Optogenetic activation of Kenyon cells paired with odor stimulation is sufficient to induce appetitive memory. Simultaneous impairment of the dopaminergic pPAM neurons abolishes appetitive memory expression. Thus, we argue that dopaminergic pPAM neurons mediate reward information to the Kenyon cells, and in turn receive feedback from Kenyon cells. We further show that this feedback signaling is dependent on short neuropeptide F, but not on acetylcholine known to be important for odor-shock memories in adult flies. Our data suggest that recurrent signaling routes within the larval mushroom body circuitry may represent a mechanism subserving memory stabilization.

Rational design of inducible CRISPR guide RNAs for de novo assembly of transcriptional programs.
CRISPR-based transcription regulators (CRISPR-TRs) have transformed the current synthetic biology landscape by allowing specific activation or repression of any target gene. Here we report a modular and versatile framework enabling rapid implementation of inducible CRISPR-TRs in mammalian cells. This strategy relies on the design of a spacer-blocking hairpin (SBH) structure at the 5' end of the single guide RNA (sgRNA), which abrogates the function of CRISPR-transcriptional activators. By replacing the SBH loop with ligand-controlled RNA-cleaving units, we demonstrate conditional activation of quiescent sgRNAs programmed to respond to genetically encoded or externally delivered triggers. We use this system to couple multiple synthetic and endogenous target genes with specific inducers, and assemble gene regulatory modules demonstrating parallel and orthogonal transcriptional programs. We anticipate that this 'plug and play' approach will be a valuable addition to the synthetic biology toolkit, facilitating the understanding of natural gene circuits and the design of cell-based therapeutic strategies.

Potency of transgenic effectors for neurogenetic manipulation in Drosophila larvae.

Genetic manipulations of neuronal activity are a cornerstone of studies aimed to identify the functional impact of defined neurons for animal behavior. With its small nervous system, rapid life cycle, and genetic amenability, the fruit fly Drosophila melanogaster provides an attractive model system to study neuronal circuit function. In the past two decades, a large repertoire of elegant genetic tools has been developed to manipulate and study neural circuits in the fruit fly. Current techniques allow genetic ablation, constitutive silencing, or hyperactivation of neuronal activity and also include conditional thermogenetic or optogenetic activation or inhibition. As for all genetic techniques, the choice of the proper transgenic tool is essential for behavioral studies. Potency and impact of effectors may vary in distinct neuron types or distinct types of behavior. We here systematically test genetic effectors for their potency to alter the behavior of Drosophila larvae, using two distinct behavioral paradigms: general locomotor activity and directed, visually guided navigation. Our results show largely similar but not equal effects with different effector lines in both assays. Interestingly, differences in the magnitude of induced behavioral alterations between different effector lines remain largely consistent between the two behavioral assays. The observed potencies of the effector lines in aminergic and cholinergic neurons assessed here may help researchers to choose the best-suited genetic tools to dissect neuronal networks underlying the behavior of larval fruit flies.

Fetal Alcohol Spectrum Disorders (FASD) are characterized by a variety of cognitive and behavioral disorders, with intellectual, attentional, and executive impairments being the most reported. In clinical practice, the Intelligence Quotient (IQ) is rarely interpreted in this population because of a deemed too strong heterogeneity of the psychometric profile. We propose here an objective characterization of this heterogeneity and a differential analysis between global intellectual functioning and elementary reasoning, in a large retrospective monocentric sample of FASD. Using clinical and psychometric data (WISC 4th or 5th ed.) from 107 children with FASD, with or without fetal alcohol syndrome, we characterized intra-individual heterogeneity (inter-subtest/index variance or excessive difference at 10thp cutoff), searched for profile weaknesses (average at group level, frequency of anomalies at individual level), and specified intellectual functioning in terms of IQ and elementary reasoning (GAI, best reasoning subtest), in comparison to standardization norms and/or a Monte-Carlo simulated population of normalization. Patient performance was poorer than expected on all subtests, with significant weakness in digit memory, letter-number sequencing and coding, and a trend toward better verbal performance. We found no increase in inter-subtest variance or frequency of excessive inter-index differences, but a discordance between the assessment of global efficiency (IQ 32% borderline, 21% deficient) and that of elementary reasoning (12-23% borderline, 2-16% deficient). Our results, which question the notion of cognitive heterogeneity, point to attentional, executive, and procedural cognitive fragility, with strong global repercussions but most often preserving elementary reasoning in at least one modality.

Neuroimaging studies have suggested the ability to use the brain activity of a group of individuals to forecast the behavior of a larger independent group at the population level. The current study aimed to forecast the outcome of the digital media campaign using electroencephalography (EEG), eye-tracking, and behavioral measurements. During two studies, 2 groups of participants were exposed to banners, which were used in the real digital marketing campaign of a large food retailer. We calculated EEG, eye-tracking, and behavioral indexes obtained during participants' visual processing of the banners and investigated the relationship between them and the banners' aggregated efficiency calculated based on the decisions of 291,301 Internet users. The central beta/alpha ratio—an EEG-based engagement index—significantly correlated with the aggregated efficiency of banner advertisements. Our multiple linear regression models demonstrated that a combination of EEG and eye-tracking data better explained the market-level efficiency of banner advertisements than behavioral measurements. Overall, our results confirm those of prior studies in neuroforecasting field that the brain activity of a relatively small number of individuals can forecast the aggregate choice of a larger independent group of people.

Alcohol use represents a significant health concern, accounting for 4.5% of global disease burden. Only a small proportion of individuals develop persistent alcohol used disorder though. With current pharmacotherapies largely unsatisfying, discovering novel alternatives to prevent alcohol use disorder becomes a priority. Hence, identifying biological markers predicting vulnerability to develop excessive alcohol consumption may lead to real improvement of clinical care. Converging evidence suggests that gut microbiota is capable of influencing immunity, brain and behavior. We thus investigated gut microbiome and signs of peripheral inflammation in stressed rats exhibiting uncontrolled alcohol seeking behaviors defined as: 1)Inability to abstain during a signaled period of reward unavailability, 2)Increased motivation and 3)Persistent alcohol seeking despite aversive foot shocks. Compared to controls, rats exposed to chronic stress during adolescence exhibited impulsive, inattentive and disinhibited behaviors. After 33sessions of daily alcohol (10%weight/volume) self-administration, all rats were screened according to the 3criteria defined above. Majority of the vulnerable group was composed of stressed rats, and most of the resilient group was composed of controls, confirming that stress during adolescence increases the vulnerability to develop AUD-like behavior. All rats were then given access to 2sources of reward: 10%w/v ethanol and saccharine (0.2 %, 0.00625%, 0%), 2consecutive sessions for each concentration, during which stressed rats exhibited a clear-cut preference for alcohol compared to controls. Strikingly, we identify a long-lasting peripheral inflammation in stressed rats (CCL5, IL-4). Not only fecal microbiota transfer lowered stressed rats' preference for alcohol but it restored inflammation modulators levels to those observed in controls.

Depression is a disorder that is twice as common in women than in men, and there are sex differences in the symptomatology and treatment response to this disorder. Mesolimbic dopamine (DA) regulates effort-based decision-making and behavioral activation. Impairments in behavioral activation such as anergia are often seen in people with depression and are highly resistant to treatment. The role of DA in regulating behavioral activation has been extensively studied in male rodents, but little is known about female rodents.**Aims:** We studied the impact of Tetrabenazine (TBZ, a VMAT-2 inhibitor that depletes DA) in male and female CD1 mice on behavioral measures assessing different aspects of depressive-like behavior. Behavioral activation was analyzed using the Forced Swim Test, (FST), social withdrawal was assessed in a Social Interaction (SI) test, anxiety in the Dark and Light box (DL), and sucrose preference and consumption using the two bottle test.**Results:** TBZ increased immobility in the FST both in male and female mice, however it only reduced active behaviors such as climbing in male mice. TBZ did not affect anxiety (as time in the light compartment), SI (as time exploring the conspecific) or sucrose consumption and preference. The DAT blocker bupropion reversed the effect of TBZ in the FST in both sexes. However, the SERT blocker fluoxetine was only effective in female mice. **Conclusions:** These results confirm that DA is involved in behavioral activation. Pro-dopaminergic antidepressants may be able to improve impairments related to anergia, but not other aspects of depression, at least in male mice.

Complexities and paradoxes in understanding the role of dopamine in incentive motivation and instrumental action: Exertion of effort vs. anhedonia.
Instrumental behavior is a very complex and multifaceted process. Behavioral output during instrumental performance is influenced by a variety of factors, including associative conditioning, directional and activational aspects of motivation, affect, action selection and execution, and decision-making functions. Detailed assessments of instrumental behavior can focus on the temporal characteristics of instrumental behavior such as local frequency and response duration, and biophysical measures of response topography such as force output over time. Furthermore, engaging in motivated behavior can require exertion of effort and effort-based decision making. The present review provides an overview of research on the specific deficits in operant behavior induced by dopamine antagonism and depletion. Furthermore, it discusses research on effort-based decision making, and highlights the complexities and seeming paradoxes that are revealed when detailed analyses of operant behavior are conducted, and instrumental behavior is put in the context of factors such as primary or unconditioned food reinforcement, appetite, binge-like eating, and response choice. Although impairments in mesolimbic dopamine are sometimes labeled as being due to "anhedonia", a detailed deconstruction of the findings in this area of research point to a much more complex and nuanced picture of the role that dopamine plays in regulating instrumental behavior. Low doses of DA antagonists and accumbens dopamine depletions blunt the exertion of physical effort as measured by several different challenges in animal studies (e.g., lever pressing, barrier climbing, wheel running), and yet leave fundamental aspects of hedonic reactivity, food motivation, and reinforcement intact. Continued research on the specific features of instrumental behaviors that regulate the sensitivity to impaired dopamine transmission across a number of contexts is important for resolving some of the complexities that are evident in this area of inquiry. These investigations can also provide insights into psychomotor and motivational dysfunctions that are seen in neuropsychiatric conditions such as depression, schizophrenia, and Parkinson's disease.

Energizing effects of bupropion on effortful behaviors in mice under positive and negative test conditions: modulation of DARPP-32 phosphorylation patterns.
Motivational symptoms such as anergia, fatigue, and reduced exertion of effort are seen in depressed people. To model this, nucleus accumbens (Nacb) dopamine (DA) depletions are used to induce a low-effort bias in rodents tested on effort-based decision-making. We evaluated the effect of the catecholamine uptake blocker bupropion on its own, and after administration of tetrabenazine (TBZ), which blocks vesicular storage, depletes DA, and induces depressive symptoms in humans. Male CD1 mice were tested on a 3-choice-T-maze task that assessed preference between a reinforcer involving voluntary physical activity (running wheel, RW) vs. sedentary activities (sweet food pellet intake or a neutral non-social odor). Mice also were tested on the forced swim test (FST), two anxiety-related measures (dark-light box (DL), and elevated plus maze (EPM)). Expression of phosphorylated DARPP-32 (Thr34 and Thr75) was evaluated by immunohistochemistry as a marker of DA-related signal transduction. Bupropion increased selection of RW activity on the T-maze. TBZ reduced time running, but increased time-consuming sucrose, indicating an induction of a low-effort bias, but not an effect on primary sucrose motivation. In the FST, bupropion reduced immobility, increasing swimming and climbing, and TBZ produced the opposite effects. Bupropion reversed the effects of TBZ on the T-maze and the FST, and also on pDARPP32-Thr34 expression in Nacb core. None of these manipulations affected anxiety-related parameters. Thus, bupropion improved active behaviors, which were negatively motivated in the FST, and active behaviors that were positively motivated in the T-maze task, which has implications for using catecholamine uptake inhibitors for treating anergia and fatigue-like symptoms.

Impact of Fluoxetine on Behavioral Invigoration of Appetitive and Aversively Motivated Responses: Interaction With Dopamine Depletion.
Impaired behavioral activation and effort-related motivational dysfunctions like fatigue and anergia are debilitating treatment-resistant symptoms of depression. Depressed people show a bias towards the selection of low effort activities. To determine if the broadly used antidepressant fluoxetine can improve behavioral activation and reverse dopamine (DA) depletion-induced anergia, male CD1 mice were evaluated for vigorous escape behaviors in an aversive context (forced swim test, FST), and also with an exercise preference choice task [running wheel (RW)-T-maze choice task]. In the FST, fluoxetine increased active behaviors (swimming, climbing) while reducing passive ones (immobility). However, fluoxetine was not effective at reducing anergia induced by the DA-depleting agent tetrabenazine, further decreasing vigorous climbing and increasing immobility. In the T-maze, fluoxetine alone produced the same pattern of effects as tetrabenazine. Moreover, fluoxetine did not reverse tetrabenazine-induced suppression of RW time but it reduced sucrose intake duration. This pattern of effects produced by fluoxetine in DA-depleted mice was dissimilar from devaluing food reinforcement by pre-feeding or making the food bitter since in both cases sucrose intake time was reduced but animals compensated by increasing time in the RW. Thus, fluoxetine improved escape in an aversive context but decreased relative preference for active reinforcement. Moreover, fluoxetine did not reverse the anergic effects of DA depletion. These results have implications for the use of fluoxetine for treating motivational symptoms such as anergia in depressed patients.

Sex differences in lever pressing and running wheel tasks of effort-based choice behavior in rats: Suppression of high effort activity by the serotonin transport inhibitor fluoxetine.
Selective serotonin transport (SERT) inhibitors such as fluoxetine are the most commonly prescribed treatments for depression. Although efficacious for many symptoms of depression, motivational impairments such as psychomotor retardation, anergia, fatigue and amotivation are relatively resistant to treatment with SERT inhibitors, and these drugs have been reported to exacerbate motivational deficits in some people. In order to study motivational dysfunctions in animal models, procedures have been developed to measure effort-related decision making, which offer animals a choice between high effort actions leading to highly valued reinforcers, or low effort/low reward options. In the present studies, male and female rats were tested on two different tests of effort-based choice: a fixed ratio 5 (FR5)/chow feeding choice procedure and a running wheel (RW)/chow feeding choice task. The baseline pattern of choice differed across tasks for males and females, with males pressing the lever more than females on the operant task, and females running more than males on the RW task. Administration of the SERT inhibitor and antidepressant fluoxetine suppressed the higher effort activity on each task (lever pressing and wheel running) in both males and females. The serotonin receptor mediating the suppressive effects of fluoxetine is uncertain, because serotonin antagonists with different patterns of receptor selectivity failed to reverse the effects of fluoxetine. Nevertheless, these studies uncovered important sex differences, and demonstrated that the suppressive effects of fluoxetine on high effort activities are not limited to tasks involving food reinforced behavior or appetite

suppressive effects. It is possible that this line of research will contribute to an understanding of the neurochemical factors regulating selection of voluntary physical activity vs. sedentary behaviors, which could be relevant for understanding the role of physical activity in psychiatric disorders.

Preference for vigorous exercise versus sedentary sucrose drinking: an animal model of anergia induced by dopamine receptor antagonism.
Motivation has activational and directional components. Mesolimbic dopamine is critical for the regulation of behavioral activation and effort-related processes in motivated behaviors. Impairing mesolimbic dopamine function leads to fatigue and anergia, but leaves intact other aspects of reinforce seeking behaviors, such as the consummatory or hedonic component. In male Swiss mice, we characterized the impact of dopamine antagonism on the selection of concurrently presented stimuli that have different vigor requirements. We analyzed running wheel activity versus sucrose solution intake, typically used as a measure of anhedonia. Results are compared with data from nonconcurrent presentation to those stimuli. In the concurrent presentation experiment, control mice preferred to spend time running compared to sucrose intake. Dopamine antagonism shifted relative reinforcer preference, reducing time spent on the running wheel, but actually increasing time-consuming sucrose. Mice increased frequency of bouts for both reinforcers, suggesting that there was fatigue in the running wheel rather than aversion. Moreover, satiation or habituation by preexposing animals to both reinforcers did not shift preferences. In the nonconcurrent experiments, haloperidol reduced running wheel but had no impact on sucrose consumption. Dopamine antagonism did not change preference for sucrose or total volume consumed. Additional correlational analyses indicated that baseline differences in sucrose consumption were independent of baseline running or novelty exploration. Thus, dopamine antagonism seems to have anergic rather than anhedonic effects, and the concurrent presentation in this setting could be useful for assessing preferences based on effort requirements.

Preference for Exercise vs. More Sedentary Reinforcers: Validation of an Animal Model of Tetrabenazine-Induced Anergia.
Physical activities can have intrinsic motivational or reinforcing properties. The choice to engage in voluntary physical activity is undertaken in relation to the selection of other alternatives, such as sedentary behaviors, drugs, or food intake. The mesolimbic dopamine (DA) system plays a critical role in behavioral activation or exertion of effort, and DA antagonism or depletion induces anergia in effort-based decision-making tasks. However, little is known about the neural mechanisms underlying the decision-making processes that establish preferences for sedentary vs. activity-based reinforcers. In the present work with male CD1 mice, we evaluated the effect of tetrabenazine (TBZ), a DA-depleting agent, on a three-choice T-maze task developed to assess preference between reinforcers with different behavioral activation requirements and sensory properties [i.e., a running wheel (RW) vs. sweet pellets or a neutral nonsocial odor]. We also studied the effects of TBZ on the forced swim test (FST), which measures climbing and swimming in a stressful setting, and on anxiety tests [dark-light (DL) box and elevated plus maze (EPM)]. In the three-choice task, TBZ reduced time running in the wheel but increased time spent consuming sucrose, thus indicating reduced activation but relatively intact sucrose reinforcement. The effect of TBZ was not mimicked by motivational manipulations that change the value of the reinforcers, such as making the RW aversive or harder to move, food-restricting the animals, inducing a binge-like eating pattern, or introducing social odors. In the FST, TBZ decreased time climbing (most active behavior) and increased immobility but did not affect anxiety in the DL or EPM. These results indicate that the three-choice T-maze task could be useful for assessing DA modulation of preferences for exercise based on activation and effort requirements, differentiating those effects from changes in preference produced by altering physical requirements, food restriction state, and stress during testing.

Caffeine Modulates Food Intake Depending on the Context That Gives Access to Food: Comparison With Dopamine Depletion.
Caffeine is a methylxanthine consumed in different contexts to potentiate alertness and reduce fatigue. However, caffeine

can induce anxiety at high doses. Caffeine is also a minor psychostimulant that seems to act as an appetite suppressant, but there are also reports indicating that it could stimulate appetite. Dopamine also is involved in food motivation and in behavioral activation. In the present series of experiments, we evaluated the effects of acute administration of caffeine on food consumption under different access conditions. CD1 male adult mice had access to highly palatable food (50% sucrose) in a restricted but habitual context, under continuous or intermittent access as well as under anxiogenic, or effortful conditions. Caffeine (2.5-20.0 mg/kg) increased intake at the highest dose under familiar continuous and intermittent access. However, this high dose reduced food intake in the dark-light paradigm. In contrast, a dopamine-depleting agent, tetrabenazine (TBZ; 1.0-8.0 mg/kg) did not affect food intake in any of those experimental conditions. In the T-maze-barrier task that evaluates seeking and taking of food under effortful conditions, caffeine (10.0 mg/kg) decreased latency to reach the food, but did not affect selection of the high-food density arm that required more effort, or the total amount of food consumed. In contrast, TBZ (4.0 mg/kg) reduced selection of the high food density arm with the barrier, thus affecting amount of food consumed. Interestingly, a small dose of caffeine (5.0 mg/kg) was able to reverse the anergia-inducing effects produced by TBZ in the T-maze. These results suggest that caffeine can potentiate or suppress food consumption depending on the context. Moreover, caffeine did not change appetite, and did not impair orientation toward food under effortful conditions, but it rather helped to achieve the goal by improving speed and by reversing performance to normal levels when fatigue was induced by dopamine depletion.

Individual differences in the energizing effects of caffeine on effort-based decision-making tests in rats.
Motivated behavior is characterized by activation and high work output. Nucleus accumbens (Nacb) modulates behavioral activation and effort-based decision-making. Caffeine is widely consumed because of its energizing properties. This methylxanthine is a non-selective adenosine A/A receptor antagonist. Adenosine receptors are highly concentrated in Nacb. Adenosine agonists injected into Nacb, shift preference towards low effort alternatives. The present studies characterized effort-related effects of caffeine in a concurrent progressive ratio (PROG)/free reinforcer choice procedure that requires high levels of work output, and generates great variability among different animals. Male Sprague-Dawley rats received an acute dose of caffeine (2.5-20.0 mg/kg, IP) and 30 min later were tested in operant boxes. One group was food-restricted and had to lever pressed for high carbohydrate pellets, another group was non-food-restricted and lever pressed for a high sucrose solution. Caffeine (2.5 and 5.0 mg/kg) increased lever pressing in food-restricted animals that were already high responders. However, in non-restricted animals, caffeine (5.0 and 10.0 mg/kg) increased work output only among low responders. In fact, caffeine (10.0 and 20.0 mg/kg) in non-restricted animals, reduced lever pressing among high responders in the PROG task, and also in a different group of animals lever pressing in an easy task (fixed ratio 7 schedule) that uniformly generates high levels of responding. Caffeine did not modify sucrose preference or consumption under free access conditions. Thus, when animals do not have a homeostatic need, caffeine can help those not very intrinsically motivated to work harder for a more palatable reward. However, caffeine can disrupt performance of animals intrinsically motivated to work hard for a better reward.

Dopamine depletion shifts behavior from activity based reinforcers to more sedentary ones and adenosine receptor antagonism reverses that shift: Relation to ventral striatum DARPP32 phosphorylation patterns.
The mesolimbic dopamine (DA) system plays a critical role in behavioral activation and effort-based decision-making. DA depletion produces anergia (shifts to low effort options) in animals tested on effort-based decision-making tasks. Caffeine, the most consumed stimulant in the world, acts as an adenosine A/A receptor antagonist, and in striatal areas DA D and D receptors are co-localized with adenosine A and A receptors respectively. In the present work, we evaluated the effect of caffeine on anergia induced by the VMAT-2 inhibitor tetrabenazine (TBZ), which depletes DA. Anergia was evaluated in a three-chamber T-maze task in which animals can chose between running on a wheel (RW) vs. sedentary activities such as consuming sucrose or sniffing a neutral odor. TBZ-caffeine interactions in ventral striatum were evaluated using DARPP-32 phosphorylation patterns as an intracellular marker of DA-adenosine receptor interaction. In the T-maze, control mice spent more time running and much less consuming sucrose or sniffing. TBZ (4.0 mg/kg) reduced ventral striatal DA tissue levels as measured by HPLC, and also shifted preferences in the T-maze, reducing selection of the reinforcer that involved vigorous activity (RW), but increasing consumption of a reinforcer that required little effort (sucrose), at doses that had no effect on independent measures of appetite or locomotion in a RW. Caffeine at doses that had no effect on their own reversed the effects of TBZ on T-maze performance, and also suppressed TBZ-induced pDARPP-32(Thr34) expression as measured by western blot, suggesting a role for D-A interactions. These results support the idea that DA depletion produces anergia, but does not affect the primary motivational effects of sucrose. Caffeine, possibly by acting on A receptors in ventral striatum, reversed the DA depletion effects. It is possible that caffeine, like selective adenosine A2A antagonists, could have some

therapeutic benefit for treating effort-related symptoms.

Impulsivity is defined as acting on the spur of the moment in response to immediate stimuli. Two forms of impulsivity are impulsive action involving deficiency in response inhibition and impulsive choice referring to impairment in delayed gratification. Both forms of impulsivity are associated with many psychiatric disorders including addiction, ADHD and bipolar disorder. While impulse control disorders show moderate to high degrees of heritability, the genetics of impulsivity is not widely studied. We aimed to identify genes and pathways underlying impulsivity using a forward genetic screen of ENU-mutagenised zebrafish. We screened 102 families estimated to cover 7926 dominant and 3554 recessive alleles. We assessed impulsive action using a zebrafish version of 5-choice serial reaction time task. In this task, after the animal learns the association between a stimulus and a reward, a pre-stimulus interval is applied during which a premature response is recorded as a measure of impulsive action. We identified seven candidate families of which one has been further analysed revealing a heritable deficit in impulse control. The exome sequencing of the founder of the family identified 29 candidate mutations of which three are associated with ADHD in GWASs. Our next step is to identify causal mutation and underlying pathways using RNA sequencing. We demonstrated for the first time that a forward genetic screen of zebrafish for impulsivity could identify lines of potential translational relevance to human.

Background. Cholinergic interneurons are major regulators of striatal function and have the particularity to express both the vesicular acetylcholine transporter (VAChT) and the atypical type 3 vesicular glutamate transporter (VGLUT3). VGLUT3 allows cholinergic interneurons to communicate with glutamate as well as to increase acetylcholine vesicular stores by a mechanism named vesicular synergy. We previously reported an increased frequency of allelic variations of *SCL17A8* (encoding VGLUT3) in patients with severe substances use disorders (SUDs); notably of the missense polymorphism p.T8i. **Methods.** The genetic screening of *SCL17A8* mutation was replicated in new samples of patients. Patients with pT8i mutation were extensively phenotyped for cocaine-related disorders. In parallel, a mutant mouse line was generated to understand the molecular, cellular and behavioral impact of the pT8I variant. **Results.** Patients with pT8i allele showed significant increase in clinical severity. At a molecular level, in cellular and animal models, glutamate signaling was not modified by the pT8I allele. In contrast, vesicular synergy and acetylcholine release were severely blunted in VGLUT3$^{T8I/T8I}$ mice. Mutant mice also exhibited an uneven dopaminergic transmission in the dorsal striatum as well as an increased tendency to develop compulsive behaviors for drug or natural reward. Importantly, increasing ACh tone with donepezil in VGLUT3$^{T8I/T8I}$ mice reversed compulsive self-starvation observed in mutant mice. **Conclusions.** The current translational study shows that the VGLUT3-p.T8I mutation can be associated with SUDs and eating disorders. Common mechanisms between addiction and eating disorder could be targeted using cholinergic enhancement with donepezil.

Leveraging VGLUT3 Functions to Untangle Brain Dysfunctions.
Vesicular glutamate transporters (VGLUTs) were long thought to be specific markers of glutamatergic excitatory transmission. The discovery, two decades ago, of the atypical VGLUT3 has thoroughly modified this oversimplified view. VGLUT3 is strategically expressed in discrete populations of glutamatergic, cholinergic, serotonergic, and even GABAergic neurons. Recent reports show the subtle, but critical, implications of VGLUT3-dependent glutamate co-transmission and its roles in the regulation of diverse brain functions and dysfunctions. Progress in the neuropharmacology of VGLUT3 could lead to decisive

breakthroughs in the treatment of Parkinson's disease (PD), addiction, eating disorders, anxiety, presbycusis, or pain. This review summarizes recent findings on VGLUT3 and its vesicular underpinnings as well as on possible ways to target this atypical transporter for future therapeutic strategies.

Cholinergic dysfunction in the dorsal striatum promotes habit formation and maladaptive eating.
Dysregulation of habit formation has been recently proposed as pivotal to eating disorders. Here, we report that a subset of patients suffering from restrictive anorexia nervosa have enhanced habit formation compared with healthy controls. Habit formation is modulated by striatal cholinergic interneurons. These interneurons express vesicular transporters for acetylcholine (VAChT) and glutamate (VGLUT3) and use acetylcholine/glutamate cotransmission to regulate striatal functions. Using mice with genetically silenced VAChT (VAChT conditional KO, VAChTcKO) or VGLUT3 (VGLUT3cKO), we investigated the roles that acetylcholine and glutamate released by cholinergic interneurons play in habit formation and maladaptive eating. Silencing glutamate favored goal-directed behaviors and had no impact on eating behavior. In contrast, VAChTcKO mice were more prone to habits and maladaptive eating. Specific deletion of VAChT in the dorsomedial striatum of adult mice was sufficient to phenocopy maladaptive eating behaviors of VAChTcKO mice. Interestingly, VAChTcKO mice had reduced dopamine release in the dorsomedial striatum but not in the dorsolateral striatum. The dysfunctional eating behavior of VAChTcKO mice was alleviated by donepezil and by l-DOPA, confirming an acetylcholine/dopamine deficit. Our study reveals that loss of acetylcholine leads to a dopamine imbalance in striatal compartments, thereby promoting habits and vulnerability to maladaptive eating in mice.

Implication of dorsostriatal D3 receptors in motivational processes: a potential target for neuropsychiatric symptoms in Parkinson's disease.
Beyond classical motor symptoms, motivational and affective deficits are frequently observed in Parkinson's disease (PD), dramatically impairing the quality of life of patients. Using bilateral 6-hydroxydopamine (6-OHDA) lesions of the substantia nigra pars compacta (SNc) in rats, we have been able to reproduce these neuropsychiatric/non-motor impairments. The present study describes how bilateral 6-OHDA SNc lesions affect the function of the main striatal dopaminergic (DA) receptor subtypes. Autoradiography was used to measure the levels of striatal DA receptors, and operant sucrose self-administration and neuropharmacological approaches were combined to investigate the causal implication of specific DA receptors subtypes in the motivational deficits induced by a dorsostriatal DA denervation. We found that D3 receptors (DR) exclusively are down-regulated within the dorsal striatum of lesioned rats. We next showed that infusion of a DR antagonist (SB-277011A) in non-lesioned animals specifically disrupts preparatory, but not consummatory behaviors. Our findings reveal an unexpected involvement of dorsostriatal DR in motivational processes. They strongly suggest an implication of dorsostriatal DR in the neuropsychiatric symptoms observed in PD, highlighting this receptor as a potential target for pharmacological treatment.

Subthalamic deep brain stimulation differently alters striatal dopaminergic receptor levels in rats.
High-frequency stimulation (HFS) of the subthalamic nucleus (STN) is recognized as an effective treatment for the motor symptoms of Parkinson's disease (PD), but its mechanisms, particularly as concern dopaminergic transmission, remain unclear. The aim of this study was to evaluate changes in the expression of dopaminergic receptors (D1, D2, and D3 receptors) after prolonged (4 h) unilateral STN-HFS in anesthetized intact rats and rats with total dopaminergic denervation. We used [(3)H]SCH 23390, [(125)I]iodosulpride, and [(125)I]OH-PIPAT to assess the densities of D1R, D2R, and D3R, respectively, within different areas of the striatum-a major input structure of the basal ganglia-including the nucleus

accumbens. We found that STN-HFS increased D1 R levels in almost all of the striatal areas examined, in both intact and denervated rats. By contrast, STN-HFS led to a large decrease in D2 R and D3R levels, limited to the nucleus accumbens and independent of the dopaminergic state of the animals. These data suggest that the influence of STN-HFS on striatal D1 R expression may contribute to its therapeutic effects on motor symptoms, whereas its impact on D2R/D3 R levels in the nucleus accumbens may account for the neuropsychiatric side effects often observed in stimulated PD patients, such as postoperative apathy.

Pramipexole reverses Parkinson's disease-related motivational deficits in rats.
Recent evidence suggests that Parkinson's disease affects not only movement, but also cognitive and psychiatric functions. Among these nonmotor complications, apathy, which is defined as a lack of motivation and operationalized as a quantitative reduction in goal-directed behavior, may even precede motor impairments, disappearing with the introduction of dopaminergic (DA) therapies and possibly reappearing with its discontinuation, suggesting a causal role of DA. We recently developed a lesion-based model, with stereotaxic infusion of 6-hydroxydopamine (6-OHDA) into precise areas of the rat SNc or ventral tegmental area and showed, in several operant tasks, that a partial denervation of the nigrostriatal, but not of the mesocorticolimbic, DA system induced profound motivational deficits during instrumental action. We investigated the time course of the effects of nigrostriatal DA denervation on motivation in rats, by assessing the negative effect of SNc bilateral 6-OHDA infusion on preacquired operant behavior, and determining whether the induced deficits were sensitive to the introduction and withdrawal of a clinically relevant PD treatment, the DA D2/D3 receptor agonist, pramipexole (PRA). Partial nigrostriatal DA denervation was accompanied by a significant reduction in operant behavior. This deficit, indicative of a decrease in motivation, was fully reversed by PRA and reappeared after treatment withdrawal. This longitudinal preclinical study provides evidence for the implication of the DA nigrostriatal system in PD-associated apathy. Moreover, by showing a good isomorphy and predictive value, our model highlights the relevance of D2/D3 receptors as potential targets for alleviating apathy in PD.

High-frequency stimulation of the subthalamic nucleus modifies the expression of vesicular glutamate transporters in basal ganglia in a rat model of Parkinson's disease.
It has been suggested that glutamatergic system hyperactivity may be related to the pathogenesis of Parkinson's disease (PD). Vesicular glutamate transporters (VGLUT1-3) import glutamate into synaptic vesicles and are key anatomical and functional markers of glutamatergic excitatory transmission. Both VGLUT1 and VGLUT2 have been identified as definitive markers of glutamatergic neurons, but VGLUT 3 is also expressed by non glutamatergic neurons. VGLUT1 and VGLUT2 are thought to be expressed in a complementary manner in the cortex and the thalamus (VL/VM), in glutamatergic neurons involved in different physiological functions. Chronic high-frequency stimulation (HFS) of the subthalamic nucleus (STN) is the neurosurgical therapy of choice for the management of motor deficits in patients with advanced PD. STN-HFS is highly effective, but its mechanisms of action remain unclear. This study examines the effect of STN-HFS on VGLUT1-3 expression in different brain nuclei involved in motor circuits, namely the basal ganglia (BG) network, in normal and 6-hydroxydopamine (6-OHDA) lesioned rats.

ACTIVATING NEURONAL ENSEMBLES IN THE NUCLEUS ACCUMBENS ENHANCES COCAINE-CONDITIONED PLACE PREFERENCE

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Tawna Herrera, Kathryn Sandum
University of Wyoming, Pharmaceutical Sciences, Laramie, United States of America

Background: The nucleus accumbens core (NAcore) is a part of the basal ganglia which is involved in motivation, reward-seeking behavior, and reinforcement. Its activation plays a role in substance use disorder and relapse. Neuronal ensembles, i.e, a sparse network of neurons coactivated during a specific behavior, are linked to drug-seeking behavior that leads to relapse. However, whether these ensembles are sufficient for drug and reward seeking is not yet clear. Aims: We seek to establish whether activating the ensemble in the NAcore involved in seeking a reward is sufficient to produce seeking behavior. Methods: To test this, we first performed a cocaine conditioned place preference (CPP) with FosiCre x Ai14 genetically modified mice. CPP models cocaine seeking by exposing an animal to a choice between a drug-paired context and a neutral context. The mice were injected with a Cre- dependent Gq-DREADD (designer receptor exclusively activated by designer drug) virus in the NAcore to allow specific reactivation of the cocaine-seeking ensemble. Results: We found that specific activation of the cocaine-seeking ensemble via administration of clozapine-N-oxide significantly potentiated cocaine seeking. Conclusions: These results show the sufficiency of the cocaine-seeking ensemble in the NAcore to drive drug seeking and advance our understanding of substance use disorder and relapse.

A SELF-ADJUSTING PROGRESSIVE-SHOCK PROCEDURE TO INVESTIGATE RESISTANCE TO PUNISHMENT: CHARACTERIZATION IN MALE AND FEMALE RATS

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Stevenson Desmercières[1], Virginie Lardeux[1], Jean-Emmanuel Longueville[1], Leigh V. Panlilio[2], Nathalie Thiriet[1], Marcello Solinas[1]
[1]Inserm U1084, Lnec-university Of Poitiers, Poitiers, France, [2]NIDA-IRP, Real-world Assessment, Prediction, And Treatment Unit, Translational Addiction Medicine Branch, Baltimore, United States of America

Indifference to harmful consequences is one of the main characteristics of compulsive behaviors and addiction. Animal models of punishment that provide a rapid and effective measure of resistance to punishment could be critical for the investigation of mechanisms underlying this maladaptive behavior. Here, analogous to the progressive ratio (PR) procedure widely used to evaluate appetitive motivation as the response requirement is increased, we developed a self-adjusting progressive shock intensity (PSI) procedure that provides, within a single session, a PSI break point that quantifies the propensity to work for a reward in spite of receiving electric footshock that progressively increases in duration. In both male and female rats, the PSI breaking point was sensitive to 1) the hunger drive; and 2) changes in the qualitative, but not quantitative, incentive value of the reward. In systematic comparisons between PSI and PR procedures in the same rats, we found that both measures are sensitive to manipulations of motivational states, but they are not correlated, suggesting that they measure overlapping but distinct processes. This self-adjusting PSI procedure may represent a useful tool to investigate mechanisms underlying maladaptive behavior that persist in certain individuals despite harmful consequences.

ROLE OF DOPAMINE NEURONS IN INTER-INDIVIDUAL VARIABILITY DURING SOCIAL LABOR DIVISION TASK IN MICE

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Clément Solié, Robin Justo, Sophie Fayad, Fabio Marti, Tinaïg Le Borgne, Philippe Faure
CNRS - ESPCI - PSL Research, Brain Plasticity Unit, Paris, France

Individuals living in group have to adapt to the physical and social constraints of the environment. In that context, access to shared resources leads to the emergence of specific strategies, such as competition or cooperation and division of labor among individuals. To assess individual adaptation and inter-individual variability, we developed a task where mice are tracked continuously across several days in an environment where the food is accessible through a lever press. The lever and the food magazine are far apart and reachable by all the mice at any moment. When living in triads, different individual strategies emerge for food access. Interestingly, when mice are performing the task alone, different behaviors also appear illustrating that a same goal can be achieved in different manners, independently of social pressure. We aim at understanding the neuronal basis of these individual variations. Dopamine (DA) neurons of the ventral tegmental area (VTA) are known to be involved in social behaviors and decision making. We therefore hypothesized that VTA DA neurons play a major role in the different strategies observed in the social labor division task. We address this question using in-vivo electrophysiology in anesthetized mice and fiber photometry technique in freely behaving animals to record VTA DA activity in the different animals' profiles.

POOR ATTENTIONAL CONTROL AS A BIOMARKER OF VULNERABILITY TO NICOTINE ADDICTION IN MALE BUT NOT IN FEMALE MICE

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Maria-Carmen Medrano, Florence Darlot, Stephanie Caillé
INCIA CNRS UMR 5287 - Université de Bordeaux, Emotiv, Bordeaux, France

Tobacco addiction vulnerability is highly variable among smokers and between sexes; thus, the identification of biomarkers for nicotine addiction risk is vital. One property of nicotine is to increase attentional capacities. In fact, a recent study of our laboratory demonstrated that in male rats attentional abilities could predict motivation for nicotine self-administration. Our **aim** was to correlate interindividual and sex differences in attentional control in mice with their vulnerability to nicotine rewarding properties, a crucial step in the initiation of drug taking. **Methods**: Mice underwent the cued-Fixed Consecutive Number task (FCNcue) to examine their attentional control and the Conditioning Place Preference (CPP) for nicotine. **Results**: Mice showed wide heterogeneity in their attentional performances. As a group, males showed better attentional capacities than females. Acute administration of nicotine showed pro-cognitive effects in both sexes. However, while nicotine improved the performance of all males, it only enhanced attention in already good performer females. Principal component analysis using data from the FCNcue and the CPP, showed a link between preference for nicotine and poor attentional control in males but not in females. **Conclusion**: FCNcue allowed us to reveal interindividual variability and sex differences in attentional control in mice. Our multidimensional analysis show a sexual dichotomy for the effects of nicotine. In males, which are more sensitive to nicotine procognitive effects, poor attentional control is a risk factor to develop nicotine addiction. Whereas sensitivity to the procognitive effect of nicotine and poor attentional control are not risk factors to develop nicotine addiction in females

ANXIETY LEVELS AFTER VICARIOUS SOCIAL DEFEAT STRESS ARE ASSOCIATED WITH VULNERABILITY AND RESILIENCE TO COCAINE-INDUCED CONDITIONED PLACE PREFERENCE IN FEMALE MICE

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Maria Aguilar[1], Maria Martínez-Caballero[1], Claudia Calpe-López[1], Maria García-Pardo[2]
[1]University of Valencia, Psychobiology, Valencia, Spain, [2]University of Zaragoza, Psychology And Sociology, Teruel, Spain

Exposure to social defeat stress has been associated with enhanced vulnerability of male mice to the rewarding effects of cocaine, although some individuals are resilient to this effect. Our aim was to evaluate whether exposure to vicarious social defeat stress induces anxiety in the elevated plus maze (EPM) and increases the rewarding effects of cocaine in females. On PND 47, 50, 53 and 56, female C57BL/6 mice witnessed an episode of social defeat of a male of the same strain by an aggressive opponent mouse of the OF1 strain. A control group of females spent the same period of time in an empty cage. Both groups of females were tested in the EPM and in the conditioned place preference (CPP) paradigm with 1.5 mg/kg of cocaine (24 hours and 3 weeks after the last episode of repeated social defeat, respectively). Social stress reduced the percentage of time spent in the open arms of the elevated plus maze and increased the CPP score, but these effects were not significant. A subgroup of stressed mice acquired clear CPP and displayed anxiety in the EPM, while another subgroup was resilient to both effects of stress. These results suggest that the absence of short-term anxiety after stress predicts the subsequent resilience of female mice to the potentiating effects of stress on cocaine reward. EFFECTS OF COHOUSING MICE AND RATS ON STRESS LEVELS AND THE ATTRACTIVENESS OF DYADIC SOCIAL INTERACTION IN C57BL/6J AND CD1 MICE AND SPRAGUE DAWLEY RATS

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Gerald Zernig, Hussein Ghareh, Helena Berchtold
Medical University of Innsbruck, Pharmacology, Innsbruck, Austria

Rats may kill mice. Therefore it is standard practice in many research animal housing facilities – despite often very limited space - to separate mice from rats (i.e., the predators) to minimize stress for the mice. We tested the effect of cohousing on the stress levels of mice from either the C57BL/6J (BL6) or the CD1 strain and Sprague Dawley rats by quantifying their fecal corticosterone and metabolites (FCM) concentration and investigated how cohousing impacts a behavioral assay, i.e., conditioned place preference for mouse-mouse or rat-rat social interaction. Mice from the BL6 strain (but not CD1 mice) that were cohoused with rats had significantly increased FCM concentrations, indicative of higher stress levels. In contrast to their elevated stress levels, the attractiveness for contextual cues associated with mouse-mouse social interaction even increased in rat-cohoused mice, albeit nonsignificantly. Thus, cohousing BL6 mice and rats did not impair a behavior of BL6 mice that had proved to be sensitive to social factors, especially handling by humans, in our laboratory. Our findings suggest that the effect of cohousing rats and mice on their stress levels and behavior might be less clearcut than generally assumed and might be overriden by conditions that cannot be controlled, i.e., different deliveries. Our findings can help to use research animal housing resources more efficiently. Publication: Zernig, Ghareh, Berchtold, 2022, Biology (Basel) 11,291. NEUROPHYSIOLOGICAL CORRELATES OF SUB-DIMENSIONS OF ALCOHOL USE DISORDER IN RODENTS

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Ana Domi
University of Gothenburg, Department Of Pharmacology, Gothenburg, Sweden

Aim: Alcohol use disorder (AUD) is the most demanding area of unmet medical needs in psychiatry. Improving the predictive validity of AUD animal models is crucial to bring forward novel and effective medications. **Methods:** Based on the DSM-IV/5 diagnostic criteria, we used a multidimensional operant model to characterize an alcohol addiction prone phenotype in outbred Wistar rats combined with electrophysiological assessments. **Results:** In line with clinical studies rats as humans showed individual variability in the propensity to develop AUD that includes the motivation to seek for alcohol (crit1), increased effort to obtain the substance (crit 2) and continued alcohol drinking despite negative consequences (crit 3). Only a subset of rats met all the aforementioned criteria for AUD (3crit, AUD-prone phenotype), while a larger fraction was considered AUD-resilient (0 crit). In further analysis, by computing a Global Addiction Score (GAS) for each animal, we could establish that GAS correlated with animal distribution within the criteria. Compulsive alcohol seeking was encoded by specific neuronal changes within the basolateral amygdala (BLA), where both presynaptic and postsynaptic activity were depressed in the alcohol addiction-prone phenotype compared to the resilient phenotype. The latter did not differ in neuronal properties compared to water drinking controls. Ex vivo pharmacological manipulation of the BLA further indicated adaptations in mGluR2/3 signalling, specifically in the AUD prone phenotype. **Conclusion:** Our findings suggest that glutamatergic changes within the BLA might contribute to the vulnerability to develop AUD. The mGluR2/3 could thus represent an ideal pharmacological intervention for a target-phenotypic-based treatment in AUD.

Genetic deletion or pharmacological blockade of nociceptin/orphanin FQ receptors in the ventral tegmental area attenuates nicotine-motivated behaviour.
The nociceptin/orphanin FQ (N/OFQ)-nociceptin opioid-like peptide (NOP) receptor system is widely distributed in the brain and pharmacological activation of this system revealed therapeutic potential in animal models of substance use disorder. Studies also showed that genetic deletion or pharmacological blockade of NOP receptors confer resistance to the development of alcohol abuse. Here, we have used a genetic and pharmacological approach to evaluate the therapeutic potential of NOP antagonism in smoking cessation.

Targeting the Opioid Receptors: A Promising Therapeutic Avenue for Treatment in "Heavy Drinking Smokers".
Despite a general decline in tobacco use in the last decades, the prevalence of tobacco smoking in individuals with alcohol use disorder (AUD) remains substantial (45-50%). Importantly, the co-use of both substances potentiates the adverse effects, making it a significant public health problem. Substantial evidence suggests that AUD and Tobacco use disorder (TUD) may share common mechanisms. Targeting these mechanisms may therefore provide more effective therapy. Numerous studies describe a potential role of the endogenous opioid system in both AUD and TUD. Reviewing this literature, we aim to evaluate the efficacy of molecules that target the opioid system as promising therapeutic interventions for treating alcohol and tobacco co-use disorders.

Sub-dimensions of Alcohol Use Disorder in Alcohol Preferring and Non-preferring Rats, a Comparative Study.
Recent animal models of alcohol use disorder (AUD) are centered in capturing individual vulnerability differences in disease progression. Here, we used genetically selected Marchigian Sardinian alcohol-preferring (msP) and Wistars rats to apply a multidimensional model of AUD adapted from a previously described DSM-IV/DSM-5 multisymptomatic cocaine addiction model. As proof of concept, we hypothesized that msP rats, genetically selected for excessive drinking, would be more prone to develop dependence-like behavior compared to Wistars. Before exposure of animals to alcohol, we monitored basal

anxiety in the elevated plus maze (EPM). Animals were then trained in prolonged operant alcohol self-administration, consisting of 30-min daily sessions for 60 days in total. Each session consisted of two 10-min periods of alcohol reinforcement separated by 10-min interval of non-reinforcement. Following training, we applied three criteria of individual vulnerability for AUD: (1) persistence of lever pressing for alcohol when it was not available; (2) motivation for alcohol in a progressive ratio (PR) schedule of reinforcement; and (3) resistance to punishment when alcohol delivery was anticipated by a foot-shock (0.3 mA). We obtained four groups corresponding to the number of criteria met (0-3 crit). Rats in the 0crit and 1crit groups were characterized as resilient, whereas rats in the 2crit and 3crit groups were characterized as prone to develop a dependent-like phenotype. As predicted, the 2-3crit groups were enriched with msP rats while the 0-1crit groups were enriched in Wistar rats. In further analysis, we calculated the global addiction score (GAS) per subject by the sum of the normalized score (z-score) of each criterion. Results showed GAS was highly correlated with animal distribution within the 3 criteria. Specifically, GAS was negative in the 0-1crit groups, and positive in the 2-3crit groups. A positive correlation between basal anxiety and quantity of alcohol intake was detected in msP rats but not Wistars. In conclusion, we demonstrated that the 0/3criteria model is a suitable approach to study individual differences in AUD and that msP rats, selected for excessive-alcohol drinking, show a higher propensity to develop AUD compared to non-preferring Wistars.

Neurobiology of alcohol seeking behavior.
Alcohol addiction is a chronic relapsing brain disease characterized by an impaired ability to stop or control alcohol use despite adverse consequences. A main challenge of addiction treatment is to prevent relapse, which occurs in more than >50% of newly abstinent patients with alcohol disorder within 3 months. In people suffering from alcohol addiction, stressful events, drug-associated cues and contexts, or re-exposure to a small amount of alcohol trigger a chain of behaviors that frequently culminates in relapse. In this review, we first present the preclinical models that were developed for the study of alcohol seeking behavior, namely the reinstatement model of alcohol relapse and compulsive alcohol seeking under a chained schedule of reinforcement. We then provide an overview of the neurobiological findings obtained using these animal models, focusing on the role of opioids systems, corticotropin-release hormone and neurokinins, followed by dopaminergic, glutamatergic, and GABAergic neurotransmissions in alcohol seeking behavior.

Astrocytes modulate extracellular neurotransmitter levels and excitatory neurotransmission in dorsolateral striatum via dopamine D2 receptor signaling.
Astrocytes provide structural and metabolic support of neuronal tissue, but may also be involved in shaping synaptic output. To further define the role of striatal astrocytes in modulating neurotransmission we performed in vivo microdialysis and ex vivo slice electrophysiology combined with metabolic, chemogenetic, and pharmacological approaches. Microdialysis recordings revealed that intrastriatal perfusion of the metabolic uncoupler fluorocitrate (FC) produced a robust increase in extracellular glutamate levels, with a parallel and progressive decline in glutamine. In addition, FC significantly increased the microdialysate concentrations of dopamine and taurine, but did not modulate the extracellular levels of glycine or serine. Despite the increase in glutamate levels, ex vivo electrophysiology demonstrated a reduced excitability of striatal neurons in response to FC. The decrease in evoked potentials was accompanied by an increased paired pulse ratio, and a reduced frequency of spontaneous excitatory postsynaptic currents, suggesting that FC depresses striatal output by reducing the probability of transmitter release. The effect by FC was mimicked by chemogenetic inhibition of astrocytes using G-coupled designer receptors exclusively activated by designer drugs (DREADDs) targeting GFAP, and by the glial glutamate transporter inhibitor TFB-TBOA. Both FC- and TFB-TBOA-mediated synaptic depression were inhibited in brain slices pre-treated with the dopamine D2 receptor antagonist sulpiride, but insensitive to agents acting on presynaptic glutamatergic autoreceptors, NMDA receptors, gap junction coupling, cannabinoid 1 receptors, μ-opioid receptors, P2 receptors or GABA receptors. In conclusion, our data collectively support a role for astrocytes in modulating striatal neurotransmission and suggest that reduced transmission after astrocytic inhibition involves dopamine.

Downregulation of Synaptotagmin 1 in the Prelimbic Cortex Drives Alcohol-Associated Behaviors in Rats.
Alcohol addiction is characterized by persistent neuroadaptations in brain structures involved in motivation, emotion, and decision making, including the medial prefrontal cortex, the nucleus accumbens, and the amygdala. We previously reported that induction of alcohol dependence was associated with long-term changes in the expression of genes involved in neurotransmitter release. Specifically, Syt1, which plays a key role in neurotransmitter release and neuronal functions, was downregulated. Here, we therefore examined the role of Syt1 in alcohol-associated behaviors in rats.

Activation of PPARγ Attenuates the Expression of Physical and Affective Nicotine Withdrawal Symptoms through Mechanisms Involving Amygdala and Hippocampus Neurotransmission.
An isoform of peroxisome proliferator-activated receptors (PPARs), PPARγ, is the receptor for the thiazolidinedione class of anti-diabetic medications including pioglitazone. Neuroanatomical data indicate PPARγ localization in brain areas involved in drug addiction. Preclinical and clinical data have shown that pioglitazone reduces alcohol and opioid self-administration, relapse to drug seeking, and plays a role in emotional responses. Here, we investigated the behavioral effect of PPARγ manipulation on nicotine withdrawal in male Wistar rats and in male mice with neuron-specific PPARγ deletion (PPARγ) and their littermate wild-type (PPARγ) controls. Real-time quantitative RT-PCR and RNAscope hybridization assays were used for assessing the levels of expression and cell-type localization of PPARγ during nicotine withdrawal. Brain site-specific microinjections of the PPARγ agonist pioglitazone were performed to explore the role of this system on nicotine withdrawal at a neurocircuitry level. Results showed that activation of PPARγ by pioglitazone abolished the expression of somatic and affective nicotine withdrawal signs in rats and in (PPARγ) mice. This effect was blocked by the PPARγ antagonist GW9662. During early withdrawal and protracted abstinence, the expression of PPARγ increased in GABAergic and glutamatergic cells of the amygdala and hippocampus, respectively. Hippocampal microinjections of pioglitazone reduced the expression of the physical signs of withdrawal, whereas excessive anxiety associated with protracted abstinence was prevented by pioglitazone microinjection into the amygdala. Our results demonstrate the implication of the neuronal PPARγ in nicotine withdrawal and indicates that activation of PPARγ may offer an interesting strategy for smoking cessation. Smoking cessation leads the occurrence of physical and affective withdrawal symptoms representing a major burden to quit tobacco use. Here, we show that activation of PPARγ prevents the expression of both somatic and affective signs of nicotine withdrawal. At molecular levels results show that PPARγ expression increases in GABAergic cells in the hippocampus and in GABA- and glutamate-positive cells in the basolateral amygdala. Hippocampal microinjections of pioglitazone reduce the insurgence of the physical withdrawal signs, whereas anxiety linked to protracted abstinence is attenuated by pioglitazone injected into the amygdala. Our results demonstrate the implication of neuronal PPARγ in nicotine withdrawal and suggest that PPARγ agonism may represent a promising treatment to aid smoking cessation.

Further evidence for the involvement of the PPARγ system on alcohol intake and sensitivity in rodents.
Peroxisome Proliferator Activator receptors (PPARs) are intracellular receptors that function as transcription factors, which regulate specific metabolic and inflammatory processes. PPARs are broadly distributed in the body and are also expressed in the central nervous system, especially in areas involved in addiction-related behavioral responses. Recent studies support a role of PPARs in alcoholism and pioglitazone: a PPARγ agonist used for treatment of type 2 diabetes showed efficacy in reducing alcohol drinking, stress-induced relapse, and alcohol withdrawal syndrome in rats.

NOP receptor antagonism attenuates reinstatement of alcohol-seeking through modulation of the mesolimbic circuitry in male and female alcohol-preferring rats.
In patients suffering from alcohol use disorder (AUD), stress and environmental stimuli associated with alcohol availability are important triggers of relapse. Activation of the nociceptin opioid peptide (NOP) receptor by its endogenous ligand Nociceptin/Orphanin FQ (N/OFQ) attenuates alcohol drinking and relapse in rodents, suggesting that NOP agonists may be efficacious in treating AUD. Intriguingly, recent data demonstrated that also blockade of NOP receptor reduced alcohol drinking in rodents. To explore further the potential of NOP antagonism, we investigated its effects on the reinstatement of alcohol-seeking elicited by administration of the α2 antagonist yohimbine (1.25 mg/kg, i.p.) or by environmental conditioning factors in male and female genetically selected alcohol-preferring Marchigian Sardinian (msP) rats. The selective NOP receptor antagonist LY2817412 (0.0, 3.0, 10.0, and 30.0 mg/kg) was first tested following oral (p.o.) administration. We then investigated the effects of LY2817412 (1.0, 3.0, 6.0 µg/µl/rat) microinjected into three candidate mesolimbic brain regions: the ventral tegmental area (VTA), the central nucleus of the amygdala (CeA), and the nucleus accumbens (NAc). We found that relapse to alcohol seeking was generally stronger in female than in male rats and oral administration of LY2817412 reduced yohimbine- and cue-induced reinstatement in both sexes. Following site-specific microinjections, LY2817412 reduced yohimbine-induced reinstatement of alcohol-seeking when administered into the VTA and the CeA, but not in the NAc. Cue-induced reinstatement was suppressed only when LY2817412 was microinjected into the VTA. Infusions of LY2817412 into the VTA and the CeA did not alter saccharin self-administration. These results demonstrate that NOP receptor blockade prevents the reinstatement of alcohol-seeking through modulation of mesolimbic system circuitry, providing further evidence of the therapeutic potential of NOP receptor antagonism in AUD.

Inhibition of fatty acid amide hydrolase in the central amygdala alleviates co-morbid expression of innate anxiety and excessive alcohol intake.
Fatty acid amide hydrolase (FAAH) is an enzyme that prominently degrades the major endocannabinoid N-arachidonoylethanolamine (anandamide). Inhibition of this enzyme leads to increased anandamide levels in brain regions that modulate stress and anxiety. Recently, we found that genetically selected Marchigian Sardinian alcohol-preferring (msP) rats display hyperactive FAAH in amygdalar regions that was associated with increased stress sensitivity and a hyper-anxious phenotype. Our previous work has also demonstrated that msPs display an innate preference for and excessive consumption of alcohol, potentially reflecting a form of self-medication to gain relief from hyper-anxious states. Here, we expand on our previous work by microinjecting the selective FAAH inhibitor URB597 (vehicle, 0.03, 0.1 and 1.0 μg per rat) into the central amygdala (CeA) and basolateral amygdala in msP versus non-selected Wistar rats to evaluate the effects of localized FAAH inhibition on operant alcohol self-administration and restraint-induced anxiety using the elevated plus maze. Intra-CeA URB597 significantly reduced alcohol self-administration in msP but not in Wistar rats. Intra-basolateral amygdala URB597 also attenuated alcohol drinking in msPs, although the effect was less pronounced relative to CeA treatment. In contrast, control experiments administering URB597 into the ventral tegmental area produced no genotypic differences in drinking. We also found that URB597 treatment in the CeA significantly reduced the anxiogenic effects of restraint stress in msPs, although no effects were detected in Wistars. Dysregulation of FAAH regulated systems in the major output region of the amygdala may drive the propensity for co-morbid expression of anxiety and excessive alcohol use.

SEX-SPECIFIC ALTERATIONS IN δ OPIOID RECEPTOR EXPRESSION AND FUNCTION AFTER EARLY-LIFE ADVERSITY

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Sophia Levis[1], Matthew Birnie[1], Noriko Kamei[1], Tallie Baram[1], Stephen Mahler[2]
[1]UC Irvine, Anatomy & Neurobiology, Irvine, United States of America, [2]UC Irvine, Neurobiology & Behavior, Irvine, United States of America

Aims: Early life adversity (ELA) is associated with vulnerabilities to reward-related problems, such as opioid use disorder. To test the hypothesis that ELA perturbs the normal maturation and function of endogenous opioid systems, we employed a naturalistic model of ELA, in which bedding and nesting materials are limited during the first week of life, and examined the impacts of ELA on expression and function of opioid ligands and receptors and on opioid drug seeking behaviors. **Methods:** Adult rats were tested for aspects of opioid addiction-like behaviors including intravenous self-administration, extinction, reinstatement, and economic demand elasticity to measure consumption and motivation for opioids at changing costs following ELA. To gain insight into ELA-induced molecular changes, we employed RT-qPCR for a suite of molecular candidates in reward-related regions. Following on our intriguing findings, we pharmacologically manipulated endogenous opioid signaling during opioid self-administration to test the mechanism of ELA-enhanced opioid seeking. **Results:** ELA led to enhanced motivation for opioid drugs in female rats, in accord with our prior findings. RT-qPCR revealed a sex-specific, selective reduction in δ opioid receptor expression in amygdala and nucleus accumbens of female rats following ELA. Preliminary results from pharmacological manipulation of δ opioid receptors during opioid self-administration suggest a possible mechanism by which ELA may cause vulnerability to addiction. **Conclusions:** ELA causes enduring, sex-specific changes in δ opioid receptor expression, which may underlie the pro-addiction phenotype caused by ELA in female rats.

Developmental Trajectories of Anhedonia in Preclinical Models.
This chapter discusses how the complex concept of anhedonia can be operationalized and studied in preclinical models. It provides information about the development of anhedonia in the context of early-life adversity, and the power of preclinical models to tease out the diverse molecular, epigenetic, and network mechanisms that are responsible for anhedonia-like behaviors.Specifically, we first discuss the term anhedonia, reviewing the conceptual components underlying reward-related behaviors and distinguish anhedonia pertaining to deficits in motivational versus consummatory behaviors. We then describe the repertoire of experimental approaches employed to study anhedonia-like behaviors in preclinical models, and the progressive refinement over the past decade of both experimental instruments (e.g., chemogenetics, optogenetics) and conceptual constructs (salience, valence, conflict). We follow with an overview of the state of current knowledge of brain circuits, nodes, and projections that execute distinct aspects of hedonic-like behaviors, as well as neurotransmitters, modulators, and receptors involved in the generation of anhedonia-like behaviors. Finally, we discuss the special case of anhedonia that arises following early-life adversity as an eloquent example enabling the study of causality, mechanisms, and sex dependence of anhedonia.Together, this chapter highlights the power, potential, and limitations of using preclinical models to advance our understanding of the origin and mechanisms of anhedonia and to discover potential targets for its prevention and mitigation.

Neurodevelopmental origins of substance use disorders: Evidence from animal models of early-life adversity and addiction.
Addiction is a chronic relapsing disorder with devastating personal, societal, and economic consequences. In humans, early-life adversity (ELA) such as trauma, neglect, and resource scarcity are linked with increased risk of later-life addiction, but the brain mechanisms underlying this link are still poorly understood. Here, we focus on data from rodent models of ELA and addiction, in which causal effects of ELA on later-life responses to drugs and the neurodevelopmental mechanisms by which ELA increases vulnerability to addiction can be determined. We first summarize evidence for a link between ELA and

addiction in humans, then describe how ELA is commonly modeled in rodents. Since addiction is a heterogeneous disease with many individually varying behavioral aspects that may be impacted by ELA, we next discuss common rodent assays of addiction-like behaviors. We then summarize the specific addiction-relevant behavioral phenotypes caused by ELA in male and female rodents and discuss some of the underlying changes in brain reward and stress circuits that are likely responsible. By better understanding the behavioral and neural mechanisms by which ELA promotes addiction vulnerability, we hope to facilitate development of new approaches for preventing or treating addiction in those with a history of ELA.

The Developmental Origins of Opioid Use Disorder and Its Comorbidities.
Opioid use disorder (OUD) rarely presents as a unitary psychiatric condition, and the comorbid symptoms likely depend upon the diverse risk factors and mechanisms by which OUD can arise. These factors are heterogeneous and include genetic predisposition, exposure to prescription opioids, and environmental risks. Crucially, one key environmental risk factor for OUD is early life adversity (ELA). OUD and other substance use disorders are widely considered to derive in part from abnormal reward circuit function, which is likely also implicated in comorbid mental illnesses such as depression, bipolar disorder, and schizophrenia. ELA may disrupt reward circuit development and function in a manner predisposing to these disorders. Here, we describe new findings addressing the effects of ELA on reward circuitry that lead to OUD and comorbid disorders, potentially shared neural mechanisms. We discuss some of these OUD-related problems in both humans and animals. We also highlight the increasingly apparent, crucial contribution of biological sex in mediating the range of ELA-induced disruptions of reward circuitry which may confer risk for the development of OUD and comorbid neuropsychiatric disorders.

31822817: Levis SC, Bentzley BS, Molet J, Bolton JL, Perrone CR, Baram TZ, Mahler SV
On the early life origins of vulnerability to opioid addiction.
The origins and neural bases of the current opioid addiction epidemic are unclear. Genetics plays a major role in addiction vulnerability, but cannot account for the recent exponential rise in opioid abuse, so environmental factors must contribute. Individuals with history of early life adversity (ELA) are disproportionately prone to opioid addiction, yet whether ELA interacts with factors such as increased access to opioids to directly influence brain development and function, and cause opioid addiction vulnerability, is unknown. We simulated ELA in female rats and this led to a striking opioid addiction-like phenotype. This was characterized by resistance to extinction, increased relapse-like behavior, and, as in addicted humans, major increases in opioid economic demand. By contrast, seeking of a less salient natural reward was unaffected by ELA, whereas demand for highly palatable treats was augmented. These discoveries provide novel insights into the origins and nature of reward circuit malfunction that may set the stage for addiction.

Role of dopamine D-like receptors and their modulation by adenosine receptor stimulation in the reinstatement of methamphetamine seeking.
Previous work has demonstrated that dopamine and adenosine receptors are involved in drug-seeking behaviors, yet the pharmacological interactions between these receptors in methamphetamine (MA) seeking are not well characterized. The present studies examined the role of the dopamine D-like receptors in MA seeking and identified the interactive effects of adenosine receptor stimulation.

Innate immune signaling in the ventral tegmental area contributes to drug-primed reinstatement of cocaine seeking.
Cocaine addiction is a chronic relapsing disorder characterized by persistent perturbations to an organism's homeostatic processes that result in maladaptive drug seeking. Although considerable attention has been directed at the consequences of neuronal changes following chronic cocaine taking, few studies have examined the role of microglia, the brain's resident immune cells, following chronic cocaine administration. Toll-Like Receptor 4 (TLR4) is a molecular pattern receptor that recognizes pathogens, danger signals, and xenobiotics and induces proinflammatory signaling in the central nervous system. TLR4 is generally considered to be expressed primarily by microglia. Here, we used a rodent model of cocaine addiction to investigate the role of TLR4 in the ventral tegmental area (VTA) in cocaine seeking. Male Sprague-Dawley rats were trained to self-administer cocaine in daily 2-h sessions for 15days. Following self-administration, rats underwent extinction training and were tested in a drug-primed reinstatement paradigm. Pharmacological antagonism of TLR4 in the VTA using lipopolysaccharide from the bacterium Rhodobacter sphaeroides (LPS-RS) significantly reduced cocaine-primed reinstatement of drug seeking but had no effect on sucrose seeking. TLR4 activation within the VTA using the TLR4 activator, lipopolysaccharide, was sufficient to moderately reinstate cocaine seeking. We also assessed changes in proinflammatory cytokine expression in the VTA following cocaine self-administration. Cocaine self-administration increased the expression of

mRNA for the proinflammatory cytokine interleukin-1ß, but not tumor necrosis factor alpha, in the VTA. Pharmacological antagonism of the interleukin-1 receptor in the VTA reduced cocaine-primed drug seeking. These results are consistent with the hypothesis that chronic cocaine produces inflammatory signaling that contributes to cocaine seeking.

Adolescent caffeine consumption increases adulthood anxiety-related behavior and modifies neuroendocrine signaling.
Caffeine is a commonly used psychoactive substance and consumption by children and adolescents continues to rise. Here, we examine the lasting effects of adolescent caffeine consumption on anxiety-related behaviors and several neuroendocrine measures in adulthood. Adolescent male Sprague-Dawley rats consumed caffeine (0.3g/L) for 28 consecutive days from postnatal day 28 (P28) to P55. Age-matched control rats consumed water. Behavioral testing for anxiety-related behavior began in adulthood (P62) 7 days after removal of caffeine. Adolescent caffeine consumption enhanced anxiety-related behavior in an open field, social interaction test, and elevated plus maze. Similar caffeine consumption in adult rats did not alter anxiety-related behavior after caffeine removal. Characterization of neuroendocrine measures was next assessed to determine whether the changes in anxiety were associated with modifications in the HPA axis. Blood plasma levels of corticosterone (CORT) were assessed throughout the caffeine consumption procedure in adolescent rats. Adolescent caffeine consumption elevated plasma CORT 24h after initiation of caffeine consumption that normalized over the course of the 28-day consumption procedure. CORT levels were also elevated 24h after caffeine removal and remained elevated for 7 days. Despite elevated basal CORT in adult rats that consumed caffeine during adolescence, the adrenocorticotropic hormone (ACTH) and CORT response to placement on an elevated pedestal (a mild stressor) was significantly blunted. Lastly, we assessed changes in basal and stress-induced c-fos and corticotropin-releasing factor (Crf) mRNA expression in brain tissue collected at 7 days withdrawal from adolescent caffeine. Adolescent caffeine consumption increased basal c-fos mRNA in the paraventricular nucleus of the hypothalamus. Adolescent caffeine consumption had no other effects on the basal or stress-induced c-fos mRNA changes. Caffeine consumption during adolescence increased basal Crf mRNA in the central nucleus of the amygdala, but no additional effects of stress or caffeine consumption were observed in other brain regions. Together these findings suggest that adolescent caffeine consumption may increase vulnerability to psychiatric disorders including anxiety-related disorders, and this vulnerability may result from dysregulation of the neuroendocrine stress response system.
Psychoneuroendocrinology, 2016; 67
25328052: O'Neill CE, Levis SC, Schreiner DC, Amat J, Maier SF, Bachtell RK
Effects of adolescent caffeine consumption on cocaine sensitivity.
Caffeine is the most commonly used psychoactive substance, and consumption by adolescents has risen markedly in recent years. We identified the effects of adolescent caffeine consumption on cocaine sensitivity and determined neurobiological changes within the nucleus accumbens (NAc) that may underlie caffeine-induced hypersensitivity to cocaine. Male Sprague-Dawley rats consumed caffeine (0.3 g/l) or water for 28 days during adolescence (postnatal day 28-55; P28-P55) or adulthood (P67-P94). Testing occurred in the absence of caffeine during adulthood (P62-82 or P101-121). Cocaine-induced and quinpirole (D2 receptor agonist)-induced locomotion was enhanced in rats that consumed caffeine during adolescence. Adolescent consumption of caffeine also enhanced the development of a conditioned place preference at a sub-threshold dose of cocaine (7.5 mg/kg, i.p.). These behavioral changes were not observed in adults consuming caffeine for an equivalent period of time. Sucrose preferences were not altered in rats that consumed caffeine during adolescence, suggesting there are no differences in natural reward. Caffeine consumption during adolescence reduced basal dopamine levels and augmented dopamine release in the NAc in response to cocaine (5 mg/kg, i.p.). Caffeine consumption during adolescence also increased the expression of the dopamine D2 receptor, dopamine transporter, and adenosine A1 receptor and decreased adenosine A2A receptor expression in the NAc. Consumption of caffeine during adulthood increased adenosine A1 receptor expression in the NAc, but no other protein expression changes were observed. Together these findings suggest that caffeine consumption during adolescence produced changes in the NAc that are evident in adulthood and may contribute to increases in cocaine-mediated behaviors.

Role of adenosine receptor subtypes in methamphetamine reward and reinforcement.
The neurobiology of methamphetamine (MA) remains largely unknown despite its high abuse liability. The present series of studies explored the role of adenosine receptors on MA reward and reinforcement and identified alterations in the expression of adenosine receptors in dopamine terminal areas following MA administration in rats. We tested whether stimulating adenosine A1 or A2A receptor subtypes would influence MA-induced place preference or MA self-administration on fixed and progressive ratio schedules in male Sprague-Dawley rats. Stimulation of either adenosine A1 or A2A receptors significantly reduced the development of MA-induced place preference. Stimulating adenosine A1, but not A2A, receptors reduced MA

self-administration responding. We next tested whether repeated experimenter-delivered MA administration would alter the expression of adenosine receptors in the striatal areas using immunoblotting. We observed no change in the expression of adenosine receptors. Lastly, rats were trained to self-administer MA or saline for 14 days and we detected changes in adenosine A1 and A2A receptor expression using immunoblotting. MA self-administration significantly increased adenosine A1 in the nucleus accumbens shell, caudate-putamen and prefrontal cortex. MA self-administration significantly decreased adenosine A2A receptor expression in the nucleus accumbens shell, but increased A2A receptor expression in the amygdala. These findings demonstrate that MA self-administration produces selective alterations in adenosine receptor expression in the nucleus accumbens shell and that stimulation of adenosine receptors reduces several behavioral indices of MA addiction. Together, these studies shed light onto the neurobiological alterations incurred through chronic MA use that may aid in the development of treatments for MA addiction.

INVESTIGATING THE ROLE OF OXYTOCIN IN EARLY ADVERSITY-INDUCED VULNERABILITY TO REWARDING STIMULI

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Diana Munícchi[1,2], Camilla Mancini[3], Sebastian Luca D'Addario[1,2], Matteo Di Segni[1,2], Lucy Babicola[1], Rossella Ventura[1,2]

Early life experiences have the potential role to alter both the brain development and adult behavior. In particular, the formation of the attachment bond is crucial for well-being and mental health, and its disruption has been related to expression of several psychopathologies, such as addiction. Interestingly, oxytocin plays an important role in the formation of the attachment bond and dopaminergic system development, and alterations of oxytocin levels are involved in drug addiction. We have recently showed that an early manipulation (Repeated Cross Fostering, RCF) able to alter the mother-pups bond induces in C57 female mice a behavioral phenotype in adulthood characterized by increased vulnerability to cocaine effects. Given the role of oxytocin in both the formation of attachment bond and the neurobiological mechanisms underlying drug addiction, our aim is to investigate if RCF manipulation affects oxytocin levels that, in turn, are responsible for increased cocaine sensitivity in adulthood. Through ELISA and RT-PCR techniques, we demonstrated that RCF manipulation induces a reduction in both oxytocin and oxytocin receptor levels in the brain of C57 female mice at postnatal day (PND) 5. Moreover, restoring brain oxytocin levels through subcutaneous injection of oxytocin (20ul, 0.2 ng/ul) from PND1 to PND4, adult RCF females show reduced sensitivity for cocaine. These data indicate a critical role for oxytocin in increased sensitivity to cocaine induced by early adversity.

Early life adversity affecting the attachment bond alters ventral tegmental area transcriptomic patterning and behavior almost exclusively in female mice.
Early life experiences that affect the attachment bond formation can alter developmental trajectories and result in pathological outcomes in a sex-related manner. However, the molecular basis of sex differences is quite unknown. The dopaminergic system originating from the ventral tegmental area has been proposed to be a key mediator of this process. Here we exploited a murine model of early adversity (Repeated Cross Fostering, RCF) to test how interfering with the attachment bond formation affects the VTA-related functions in a sex-specific manner. Through a comprehensive behavioral screening, within the NiH RDoC framework, and by next-generation RNA-Seq experiments, we analyzed the long-lasting effect of RCF on behavioral and transcriptional profiles related to the VTA, across two different inbred strains of mouse in both sexes. We found that RCF impacted to an extremely greater extent VTA-related behaviors in females than in males and this result mirrored the transcriptional alterations in the VTA that were almost exclusively observed in females. The sexual dimorphism was conserved across two different inbred strains in spite of their divergent long lasting consequences of RCF exposure. Our data suggest that to be female primes a sub-set of genes to respond to early environmental perturbations. This is, to the best of our knowledge, the first evidence of an almost exclusive effect of early life experiences on females, thus mirroring the extremely stronger impact of precocious aversive events reported in clinical studies in women.

DIFFERENTIAL ROLE OF ROSTROMEDIAL TEGMENTAL NUCLEUS (RMTG) OUTPUTS IN FOOD INTAKE DURING AN OBESOGENIC DIET

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Florian Schoukroun, Katia Befort, Romain Bourdy
University of Strasbourg, Faculty Of Psychology, Laboratoire Des Neurosciences Cognitives Et Adaptatives (lnca), Strasboug, France

The rise of obesity prevalence represents a global public health issue. This phenomenon could be explained by a shift in our eating habits towards the consumption of palatable foods, rich in fat and sugar that are associated to a pleasurable sensation. The RMTg is a recently discovered mesencephalic inhibitory brain region projecting to the ventral tegmental area (VTA) and the lateral hypothalamus (LH), two structures involved in hedonic and homeostatic regulation of food intake. Our objective was to investigate the role of the RMTg, as well as the RMTg --> VTA and RMTg --> LH pathways in food intake regulation and associated locomotor behavior. We performed excitotoxic lesions of the RMTg and, in parallel, projection-specific lesions using a combination of viral vectors in rats. Animals were exposed to a 6-week free choice obesogenic diet (fat, 10% sucrose, water, chow). Palatable food was then removed for 4 weeks before a 24h re-access period. Food intake was measured daily, and locomotor activity was recorded at different steps. The RMTg global lesions durably affected sucrose and fat consumption throughout the diet and an increased locomotor activity was observed afterwards., Lesion of the RMTg--> VTA or the RMTg--> LH projections did not modify food intake during the diet. Interestingly, locomotor activity during the removal period and palatable food intake on the re-access day were differentially impacted by the lesions.Our results point towards a role for the RMTg in the control of palatable food intake within a feeding network including both the LH and VTA.

MATERNAL REWARD FOR DAM RATS: ROLE OF THE TAIL OF THE VENTRAL TEGMENTAL AND IMPACT ON OTHER DOPAMINE-RELATED BRAIN REGIONS

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Julia Lara Gutierrez Arroyo, Clara Pérez-Gozalbo, Manuela Barneo-Muñoz, Fernando Martínez-García, María José Sánchez-Catalán
Universitat Jaume I, Unitat Predepartamental De Medicina, Facultat De Ciències De La Salut, Castellón de la Plana, Spain

The tail of the ventral tegmental area (tVTA) or rostromedial tegmental nucleus, receives lateral habenula inputs and projects to midbrain dopamine neurons, both participating in learning processes predicting the outcomes of actions. Thus, the tVTA is in a critical location into prediction error pathways. Indeed, tVTA GABA neurons display electrophysiological inhibition or activation after reward and aversive stimuli, respectively, and their predictive cues. In the present study, we explored the tVTA contribution in the context of maternal behaviour and its association to dopamine-related brain regions, as lateral habenula, ventral tegmental area, nucleus accumbens and medial prefrontal cortex To this end, pregnant and virgin Sprague-Dawley female rats were housed in pairs. Following 4-5 days after delivery, rats underwent four conditioning sessions. During this period, female rats were separated 1h per day from their pups, which were reintroduced in the homecage in a specific context after separation. On the test day, only half of the females received their pups after separation, to explore the impact of pup-predicting cues on c-Fos expression. Our behavioural results revealed that maternal behaviour during the conditioning sessions was only displayed by lactating females, but not by virgin rats, although they were pup-sensitized. Moreover, we showed that pup-predicting cues induce higher c-Fos in the tVTA of lactating pup-deprived females compared to lactating non-pup deprived and to virgin females, suggesting a role of the tVTA in maternal reward prediction error. Moreover, we explored the possible tVTA impact on the recruitment of dopamine-related brain regions.

The impact of CD160 deficiency on alloreactive CD8 T cell responses and allograft rejection.
CD160 is a member of the immunoglobulin superfamily with a pattern of expression mainly restricted to cytotoxic cells. To assess the functional relevance of the HVEM/CD160 signaling pathway in allogeneic cytotoxic responses, exon 2 of the CD160 gene was targeted by CRISPR/Cas9 to generate CD160 deficient mice. Next, we evaluated the impact of CD160 deficiency in the course of an alloreactive response. To that aim, parental donor WT (wild-type) or CD160 KO (knock-out) T cells were adoptively transferred into non-irradiated semiallogeneic F1 recipients, in which donor alloreactive CD160 KO CD4 T cells and CD8 T cells clonally expanded less vigorously than in WT T cell counterparts. This differential proliferative response rate at the early phase of T cell expansion influenced the course of CD8 T cell differentiation and the composition of the effector T cell pool that led to a significant decreased of the memory precursor effector cells (MPECs) / short-lived effector cells (SLECs) ratio in CD160 KO CD8 T cells compared to WT CD8 T cells. Despite these differences in T cell proliferation and differentiation, allogeneic MHC class I mismatched (bm1) skin allograft survival in CD160 KO recipients was comparable to that of WT recipients. However, the administration of CTLA-4.Ig showed an enhanced survival trend of bm1 skin allografts in CD160 KO with respect to WT recipients. Finally, CD160 deficient NK cells were as proficient as CD160 WT NK cells in rejecting allogeneic cellular allografts or MHC class I deficient tumor cells. CD160 may represent a CD28 alternative costimulatory molecule for the modulation of allogeneic CD8 T cell responses either in combination with costimulation blockade or by direct targeting of alloreactive CD8 T cells that upregulate CD160 expression in response to alloantigen stimulation.

Postnatal Catch-Up Growth Programs Telomere Dynamics and Glucose Intolerance in Low Birth Weight Mice.
Low birth weight and rapid postnatal weight gain are independent predictors of obesity and diabetes in adult life, yet the molecular events involved in this process remain unknown. In inbred and outbred mice, this study examines natural

intrauterine growth restriction (IUGR) in relation to body weight, telomere length (TL), glucose tolerance, and growth factor gene (, , , , and) mRNA expression levels in the brain, liver, and muscle at 2- and 10 days of age and then at 3- and 9 months of age. At birth, ~15% of the animals showed IUGR, but by 3 and 9 months, half of these animals had regained the same weight as controls without IUGR (recuperated group). At 10 days, there was no difference in TL between animals undergoing IUGR and controls. However, by 3 and 9 months of age, the recuperated animals had shorter TL than the control and IUGR-non recuperated animals and also showed glucose intolerance. Further, compared to controls, and growth factor mRNA expression was lower in Day 2-IUGR mice, while and mRNA expression was higher in D10-IUGR animals. Moreover, at 3 months of age, only in the recuperated group were brain and liver , , , and expression levels higher than in the control and IUGR-non-recuperated groups. These data indicate that catch-up growth but not IUGR per se affects TL and glucose tolerance, and suggest a role in this latter process of insulin/insulin-like growth signaling pathway gene expression during early development.

D-Chiro-Inositol Treatment Affects Oocyte and Embryo Quality and Improves Glucose Intolerance in Both Aged Mice and Mouse Models of Polycystic Ovarian Syndrome.
Polycystic ovarian syndrome (PCOS) is the main cause of female infertility. It is a multifactorial disorder with varying clinical manifestations including metabolic/endocrine abnormalities, hyperandrogenism, and ovarian cysts, among other conditions. D--inositol (DCI) is the main treatment available for PCOS in humans. To address some of the mechanisms of this complex disorder and its treatment, this study examines the effect of DCI on reproduction during the development of different PCOS-associated phenotypes in aged females and two mouse models of PCOS. Aged females (8 months old) were treated or not (control) with DCI for 2 months. PCOS models were generated by treatment with dihydrotestosterone (DHT) on Days 16, 17, and 18 of gestation, or by testosterone propionate (TP) treatment on the first day of life. At two months of age, PCOS mice were treated with DCI for 2 months and their reproductive parameters analyzed. No effects of DCI treatment were produced on body weight or ovary/body weight ratio. However, treatment reduced the number of follicles with an atretic cyst-like appearance and improved embryo development in the PCOS models, and also increased implantation rates in both aged and PCOS mice. DCI modified the expression of genes related to oocyte quality, oxidative stress, and luteal sufficiency in cumulus-oocyte complexes (COCs) obtained from the aged and PCOS models. Further, the phosphorylation of AKT, a main metabolic sensor activated by insulin in the liver, was enhanced only in the DHT group, which was the only PCOS model showing glucose intolerance and AKT dephosphorylation. The effect of DCI in the TP model seemed mediated by its influence on oxidative stress and follicle insufficiency. Our results indicate that DCI works in preclinical models of PCOS and offer insight into its mechanism of action when used to treat this infertility-associated syndrome.

THE EFFECTS OF LPS-INDUCED NEUROINFLAMMATION AND AN MGLU2/3 RECEPTOR ANTAGONIST ON INTRACRANIAL SELF-STIMULATION REWARD IN MICE

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Anni-Maija Linden
University of Helsinki, Department Of Pharmacology, Faculty Of Medicine, Helsinki, Finland

Our aim was to elucidate how immune system activation induced by bacterial lipopolysaccharide (LPS) administration alters mouse reward-related behaviors. In addition, we analyzed how acute administration of the mGlu2/3 receptor antagonist LY341495 affects intracranial self-stimulation (ICSS). We used an operant ICSS method and adult C57Bl/6J male mice. A bipolar electrode was implanted into the lateral hypothalamus under anesthesia. After recovery, the mice were trained to self-stimulate the brain reward pathway by turning an operant wheel. After reaching a stable baseline stimulation threshold, the mice were treated with LPS (*E.coli* strain 0111:B4, Sigma; 0.5 mg/kg, i.p.) or saline and tested at different time points (4 h to 2 weeks). Several weeks later, the effect of a lower LPS dose (0.05 mg/kg, i.p.) was tested. Also, the effect of LY341495 (0.3-3 mg/kg, i.p.) on ICSS threshold was tested at 1 h and 24 h timepoints. Both doses of LPS acutely increased the stimulation threshold, the lower 0.05-mg/kg dose only at a 4-h time point. The 3-mg/kg dose of LY341495 increased the stimulation threshold, while lower doses had no significant effect on the threshold. In conclusion, C57Bl/6J mice appear to be suitable for ICSS studies by establishing a stable baseline stimulation threshold, showing sensitivity to aversive properties of acute LPS treatment. mGlu2/3 receptor antagonists may have acute aversive properties at high doses. SEX DIFFERENCES IN MOTIVATED BEHAVIOR: RODENT MODELS OF EFFORT-BASED DECISION-MAKING FOR SWEET REINFORCERS.

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Paula Matas-Navarro[1], Régulo Olivares-García[1], Andrea Martínez-Verdú[1], Carla Carratalà-Ros[1], John D. Salamone[2], Mercè Correa[1]
[1]UNIVERSITAT JAUME I, Area De Psicobiología, CASTELLON DE LA PLANA, Spain, [2]UNIVERSITY OF CONNECTICUT, Behavioral Neuroscience, Storrs, United States of America

The study of the neural and behavioral components of effort-based decision-making processes in motivated behavior has advanced in the last few decades mainly with studies using male rodent models. However, studies in female animals are still very limited. Aims: We evaluate adult CD1 male and female mice in behavioral activation and effort in tests of motivation. Some of these tests offer choices between several positive reinforcers that require different levels of effort (PROG/choice task and T-maze-RW-pellet-odor task). Sweet reinforcers such as high carbohydrate food or sucrose solutions, and voluntary wheel running were used to evaluate preference for sedentary reinforcers or behaviors that require high levels of activation. Results: Female mice are as active as males in the RW, and they also have a strong preference for the RW compared to more sedentary reinforcers in the T-maze. In the T-maze, females consume higher amounts of sucrose pellets than males under no-choice conditions, but also when they can choose between other reinforcers. In the operant task, males and females do not differ in preference for higher concentrations of sucrose under free concurrent presentation, but females consume higher amounts of the most preferred solution and also work harder to get access to the high concentration of sucrose. This difference between sexes increases when the task becomes more effort-demanding. Conclusions: Females are equally active in a RW and they have a strong preference for this reinforcing activity, but they consume more sucrose reinforcers, and therefore, work harder than males to get access to sucrose.

COMPARING THE INFLUENCE OF DIFFERENT MONOAMINE TRANSPORTERS ON FLEXIBLE FORAGING

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Raquel Pinacho[1], Emily Read[1], François Cinotti[1], Dario Sarra[2], Madalena Fonseca[3], Laura Grima[4], Thomas Akam[1], Mark Walton[1]
[1]University of Oxford, Department Of Experimental Psychology, Oxford, United Kingdom, [2]University of Oxford, Nuffield Department Of Clinical Neurosciences, Oxford, United Kingdom, [3]Wellcome Centre for Integrative Neuroimaging, Fmrib Centre, University Of Oxford, Oxford, United Kingdom, [4]HHMI Janelia Research Campus, Mechanistic Cognitive Neuroscience, Ashburn, VA, United States of America

Aims: Efficient monoamine signalling plays a key role in the regulation of adaptive decision making. However, previous experiments have tended to utilise tasks where one particular strategy – continued persistence or rapid flexibility, for example – is clearly more beneficial. By contrast, to harvest rewards efficiently in naturalistic environments, animals have to adjust how persistent or flexible to be based on the statistics of their environment. Therefore, we aimed to examine how pharmacological manipulation of monoamine signalling affects how mice respond to a changing foraging environment. **Methods:** Adult DAT-ires-Cre mice (n=18) were trained in an operant foraging task in which both local richness (reward rate within each patch) and global richness (time to travel to a new patch) were manipulated. Once trained, mice were tested after serotonin (SERT), dopamine (DAT) or noradrenaline (NET) transporter blockade (citalopram, 10 mg/kg; GBR12909, 6 mg/kg; or atomoxetine,1 mg/kg respectively), as well as after administration of 5-HT2a (MDL100907, 1 mg/kg) or 2c (SB242084, 0.5 mg/kg) antagonists, following a Latin square, within-subject design. **Results:** Both SERT and DAT, but not NET blockade, increased the time spent foraging within each patch. However, while DAT blockade generally increased patch persistence, the effect of SERT blockade was modulated by local richness, an effect also observed following 5-HT2a blockade. Ongoing work is aimed at understanding these changes by simulating behaviour using foraging models. **Conclusions:** Increasing the availability of synaptic serotonin and dopamine have complementary but distinct effects on foraging patience and persistence.

Calcium-binding proteins are altered in the cerebellum in schizophrenia.
Alterations in the cortico-cerebellar-thalamic-cortical circuit might underlie the diversity of symptoms in schizophrenia. However, molecular changes in cerebellar neuronal circuits, part of this network, have not yet been fully determined. Using LC-MS/MS, we screened altered candidates in pooled grey matter of cerebellum from schizophrenia subjects who committed suicide (n = 4) and healthy individuals (n = 4). Further validation by immunoblotting of three selected candidates was performed in two cohorts comprising schizophrenia (n = 20), non-schizophrenia suicide (n = 6) and healthy controls (n = 21). We found 99 significantly altered proteins, 31 of them previously reported in other brain areas by proteomic studies. Transport function was the most enriched category, while cell communication was the most prevalent function. For validation, we selected the vacuolar proton pump subunit 1 (VPP1), from transport, and two EF-hand calcium-binding proteins, calmodulin and parvalbumin, from cell communication. All candidates showed significant changes in schizophrenia (n = 7) compared to controls (n = 7). VPP1 was altered in the non-schizophrenia suicide group and increased levels of parvalbumin were linked to antipsychotics. Further validation in an independent cohort of non-suicidal chronic schizophrenia subjects (n = 13) and non-psychiatric controls (n = 14) showed that parvalbumin was increased, while calmodulin was decreased in schizophrenia. Our findings provide evidence of calcium-binding protein dysregulation in the cerebellum in schizophrenia, suggesting an impact on normal calcium-dependent synaptic functioning of cerebellar circuits. Our study also links VPP1 to suicide behaviours, suggesting a possible impairment in vesicle neurotransmitter refilling and release in these phenotypes.

Differential regulation of the TLR4 signalling pathway in post-mortem prefrontal cortex and cerebellum in chronic schizophrenia: Relationship with SP transcription factors.

Alterations in innate immunity may underlie the pathophysiology of schizophrenia (SZ). Toll-like receptor-4 (TLR4) is a master element of innate immunity. The specificity proteins (SPs), transcription factors recently implicated in SZ, are putative regulatory agents of this. This work was aimed at describing alterations in the TLR4 signalling pathway in postmortem brain prefrontal cortex (PFC) and cerebellum (CB) of 16 chronic SZ patients and 14 controls. The possible association of TLR4 pathway with SP1 and SP4 and SZ negative symptomatology is explored. In PFC, TLR4/myeloid differentiation factor 88 (MyD88)/inhibitory subunit of nuclear factor kappa B alpha (IκBα) protein levels were lower in SZ patients, while nuclear transcription factor-κB (NFκB) activity, cyclooxygenase-2 (COX-2) expression and the lipid peroxidation index malondialdehyde (MDA) appeared increased. The pattern of changes in CB is opposite, except for COX-2 expression that remained augmented and MDA levels unaltered. Network interaction analysis showed that TLR4/MyD88/IκBα/NFκB/COX-2 pathway was coupled in PFC and uncoupled in CB. SP4 co-expressed with TLR4 and NFκB in PFC and both SP1 and SP4 co-expressed with NFκB in CB. In PFC, correlation analysis found an inverse relationship between NFκB and negative symptoms. In summary, we found brain region-specific alterations in the TLR4 signalling pathway in chronic SZ, in which SP transcription factors could participate at different levels. Further studies are required to elucidate the regulatory mechanisms of innate immunity in SZ and its relationship with symptoms.

Altered CSNK1E, FABP4 and NEFH protein levels in the dorsolateral prefrontal cortex in schizophrenia.
Schizophrenia constitutes a complex disease. Negative and cognitive symptoms are enduring and debilitating components of the disorder, highly associated to disability and burden. Disrupted neurotransmission circuits in dorsolateral prefrontal cortex (DLPFC) have been related to these symptoms. To identify candidates altered in schizophrenia, we performed a pilot proteomic analysis on postmortem human DLPFC tissue from patients with schizophrenia (n=4) and control (n=4) subjects in a pool design using differential isotope peptide labelling followed by liquid chromatography tandem mass spectrometry (LC-MS/MS). We quantified 1315 proteins with two or more unique peptides, 116 of which showed altered changes. Of these altered proteins, we selected four with potential roles on cell signaling, neuronal development and synapse functioning for further validation: casein kinase I isoform epsilon (CSNK1E), fatty acid-binding protein 4 (FABP4), neurofilament triplet H protein (NEFH), and retinal dehydrogenase 1 (ALDH1A1). Immunoblot validation confirmed our proteomic findings of these proteins being decreased in abundance in the schizophrenia samples. Additionally, we conducted immunoblot validation of these candidates on an independent sample cohort comprising 23 patients with chronic schizophrenia and 23 matched controls. In this second cohort, CSNK1E, FABP4 and NEFH were reduced in the schizophrenia group while ALDH1A1 did not significantly change. This study provides evidence indicating these proteins are decreased in schizophrenia: CSNK1E, involved in circadian molecular clock signaling, FABP4 with possible implication in synapse functioning, and NEFH, important for cytoarchitecture organization. Hence, these findings suggest the possible implication of these proteins in the cognitive and/or negative symptoms in schizophrenia.

The glial phosphorylase of glycogen isoform is reduced in the dorsolateral prefrontal cortex in chronic schizophrenia.
Reduced glutamatergic activity and energy metabolism in the dorsolateral prefrontal cortex (DLPFC) have been described in schizophrenia. Glycogenolysis in astrocytes is responsible for providing neurons with lactate as a transient energy supply helping to couple glutamatergic neurotransmission and glucose utilization in the brain. This mechanism could be disrupted in schizophrenia. The aim of this study was to explore whether the protein levels of the astrocyte isoform of glycogen phosphorylase (PYGM), key enzyme of glycogenolysis, and the isoform A of Ras-related C3 botulinum toxin substrate 1 (RAC1), a kinase that regulates PYGM activity, are altered in the postmortem DLPFC of chronic schizophrenia patients (n=23) and matched controls (n=23). We also aimed to test NMDAR blockade effect on these proteins in the mouse cortex and cortical astrocytes and antipsychotic treatments in rats. Here we report a reduction in PYGM and RAC1 protein levels in the DLPFC in schizophrenia. We found that treatment with the NMDAR antagonist dizocilpine in mice as a model of psychosis increased PYGM and reduced RAC1 protein levels. The same result was observed in rat cortical astroglial-enriched cultures. 21-day haloperidol treatment increased PYGM levels in rats. These results show that PYGM and RAC1 are altered in the DLPFC in chronic schizophrenia and are controlled by NMDA signalling in the rodent cortex and cortical astrocytes suggesting an altered NMDA-dependent glycogenolysis in astrocytes in schizophrenia. Together, this study provides evidence of a NMDA-dependent transient local energy deficit in neuron-glia crosstalk in schizophrenia, contributing to energy deficits of the disorder.

Transcription factor SP4 phosphorylation is altered in the postmortem cerebellum of bipolar disorder and schizophrenia subjects.

Transcription factors play important roles in the control of neuronal function in physiological and pathological conditions. We previously reported reduced levels of transcription factor SP4 protein, but not transcript, in the cerebellum in bipolar disorder and associated with more severe negative symptoms in schizophrenia. We have recently reported phosphorylation of Sp4 at S770, which is regulated by membrane depolarization and NMDA receptor activity. The aim of this study was to investigate SP4 S770 phosphorylation in bipolar disorder and its association with negative symptoms in schizophrenia, and to explore the potential relationship between phosphorylation and protein abundance. Here we report a significant increase in SP4 phosphorylation in the cerebellum, but not the prefrontal cortex, of bipolar disorder subjects (n=10) (80% suicide) compared to matched controls (n=10). We found that SP4 phosphorylation inversely correlated with SP4 levels independently of disease status in both areas of the human brain. Moreover, SP4 phosphorylation in the cerebellum positively correlated with negative symptoms in schizophrenia subjects (n=15). Further, we observed that a phospho-mimetic mutation in truncated Sp4 was sufficient to significantly decrease Sp4 steady-state levels, while a non-phosphorylatable mutant showed increased stability in cultured rat cerebellar granule neurons. Our results indicate that SP4 S770 phosphorylation is increased in the cerebellum in bipolar disorder subjects that committed suicide and in severe schizophrenia subjects, and may be part of a degradation signal that controls Sp4 abundance in cerebellar granule neurons. This opens the possibility that modulation of SP4 phosphorylation may contribute to the molecular pathophysiology of psychotic disorders.

Phosphorylation of transcription factor specificity protein 4 is increased in peripheral blood mononuclear cells of first-episode psychosis.
Altered expression of transcription factor specificity protein 4 (SP4) has been found in the postmortem brain of patients with psychiatric disorders including schizophrenia and bipolar disorder. Reduced levels of SP4 protein have recently been reported in peripheral blood mononuclear cells in first-episode psychosis. Also, SP4 levels are modulated by lithium treatment in cultured neurons. Phosphorylation of SP4 at S770 is increased in the cerebellum of bipolar disorder subjects and upon inhibition of NMDA receptor signaling in cultured neurons. The aim of this study was to investigate whether SP4 S770 phosphorylation is increased in lymphocytes of first-episode psychosis patients and the effect of lithium treatment on this phosphorylation.

Increased SP4 and SP1 transcription factor expression in the postmortem hippocampus of chronic schizophrenia.
Altered levels of transcription factor specificity protein 4 (SP4) and 1 (SP1) in the cerebellum, prefrontal cortex and/or lymphocytes have been reported in severe psychiatric disorders, including early psychosis, bipolar disorder, and chronic schizophrenia subjects who have undergone long-term antipsychotic treatments. SP4 transgenic mice show altered hippocampal-dependent psychotic-like behaviours and altered development of hippocampal dentate gyrus. Moreover, NMDAR activity regulates SP4 function. The aim of this study was to investigate SP4 and SP1 expression levels in the hippocampus in schizophrenia, and the possible effect of antipsychotics and NMDAR blockade on SP protein levels in rodent hippocampus. We analysed SP4 and SP1 expression levels in the postmortem hippocampus of chronic schizophrenia (n = 14) and control (n = 11) subjects by immunoblot and quantitative RT-PCR. We tested the effect of NMDAR blockade on SP factors in the hippocampus of mouse treated with an acute dose of MK801. We also investigated the effect of subacute treatments with haloperidol and clozapine on SP protein levels in the rat hippocampus. We report that SP4 protein and both SP4 and SP1 mRNA expression levels are significantly increased in the hippocampus in chronic schizophrenia. Likewise, acute treatment with MK801 increased both SP4 and SP1 protein levels in mouse hippocampus. In contrast, subacute treatment with haloperidol and clozapine did not significantly alter SP protein levels in rat hippocampus. These results suggest that SP4 and SP1 upregulation may be part of the mechanisms deregulated downstream of glutamate signalling pathways in schizophrenia and might be contributing to the hippocampal-dependent cognitive deficits of the disorder.

Transcription factor Sp4 regulates expression of nervous wreck 2 to control NMDAR1 levels and dendrite patterning.
Glutamatergic signaling through N-methyl-d-aspartate receptors (NMDARs) is important for neuronal development and plasticity and is often dysregulated in psychiatric disorders. Mice mutant for the transcription factor Sp4 have reduced levels of NMDAR subunit 1 (NR1) protein, but not mRNA, and exhibit behavioral and memory deficits (Zhou et al., [2010] Human Molecular Genetics 19: 3797-3805). In developing cerebellar granule neurons (CGNs), Sp4 controls dendrite patterning (Ramos et al., [2007] Proc Natl Acad Sci USA 104: 9882-9887). Sp4 target genes that regulate dendrite pruning or NR1 levels are not known. Here we report that Sp4 activates transcription of Nervous Wreck 2 (Nwk2; also known as Fchsd1) and, further, that Nwk2, an F-BAR domain-containing protein, mediates Sp4-dependent regulation of dendrite patterning and cell surface expression of NR1. Knockdown of Nwk2 in CGNs increased primary dendrite number, phenocopying Sp4

knockdown, and exogenous expression of Nwk2 in Sp4-depleted neurons rescued dendrite number. We observed that acute Sp4 depletion reduced levels of surface, but not total, NR1, and this was rescued by Nwk2 expression. Furthermore, expression of Nr1 suppressed the increase in dendrite number in Sp4- or Nwk2- depleted neurons. We previously reported that Sp4 protein levels were reduced in cerebellum of subjects with bipolar disorder (BD) (Pinacho et al., [2011] Bipolar Disorders 13: 474-485). Here we report that Nwk2 mRNA and NR1 protein levels were also reduced in postmortem cerebellum of BD subjects. Our data suggest a role for Sp4-regulated Nwk2 in NMDAR trafficking and identify a Sp4-Nwk2-NMDAR1 pathway that regulates neuronal morphogenesis during development and may be disrupted in bipolar disorder.

Analysis of Sp transcription factors in the postmortem brain of chronic schizophrenia: a pilot study of relationship to negative symptoms.
Negative symptoms are the most resilient manifestations in schizophrenia. An imbalance in dopamine and glutamate pathways has been proposed for the emergence of these symptoms. SP1, SP3 and SP4 transcription factors regulate genes in these pathways, suggesting a possible involvement in negative symptoms. In this study, we characterized Sp factors in the brains of subjects with schizophrenia and explored a possible association with negative symptoms. We also included analysis of NR1, NR2A and DRD2 as Sp target genes. Postmortem cerebellum and prefrontal cortex from an antemortem clinically well-characterized and controlled collection of elderly subjects with chronic schizophrenia (n = 16) and control individuals (n = 14) were examined. We used the Positive and Negative Syndrome and the Clinical Global Impression Schizophrenia scales, quantitative PCR and immunoblot. SP1 protein and mRNA were reduced in the prefrontal cortex in schizophrenia whereas none of Sp factors were altered in the cerebellum. However, we found that SP1, SP3 and SP4 protein levels inversely correlated with negative symptoms in the cerebellum. Furthermore, NR2A and DRD2 mRNA levels correlated with negative symptoms in the cerebellum. In the prefrontal cortex, SP1 mRNA and NR1 and DRD2 inversely correlated with these symptoms while Sp protein levels did not. This pilot study not only reinforces the involvement of SP1 in schizophrenia, but also suggests that reduced levels or function of SP1, SP4 and SP3 may participate in negative symptoms, in part through the regulation of NMDA receptor subunits and/or Dopamine D2 receptor, providing novel information about the complex negative symptoms in this disorder.

The transcription factor SP4 is reduced in postmortem cerebellum of bipolar disorder subjects: control by depolarization and lithium.
Regulation of gene expression is important for the development and function of the nervous system. However, the transcriptional programs altered in psychiatric diseases are not completely characterized. Human gene association studies and analysis of mutant mice suggest that the transcription factor specificity protein 4 (SP4) may be implicated in the pathophysiology of psychiatric diseases. We hypothesized that SP4 levels may be altered in the brain of bipolar disorder (BD) subjects and regulated by neuronal activity and drug treatment.

GENETICS OF ADDICTION - IDENTIFICATION OF NOVEL GENETIC VARIANTS ASSOCIATED WITH REWARD MECHANISM IN ZEBRAFISH

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Aleksandra Mech[1], Munise Merteroglu[1], William Havelange[1], Adele Leggieri[1], Saeedeh Husseinian[1], Ian Sealy[2], Elisabeth Busch-Nentwich[2], Caroline Brennan[1]

Nicotine addiction is one of the major mental health disorders that affects over 29% of the European population and generates enormous cost in medical care and in lost productivity. Previous studies have shown the relevance of genetic factors responsible for a progression to abusive usage, with data from twin studies estimating that approximately 50% of vulnerability to nicotine addiction is due to heritable factors. Here, we developed a novel self-administration assay for juvenile fish to screen ENU-mutagenized zebrafish lines for nicotine seeking. The assay consists of 3 asymmetrically connected chambers with nicotine being administered to one of the chambers by diffusion from a point source thereby setting up a concentration gradient across the 3 chambers. Increased time spent in proximity to the nicotine source is taken as evidence of nicotine seeking behaviour. We screened 54 families covering approximately 3318 dominant and 1037 recessive alleles for nicotine seeking. Wild-type fish showed limited tendency to approach or avoid the nicotine source. However, 10 families of ENU mutagenized fish showed preference for, or aversion to, the nicotine chamber. Two of these families are predicted to carry a dominant mutation affecting the behavior and 8 are predicted to carry recessive mutations. So far, we have shown the heritability of the observed phenotype for five of the mutant lines. Future work will assess the heritability for the remaining families and identify the pathways involved. Increased understanding of the genetics of smoking is necessary to identify novel drug targets and to develop new therapeutic approaches.

Behavioral and Gene Regulatory Responses to Developmental Drug Exposures in Zebrafish.
Developmental consequences of prenatal drug exposure have been reported in many human cohorts and animal studies. The long-lasting impact on the offspring-including motor and cognitive impairments, cranial and cardiac anomalies and increased prevalence of ADHD-is a socioeconomic burden worldwide. Identifying the molecular changes leading to developmental consequences could help ameliorate the deficits and limit the impact. In this study, we have used zebrafish, a well-established behavioral and genetic model with conserved drug response and reward pathways, to identify changes in behavior and cellular pathways in response to developmental exposure to amphetamine, nicotine or oxycodone. In the presence of the drug, exposed animals showed altered behavior, consistent with effects seen in mammalian systems, including impaired locomotion and altered habituation to acoustic startle. Differences in responses seen following acute and chronic exposure suggest adaptation to the presence of the drug. Transcriptomic analysis of exposed larvae revealed differential expression of numerous genes and alterations in many pathways, including those related to cell death, immunity and circadian rhythm regulation. Differential expression of circadian rhythm genes did not correlate with behavioral changes in the larvae, however, two of the circadian genes, and , were also differentially expressed at later stages of development, suggesting a long-lasting impact of developmental exposures on circadian gene expression. The immediate-early genes, , and , which are associated with synaptic plasticity, were downregulated by all three drugs and hybridization showed that the expression for all four genes was reduced across all neuroanatomical regions, including brain regions implicated in reward processing, addiction and other psychiatric conditions. We anticipate that these early changes in gene expression in response to drug exposure are likely to contribute to the consequences of prenatal exposure and their discovery might pave the way to therapeutic intervention to ameliorate the long-lasting deficits.

Translational relevance of forward genetic screens in animal models for the study of psychiatric disease.

Psychiatric disorders represent a significant burden in our societies. Despite the convincing evidence pointing at gene and gene-environment interaction contributions, the role of genetics in the etiology of psychiatric disease is still poorly understood. Forward genetic screens in animal models have helped elucidate causal links. Here we discuss the application of mutagenesis-based forward genetic approaches in common animal model species: two invertebrates, nematodes (Caenorhabditis elegans) and fruit flies (Drosophila sp.); and two vertebrates, zebrafish (Danio rerio) and mice (Mus musculus), in relation to psychiatric disease. We also discuss the use of large scale genomic studies in human populations. Despite the advances using data from human populations, animal models coupled with next-generation sequencing strategies are still needed. Although with its own limitations, zebrafish possess characteristics that make them especially well-suited to forward genetic studies exploring the etiology of psychiatric disorders.

Altered Sensory Neuron Development in CMT2D Mice Is Site-Specific and Linked to Increased GlyRS Levels.
Dominant, missense mutations in the widely and constitutively expressed gene cause peripheral neuropathy that usually begins in adolescence and principally impacts the upper limbs. Caused by a toxic gain-of-function in the encoded glycyl-tRNA synthetase (GlyRS) enzyme, the neuropathology appears to be independent of the canonical role of GlyRS in aminoacylation. Patients display progressive, life-long weakness and wasting of muscles in hands followed by feet, with frequently associated deficits in sensation. When dysfunction is observed in motor and sensory nerves, there is a diagnosis of Charcot-Marie-Tooth disease type 2D (CMT2D), or distal hereditary motor neuropathy type V if the symptoms are purely motor. The cause of this varied sensory involvement remains unresolved, as are the pathomechanisms underlying the selective neurodegeneration characteristic of the disease. We have previously identified in CMT2D mice that neuropathy-causing mutations perturb sensory neuron fate and permit mutant GlyRS to aberrantly interact with neurotrophin receptors (Trks). Here, we extend this work by interrogating further the anatomy and function of the CMT2D sensory nervous system in mutant mice, obtaining several key results: (1) sensory pathology is restricted to neurons innervating the hindlimbs; (2) perturbation of sensory development is not common to all mouse models of neuromuscular disease; (3) axonal transport of signaling endosomes is not impaired in afferent neurons of all CMT2D mouse models; and (4) expression is selectively elevated in a subset of sensory neurons and linked to sensory developmental defects. These findings highlight the importance of comparative neurological assessment in mouse models of disease and shed light on key proposed neuropathogenic mechanisms in -linked neuropathy.

Developmental demands contribute to early neuromuscular degeneration in CMT2D mice.
Dominantly inherited, missense mutations in the widely expressed housekeeping gene, GARS1, cause Charcot-Marie-Tooth type 2D (CMT2D), a peripheral neuropathy characterised by muscle weakness and wasting in limb extremities. Mice modelling CMT2D display early and selective neuromuscular junction (NMJ) pathology, epitomised by disturbed maturation and neurotransmission, leading to denervation. Indeed, the NMJ disruption has been reported in several different muscles; however, a systematic comparison of neuromuscular synapses from distinct body locations has yet to be performed. We therefore analysed NMJ development and degeneration across five different wholemount muscles to identify key synaptic features contributing to the distinct pattern of neurodegeneration in CMT2D mice. Denervation was found to occur along a distal-to-proximal gradient, providing a cellular explanation for the greater weakness observed in mutant Gars hindlimbs compared with forelimbs. Nonetheless, muscles from similar locations and innervated by axons of equivalent length showed significant differences in neuropathology, suggestive of additional factors impacting on site-specific neuromuscular degeneration. Defective NMJ development preceded and associated with degeneration, but was not linked to a delay of wild-type NMJ maturation processes. Correlation analyses indicate that muscle fibre type nor synaptic architecture explain the differential denervation of CMT2D NMJs, rather it is the extent of post-natal synaptic growth that predisposes to neurodegeneration. Together, this work improves our understanding of the mechanisms driving synaptic vulnerability in CMT2D and hints at pertinent pathogenic pathways.
Cell Death Dis, 2020; 11

Morphological variability is greater at developing than mature mouse neuromuscular junctions.
The neuromuscular junction (NMJ) is the highly specialised peripheral synapse formed between lower motor neuron terminals and muscle fibres. Post-synaptic acetylcholine receptors (AChRs), which are found in high density in the muscle membrane, bind to acetylcholine released into the synaptic cleft of the NMJ, thereby enabling the conversion of motor action potentials to muscle contractions. NMJs have been studied for many years as a general model for synapse formation, development and function, and are known to be early sites of pathological changes in many neuromuscular diseases. However, information is limited on the diversity of NMJs in different muscles, how synaptic morphology changes during development, and the

relevance of these parameters to neuropathology. Here, this crucial gap was addressed using a robust and standardised semi-automated workflow called NMJ-morph to quantify features of pre- and post-synaptic NMJ architecture in an unbiased manner. Five wholemount muscles from wild-type mice were dissected and compared at immature (post-natal day, P7) and early adult (P31-32) timepoints. The inter-muscular variability was greater in mature post-synaptic AChR morphology than that of the pre-synaptic motor neuron terminal. Moreover, the developing NMJ showed greater differences across muscles than the mature synapse, perhaps due to the observed distinctions in synaptic growth between muscles. Nevertheless, the amount of nerve to muscle contact was consistent, suggesting that pathological denervation can be reliably compared across different muscles in mouse models of neurodegeneration. Additionally, mature post-synaptic endplate diameters correlated with fibre type, independently of muscle fibre diameter. Altogether, this work provides detailed information on healthy pre- and post-synaptic NMJ morphology from five anatomically and functionally distinct mouse muscles, delivering useful reference data for future comparison with neuromuscular disease models.

EFFECT OF YOHIMBINE ON VOLUNTARY ETHANOL INTAKE OF ADULT MALE AND FEMALE WISTAR RATS

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Lourdes De La Torre Vacas, Inmaculada Ruíz García, M. Dolores Escarabajal Arrieta, Ángeles Agüero Zapata
University of Jaen, Psychology, Jaén, Spain

Stress is commonly reported to increase the rewarding effects of alcohol. However, results are not always comparable between laboratories. The numerous variations in experimental methods are contributing to these contradictory results. On the other hand, there is a limited number of studies that have investigated sex differences in stress-alcohol interactions (see Logrip et al., 2018), and the reported results are inconsistent. In this work, we analyze the effect of stress (induced by Yohimbine, 4 mg/kg) on a free choice drinking procedure (the concentration of ethanol was increased gradually from 2% to 10%) in adult Wistar rats. The obtained results show a similar pattern of escalation of alcohol intake as ethanol concentration increases in Yohimbine (YOH) and in vehicle (VEH) injected animals, although YOH-injected animals showed a slightly higher increase of consumption of the 10% ethanol solution. Regarding sex, the results show that female ethanol-intake levels were higher than the exhibited by males. Sex differences in ethanol intake are well documented in rodents with intake in females being higher than that in males (de la Torre et al., 2015). Concerning the possible differential effect of YOH on ethanol intake of male and female rats, the results show absence of significant differences. However, it was found that only in the case of male rats the YOH-injected group ingested a greater amount of 10% ethanol solution than the VEH-injected group. These results may contribute to clarify sex differences in stress-alcohol interactions.

NEURAL SIGNALING IN THE VTA-ACCUMBENS AXIS CORRELATED WITH CANNABIS EXTRACT EFFECTS ON METHAMPHETAMINE CONDITIONED PLACE PREFERENCE IN MICE

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Jakkrit Nukitram
Prince of Songkla University, Physiology Program, Hat Yai, Thailand

Background: Cannabidiol (CBD) and tetrahydrocannabinol (THC) are natural compounds in *Cannabis* species. A 1:1 ratio of CBD:THC (CT) has been found to improve many psychological illnesses. However, effects of this cannabis mixture on methamphetamine (METH) conditioned place preference (CPP) have not been elucidated. Aims: To evaluate animal behaviors and characterize local filed potential (LFP) oscillations in the nucleus accumbens (NAcc) and ventral tegmental area (VTA) of mice with METH CPP treated with CT Methods: Male albino ICR mice were implanted LFP electrodes and divided into control, METH CPP groups treated with either vehicle (METH+CMC) or 10 mg/kg CT (METH+CT). To induce METH CPP, mice were intraperitoneally injected with 1 mg/kg METH and 0.9% saline in alternative day for 10 sessions and confined to corresponding compartments for 30 min in each session. Control mice were administered with 0.9% saline on all days for both compartments. Animals received treatments 60 min before CPP testing. LFP signals and animal behaviors were recorded simultaneously for 15 min during pre-conditioning and post-conditioning phases. Results: Elevated CPP scores and changes in NAcc thata, gamma I and VTA delta were found in METH+CMC mice. These animals exhibited the enhanced VTA-NAcc gamma I coherence. However, these alterations were significantly attenuated by the cannabis mixture found in METH+CT group. Conclusions: The data confirmed that the cannabis mixture was effective in treatment of METH CPP in mice. The cannabis extract might be useful as an alternative medicine for treatment of methamphetamine

dependence.

Locomotor activity and resting local field potential oscillatory rhythms of 6-OHDA mouse model of Parkinson's disease in response to acute and repeated treatments with L-dopa.
Phase-amplitude coupling (PAC) of local field potential (LFP) has been recognized as higher-order representation of brain

states. Neuronal loss in the striatum leads to Parkinson's disease (PD) symptoms and modifies LFP oscillation. However, PAC in the striatum of PD mouse model induced by 6-hydroxydopamne (6-OHDA) remained to be investigated. Male Swiss albino ICR mice were implanted with intracranial electrode and injected with 6-OHDA to the left striatum. Levodopa (L-dopa) (10 mg/kg, oral) was used for treatment once a day from day 15-19. Locomotor activity and resting LFP signals were selectively analyzed on day 15 and 19. One-way ANOVA revealed significant decreases in travelled distance induced by 6-OHDA on both days ($p \leq 0.05$). However, the decreased travelled distances were significantly reversed by L-dopa. On day 15, LFP powers of theta, alpha, beta and low gamma waves were significantly increased by 6-OHDA injection and the powers of beta and low gamma were significantly reversed to control level by treatment with L-dopa. On day 19, LFP powers of delta, theta, alpha, beta and low gamma waves were significantly increased by 6-OHDA injection and the powers of low gamma were significantly reversed to control level by treatment with L-dopa. Theta-gamma PAC analyses also confirmed significant increase in modulation index (MI) induced by 6-OHDA on day 19. However, L-dopa failed to significantly reverse the MI to control level. These findings indicated theta-gamma coupling in the striatum of PD mouse model. Taken together, change in striatal theta-gamma PAC might be one of biomarkers in addition to hypokinesia and increased LFP powers that reflect disrupted neural mechanisms in PD mouse model.

Spectral power and theta-gamma coupling in the basolateral amygdala related with methamphetamine conditioned place preference in mice.

The basolateral amygdala (BLA) plays a crucial role in conditioned place preference (CPP) for addictive drugs. However, neural signaling associated with methamphetamine (METH) craving and seeking remained to be investigated. This study characterized local field potential (LFP) oscillatory patterns in the BLA and conditioned place preference induced by METH-related context. Male Swiss albino ICR mice were deeply anesthetized for LFP intracranial electrode implantation in the BLA. Control and METH groups received sessions to learn to associate saline-paired and METH-paired compartments of the CPP apparatus with saline and METH injections, respectively, for 10 days. LFP signals and exploring behavior were recorded simultaneously during pre- and post-conditioning phases. Time spent in METH-paired compartment was normalized and expressed as CPP scores. Fast Fourier Transform (FFT) algorithm was used to analyze LFP powers of 8 discrete frequency ranges (delta, theta, alpha, beta, gamma I-IV). During post-conditioning phase of METH CPP with METH cues, statistical analysis revealed that METH group significantly increased time spent in METH-paired compartment. Significant suppressions of theta and alpha powers were observed. Phase-amplitude cross frequency coupling analyses confirmed significant increases in maximal modulation index (MI), frequency for phase of slow wave and MI of theta-gamma II coupling. Taken together, LFP oscillation in the BLA was sensitive in association with METH CPP. These research findings might suggest the underlying mechanisms of drug reward learning and adaptive changes in the BLA in acquisition of METH CPP and dependence.

A TRANSLATIONAL APPROACH ON REWARD ABNORMALITIES IN ANOREXIA NERVOSA: THE ROLE OF METABOLIC SENSING ON DELAYED GRATIFICATION.

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Chloé Tezenas Du Montcel[1], Philibert Duriez[2], Sabrina Jaza[2], Odile Viltart[3], Virginie Tolle[2], Philip.Gorwood Gorwood[2]
[1]Institut de Psychiatrie et Neurosciences de Paris, Genetic Vulnerability To Addiction And Psychiatric Disorder, Paris, France, [2]InsermU1266, Ipnp, Paris, France, [3]Inserm U1266, Ipnp, Paris, France

Reward abnormalities in anorexia nervosa (AN) are characterized by compulsive behaviors but increased sensitivity to delayed gratification. Rodent exposed to food restriction (FR) exhibit strong preference for a running wheel activity in anticipation to food reward, when orexigenic peptides such as ghrelin are elevated in response to fasting. These metabolic sensors drive motivational aspects of feeding modulating the dopaminergic circuit and could acquire reinforcing properties leading to addictive-like behaviors towards undernutrition. We aim to identify metabolic biomarkers associated with sensitivity to delayed gratification in an innovative animal model of chronic undernutrition and in AN patients. We explore the sensitivity to delayed gratification in seven weeks-old female mice before and after a chronic 50% FR with running wheel (FRW) using an innovative operant conditioning paradigm of delay-discounting task (DDT). Clinical data from a cohort of AN will explore the kinetic of reward abnormalities in a human DDT. Data are correlated with metabolic sensors of energy loss (e.g. ghrelin). We validated the DDT in 16 ad-libitum mice, where the preference for a large delayed gratification decreased from 80% to 40% with increasing delay from 0 to 40 sec ($p<0.0001$). We are currently exploring how food restriction modifies response to delayed gratification and perseverative behaviors associated with energy deprivation signals, both in rodent and patients. An innovative step of this project is to identify reliable biomarkers specific for reward abnormalities, possibly involving common pathways in both rodent and humans that might be relevant for diagnosis and prognosis in AN.

CELLULAR DETERMINANT OF NEGATIVE REINFORCEMENT IN FENTANYL ADDICTION

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Fabrice Chaudun, Sylvia Yu Liu, Vincent Pascoli, Christian Lüscher
Unige, Neuroscience Departement, Geneve, Switzerland

Opioids have been used for centuries for their potent effect as painkillers ; however about a third of opioid users will eventually lose control and develop addiction (30%), a number that exceeds the one for a psychostimulant like cocaine (16%) (Anthony et al.,1994). Despite its rewarding property, it is well established that opioids also induce strong dependence, defined by a stereotypical withdrawal syndrome (Comer and Cahill, 2018). This is the case for example, upon cessation of fentanyl consumption, when subjects experience strong dysphoria, tremor, hyperalgesia and sweating. Avoiding this aversive state may contribute to relapse though negative reinforcement (Koob, 2019). While we know much about the circuits of positive reinforcement, much less is known about neural connections of negative reinforcement. To address this question, we use genetic manipulation and in vivo recording in mice precipitate withdrawal with naloxone. We found that withdrawal was associated with an increased activity of central amygdala. Furthermore, we demonstrate that knocking-down MuOR in central amygdala prevent some withdrawal symptoms. We currently explore how and through which projections neurons in the amygdala may contribute to the negative reinforcement.

TOWARDS DEVELOPING A MOUSE MODEL OF CO-MORBID BINGE-EATING AND -DRINKING.

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Karen Szumlinski[1], Ida Kazerani[1], Aadithya Kharwa[1], Lauren Madory[1], Camron Bryant[2]
[1]University of California, Santa Barbara, Psychological And Brain Sciences, Santa Barbara, United States of America, [2]Boston University, Pharmacology And Experimental Therapeutics, Boston, United States of America

A high rate of co-morbidity exists between binge-eating and binge-drinking disorders, suggesting a common neuropathology. To test this hypothesis, we have worked to develop a mouse model of co-morbid binge-eating and -drinking, using C57BL/6NJ (B6NJ) mice. In our first study, *ad libitum*-fed and -watered female and male B6NJ mice underwent 1-h binge-eating sessions in the morning, every other day. Every afternoon, mice were offered 20 and 40% alcohol for 2 h. As expected, females binge-ate and binge-drank more than males. However, opposite our expectation, mice consuming either SPF or control Chow pellets both exhibited lower alcohol intake on binge-eating days, than on non-eating days, suggesting that mice were regulating their total caloric intake under this concurrent procedure. In a second experiment, mice underwent 10 days of binge-eating (5 days/week), followed by 10 days of binge-drinking. Under this "BE-BD" procedure, females escalated their SPF intake more rapidly than males, and female-SPF mice also consumed the most alcohol on the first day of binge-drinking. Although males did not exhibit behavioral cross-sensitization on day 1 of drinking, both male and female SPF mice consumed more alcohol, overall, than no SPF controls. These data indicate that binge-drinking cross-sensitizes with binge-eating in both male and female B6NJ mice, with females more sensitive to this behavioral phenomenon. Such findings support the notion that common or overlapping mechanisms drive these two forms of excessive behavior, which might account for their high rate of co-morbidity and future work will examine for potential biomolecular correlates within the extended amygdala.

ROLE OF CYFIP2 ON MEDIAL PREFRONTAL CORTEX TO NUCLEUS ACCUMBENS PATHWAY IN REGULATION OF COCAINE REWARD

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Young-Jung Kim, Seon-Kyung Kim, Youyoung Lee, Choon-Gon Jang
Sungkyunkwan University, School Of Pharmacy, Suwon, Korea, Republic of

Cytoplasmic FMR1-interacting protein 2 (CYFIP2) consists of the WAVE regulatory complex and is involved in actin polymerization, which contributes to neuronal development and synaptic plasticity through transmitting the Rac1 GTPase signaling to WAVE regulatory complex. It has been reported that S968F point mutation of CYFIP2 is attributed to decreased locomotor response to cocaine administration and facilitates the excessive activation of the WAVE regulatory complex. However, the functional role of which CYFIP2 regulates the rewarding properties of cocaine remains largely unknown. Here, I performed the cocaine reward-related behavioral tests and examined the changes in biochemical and neuronal morphology in nucleus accumbens (NAc) using CYFIP2 S968F knock-in mice to investigate the role of CYFIP2 in regulating cocaine reward. My findings revealed that CYFIP2 S968F attenuated the cocaine behavioral sensitization and conditioned place preference. The CYFIP2 S968F blocked the cocaine-induced neuronal activity of NAc and enhancement of reward-related behaviors by optogenetic activation of NAc or medial prefrontal cortex (mPFC) to NAc pathway. Moreover, CYFIP2 S968F disturbed cocaine-mediated changes in CYFIP2 downstream signaling proteins and dendritic spine plasticity in NAc. These results suggest CYFIP2 plays a role in controlling cocaine-mediated neuronal activity and synaptic plasticity in the mPFC to NAc pathway, and CYFIP2 could serve as a target for regulating cocaine rewards.

REPEATED ADMINISTRATION OF N-ACETYLCYSTEINE COULD REDUCE EXTINCTION-RESPONDING IN THE MORPHINE CONDITIONED RATS

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Seyedeh-Najmeh Katebi[1], Anahita Torkaman-Boutorabi[1], Abbas Haghparast[2]

Many animal studies and early clinical trials suggested that N-acetylcysteine (NAC) may benefit addiction treatment. The present study tried to evaluate whether chronic administration of systemic NAC during the extinction period could reduce the maintenance of the morphine rewarding properties in the conditioned place preference (CPP) paradigm in the rats. forty-six adult male Wistar rats (190-220 g) were examined with morphine (7 mg/kg; sc) and saline (1 mL/kg; sc) during the 3-day conditioning phase in the CPP paradigm. After the acquisition of morphine CPP, different doses of NAC were daily administered during the extinction period (5, 10, 25, and 50 mg/kg; ip). Conditioning score and locomotor activity were recorded by the video tracking system and Ethovision software after acquisition on the postconditioning day, the extinction period. Daily NAC administration in high doses (25 and 50 mg/kg; ip) reduced extinction-responding compared with the vehicle-control group during the extinction period. These are the first data suggesting that NAC's application during the extinction period could attenuate the morphine reward associated behaviors in the rats which adds to the growing appreciation that the NAC may have potential therapeutic use in combating morphine dependence. It can be consistent with the hypothesis of the involvement of the glutamatergic system in the pathophysiology of addiction.

Systemic administration of N-acetylcysteine during the extinction period and on the reinstatement day decreased the maintenance of morphine rewarding properties in the rats.
Many animal studies and early clinical trials suggested that N-acetylcysteine (NAC) may benefit addiction treatment. The present study tried to evaluate whether chronic administration of systemic NAC during the extinction period and acute administration of systemic NAC on the reinstatement day could reduce the maintenance of the morphine rewarding properties in the conditioned place preference (CPP) paradigm in the rats. Ninety-six adult male Wistar rats (190-220 g) were examined with morphine (7 mg/kg; sc) and saline (1 mL/kg; sc) during the 3-day conditioning phase in the CPP paradigm. After the acquisition of morphine CPP, different doses of NAC were daily administered during the extinction period (5, 10, 25, and 50 mg/kg; ip), or 30 min before the CPP test on the reinstatement day (2, 5, 10, 25, and 50 mg/kg; ip). Conditioning score and locomotor activity were recorded by the video tracking system and Ethovision software after acquisition on the post-conditioning day, the extinction period, and reinstatement day. Daily NAC administration in high doses (25 and 50 mg/kg; ip) reduced extinction-responding compared with the vehicle-control group during the extinction period. Although a single injection of NAC in doses 10, 25, 50 mg/kg decreased the reinstatement of morphine-induced CPP, two lower doses (2 and 5 mg/kg) could not significantly reduce the CPP scores. These are the first data suggesting that NAC's application during the extinction period could attenuate the morphine reward-associated behaviors in the rats. Moreover, NAC could inhibit the reinstatement of morphine CPP, which adds to the growing appreciation that the NAC may have potential therapeutic use in combating morphine dependence. It can be consistent with the hypothesis of the involvement of the glutamatergic system in the pathophysiology of addiction.

Involvement of D1- and D2-like dopamine receptors in the dentate gyrus in the acquisition, expression, and extinction of the morphine-induced conditioned place preference in rats.
In the current study, we investigated the role of intra-dentate gyrus (DG) administration of D1 and/or D2 receptor antagonists on the expression, acquisition, and extinction of morphine-CPP. Cannulae were implanted bilaterally into the DG region in male Wistar rats and CPP was induced by the subcutaneous injection of morphine (5 mg/kg) during a 3-day conditioning phase. Three experimental designs were separately employed in the CPP paradigm during the acquisition, expression and

extinction phases, and different doses (0.25, 1, or 4 µg/0.5 µl saline) of SCH23390, as a selective D1-like receptor antagonist, and sulpiride (0.25, 1, or 4 µg/0.5 µl DMSO), as a selective D2-like receptor antagonist, were bilaterally microinjected into the DG region. Conditioning scores and locomotor activities were recorded during the test. Results showed that the injection of the antagonists into the DG region dose-dependently attenuated the acquisition and expression of the morphine-induced CPP and sulpiride revealed prominent behavioral results compared to SCH23390 in both mentioned phases. Moreover, the blockade of D1- and D2-like receptors shortened the extinction phase of the morphine-induced CPP but had no effect on the locomotor activity. We found that the dopamine receptors within the DG region are involved in the acquisition and expression of morphine-CPP and have a critical role in the association between a morphine-paired context and the rewarding proprieties of morphine.

Morphine could increase apoptotic factors in the nucleus accumbens and prefrontal cortex of rat brain's reward circuitry.
The nucleus accumbens (NAc) and prefrontal cortex (PFC) are two parts of neuronal reward circuit involved in motivated and goal-directed behaviors. Some data suggest that morphine is toxic to neurons and induces apoptosis, while other evidence shows that morphine could have beneficial effects against cell death. This study was designed to evaluate the effect of morphine on apoptosis by measuring the expression of apoptotic proteins in two important regions, the NAc and PFC, in the rat brain's reward circuitry. Morphine subchronic administration in different doses (0.5, 5 and 10mg/kg) in conditioned place preference (CPP) paradigm (3 times in 3 days, for each dose in each group of rats) was used to induce its rewarding effect. Then, the expression of four apoptotic factors; Bax, Bcl2, caspase3 and PARP, in the NAc and PFC were assessed using the Western blot technique. All of morphine-treated groups showed increase of apoptotic factors in these regions. In the NAc, morphine significantly increased the Bax/Bcl-2 ratio, caspase3 and PARP in the lowest dose (0.5mg/kg) but in the PFC considerable increase was seen in dose of 5mg/kg. Elevation of apoptotic factors in the NAc and PFC implies that morphine can affect the molecular mechanisms which interfere with apoptosis through different receptors. Our findings suggest that the NAc and PFC may have a different distribution of receptors which become active in different doses of morphine.

Morphine-induced apoptosis in the ventral tegmental area and hippocampus after the development but not extinction of reward-related behaviors in rats.
Some data suggest that morphine induces apoptosis in neurons, while other evidences show that morphine could have protective effects against cell death. In this study, we suggested that there is a parallel role of morphine in reward circuitry and apoptosis processing. Therefore, we investigated the effect of morphine on modifications of apoptotic factors in the ventral tegmental area (VTA) and hippocampus (HPC) which are involved in the reward circuitry after the acquisition and extinction periods of conditioned place preference (CPP). In behavioral experiments, different doses of morphine (0.5, 5, and 10 mg/kg) and saline were examined in the CPP paradigm. Conditioning score and locomotor activity were recorded by Ethovision software after acquisition on the post-conditioning day, and days 4 and 8 of extinction periods. In order to investigate the molecular mechanisms in each group, we then dissected the brains and measured the expression of apoptotic factors in the VTA and HPC by western blotting analysis. All of the morphine-treated groups showed an increase of apoptotic factors in these regions during acquisition but not in extinction period. In the HPC, morphine significantly increased the ratio of Bax/Bcl-2, caspases-3, and PARP by the lowest dose (0.5 mg/kg), but, in the VTA, a considerable increase was seen in the dose of 5 mg/kg; promotion of apoptotic factors in the HPC and VTA insinuates that morphine can affect the molecular mechanisms that interfere with apoptosis through different receptors. Our findings suggest that a specific opioid receptor involves in modification of apoptotic factors expression in these areas. It seems that the reduction of cell death in response to high dose of morphine in the VTA and HPC may be due to activation of low affinity opioid receptors which are involved in neuroprotective features of morphine.

The orexin receptors in the ventral tegmental area are involved in the development of sensitization to expression of morphine-induced preference in rats.
Recent studies have shown that orexin neurons in the lateral hypothalamus send a compelling project to the ventral tegmental area (VTA). Besides, orexin-1 (OX1) and orexin-2 (OX2) in the VTA are necessary for the development of morphine-induced place preference. Also, sensitivity to morphine can reinforce the rewarding effects of morphine. The current study aims to determine the role of VTAs orexin receptors in morphine sensitization in rats. In 84 adult male albino Wistar rats, two separate cannulae bilaterally implanted into the VTA. They received intra-VTA infusions of SB334867 (0.1, 1 and 10 nM) and TCS OX2 29 (1, 7 and 20 nM) as OX1 and OX2 receptor antagonists, respectively, 10 min before subcutaneous administration of morphine (5 mg/kg) during 3-day sensitization period. After a 5-day drug-free period, the conditioned place

preference (CPP) paradigm induced by subthreshold doses of morphine (0.5 mg/kg), and CPP scores were measured by EthoVision software. The results revealed that the blockade of both OX1 and OX2 receptors within the VTA reduced the expression of morphine-induced CPP in the sensitized rats. It is plausible that VTAs orexin receptors are involved in the development/acquisition of sensitization to morphine-induced CPP in the rats.

EFFECT OF TESTOSTERONE ON MAINTENANCE OF MORPHINE-INDUCED CONDITIONED PLACE PREFERENCE: ROLE OF ANDROGEN AND MU-OPIOID RECEPTORS EXPRESSION IN PREFRONTAL CORTEX AND NAC OF MALE RATS.

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Anahita Torkaman-Boutorabi
Tehran University of Medical Sciences, School Of Advanced Technologies In Medicine, Tehran, Iran

Rewarding properties of androgens has been suggested. The present study aimed to evaluate the effect of androgen system during the extinction period on morphine induced conditioned place preference (CPP). Androgen and μ-opioid receptor gene expression were also evaluated in PFC and NAC in the rats. CPP was induced by morphine injection (3, 5 and 7 mg/kg, i.p.) for three consecutive days. Testosterone (androgen receptor agonist, 2.5 mg/kg; i.m.) and flutamide (androgen receptor antagonist 10 mg/kg, i.m.) were administered in subsequent extinction period. In 2 castrated groups one group was considered as control and the other one received testosterone during extinction phase. The mRNA expression levels of μ-opioid and androgen receptors in PFC and NAC were evaluated using quantitative Real-time PCR following CPP reinstatement. Testosterone prolonged while flutamide shortened extinction period. Castration facilitated morphine-extinction and testosterone could not reverse this effect. The expression of μ-opioid and androgen receptors were increased in PFC and NAC of castrated animals compared to control group which were revesed by testosterone. In conclusion our results indicated that decreased level of testosterone facilities extinction period in morphine CPP model in rats. This result could be due to the changes in the expression of opioid and androgenic receptors in PFC and NAC. This study confirms the crucial role of androgen system in modulating drug reward. Key words: Androgen, Conditioned place preference, Nucleus accumbens, Morphine, Prefrontal cortex

Thymol protects against 6-hydroxydopamine-induced neurotoxicity in in vivo and in vitro model of Parkinson's disease via inhibiting oxidative stress.
Parkinson's disease (PD) is a multifactorial movement disorder with the progressive degeneration of the nigrostriatal system that impairs patients' movement ability. Oxidative stress has been found to affect the etiology and pathogenesis of PD. Thymol, a monoterpenic phenol, is one of the most important dietary constituents in thyme species. It has been used in traditional medicine and possesses some properties including antioxidant, free radical scavenging, anti-inflammatory. In this study, in vitro and in vivo experiments were performed with the thymol in order to investigate its potential neuroprotective effects in models of PD.

Effect of histone acetylation on maintenance and reinstatement of morphine-induced conditioned place preference and ΔFosB expression in the nucleus accumbens and prefrontal cortex of male rats.
Recently, epigenetic mechanisms are considered as the new potential targets for addiction treatment. This research was designed to explore the effect of histone acetylation on ΔFosB gene expression in morphine-induced conditioned place preference (CPP) in male rats. CPP was induced via morphine injection (5 mg/kg) for three consecutive days. Animals received low-dose theophylline (LDT) or Suberoylanilide Hydroxamic acid (SAHA), as an histone deacetylase (HDAC) activator or inhibitor, respectively, and a combination of both in subsequent extinction days. Following extinction, a priming dose of morphine (1 mg/kg) was administered to induce reinstatement. H4 acetylation and ΔFosB expression in the nucleus accumbens (NAc) and medial prefrontal cortex (mPFC) were assessed on the last day of extinction and the following CPP reinstatement. Our results demonstrated that daily administration of SAHA (25 mg/kg; i.p.), facilitated morphine-extinction and decreased CPP score in reinstatement of place preference. Conversely, injections of LDT (20 mg/kg; i.p.) prolonged extinction in animals. Co-administration of LDT and SAHA on extinction days counterbalanced each other, such that maintenance and reinstatement were no different than the control group. The gene expression of ΔFosB was increased by SAHA in NAc and mPFC compared to the control group. Administration of SAHA during extinction days, also altered histone acetylation in the NAc and mPFC on the last day of extinction, but not on reinstatement day. Collectively, administration of SAHA facilitated extinction and reduced reinstatement of morphine-induced CPP in rats. This study confirms the essential role of epigenetic mechanisms, specifically histone acetylation, in regulating drug-induced plasticity and seeking behaviors.

MECP2 CONTROLS DRUG ADDICTION DIFFERENTLY DEPENDING ON CELL TYPE IN THE NUCLEUS ACCUMBENS

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Jinhee Bae, Nazarii Frankiv, Heh-In Im
Korea Institute of Science and Technology, Brain Science Institute, Seoul, Korea, Republic of

Methyl CpG-binding protein 2 (MeCP2) is a transcriptional regulator that binds to DNA and inhibits or activates the expression of a target gene. Recent studies have reported that MeCP2 plays an important role in addiction regulation in the nucleus accumbens (NAc), which is one of the key reward-related areas. However, little is known about the cell type-specific function of MeCP2 in the mechanisms leading to addiction. Here, we investigated how MeCP2 regulates drug addiction according to the cell type of D1R (dopamine 1 receptor) and D2R (dopamine 2 receptor) neurons, which account for the majority of the NAc. We found that mice repeatedly exposed to cocaine increased their behavioral sensitivity and preference to the drug. Interestingly, repeated exposure to cocaine markedly decreased MeCP2 in D2R neurons, but not in D1R. We also found that when we mimics these changes of MeCP2 by using AAV viruses, MeCP2 knockdown only in D2R neurons of the NAc increased cocaine preference. Additionally, we confirmed whether the alteration in MeCP2 modulates the level of neuronal activity closely related to the regulation of drug response by using MEA (multi-electrode array). We found that a decrease in MeCP2 of the D2R neurons reduces neuronal activity levels of the NAc in response to electrical stimulation. Taken together, MeCP2 in D2R neurons of the NAc is a key mediator in drug addiction. In addition, these results suggest the possibility that MeCP2 may modulate response to the addictive drug by regulating neuronal activity.

Prior failures, laboring in vain, and knowing when to give up: Incremental versus entity theories.
Against intuition, a set of "desirable difficulties" has been touted as a way in which to improve learning and lengthen retention. This includes, for instance, varying the conditions of learning to allow for more active, effortful, or challenging, contexts. In the current paper, we introduce data that show that, on the contrary, learning to know when to take the road may be crucial when it comes to avoiding "laboring in vain." We presented participants with prior problems - either easy or difficult - followed by choices of selecting an easy or a difficult current problem. Our primary goal was to examine the notion that past failures (which are more likely on the difficult prior items) may be a basis for allowing learners to then choose the easy rather than the difficult current problem. In other words, if one has labored in vain already, the easier items may now be more desirable. In addition, we compare the selections that are made between and perspectives, given their fundamentally opposing views on effort. Our results showed that, interestingly, incremental theorists, who generally are proponents of effort, were more likely to select the easy problems, but only when they had experienced failure on prior, and similar, difficult tasks. We interpret these data to suggest that those holding an incremental view may be more in tune with their past efforts, resulting in a Metacognition-by-Experience, or ME strategy, and also hint at its generalizability through cross-cultural comparisons. MICE EXPRESSING ALLELIC VARIANT OR DELETION OF CHRNA5 SHOW INCREASED ALCOHOL CONSUMPTION BUT OPPOSITE MOTIVATIONAL PROFILES: PRECLINICAL SUPPORT FOR CLONINGER ALCOHOLIC SUBTYPES

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Léa Tochon[1], Nadia Henkous[1], Morgane Besson[2], Noémie Dominique[2], Uwe Maskos[2], Vincent David[1]
[1]Bordeaux Neurocampus, Incia Cnrs Umr5287, Bordeaux, France, [2]Institut Pasteur, Integrative Neurobiology Of Cholinergic Systems, Paris, France

Human genetic association studies have linked single nucleotide polymorphisms (SNPs) of the CHRNA5 gene, encoding the α5 nicotinic acetylcholine receptor subunit (α5-nAChR), to an increased risk of alcohol use disorders (AUDs). To understand how α5-nAChR subunit mutations may influence alcohol-drinking behavior and preconsummatory traits relevant to AUDs (anxiety, sensation-seeking, impulsivity), we tested male and female transgenic mice expressing either the most common SNP (D398N_α5KI) or a deletion of the CHRNA5 gene (α5KO) in the elevated-plus maze, novelty-place preference and step-down tasks. Their alcohol consumption was then assessed through an intermittent two-bottle choice self-administration protocol. As this is where α5-nAChR is most densely expressed, we investigated the implication of the α5*nAChR-expressing IPN-GABAergic neurons in these changes using neurospecific reexpression of the subunit in α5KOxGAD-Cre mice. α5KI and α5KO mice both showed alcohol over-consumption for highly concentrated solutions but displayed opposite anxiety-related behaviour (hyper vs hypo-anxious) and behavioural control (impulsive-like vs not impulsive, respectively). These opposite phenotypes strongly evoke characteristics of Cloninger's avoidant (Type-I) and sensation-seeking (Type-II) AUDs. Moreover, viral reexpression of α5-nAChR in IPN-GABAergic neurons decreased alcohol consumption and improved the impulsive-like phenotype observed in α5KO. These results support that mutations of the α5-nAChR subunit resulting in loss of α5*nAChRs function shift the alcohol consumption toward high doses, and in contrast, that α5*nAChR-expressing IPN-GABAergic neurons contribute to its control. Furthermore, we hypothesize that α5-nicotinic mutants may provide a preclinical model of Cloninger's AUD subtypes, which could represent a major step toward the development of personalized and more effective therapeutic strategies.

Bordeaux Neurocampus, Incia Cnrs Umr5287, Bordeaux, France

Human genetic association studies have linked different single nucleotide polymorphisms (SNPs) of the alpha5-subunit of nicotinic acetylcholine receptors to an increased risk of alcohol use disorders (AUDs). Transgenic mice expressing either a common SNP (D398N, α5KI) or a deletion of the CHRNA5 gene altogether (α5KO) are both prone to alcohol over-consumption but display opposite anxiety-related behaviour (hyper vs hypo-anxious) and behavioural control (impulsive-like vs not impulsive, respectively). These opposite phenotypes strongly evoke characteristics of Cloninger's avoidant (Type-I) and sensation-seeking (Type-II) AUDs. To further explore the possibility that α5-nicotinic mutants may provide a preclinical model of Cloninger's AUD subtypes, we investigated their social-emotional profiles as well as the activity of the amygdalo-hippocampal pathway, involved in social-emotional processes. Emotion recognition abilities were assessed using the Affective State Discrimination Task, and rescuing behaviour using the Restrainer Tube Test. Male α5KO mice were impaired in recognition of a stressed affective state and did not display rescuing behaviour towards trapped peers, or were doing so in an inappropriate manner by assaulting them. In contrast, female α5KI mice exhibited normal emotion recognition and improved rescuing behaviour. Moreover, *in vivo* electrophysiological recordings revealed opposite changes in amygdalo-hippocampal activity in relation with these social-emotional profiles, such as a higher potentiation versus a loss of potentiation of the BLA-vCA1 neurotransmission in α5KI and α5KO respectively. These results further support the parallel between social-emotional profiles of AUD type-I and female α5KI mice, and between AUD type-II and male α5KO mice and the implication of the amygdalo-hippocampal pathway in these differences.

Aims: Food addiction is a chronic multifactorial brain disorder resulting from dynamic gene network interactions and environmental factors. A growing body of literature implicates a role of the gut microbiota in various diseases, including eating disorders. Similarities in the microbial composition and functions among healthy individuals suggest that the microbiome is required for proper host health. Previous studies conducted in our laboratory have found differential microbiota signatures in food addiction vulnerable and resilient mice despite identical experimental conditions. We found a significantly higher proportion of *Blautia* spp. in non-addicted mice compared with addicted, thus showing its possible protective role in the development of food addiction. Thus, the present study aimed to investigate the effect of *Blautia* spp. on food addictive-like behavior. **Methods:** We had set up a primary protocol for the anaerobic cultivation of *Blautia wexleare.* As *Blautia wexlerae* is a strict anaerobe, we decided to administer it to mice by gavage to maintain as much viable bacteria as possible. A validated food addiction model was used to analyze the effect of *Blautia wexlerae.* **Results:** Results show that *Blautia* spp. might be beneficial in preventing food addiction. This differential gut microbiota signature was revealed despite similar food intake. **Conclusions:** This novel understanding of the role of gut microbiota in the development of food addiction may open new approaches for the development of biomarkers and innovative therapies for food addiction and related eating disorders. **Acknowledgements:** This work was supported by the Spanish Ministerio de Economía y Competitividad-MINECO' (PID2020-120029GB-I00) and (FPU-2021).

Addiction is a brain disease in which aberrant learning processes hijack the neural mechanisms necessary to mediate appropriate responses to natural rewards. Maladaptive conditioned memories (context-drug) promote drug-seeking behavior. Extinction involves the formation of new inhibitory memories and prevents drug-directed behaviors. The noradrenergic system (NA) is involved in the consolidation and extinction of drug-associated memories. Our aim is to explore Atomoxetine (ATO: NA reuptake inhibitor) effects on extinction of cocaine-induced conditioned place preference (CPP). C57BL/6 male mice were trained on CPP induced by cocaine (20 mg/kg). Before CPP expression (T1), mice were divided in three groups: SAL-SAL (saline from T1-T6), SAL-ATO (saline on T1, ATO from T2-T6) and ATO-ATO (ATO from T1-T6). ATO was injected 30 min before each test. We performed these experiments at two levels; 1) all mice repeated extinction sessions until the whole group fulfilled the extinction's criteria. 2) We examined individual differences and brains were collected when each mouse reached the extinction's criteria. A two-way ANOVA showed that animals treated with ATO-ATO differed in rate of extinction with mice treated with SAL-SAL ($p=0.0219$). Kolmogorov-Smirnov analysis showed significant differences between SAL-SAL and ATO-ATO on T3 ($p=0.0204$). Additionally, a survival analysis determined that the probabilities to extinguish CPP is higher for the ATO-ATO group than SAL-SAL (T1-T5; $p=0.0377$). These effects were not observed for SAL-ATO group. ATO given before T1 (T1-T6), but not from T2-T6, facilitates extinction of cocaine-induced CPP. These findings indicate that NA modulation of cocaine-CPP extinction might be sensitive to the initial expression of CPP.

Addiction is a neuroplasticity disorder in which the exposure to environmental stimuli (CS) associated with the drug (US) triggers relapse after abstinence. Memory reconsolidation involves the return to the original CS–US association. Extinction implies a new learning; the CS ceased predicting the US. Following a short CS-alone session, memory reconsolidation is dominant, whereas extended, repeated sessions lead to extinction. β2-adrenergic receptors (β2-ARs) are important for the reconsolidation and extinction of memory. The objective was to evaluate whether the activation of the β2-ARs, would modulate reconsolidation, extinction and reinstatement of cocaine-induced conditioned place preference (CPP). Male C57Bl/6J mice were trained following a cocaine (20 mg/kg)-induced CPP. Following a CPP test, animals were divided into two groups: Exp.1) a short CS-reactivation trial followed by a CPP test (5 series) and Exp.2) 5 consecutive extinction trials followed by a CPP test (2 series). Animals received clenbuterol (β2-ARs agonist; 0, 0.5 and 2 mg/kg) immediately after each trial. Reinstatement was tested 24h, 72h and 30 days after extinction. On Exp.1, activation of β2-ARs had no effect on extinction. However, clenbuterol (0.5 mg/kg; $p = 0.0375$ and 2 mg/kg; $p = 0.0018$) promoted reinstatement 30 days after extinction. On Exp.2, activation of β2-Ars facilitated extinction ($p = 0.0579$) and preliminary data suggested a prevention of reinstatement. Our results indicated that methodological variables (such as the duration of the CS exposure) influence the memory processes activated during retrieval. The effects of β2-Ars activation may be different depending on two dissociable processes; memory reconsolidation and extinction.

Effects of naltrexone on alcohol, sucrose, and saccharin binge-like drinking in C57BL/6J mice: a study with a multiple bottle choice procedure.
Chronic alcohol (ethyl alcohol, EtOH) binging has been associated with long-term neural adaptations that lead to the development of addiction. Many of the neurobiological features of EtOH abuse are shared with other forms of binging, like pathological feeding. The drinking-in-the-dark (DID) paradigm has been used extensively to study the neurobiology of EtOH binge-like drinking due to its ability to promote high intakes relevant to human behavior. DID can also generate high consumption of other tastants, but this procedure has not been fully adapted to study forms of binging behavior that are not alcohol-driven. In the present study, we used a modified version of DID that uses multiple bottle availability to promote even higher levels of EtOH drinking in male C57BL/6J mice and allows a thorough investigation of tastant preferences. We assessed whether administration of systemic naltrexone could reduce binging on EtOH, sucrose, and saccharin separately as well as in combination. Our multiple bottle DID procedure resulted in heightened levels of consumption compared with previously reported data using this task. We found that administration of the opioid receptor antagonist naltrexone reduced intakes of preferred, highly concentrated EtOH, sucrose, and saccharin. We also report that naltrexone was able to reduce overall intakes when animals were allowed to self-administer EtOH, sucrose, or saccharin in combination. Our modified DID procedure provides a novel approach to study binging behavior that extends beyond EtOH to other tastants (i.e. sucrose and artificial sweeteners), and has implications for the study of the neuropharmacology of binge drinking.

Alcohol Binge Drinking and Anxiety-Like Behavior in Socialized Versus Isolated C57BL/6J Mice.
Binge alcohol drinking has been characterized as a key feature of alcoholism. The drinking-in-the-dark (DID) preclinical model, a procedure that promotes high levels of ethanol (EtOH) intake in short periods of time, has been extensively used to

investigate neuropharmacological and genetic determinants of binge-like EtOH consumption. Using DID methodology, alcohol-preferring strains of mice such as C57BL/6J (B6) mice consume enough EtOH to achieve blood concentrations (≥1.0 mg/ml) associated with behavioral intoxication (i.e., motor incoordination). DID procedures typically involve the use of socially isolated animals (single-housed prior to and during the experiment). Previous research indicates that stress associated with social isolation can induce anxiety-like behavior and promote increases in EtOH intake. The present study investigates the role of housing conditions in anxiety-like behavior and binge-like EtOH intake using a DID procedure. Alcohol Clin Exp Res, 2020; 44

THE INTERPEDUNCULAR NUCLEUS ACTS AS A KEY MODULATOR BETWEEN REINFORCEMENT AND AVERSIVE CIRCUITS IN NICOTINE INTAKE

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Joachim Jehl, Éléonore Vicq, Maria Ciscato, Nicolas Guyon, Philippe Faure, Alexandre Mourot
ESPCI, Brain Plasticity Lab Umr8249 Cnrs, Paris, France

Aims: Nicotine drives reinforcement primarily by activating nicotine acetylcholine receptors (nAChRs) on dopaminergic (DA) neurons in the ventral tegmental area (VTA). But nicotine also acts concurrently on the interpeduncular nucleus (IPN) to induce aversion to the drug. We wish to understand how IPN neurons respond to nicotine *in vivo* and whether this response influences nicotine's reinforcing effect in the VTA. **Methods:** We used *in vivo* electrophysiological and fiber photometry recordings in adult mice, coupled with a novel chemogenetic strategy for manipulating specific nAChR subtypes, to probe nicotinic transmission in the IPN and its influence on VTA DA neurons. **Results:** We show that nicotine activates and inhibits two different populations of IPN neurons starting at low doses that elicit no response in VTA DA neurons. To pharmacologically dissect these effects, we developed two novel mutant mouse models, which allow chemogenetic inhibition of specific nAChR subtypes (β2- and β4-containing receptors). The mutation (E61C) does not alter receptor function, but allows the covalent attachment of an irreversible antagonist (called MPEG4Ch). Infusion of MPEG4Ch in the IPN of these mutant mice, but not of WT mice, leads to potent, pharmacologically-specific and sustained receptor antagonism. We consequently show that β2 and β4 nAChRs differentially contribute to nicotine-induced activation and inhibition. Furthermore, we show that blocking IPN β4 nAChRs significantly reduces the threshold response to nicotine in VTA DA neurons. **Conclusions:** Our results suggest that nicotine's effect on IPN neurons is mediated through specific nAChRs that will ultimately facilitate its action on VTA DA neurons.

VTA CIRCUITRY SUSTAINS OPPOSITE RESPONSES OF DOPAMINERGIC NEURONS TO DRUGS OF ABUSE

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Tinaïg Le Borgne[1], Claire Nguyen[1], Éléonore Vicq[2], Stefania Tolu[3], Alexandre Mourot[1], Fabio Marti[1], Philippe Faure[1]
[1]ESPCI, Brain Plasticity Lab Umr8249 Cnrs, Paris, France, [2]Sorbonne Université - ESPCI, Brain Plasticity Lab Umr8249 Cnrs, Paris, France, [3]PARIS DIDEROT - CNRS, Bfa - Unité De Biologie Fonctionnelle Et Adaptative - Cnrs Umr 8251, PARIS, France

AIMS: Nicotine, the main psychoactive compound of tobacco, binds on cationic nicotinic receptors (nAChRs) to increase the firing rate of dopaminergic (DA) neurons of the ventral tegmental area (VTA), leading to higher release of DA in target structures and positive reinforcement. Besides rewarding properties, nicotine also promotes negative effects. Recently, we showed heterogeneity in nicotine-induced responses on VTA DA subpopulations targeting nucleus accumbens (NAc) and amygdala (AMg) nuclei. NAc-projecting DA neurons are activated by nicotine and their optogenetic activation is reinforcing. AMg-projecting DA neurons are inhibited by nicotine and their optogenetic silencing is anxiogenic. We address 1) if alcohol, known for its rewarding and anxiolytic/anxiogenic properties, also produces distinct responses on DA subpopulations, and 2) if a circuit-based mechanism could underly drug-induced inhibition. METHODS: Combining *in vivo* juxtacellular or *ex vivo* patch-clamp recordings with injections of retrograde tracers, we investigated extrinsic/intrinsic properties and response profiles to nicotine and ethanol of NAc or AMg-projecting DA neurons. RESULTS: We demonstrated that alcohol induces two opposite responses, such as nicotine, on the same segregated DA subpopulations. NAc-projecting DA neurons are activated by nicotine and ethanol while AMg-projecting DA neurons are inhibited by both drugs. Finally, we start to investigate intrinsic properties, difference in receptor expression and local/distal GABAergic signaling of both populations. CONCLUSION: These results highlight heterogeneity of drug impact on DA subpopulations and raise the question of the role it might play in the balance between the drugs positive and negative effects that regulates their use.

MOLECULAR CANDIDATES IN THE NUCLEUS ACCUMBENS SHELL INVOLVED IN THE PROTECTIVE EFFECT OF SOCIAL INTERACTION WHEN AVAILABLE AS AN ALTERNATIVE TO COCAINE

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Inês Amaral, Cristina Lemos, Ahmad Salti, Alex Hofer, Rana El Rawas
Innsbruck Medical University, Department Of Psychiatry, Psychotherapy, Psychosomatics And Medical Psychology, Innsbruck, Austria

Aims: Social interaction, when available in a distinct context from the one associated with drug consumption, is able to eliminate preference for cocaine and prevents against cocaine relapse. The aim of this study is to investigate how these beneficial effects of social interaction against cocaine are mediated. Methods: Male Sprague Dawley rats underwent stereotaxic surgery for cannula implantation into the brain before being tested in a conditioned place preference (CPP) paradigm. Results: Rats that expressed social CPP had increased nucleus accumbens (NAc) α- calcium/calmodulin dependent protein kinase II (CaMKII) levels. Moreover, rats received an infusion of CaMKII inhibitor in the NAc shell (NAcSh) or core before the test in a concurrent CPP (social *vs* cocaine). Whereas vehicle infusions led to equal preference for both stimuli, inhibition of CaMKII in the NAcSh, but not in the core, shifted rats' preference toward the cocaine-associated context. These results suggest that social interaction reward engages NAcSh CaMKII. In rats expressing cocaine CPP, intracerebroventricular infusion of corticotropin-releasing factor (CRF) led to an increase in cocaine preference, an effect reversed in rats that received the CRF receptor antagonist, α-helical CRF. Importantly, when social interaction was available alternatively to cocaine, the CRF-induced increase in cocaine preference was completely reversed to the level of rats that received α-helical CRF. This reversal was paralleled by a decrease in NAcSh p38 MAPK expression. Conclusion: These findings suggest that social interaction positive effects against cocaine are dichotomized into rewarding effects via CaMKII and anti-stress effects via p38 MAPK, in the NAcSh.

Is p38 MAPK Associated to Drugs of Abuse-Induced Abnormal Behaviors?
The family members of the mitogen-activated protein kinases (MAPK) mediate a wide variety of cellular behaviors in response to extracellular stimuli. p38 MAPKs are key signaling molecules in cellular responses to external stresses and regulation of pro-inflammatory cytokines. Some studies have suggested that p38 MAPK in the region of the nucleus accumbens is involved in abnormal behavioral responses induced by drugs of abuse. In this review, we discuss the role of the p38 MAPK in the rewarding effects of drugs of abuse. We also summarize the implication of p38 MAPK in stress, anxiety, and depression. We opine that p38 MAPK activation is more closely associated to stress-induced aversive responses rather than drug effects per se, in particular cocaine. p38 MAPK is only involved in cocaine reward, predominantly when promoted by stress. Downstream substrates of p38 that may contribute to the p38 MAPK associated-behavioral responses are proposed. Finally, we suggest p38 MAPK inhibitors as possible therapeutic interventions against stress-related disorders by potentially increasing resilience against stress and addiction relapse induced by adverse experiences.

Social interaction reward: A resilience approach to overcome vulnerability to drugs of abuse.
Drug addiction is a multifactorial disorder resulting from the complex interaction between biological, environmental and drug-induced effects. Generally, stress is a well-known risk factor for the development of drug addiction and relapse. While most of the research focuses on risk factors that increase the vulnerability to drugs of abuse, recent studies are focusing on the areas of strength/positive coping approaches that can increase resistance to drugs of abuse. In this review, we concentrate on resilience, seen as a dynamic process, which can allow individuals to positively adapt within the context of a specific risk for psychiatric illness. Here, we discuss the effects of social stress in animal models on drug use, particularly cocaine. In contrast, we suggest social interaction reward when available as an alternative to drug use as an approach contracting negative stress effects and increasing resistance to drug use. Indeed, interventions, which aim at enhancing resilience to stress through the facilitation of social interaction and the enhancement of social support, could be particularly effective in

helping people cope with stress and preventing drug use problems or relapse. Finally, understanding the neurobiological mechanisms underlying protective factors such as social interaction reward should provide the basis for future evidence-based interventions targeting substance abuse and stress-related pathologies.

Is It Possible to Shift from Down to Top Rank? A Focus on the Mesolimbic Dopaminergic System and Cocaine Abuse.
Impaired social behavior is a common feature of many psychiatric disorders, in particular with substance abuse disorders. Switching the preference of the substance-dependent individual toward social interaction activities remains one of the major challenges in drug dependence therapy. However, social interactions yield to the emergence of social ranking. In this review, we provide an overview of the studies that examined how social status can influence the dopaminergic mesolimbic system and how drug-seeking behavior is affected. Generally, social dominance is associated with an increase in dopamine D receptor binding in the striatum and a reduced behavioral response to drugs of abuse. However, it is not clear whether higher D receptor availability is a result of increased D receptor density and/or reduced dopamine release in the striatum. Here, we discuss the possibility of a potential shift from down to top rank via manipulation of the mesolimbic system. Identifying the neurobiology underlying a potential rank switch to a resilient phenotype is of particular interest in order to promote a positive coping behavior toward long-term abstinence from drugs of abuse and a protection against relapse to drugs. Such a shift may contribute to a more successful therapeutic approach to cocaine addiction.

Social interaction reward in rats has anti-stress effects.
Social interaction in an alternative context can be beneficial against drugs of abuse. Stress is known to be a risk factor that can exacerbate the effects of addictive drugs. In this study, we investigated whether the positive effects of social interaction are mediated through a decrease in stress levels. For that purpose, rats were trained to express cocaine or social interaction conditioned place preference (CPP). Behavioural, hormonal, and molecular stress markers were evaluated. We found that social CPP decreased the percentage of incorrect transitions of grooming and corticosterone to the level of naïve untreated rats. In addition, corticotropin-releasing factor (CRF) was increased in the bed nucleus of stria terminalis after cocaine CPP. In order to study the modulation of social CPP by the CRF system, rats received intracerebroventricular CRF or alpha-helical CRF, a nonselective antagonist of CRF receptors. The subsequent effects on CPP to cocaine or social interaction were observed. CRF injections increased cocaine CPP, whereas alpha-helical CRF injections decreased cocaine CPP. However, alpha-helical CRF injections potentiated social CPP. When social interaction was made available in an alternative context, CRF-induced increase of cocaine preference was reversed completely to the level of rats receiving cocaine paired with alpha-helical CRF. This reversal of cocaine preference was also paralleled by a reversal in CRF-induced increase of p38 MAPK expression in the nucleus accumbens shell. These findings suggest that social interaction could contribute as a valuable component in treatment of substance use disorders by reducing stress levels.

Impact of blunting astrocyte activity on hippocampal synaptic plasticity in a mouse model of early Alzheimer's disease based on amyloid-β peptide exposure.
Amyloid-β peptides (Aβ) accumulate in the brain since early Alzheimer's disease (AD) and dysregulate hippocampal synaptic plasticity, the neurophysiological basis of memory. Although the relationship between long-term potentiation (LTP) and memory processes is well established, there is also evidence that long-term depression (LTD) may be crucial for learning and memory. Alterations in synaptic plasticity, namely in LTP, can be due to communication failures between astrocytes and neurons; however, little is known about astrocytes' ability to control hippocampal LTD, particularly in AD-like conditions. We now aimed to test the involvement of astrocytes in changes of hippocampal LTP and LTD triggered by Aβ , taking advantage of L-α-aminoadipate (L-AA), a gliotoxin that blunts astrocytic function. The effects of Aβ exposure were tested in two different experimental paradigms: ex vivo (hippocampal slices superfusion) and in vivo (intracerebroventricular injection), which were previously validated to impair memory and hippocampal synaptic plasticity, two features of early AD. Blunting astrocytic function with L-AA reduced LTP and LTD amplitude in hippocampal slices from control mice, but the effect on LTD was less evident, suggesting that astrocytes have a greater influence on LTP than on LTD under non-pathological conditions. However, under AD conditions, blunting astrocytes did not consistently alter the reduction of LTP magnitude, but reverted the LTD-to-LTP shift caused by both ex vivo and in vivo Aβ exposure. This shows that astrocytes were responsible for the hippocampal LTD-to-LTP shift observed in early AD conditions, reinforcing the interest of strategies targeting astrocytes to restore memory and synaptic plasticity deficits present in early AD.

Rewarding Social Interaction in Rats Increases CaMKII in the Nucleus Accumbens.
Calcium/calmodulin-dependent protein kinase II (CaMKII) is known to be involved in the sensitized locomotor responses and drug-seeking behavior to psychostimulants. However, little is known about the contribution of CaMKII signaling in the nucleus accumbens (NAc) in natural rewards such as social interaction. The present experiments explored the implication of CaMKII signaling in drug versus natural reward. In the NAc of rats expressing cocaine or social interaction conditioned place preference (CPP), αCaMKII activation was induced in those expressing social interaction but not cocaine CPP. In order to investigate the role of NAc CaMKII in the expression of reward-related learning of drug versus non-drug stimuli, we inhibited CaMKII through an infusion of KN-93, a CaMKII inhibitor, directly into the NAc shell or core, before the CPP test in a concurrent paradigm in which social interaction was made available in the compartment alternative to the one associated with cocaine during conditioning. Whereas vehicle infusions led to equal preference to both stimuli, inhibition of CaMKII by a KN-93 infusion before the CPP test in the shell but not the core of the NAc shifted the rats' preference toward the cocaine-associated compartment. Altogether, these results suggest that social interaction reward engages CaMKII in the NAc.

l-α-aminoadipate causes astrocyte pathology with negative impact on mouse hippocampal synaptic plasticity and memory.
Increasing evidence shows that astrocytes, by releasing and uptaking neuroactive molecules, regulate synaptic plasticity, considered the neurophysiological basis of memory. This study investigated the impact of l-α-aminoadipate (l-AA) on astrocytes which sense and respond to stimuli at the synaptic level and modulate hippocampal long-term potentiation (LTP) and memory. l-AA selectivity toward astrocytes was proposed in the early 70's and further tested in different systems. Although it has been used for impairing the astrocytic function, its effects appear to be variable in different brain regions. To test the effects of l-AA in the hippocampus of male C57Bl/6 mice we performed two different treatments (ex vivo and in vivo) and took advantage of other compounds that were reported to affect astrocytes. l-AA superfusion did not affect the basal synaptic transmission but decreased LTP magnitude. Likewise, trifluoroacetate and dihydrokainate decreased LTP magnitude and occluded the effect of l-AA on synaptic plasticity, confirming l-AA selectivity. l-AA superfusion altered astrocyte morphology, increasing the length and complexity of their processes. In vivo, l-AA intracerebroventricular injection not only reduced the astrocytic markers but also LTP magnitude and impaired hippocampal-dependent memory in mice. Interestingly, d-serine administration recovered hippocampal LTP reduction triggered by l-AA (2 h exposure in hippocampal slices), whereas in mice injected with l-AA, the superfusion of d-serine did not fully rescue LTP magnitude. Overall, these data show that both l-AA treatments affect astrocytes differently, astrocytic activation or loss, with similar negative outcomes on hippocampal LTP, implying that opposite astrocytic adaptive alterations are equally detrimental for synaptic plasticity.

33396297: Amaral IM, Lemos C, Cera I, Dechant G, Hofer A, El Rawas R
Involvement of cAMP-Dependent Protein Kinase in the Nucleus Accumbens in Cocaine Versus Social Interaction Reward.
Evidence suggests that PKA activity in the nucleus accumbens (NAc) plays an essential role in reward-related learning. In this study, we investigated whether PKA is differentially involved in the expression of learning produced by either natural reinforcers or psychostimulants. For that purpose, we inhibited PKA through a bilateral infusion of Rp-cAMPS, a specific PKA inhibitor, directly into the NAc. The effects of PKA inhibition in the NAc on the expression of concurrent conditioned place preference (CPP) for cocaine (drug) and social interaction (natural reward) in rats were evaluated. We found that PKA inhibition increased the expression of cocaine preference. This effect was not due to altered stress levels or decreased social reward. PKA inhibition did not affect the expression of natural reward as intra-NAc Rp-cAMPS infusion did not affect expression of social preference. When rats were trained to express cocaine or social interaction CPP and tested for eventual persisting preference 7 and 14 days after CPP expression, cocaine preference was persistent, but social preference was abolished after the first test. These results suggest that PKA in the NAc is involved in drug reward learning that might lead to addiction and that only drug, but not natural, reward is persistent.

The exercise sex gap and the impact of the estrous cycle on exercise performance in mice.
Exercise physiology is different in males and females. Females are poorly studied due to the complexity of the estrous cycle and this bias has created an exercise sex gap. Here, we evaluated the impact of sexual dimorphism and of the estrous cycle on muscle strength and running power of C57BL/6 mice. Like men, male mice were stronger and more powerful than females. Exercise-induced increase of O consumption ([Formula: see text]O) and CO production ([Formula: see text]CO) were equal between sexes, indicating that running economy was higher in males. Thermoregulation was also more efficient in males. In females, proestrus increased exercise [Formula: see text]O and [Formula: see text]CO at low running speeds (30-35% female [Formula: see text]O) and estrus worsened thermoregulation. These differences translated into different absolute

and relative workloads on the treadmill, even at equal submaximal [Formula: see text]O and belt speeds. In summary, our results demonstrate the better muscle strength, running power and economy, and exercise-induced thermoregulation of males compared to females. Proestrus and estrus still undermined the running economy and exercise-induced thermoregulation of females, respectively. These results demonstrate an important exercise sex gap in mice.

Aims: Long-term dose-escalating cocaine administration leads to dysregulation of the reward system and initiates processes that ultimately result in weakening of the rewarding effects of cocaine. Here, we studied the influence of an escalating-dose cocaine regimen on rats' drug-associated appetitive behaviour after a withdrawal period, along with changes is HPA axis, opioid and dopaminergic systems' activity in plasma and the prefrontal cortex (PFC). **Method:** We studied the effects of the escalating-dose cocaine regimen in the Conditioned Place Preference (CPP) Test and on 50-kHz ultrasonic vocalisation after withdrawal period. We assessed corticosterone, CART 55-102, β-endorphin, and proopiomelanocortin (POMC) levels in plasma (ELISA), along with mRNA levels for D2 dopaminergic receptor, κ-receptor (KOR), CART, and epigenetic factors: miR-124 and miR-137 in the PFC (PCR). **Results:** Rats subjected to the escalating-dose cocaine regimen spent less time in the cocaine-paired compartment, and presented weaker appetitive vocalisation. These changes were accompanied by a decrease in the corticosterone and CART levels, and an increase in the β-endorphin and POMC levels in plasma, combined with an increase in the mRNA for D2R, but a decrease in the mRNA levels for KOR, and CART in the PFC. We also observed an increase in the miR-124 levels in the PFC. **Conclusions:** The frequent use of high doses of cocaine leads to weakening of its rewarding effects which is possibly related to interplay between HPA axis, dopaminergic and opioid systems in the PFC.

VOLUNTARY ALCOHOL CONSUMPTION ALTERS THE NEUROBIOLOGY UNDERLYING COCAINE-SEEKING

POSTER SESSION 05 - SECTION: REWARD & ADDICTION MECHANISMS

Lori Knackstedt
University of Florida, Psychology, Gainesville, United States of America

Aims: While many medications reduce the reinstatement of cocaine-seeking in animals, these agents show little clinical efficacy at preventing relapse in humans. This is possibly due to the fact that an estimated 60-90% of cocaine users also use alcohol, but animal models of polysubstance use are seldom used. Relapse is modeled in animals using the intravenous self-administration (IVSA) extinction-reinstatement paradigm. Here we compare cocaine-seeking, glutamate efflux, and fos activation between rats that undergo cocaine IVSA alone or in combination with oral or IV alcohol. Methods: For sequential self-administration, rats self-administered cocaine for 2 hr/day, followed immediately by 6 hr homecage access to alcohol (20% v/v) and water or water alone. Self-administration continued for 12 days. For simultaneous self-administration, rats underwent IVSA of an alcohol+cocaine solution for 6 hr/day, 2 days/week for 5 weeks. Rats were tested for cued cocaine-seeking. Results: Cocaine self-administration did not alter the amount of alcohol consumed. Post-cocaine alcohol availability did not consistently alter cocaine intake. The robust reinstatement of cocaine-seeking in the sequential cocaine-alcohol group was not accompanied by glutamate efflux in the NAc, as it was in cocaine-only rats. Simultaneous cocaine-alcohol IVSA was robust, with no effect on motivation to seek cocaine or cued reinstatement of cocaine-seeking. Conclusions: While cocaine intake is not consistently increased by alcohol, polysubstance use alters neurobiology underlying drug-seeking, relative to that produced by a single drug. Medications targeting the glutamate transmitter system may not be effective therapies for preventing relapse in cocaine users that also consume alcohol.

Aims: Antidepressants are effective in only half of the patients, and their therapeutic effects occur after weeks of treatment. In our previous research, a multimodal compound HBK-15 showed significant antidepressant-like, anxiolytic-like, and memory-enhancing properties in rodents. Given the promising results, we aimed to evaluate the antidepressant-like and procognitive effects of a single administration of HBK-15 in a mouse depression model, the duration of these effects, and their dependence on BDNF. **Methods:** We used a mouse model of the unpredictable chronic mild stress with the sucrose preference and novel object recognition tests as behavioral endpoints to determine the antidepressant-like and procognitive activity, respectively. Next, we determined the BDNF, p-CREB, p-CaMKIV, p-PKA, and p-ERK1/2 levels in the prefrontal cortex and hippocampus using ELISA. To verify whether the pharmacological effects are BDNF-dependent, we used BDNF Val66Met mice. **Results:** We observed that a single administration of HBK-15 reversed reduced sucrose preference and novel object exploration time, and these effects lasted up to 24 h. HBK-15 upregulated the decreased BDNF p-CREB, p-CaMKIV, p-PKA, p-ERK1/2 levels in the prefrontal cortex of the stressed mice. The increase in sucrose preference after HBK-15 injection was still observed in the BDNF Val66Met mice. **Conclusion:** We found that HBK-15 reversed depression-like behaviors and memory impairments and regulated decreased BDNF and p-CREB levels in the prefrontal cortex via all studied pathways. Contrary to the procognitive effect, the antidepressant-like activity of HBK-15 did not depend on BDNF. This study was financed by the National Science Centre, Poland (grant number 2019/34/E/NZ7/00454, 2017/01/X/NZ7/00818).

Biased agonism in drug discovery: Is there a future for biased 5-HT receptor agonists in the treatment of neuropsychiatric diseases?
Serotonin (5-HT) is one of the fundamental neurotransmitters that contribute to the information essential for an organism's normal, physiological function. Serotonin acts centrally and systemically. The 5-HT receptor is the most widespread serotonin receptor, and participates in many brain-related disorders, including anxiety, depression, and cognitive impairments. The 5-HT receptor can activate several different biochemical pathways and signals through both G protein-dependent and G protein-independent pathways. Preclinical experiments indicate that distinct signaling pathways in specific brain regions may be crucial for antidepressant-like, anxiolytic-like, and procognitive responses. Therefore, the development of new ligands that selectively target a particular signaling pathway(s) could open new possibilities for more effective and safer pharmacotherapy. This review discusses the current state of preclinical studies focusing on the concept of functional selectivity (biased agonism) regarding the 5-HT receptor and its role in antidepressant-like, anxiolytic-like, and procognitive regulation. Such work highlights not only the differential effects of targeted autoreceptors, vs. heteroreceptors, but also the importance of targeting specific downstream intracellular signaling processes, thereby enhancing favorable over unfavorable signaling activation.

The Calcium/Calmodulin-Dependent Kinases II and IV as Therapeutic Targets in Neurodegenerative and Neuropsychiatric Disorders.
CaMKII and CaMKIV are calcium/calmodulin-dependent kinases playing a rudimentary role in many regulatory processes in the organism. These kinases attract increasing interest due to their involvement primarily in memory and plasticity and

various cellular functions. Although CaMKII and CaMKIV are mostly recognized as the important cogs in a memory machine, little is known about their effect on mood and role in neuropsychiatric diseases etiology. Here, we aimed to review the structure and functions of CaMKII and CaMKIV, as well as how these kinases modulate the animals' behavior to promote antidepressant-like, anxiolytic-like, and procognitive effects. The review will help in the understanding of the roles of the above kinases in the selected neurodegenerative and neuropsychiatric disorders, and this knowledge can be used in future drug design.

Revisiting the sigma-1 receptor as a biological target to treat affective and cognitive disorders.
Depression and cognitive disorders are diseases with complex and not-fully understood etiology. Unfortunately, the COVID-19 pandemic dramatically increased the prevalence of both conditions. Since the current treatments are inadequate in many patients, there is a constant need for discovering new compounds, which will be more effective in ameliorating depressive symptoms and treating cognitive decline. Proteins attracting much attention as potential targets for drugs treating these conditions are sigma-1 receptors. Sigma-1 receptors are multi-functional proteins localized in endoplasmic reticulum membranes, which play a crucial role in cellular signal transduction by interacting with receptors, ion channels, lipids, and kinases. Changes in their functions and expression may lead to various diseases, including depression or memory impairments. Thus, sigma-1 receptor modulation might be useful in treating these central nervous system diseases. Importantly, two sigma-1 receptor ligands entered clinical trials, showing that this compound group possesses therapeutic potential. Therefore, based on preclinical studies, this review discusses whether the sigma-1 receptor could be a promising target for drugs treating affective and cognitive disorders.

Serotonin receptors in depression and anxiety: Insights from animal studies.
Serotonin regulates many physiological processes including sleep, appetite, and mood. Thus, serotonergic system is an important target in the treatment of psychiatric disorders, such as major depression and anxiety. This natural neurotransmitter interacts with 7 families of its receptors (5-HT1-7), which cause a variety of pharmacological effects. Using genetically modified animals and selective or preferential agonists and antagonist, numerous studies demonstrated the involvement of almost all serotonin receptor subtypes in antidepressant- or anxiolytic-like effects. In this review, based on animal studies, we discuss the possible involvement of serotonin receptor subtypes in depression and anxiety.

Synthesis and Evaluation of the Antidepressant-like Properties of HBK-10, a Novel 2-Methoxyphenylpiperazine Derivative Targeting the 5-HT and D Receptors.
The increasing number of patients reporting depressive symptoms requires the design of new antidepressants with higher efficacy and limited side effects. As our previous research showed, 2-methoxyphenylpiperazine derivatives are promising candidates to fulfill these criteria. In this study, we aimed to synthesize a novel 2-methoxyphenylpiperazine derivative, HBK-10, and investigate its in vitro and in vivo pharmacological profile. After assessing the affinity for serotonergic and dopaminergic receptors, and serotonin transporter, we determined intrinsic activity of the compound at the 5-HT and D receptors. Next, we performed behavioral experiments (forced swim test, tail suspension test) to evaluate the antidepressant-like activity of HBK-10 in naïve and corticosterone-treated mice. We also assessed the safety profile of the compound. We showed that HBK-10 bound strongly to 5-HT and D receptors and presented antagonistic properties at these receptors in the functional assays. HBK-10 displayed the antidepressant-like effect not only in naïve animals, but also in the corticosterone-induced mouse depression model, i.e., chronic administration of HBK-10 reversed corticosterone-induced changes in behavior. Moreover, the compound's sedative effect was observed at around 26-fold higher doses than the antidepressant-like ones. Our study showed that HBK-10 displayed a favorable pharmacological profile and may represent an attractive putative treatment candidate for depression.

The Antiarrhythmic Activity of Novel Pyrrolidin-2-one Derivative S-75 in Adrenaline-Induced Arrhythmia.
Arrhythmia is a quivering or irregular heartbeat that can often lead to blood clots, stroke, heart failure, and other heart-related complications. The limited efficacy and safety of antiarrhythmic drugs require the design of new compounds. Previous research indicated that pyrrolidin-2-one derivatives possess an affinity for α-adrenergic receptors. The blockade of α-adrenoceptor may play a role in restoring normal sinus rhythm; therefore, we aimed to verify the antiarrhythmic activity of novel pyrrolidin-2-one derivative S-75. In this study, we assessed the influence on sodium, calcium, potassium channels, and

β-adrenergic receptors to investigate the mechanism of action of S-75. Lack of affinity for β-adrenoceptors and weak effects on ion channels decreased the role of these adrenoceptors and channels in the pharmacological activity of S-75. Next, we evaluated the influence of S-75 on normal ECG in rats and isolated rat hearts, and the tested derivative did not prolong the QT interval, which may confirm the lack of the proarrhythmic potential. We tested antiarrhythmic activity in adrenaline-, aconitine- and calcium chloride-induced arrhythmia models in rats. The studied compound showed prophylactic antiarrhythmic activity in the adrenaline-induced arrhythmia, but no significant activity in the model of aconitine- or calcium chloride-induced arrhythmia. In addition, S-75 was not active in the model of post-reperfusion arrhythmias of the isolated rat hearts. Conversely, the compound showed therapeutic antiarrhythmic properties in adrenaline-induced arrhythmia, reducing post-arrhythmogen heart rhythm disorders, and decreasing animal mortality. Thus, we suggest that the blockade of α-adrenoceptor might be beneficial in restoring normal heart rhythm in adrenaline-induced arrhythmia.

The antidepressant-like activity of chiral xanthone derivatives may be mediated by 5-HT1A receptor and β-arrestin signalling.
Our previous studies showed that xanthone derivatives with -(2-methoxyphenyl)piperazine fragment have an affinity to the 5-HT1A receptor and show antidepressant-like properties in rodents. In this study, we tested three xanthone derivatives, HBK-1 and its enantiomers, in which we increased the distance between the piperazine and xanthone fragments by using a hydroxypropoxy linker. We hypothesized that this would increase the binding to the 5-HT1A receptor and consequently, pharmacological activity.

HBK-17, a 5-HT Receptor Ligand With Anxiolytic-Like Activity, Preferentially Activates ß-Arrestin Signaling.
Numerous studies have proven that both stimulation and blockade of 5-HT and the blockade of 5-HT receptors might cause the anxiolytic-like effects. Biased agonists selectively activate specific signaling pathways. Therefore, they might offer novel treatment strategies. In this study, we investigated the anxiolytic-like activity, as well as the possible mechanism of action of 1-[(2,5-dimethylphenoxy)propyl]-4-(2-methoxyphenyl)piperazine hydrochloride (HBK-17). In our previous experiments, HBK-17 showed high affinity for 5-HT and 5-HT receptors and antidepressant-like properties. We performed the four plate test and the elevated plus maze test to determine anxiolytic-like activity. Toward a better understanding of the pharmacological properties of HBK-17 we used various functional assays to determine its intrinsic activity at 5-HT, 5-HT, 5-HT, and D receptors and UHPLC-MS/MS method to evaluate its pharmacokinetic profile. We observed the anxiolytic-like activity of HBK-17 in both behavioral tests and the effect was reversed by the pretreatment with WAY-100635, which proves that 5-HT receptor activation was essential for the anxiolytic-like effect. Moreover, the compound moderately antagonized D, weakly 5-HT and very weakly 5-HT receptors. We demonstrated that HBK-17 preferentially activated ß-arrestin signaling after binding to the 5-HT receptor. HBK-17 was rapidly absorbed after intraperitoneal administration and had a half-life of about 150 min. HBK-17 slightly penetrated the peripheral compartment and showed bioavailability of approximately 45%. The unique pharmacological profile of HBK-17 encourages further experiments to understand its mechanism of action fully.

Pitolisant protects mice chronically treated with corticosterone from some behavioral but not metabolic changes in corticosterone-induced depression model.
Histamine H receptor ligands may have antidepressant and anxiolytic effects. They can also compensate for metabolic disorders, which affect glucose or triglyceride levels. In previous studies, we have shown that pitolisant, a histamine H receptor antagonist/inverse agonist and σ1 receptor agonist, prevented the development of certain metabolic and depressive-like disorders in mice that have been treated chronically with olanzapine.

Aims: A rapidly burgeoning literature documents copious sex influence on brain anatomy, chemistry, and function. Many regions of the brain responsible for mood and cognitive processes, such as the hippocampus, amygdala, and neocortex, are sexually dimorphic. Therefore, sex matters much more for understanding the effects of the drugs than it has been widely assumed. Taking this into account, we first determined the affinity of HBK-15 for androgen and estrogen receptors. Then we investigated the antidepressant- and anxiolytic-like potential of HBK-15 in female juvenile mice. **Methods:** We used radioligand binding assays to determine the affinity of HBK-15 for androgen and estrogen receptors. We then utilized the forced swim and the tail suspension tests to evaluate the antidepressant-like effect of the compound in female mice. Finally, we used the elevated plus maze test to investigate a possible anxiolytic-like potential. **Results:** HBK-15 did not show any significant affinity for androgen and estrogen receptors. Nor did it decrease the immobility time in the forced swim and tail suspension tests. Similarly, HBK-15 did not increase the open arm entries or the time spent in the open arms of the elevated plus maze. **Conclusion:** We found that HBK-15 did not show affinity towards androgen and estrogen receptors. We also did not observe antidepressant- and anxiolytic-like effects in female juvenile mice. Given the promising results obtained in males, our results indicate the need for further experiments in other age groups to explain the mechanisms of these differences. This study was financed by the National Science Centre, Poland (grant 2019/34/E/NZ7/00454).

ELEVATING ANANDAMIDE LEVELS RESTORE DEPRESSION-LIKE PHENOTYPE AND ALTERATIONS IN MICRO-RNAS IN RATS EXPOSED TO EARLY LIFE STRESS

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Anna Portugalov, Hiba Zaidan, Inna Gaisler-Salomon, Irit Akirav
University of Haifa, School Of Psychological Sciences And The Integrated Brain And Behavior Research Center, Haifa, Israel

Introduction Early life stress (ELS) significantly increase predisposition to psychopathologies, including depression. Here, we compared the effects of treatment with the fatty acid amide hydrolase (FAAH) inhibitor, URB597 that increases anandamide levels and the selective serotonin reuptake inhibitor (SSRI), paroxetine, on depressive-like behavior and the expression of microRNAs (miRs) associated with depression and the serotonergic system in the medial prefrontal cortex (mPFC) of rats exposed to ELS. **Methods** Male and female rats were exposed to ELS using the "neglectful mother" paradigm, in which dams had limited access to nesting material, from postnatal day (P)7 to P14. During P45 to P60 (late-adolescence) URB597 (0.4 mg/kg) or paroxetine (5mg/kg), were administered i.p. for 2 weeks. On P90 (adulthood) rats were tested for depressive-like behavior and the expression of miR-16 and miR-135a. **Results** Adult male and female rats demonstrated depressive-like behavior, such as decreased social behavior and increased learned helplessness. Chronic treatment during post-adolescence with URB597, but not paroxetine, reversed these behaviors. In the mPFC, ELS males demonstrated a decrease in miR-16 and ELS females demonstrated a decrease in miR-135a. Importantly, URB597, that reversed depressive-like behavior in both sexes, also normalized mPFC miR-16 and miR-135a expression abnormalities in males and females, respectively. **Conclusions** Our findings show for the first time that enhancing anandamide signaling can prevent ELS-induced decrease in mPFC miRs and associated depression-like phenotype in both sexes. This may advance our knowledge on pathways dysfunctional in depression in cortical areas and suggest a mechanism for the beneficial effects of enhancing endocannabinoid signaling.

Major depression is the largest contributor to global disability by years lived with disability. Selective serotonergic reuptake inhibitors, including fluoxetine (FLX), are the most commonly used antidepressant for the treatment of major depression. However, they are effective for remission in only 30% of patients. Recently, we observed that the N-terminal fragment of Galanin [GAL(1-15)] enhanced the antidepressant effects of FLX in naïve animals. In this work, we have analyzed in an animal model of depression, the olfactory bulbectomy (OBX) rats, the effect of GAL(1-15) on FLX-mediated responses in the forced swimming test (FST) and the sucrose preference test (SPT), tests related with despair and anhedonic behaviours. We have also studied the corticosterone levels in OBX rats after the coadministration of GAL(1-15)+FLX. Groups of rats received a subchronic pattern of FLX(10mg/Kg) alone or in combination with GAL(1-15)(1nmol) 15min before the tests. Blood samples for corticosterone assay were collected 1h after the treatments. One-way ANOVA followed by Fisher´s least significant difference test was used. Our results show that GAL(1-15) decreases the immobility time by 50% ($p<0.05$) and increases the swimming time by 30% ($p<0.01$) compared with FLX in the FST, and in the SPT reversed the effects of the OBX procedure increasing the sucrose intake ($p<0.05$) and preference ($p<0.05$). The coadministration of GAL(1-15)(1nmol)+FLX(10mg/kg) also reduced the OBX-increased corticosterone levels by approximately 50% ($p<0.05$). In conclusion, these novelty results suggest using GAL(1-15) in combination with FLX as a novel strategy for treating depression.

ROLE OF THE ENDOCANNABINOID SYSTEM IN A GENETIC MODEL OF AUTISM BASED ON FMR1 DELETION IN RATS

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Emilia Carbone[1], Valeria Buzzelli[1], Antonia Manduca[1], Sara Schiavi[1], Viviana Trezza[2]
[1]Roma Tre University, Science, Rome, Italy, [2]Roma Tre University, Dept. Science, Rome, Italy

Autism spectrum disorder (ASD) has a multifactorial etiology and several studies are investigating ASD etiopathology to develop new therapeutic strategies. Fragile X syndrome (FXS) is the most frequent inherited cause of mental retardation and the leading monogenic cause of autism. In this context, various studies showed the involvement of the endocannabinoid system (ECS) in the pathogenesis of FXS and others focused their attention on the use of cannabinoid compounds in children affected by neurodevelopmental disorders. Beyond anecdotal reports, however, there is limited current evidence supporting such an intervention and the use of cannabinoids remains controversial. In the present work, we studied the role of the endocannabinoid neurotransmission in the autistic-like features displayed by the recently validated Fmr1-$^{\Delta}$exon8 rat model of autism. Wild-type (WT) and Fmr1-$^{\Delta}$exon8 male rats on a Sprague-Dawley background were used. We assessed whether a region-specific alteration in the ECS occurs in Fmr1-$^{\Delta}$exon8 rats by measuring the levels of the main endocannabinoids (AEA and 2-AG). Subsequently, we evaluated in these animals the behavioral effects of drugs targeting the ECS through the novel object recognition, three-chamber and social discrimination tests from adolescence to adulthood. Our results showed alterations in different components of the ECS in a region-specific manner in the brain of Fmr1-$^{\Delta}$exon8 rats. Pharmacological manipulation of endocannabinoid neurotransmission rescued the cognitive and social dysfunctions displayed by Fmr1-$^{\Delta}$exon8 animals. These findings demonstrate that endocannabinoids differentially modulate autistic-like traits in Fmr1-$^{\Delta}$exon8 rats in a brain region-specific manner, suggesting that changes in specific endocannabinoid mechanisms contribute to ASD-related behavioral phenotypes.

Healing autism spectrum disorder with cannabinoids: a neuroinflammatory story.
Autism spectrum disorder (ASD) is a complex neurodevelopmental disorder with a multifactorial etiology. Latest researches are raising the hypothesis of a link between the onset of the main behavioral symptoms of ASD and the chronic neuroinflammatory condition of the autistic brain; increasing evidence of this connection is shedding light on new possible players in the pathogenesis of ASD. The endocannabinoid system (ECS) has a key role in neurodevelopment as well as in normal inflammatory responses and it is not surprising that many preclinical and clinical studies account for alterations of the endocannabinoid signaling in ASD. These findings lay the foundation for a better understanding of the neurochemical mechanisms underlying ASD and for new therapeutic attempts aimed at exploiting the renowned anti-inflammatory properties of cannabinoids to treat pathologies encompassed in the autistic spectrum. This review discusses the current preclinical and clinical evidence supporting a key role of the ECS in the neuroinflammatory state that characterizes ASD, providing hints to identify new biomarkers in ASD and promising therapies for the future.

Detrimental effects of the 'bath salt' methylenedioxypyrovalerone on social play behavior in male rats.
Methylenedioxypyrovalerone (MDPV) is the most popular synthetic cathinone found in products marketed as 'bath salts', widely abused among teenagers and young adults. Synthetic cathinones have pharmacological effects resembling those of psychostimulants, which are known to disrupt a variety of social behaviors. However, despite the popular use of MDPV by young people in social contexts, information about its effects on social behavior is scarce. To investigate the impact of MDPV on social behavior at young age, and the underlying neurobehavioral mechanisms, we focused on social play behavior. Social play behavior is the most characteristic social behavior displayed by young mammals and it is crucial for neurobehavioral development. Treatment with MDPV reduced social play behavior in both juvenile and young adult male rats,

and its play-suppressant effect was subject to tolerance but not sensitization. As the behavioral effects of MDPV have been ascribed to dopaminergic and noradrenergic neurotransmission, and given the role of these neurotransmitters in social play, we investigated the involvement of dopamine and noradrenaline in the play-suppressant effects of MDPV. The effects of MDPV on social play were blocked by either the α2 adrenoceptor antagonist RX821002 or the dopamine receptor antagonist flupenthixol, given alone or together at sub-effective doses. In sum, MDPV selectively suppresses the most vigorous social behavior of developing rats through both noradrenergic and dopaminergic mechanisms. This study provides important preclinical evidence of the deleterious effects of MDPV on social behavior, and as such increases our understanding of the neurobehavioral effects of this popular cathinone.

Perinatal supplementation with omega-3 fatty acids corrects the aberrant social and cognitive traits observed in a genetic model of autism based on FMR1 deletion in rats.
Autism spectrum disorder (ASD) is a complex neurodevelopmental disorder for which no treatments exist. Fragile X syndrome (FXS) is the most common form of inherited mental retardation and the most frequent monogenic cause of ASD. Given the lack of pharmacological treatments for ASD, increasing interest is devoted to non-pharmacological approaches, including dietary interventions. Omega-3 polyunsaturated fatty acids (PUFAs) are critical for neurobehavioraldevelopment. This study had two aims: 1. To validatethe recently developed rat model of FXS; 2. To assess the impact of omega-3 PUFAs dietary supplementation during pregnancy and lactation on the altered behavior displayed by rats. Female and wild-type Sprague-Dawley rats were fed with either an omega-3 PUFAs enriched diet or with an isocaloric control diet during pregnancy and lactation. Behavioral experiments were carried out on the infant (Postnatal days (PNDs) 9 and 13), juvenile (PND 35) and adult (PND 90) male offspring. pups showed hypolocomotion, reduced ultrasonic vocalizations (USVs) emission and impaired social discrimination compared to wild-type controls. Juvenile and adult rats showed deficits in the social and cognitive domains, that were counteracted by perinatal omega-3 PUFAs supplementation. Our results support the validity of the rat model to mimic key autistic-like features and support an important role of omega-3 PUFAs during of neurodevelopment. Although the mechanisms underlying the beneficial effects of omega-3 PUFAs supplementation in ASD needs to be clarified, this dietary intervention holds promise to mitigate core and comorbid autistic features.

The neurochemistry of social reward during development: What have we learned from rodent models?
Social rewards are fundamental to survival and overall health. Several studies suggest that adequate social stimuli during early life are critical for developing appropriate socioemotional and cognitive skills, whereas adverse social experiences negatively affect the proper development of brain and behavior, by increasing the susceptibility to develop neuropsychiatric conditions. Therefore, a better understanding of the neural mechanisms underlying social interactions, and their rewarding components in particular, is an important challenge of current neuroscience research. In this context, preclinical research has a crucial role: Animal models allow to investigate the neurobiological aspects of social reward in order to shed light on possible neurochemical alterations causing aberrant social reward processing in neuropsychiatric diseases, and they allow to test the validity and safety of innovative therapeutic strategies. Here, we discuss preclinical research that has investigated the rewarding properties of two forms of social interaction that occur in different phases of the lifespan of mammals, that is, mother-infant interaction and social interactions with peers, by focusing on the main neurotransmitter systems mediating their rewarding components. Together, the research performed so far helped to elucidate the mechanisms of social reward and its psychobiological components throughout development, thus increasing our understanding of the neurobiological substrates sustaining social functioning in health conditions and social dysfunction in major psychiatric disorders.

EFFECTS OF ACUTE LYSERGIC ACID DIETHYLAMIDE ON INTERMITTENT ETHANOL AND SUCROSE DRINKING AND INTRACRANIAL SELF-STIMULATION IN C57BL/6 MICE

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Lauri Elsilä, Juliana Harkki, Emma Enberg, Alvar Martti, Anni-Maija Linden, Esa Korpi
University of Helsinki, Department Of Pharmacology, Faculty Of Medicine, Helsinki, Finland

Background Psychedelics, like lysergic acid diethylamide (LSD), are again being studied as potential therapies for many neuropsychiatric disorders, including addictions. At the same time, the acute effects of psychedelics on rewarding behaviours have been scarcely studied. *Aims* The current study aimed to clarify if LSD decreases binge-like ethanol drinking in mice, and whether the observed acute effects on ethanol consumption are generalisable to a natural reinforcer, sucrose, and if the effects resulted from aversive or reward-attenuating effects caused by LSD. *Methods* The effects of acute LSD were examined using 2-bottle choice intermittent ethanol (20%) and sucrose drinking (10%), discrete-trial current-intensity threshold method of intracranial self-stimulation, and short-term feeding behaviour assay in C57BL/6 male mice. *Results* The results showed that acute 0.1 mg/kg, but not 0.05 mg/kg, dose (i.p.) of LSD reduced 2-h intermittent ethanol drinking transiently without any prolonged effects. No effects were seen on intermittent 2-h sucrose drinking. The tested LSD doses had no effect on the intracranial self-stimulation current-intensity thresholds, nor did LSD affect the threshold-lowering, or rewarding, effects of simultaneous amphetamine treatment. Further, LSD did have small, acute diminishing effects on 2-h food and water intake. *Conclusions* Based on these results, LSD decreases binge-like ethanol drinking in mice, but only acutely. This effect is not likely to stem from reward-attenuating effects but could be in part due to reduced consummatory behaviour.

Serotonergic psychedelics interact with cortical serotonergic $5HT_{2A}$ Gq-coupled receptors and alter consciousness. Studies have shown that serotonergic psychedelics produce distinct transcriptional and translational changes in contrast to the non-hallucinogenic ligands of the $5HT_{2A}$ receptor. Since lipids act as important signaling molecules and are associated both in structure and downstream signaling to the $5HT_{2A}$ receptor, we were interested to study whether there are lipid associated signatures with serotonergic psychedelics and if they regulate the behavioral consequences of psychedelics in rodents. We used LC/MS to profile lipid changes in rat cortical cultures and rat and mouse brain in response to acute treatment with psychedelics. We studied associated behaviors such head-twitch response (HTR) and modified forced swim test (FST). We observe that serotonergic psychedelics like DOI, TCB-2 and 25I-NBOMe produce overlapping lipid profiles distinct from Lisuride, replicating both *in vitro* and *in vivo.* We observe psychedelics mediated upregulation of Diacylglycerol, Monoacylglycerol, Arachidonic acid, prostaglandins and 2-Arachidonoyl glycerol (2-AG) along with others lipids. Since 2-AG is an endocannabinoid agonist of the Gi-coupled CB_1 receptor, we were interested in examining whether serotonergic $5HT_{2A}$ based 2-AG production modulated CB_1 signaling and this had consequences on psychedelic associated behaviors. We observe that AM251 mediated blockade of CB_1 signaling during DOI mediated $5HT_{2A}$ signaling abrogated HTRs in rats but did not impair DOI induced reduction in despair in FST after 24 hours, suggesting synergistic interaction between $5HT_{2A}$ and CB_1 signaling on selective behaviors.

Acute Chemogenetic Activation of CamKIIα-Positive Forebrain Excitatory Neurons Regulates Anxiety-Like Behaviour in Mice. Anxiety disorders are amongst the most prevalent mental health disorders. Several lines of evidence have implicated cortical regions such as the medial prefrontal cortex, orbitofrontal cortex, and insular cortex along with the hippocampus in the top-down modulation of anxiety-like behaviour in animal models. Both rodent models of anxiety, as well as treatment with anxiolytic drugs, result in the concomitant activation of multiple forebrain regions. Here, we sought to examine the effects of chemogenetic activation or inhibition of forebrain principal neurons on anxiety and despair-like behaviour. We acutely activated or inhibited Ca/calmodulin-dependent protein kinase II α (CamKIIα)-positive forebrain excitatory neurons using the hM3Dq or the hM4Di Designer Receptor Exclusively Activated by Designer Drug (DREADD) respectively. Circuit activation was confirmed via an increase in expression of the immediate early gene, c-Fos, within both the hippocampus and the neocortex. We then examined the influence of DREADD-mediated activation of forebrain excitatory neurons on behavioural tests for anxiety and despair-like behaviour. Our results indicate that acute hM3Dq DREADD activation of forebrain excitatory neurons resulted in a significant decline in anxiety-like behaviour on the open field, light-dark avoidance, and the elevated plus maze test. In contrast, hM3Dq DREADD activation of forebrain excitatory neurons did not alter despair-like behaviour on either the tail suspension or forced swim tests. Acute hM4Di DREADD inhibition of CamKIIα-positive forebrain excitatory neurons did not modify either anxiety or despair-like behaviour. Taken together, our results demonstrate that chemogenetic activation of excitatory neurons in the forebrain decreases anxiety-like behaviour in mice.

5-HT receptor loss does not alter acute fluoxetine-induced anxiety and exhibit sex-dependent regulation of cortical immediate

early gene expression.
Acute treatment with the selective serotonin reuptake inhibitor (SSRI), fluoxetine (Flx), induces anxiety-like behavioral effects. The serotonin receptor (5-HT) is implicated in the modulation of anxiety-like behavior, however its contribution to the anxiogenic effects of acute Flx remains unclear. Here, we examined the role of the 5-HT receptor in the effects of acute Flx on anxiety-like behavior, serum corticosterone levels, neural activation and immediate early gene (IEG) expression in stress-responsive brain regions, using 5-HT receptor knockout (5-HT) mice of both sexes. 5-HT and wild-type (WT) male and female mice received a single administration of Flx or vehicle, and were examined for anxiety-like behavior, serum corticosterone levels, FBJ murine osteosarcoma viral oncogene homolog peptide (c-Fos) positive cell numbers in stress-responsive brain regions of the hypothalamus and prefrontal cortex (PFC), and PFC IEG expression. The increased anxiety-like behavior and enhanced corticosterone levels evoked by acute Flx were unaltered in 5-HT mice of both sexes. 5-HT female mice exhibited a diminished neural activation in the hypothalamus in response to acute Flx. Further, 5-HT male, but not female, mice displayed altered baseline expression of several IEGs (brain-derived neurotrophic factor (), , FBJ osteosarcoma gene (), FBJ murine osteosarcoma viral oncogene homolog B (), Fos-like antigen 2 (), Homer scaffolding protein () 1-3 (), Jun proto-oncogene ()) in the PFC. Our results indicate that the increased anxiety and serum corticosterone levels evoked by acute Flx are not influenced by 5-HT receptor deficiency. However, the loss of function of the 5-HT receptor alters the degree of neural activation of the paraventricular nucleus (PVN) of the hypothalamus in response to acute Flx, and baseline expression of several IEGs in the PFC in a sexually dimorphic manner.

CANNABIDIOL MODULATES ALTERATIONS IN PFC MICRORNAS IN A RAT MODEL OF DEPRESSION

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Uri Bright, Irit Akirav
University of Haifa, School Of Psychological Sciences And The Integrated Brain And Behavior Research Center, Haifa, Israel

Introduction: Accumulating evidence suggests that cannabidiol (CBD) may be an effective and safe anxiolytic agent and potentially also an antidepressant. MicroRNAs (miRNAs; member of small non-coding RNA family) have been recently implicated in development of various neuropsychiatric disorders and in particular depression. Here, we aimed to examine the association between the antidepressant effects of CBD and alterations in brain microRNAs and their serotonergic targets in a rat model for depression, the unpredictable chronic mild stress (UCMS). **Methods:** Male rats were exposed to four weeks of UCMS. During the last 2 weeks they were injected with Vehicle, CBD or the 5HT1a-antagonist WAY100635. Rats were tested for immobility time in the forced swim test, a common phenotype of depression and alterations in miRNAs as well as 5HT1a- and SERT-mRNAs in the prefrontal cortex (mPFC). **Results:** Exposure to UCMS increased immobility time and upregulated the expression of mPFC miR-16 and mirR-135. CBD decreased immobility time in UCMS rats, and this therapeutic-like effect was blocked by WAY100135. Importantly, CBD prevented the UCMS-induced upregulation in miR-16 and mirR-135 and this was not associated with alterations in 5HT1a and SERT mRNA expression. **Conclusions:** CBD has antidepressive-like effects and along with the currently existent knowledge of its safety and high tolerability, it should be examined as an antidepressant in humans as well. We show for the first time that these antidepressive-like effects may be mediated by alterations in the expression of miRNAs.

Rapamycin prevents the long-term impairing effects of adolescence Δ-9-tetrahydrocannabinol on memory and plasticity in male rats.
Long-lasting cognitive impairment is one of the most central negative consequences related to the exposure to cannabis during adolescence and particularly of Δ-9-tetrahydrocannabinol (THC). The aim of this study was to compare the protracted effects of adolescent versus late-adolescent chronic exposure to THC on short-term memory and plasticity and to examine whether rapamycin, a blocker of the mammalian target of rapamycin (mTOR) pathway, can restore THC-induced deficits in memory and plasticity. Male rats were injected with ascending doses of THC [2.5, 5, 10 mg/kg; intraperitoneally (i.p.)] during adolescence and late-adolescence (post-natal days 30-41 and 45-56, respectively), followed by daily injections of rapamycin (1 mg/kg, i.p.) during the first 10 days of cessation from THC. Thirty days after the last injection, rats were tested for short-term and working memory, anxiety-like behaviour, and plasticity in the pathways projecting from the ventral subiculum (vSub) of the hippocampus to the prefrontal cortex (PFC) and nucleus accumbens (NAc). THC exposure in adolescence, but not late-adolescence, was found to induce long-term deficits in object recognition short-term memory and synaptic plasticity in the hippocampal-accumbens pathway. Importantly, rapamycin rescued these persistent effects of THC administered during adolescence. Our findings show that some forms of memory and plasticity are sensitive to chronic THC administration during adolescence and that rapamycin administered during THC cessation may restore cognitive function and plasticity, thus potentially protecting against the possible long-term harmful effects of THC.

EARLY ADOLESCENCE MK-801-INDUCED BEHAVIORAL AND GENE EXPRESSION ALTERATIONS ARE REVERSED BY ANANDAMIDE HYDROLYSIS INHIBITION: DIFFERENTIAL MODULATION BY CANNABINOID RECEPTOR 1 AND 2

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Aims: NMDA receptor (NMDAr) blockade is commonly used to induce schizophrenia-like behavioral abnormalities, including treatment-resistant negative symptoms and cognitive deficits. Glutamate, GABA and neuroimmune abnormalities in medial-prefrontal cortex (mPFC) are implicated in these symptom clusters. Although endocannabinoid signaling modulates mPFC glutamate and GABA transmission, the mechanisms of its contribution to negative and cognitive symptomatology are unclear. Here, we examined if endocannabinoid activation restores behavioral and molecular deficits induced by early-adolescence NMDAr blockade by cannabinoid receptor 1 (CB1r) or 2 (CB2r)-dependent mechanisms. **Method:** Early-adolescent rats were chronically administered with the NMDAr antagonist MK-801 or Saline. During late adolescence, rats received chronic treatment of either the FAAH inhibitor URB597, URB597+AM215 (CB1r antagonist), URB597+AM630 (CB2r antagonist) or Vehicle. Adult rats were tested for schizophrenia-like behavioral dysfunction, and changes in mPFC mRNA expression of glutamate, GABA, endocannabinoid and neuroinflammatory markers. **Results**: Early-adolescence MK-801 impaired novel object recognition task performance, diminished social interaction, and dysregulated the expression of glutamate, GABA, endocannabinoid and neuroinflammatory markers in the mPFC. While CB1r antagonism prevented URB597's therapeutic influence on social behavior, CB2r antagonism prevented the reversal of recognition memory deficits. This was paralleled by URB597's reversal of CB1r and CB2r expression abnormalities in the basolateral amygdala and prelimbic mPFC, respectively. **Conclusions:** The ability of endocannabinoid enhancement to reverse behavioral and gene expression alterations in the current model impacts our understanding of endocannabinoid-dependent therapeutic mechanisms in schizophrenia models, and may lead to the development of novel anandamide-based treatment venues for schizophrenia treatment resistant symptoms.

Anandamide Hydrolysis Inhibition Reverses the Long-Term Behavioral and Gene Expression Alterations Induced by MK-801 in Male Rats: Differential CB1 and CB2 Receptor-Mediated Effects.
NMDA receptor blockade in rodents is commonly used to induce schizophrenia-like behavioral abnormalities, including cognitive deficits and social dysfunction. Aberrant glutamate and GABA transmission, particularly in adolescence, is implicated in these behavioral abnormalities. The endocannabinoid system modulates glutamate and GABA transmission, but the impact of endocannabinoid modulation on cognitive and social dysfunction is unclear. Here, we asked whether late-adolescence administration of the anandamide hydrolysis inhibitor URB597 can reverse behavioral deficits induced by early-adolescence administration of the NMDA receptor blocker MK-801. In parallel, we assessed the impact of MK-801 and URB597 on mRNA expression of glutamate and GABA markers. We found that URB597 prevented MK-801-induced novel object recognition deficits and social interaction abnormalities in adult rats, and reversed glutamate and GABA aberrations in the prelimbic PFC. URB597-mediated reversal of MK-801-induced social interaction deficits was mediated by the CB1 receptor, whereas the reversal of cognitive deficits was mediated by the CB2 receptor. This was paralleled by the reversal of CB1 and CB2 receptor expression abnormalities in the basolateral amygdala and prelimbic PFC, respectively. Together, our findings show that interfering with NMDA receptor function in early adolescence has a lasting impact on phenotypes resembling the negative symptoms and cognitive deficits of schizophrenia and on glutamate and GABA marker expression in the PFC. Prevention of behavioral and molecular abnormalities by late-adolescence URB597 via CB1 and CB2 receptors suggests that endocannabinoid stimulation may have therapeutic potential in addressing treatment-resistant symptoms.

Aims: the aim of the present study was the in vitro and in vivo pharmacological investigation of BTRX-246040 (also known as LY2940094), a nociceptin/orphanin FQ receptor (NOP) antagonist currently in clinical development as antidepressant. **Methods**: BTRX-246040 has been tested in vitro in the following assays: calcium mobilization in cells expressing NOP and classical opioid receptors and chimeric G proteins, BRET assay measuring NOP interaction with G proteins and β-arrestins, the label free dynamic mass redistribution assay, and the electrically stimulated mouse vas deferens. In vivo, BTRX-246040 antidepressant proprieties have been tested in mice in the forced swimming test (FST) and in the learned helplessness test (LH). Additionally, the ability of BTRX-246040 to modulate adult hippocampal neurogenesis has been investigated. **Results**: in all the in vitro assays BTRX-246040 behaves as a pure, potent and selective NOP antagonist. In vivo, we demonstrated that BTRX-246040 evokes antidepressant effects in mice in the FST (active doses 10 and 30 mg/kg) and in the LH test (30 mg/kg), and, when given before the induction sessions, prevents the development of helplessness. BTRX-246040 did not modulate adult hippocampal neurogenesis, neither in naive nor in stressed mice. **Conclusions**: this study, performed with a clinically viable NOP antagonist corroborates the hypothesis that NOP antagonists can be useful not only as antidepressant drugs, similar to classical antidepressants, but are also as preemptive treatments in patients with severe risk factors for depression.

ANTIDEPRESSANT-LIKE EFFECTS OF THE IRON CHELATOR DEFERIPRONE IN A MOUSE MODEL OF DEPRESSION

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Thibault Renoir[1], Volkan Uzungil[1], Connor Aitken[1], Harvey Tran[1], Shanshan Li[1], Jennyfer Payet[2], Matthew Hale[2], Anthony Hannan[1]
[1]University of Melbourne, The Florey Institute, Parkville, Australia, [2]La Trobe University, School Of Psychology And Public Health, Melbourne, Australia

Aims: Since depression severity has been recently reported to correlate with brain iron levels, our study aimed to characterise the potential antidepressant properties of the iron chelator deferiprone. Since depressed individuals who carry the short allele for the serotonin-transporter-linked promotor region are more vulnerable to stress, we will use the serotonin transporter knock-out (5-HTT KO) mouse model. Methods: Using the 5-HTT KO mouse model, we first assessed the behavioural effects of acute deferiprone on the Porsolt swim test (PST) and novelty-suppressed feeding test (NSFT). To determine the relevant brain regions activated by deferiprone, we then measured c-Fos expression and applied network-based analyses to determine the functional connectome and modular characteristics following deferiprone treatment. Results: We found that deferiprone reduced immobility time in the PST in 5-HTT KO mice and reduced latency to feed in the NSFT in both genotypes, suggesting potential antidepressant-like effects. Deferiprone reversed the increase in c-Fos expression induced by swim stress in 5-HTT KO mice in the lateral amygdala. Functional network analyses suggest that hub regions of activity in mice treated with deferiprone include the caudate putamen and prefrontal cortex. The PST-induced increase in network modularity in wild-type mice was not observed in 5-HTT KO mice. Conclusions: Altogether, our data show that the antidepressant-like effects of deferiprone could be underpinned by changes in neuronal activity in the lateral amygdala.

HBK-15 PREFERENTIALLY ACTIVATES ß-ARRESTIN RECRUITMENT AND GIRK CHANNELS AFTER BINDING TO THE 5-HT1A RECEPTOR AND REVERSES LONG-TERM MEMORY IMPAIRMENTS IN MICE

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Aims: Biased agonists selectively targeting certain signaling pathways started the development of novel pharmacologically active drugs with fewer unwanted effects. Our previous studies proved that a multimodal compound HBK-15 with a high affinity for 5-HT1A receptors possesses rapid antidepressant-like properties. In order to develop the pharmacological profile of HBK-15, we investigated its influence on various signaling pathways connected with the 5-HT1A receptor and potential anti-amnestic properties in rodent models. **Methods:** First, we carried out various cell-based functional assays to determine the intrinsic activity of HBK-15 at the 5-HT1A receptor, i.e., influence on cAMP production, Ca^{2+} mobilization, phosphorylation of ERK1/2, ß-arrestin recruitment, and GIRK activation. Next, to assess the effect of the compound on long-term recognition and spatial memory, we performed the novel object recognition and Morris water maze tests in mice, respectively. We used MK-801 (NMDA receptor antagonist) to induce memory deficits. **Results:** HBK-15 preferentially activated ß-arrestin recruitment and GIRK channels after binding to the 5-HT1A receptor. The efficacy and potency of the compound varied between the signaling pathways. HBK-15 reversed memory deficits induced by MK-801 in both behavioral tests. **Conclusion:** We found that HBK-15 preferentially activated ß-arrestin recruitment and GIRK channels, and showed anti-amnestic properties in mice. Our results indicate that HBK-15 is worth further investigation. This study was financed by the National Science Centre, Poland (grant 2019/34/E/NZ7/00454).

The Antiarrhythmic Activity of Novel Pyrrolidin-2-one Derivative S-75 in Adrenaline-Induced Arrhythmia.
Arrhythmia is a quivering or irregular heartbeat that can often lead to blood clots, stroke, heart failure, and other heart-related complications. The limited efficacy and safety of antiarrhythmic drugs require the design of new compounds. Previous research indicated that pyrrolidin-2-one derivatives possess an affinity for α-adrenergic receptors. The blockade of α-adrenoceptor may play a role in restoring normal sinus rhythm; therefore, we aimed to verify the antiarrhythmic activity of novel pyrrolidin-2-one derivative S-75. In this study, we assessed the influence on sodium, calcium, potassium channels, and β-adrenergic receptors to investigate the mechanism of action of S-75. Lack of affinity for β-adrenoceptors and weak effects on ion channels decreased the role of these adrenoceptors and channels in the pharmacological activity of S-75. Next, we evaluated the influence of S-75 on normal ECG in rats and isolated rat hearts, and the tested derivative did not prolong the QT interval, which may confirm the lack of the proarrhythmic potential. We tested antiarrhythmic activity in adrenaline-, aconitine- and calcium chloride-induced arrhythmia models in rats. The studied compound showed prophylactic antiarrhythmic activity in the adrenaline-induced arrhythmia, but no significant activity in the model of aconitine- or calcium chloride-induced arrhythmia. In addition, S-75 was not active in the model of post-reperfusion arrhythmias of the isolated rat hearts. Conversely, the compound showed therapeutic antiarrhythmic properties in adrenaline-induced arrhythmia, reducing post-arrhythmogen heart rhythm disorders, and decreasing animal mortality. Thus, we suggest that the blockade of α-adrenoceptor might be beneficial in restoring normal heart rhythm in adrenaline-induced arrhythmia.

Synthesis and Evaluation of the Antidepressant-like Properties of HBK-10, a Novel 2-Methoxyphenylpiperazine Derivative Targeting the 5-HT and D Receptors.
The increasing number of patients reporting depressive symptoms requires the design of new antidepressants with higher

efficacy and limited side effects. As our previous research showed, 2-methoxyphenylpiperazine derivatives are promising candidates to fulfill these criteria. In this study, we aimed to synthesize a novel 2-methoxyphenylpiperazine derivative, HBK-10, and investigate its in vitro and in vivo pharmacological profile. After assessing the affinity for serotonergic and dopaminergic receptors, and serotonin transporter, we determined intrinsic activity of the compound at the 5-HT and D receptors. Next, we performed behavioral experiments (forced swim test, tail suspension test) to evaluate the antidepressant-like activity of HBK-10 in naïve and corticosterone-treated mice. We also assessed the safety profile of the compound. We showed that HBK-10 bound strongly to 5-HT and D receptors and presented antagonistic properties at these receptors in the functional assays. HBK-10 displayed the antidepressant-like effect not only in naïve animals, but also in the corticosterone-induced mouse depression model, i.e., chronic administration of HBK-10 reversed corticosterone-induced changes in behavior. Moreover, the compound's sedative effect was observed at around 26-fold higher doses than the antidepressant-like ones. Our study showed that HBK-10 displayed a favorable pharmacological profile and may represent an attractive putative treatment candidate for depression.

Idalopirdine, a selective 5-HT receptor antagonist, reduces food intake and body weight in a model of excessive eating.
Obesity, from early childhood onwards, is a common societal problem. The overconsumption of sweet, salty and high-fat products are the main factors that cause excessive weight gain. It is therefore necessary to search for new drugs that affect satiety centers and reduce the sense of hunger and caloric intake. It has been suggested that the blockade of 5-HT receptors may reduce food intake, and since idalopirdine is a clinically tested, selective 5HT receptor antagonist, it was chosen to be examined in animal models of obesity. The activity of idalopirdine was measured in the rat model of excessive eating. Animals were on a high caloric diet that consisted of milk chocolate with nuts, cheese, salted peanuts and condensed milk. During a four-week experiment, the rats had constant access to standard feed and water ad libitum. Idalopirdine was administered intraperitoneally at a dose 5 mg/kg b.w./day. To establish whether idalopirdine would effectively suppress the rebound hyperphagia that accompanies refeeding, it was administered after a 20 h food deprivation period. Pica behavior was evaluated after the administration of idalopirdine to confirm that the suppression of food intake was not caused by visceral illness. The effect of the four-week treatment with idalopirdine on the amount of peritoneal adipose tissue, and on lipid and carbohydrate profiles in rats was also examined. The statistical significance was calculated using the one-way ANOVA post-hoc Tukey Multiple Comparison Test or the two-way ANOVA post-hoc Bonferroni Multiple Comparison Test. Idalopirdine significantly reduced caloric intake and prevented the development of obesity in tested animals. Rats, that received idalopirdine, had a smaller amount of adipose tissue in the peritoneum as well as lower glucose, triglyceride and cholesterol levels in comparison to the control group. Moreover, an anorectic action was not caused by abnormalities of the gastrointestinal tract, such as nausea. The obtained results indicate that idalopirdine reduces caloric intake and could be considered for further tests as a potential treatment of obesity.

The role of melatonin, neurokinin, neurotrophic tyrosine kinase and glucocorticoid receptors in antidepressant-like effect.
Over the last few decades, depression has become one of the major public health problems in our society. This problem is connected not only with morbidity, but also with treatment, specifically with the effectiveness of the therapy as well as the concomitant side effects of available antidepressants. Major depressive disorder is a complex clinical entity, including different molecular mechanisms and neurological processes. This complexity is a challenge for scientists seeking to discover an innovatory antidepressant drug with multiple and complementary mechanisms of action. In this review, we discuss the role of melatonin, neurokinin, neurotrophic tyrosine kinase and glucocorticoid receptors in depression and antidepressant-like effects.

The antidepressant- and anxiolytic-like activities of new xanthone derivative with piperazine moiety in behavioral tests in mice.
Xanthones are flavonoids with numerous activities, including antioxidant, antidepressant., or anxiolytic-like. Therefore, the aim of our study was to determine antidepressant- and anxiolytic-like properties of four xanthone derivatives (3-chloro-5-[(4-methylpiperazin-1-yl)methyl]-9H-xanthen-9-one dihydrochloride [HBK-5], 6-methoxy-2-[(4-methylpiperazin-1-yl) methyl]-9H-xanthen-9-one dihydrochloride, 2-[(4-benzylpiperazin-1-yl) methyl]-6-methoxy-9H-xanthen-9-one dihydrochloride, 2-{[4-(2-methoxyphenyl) piperazin-1-yl] methyl}-9H-xanthen-9-one hydrochloride), as well as the influence on cognitive and motor function of active compounds, using animal models.

Antiarrhythmic and α-Adrenoceptor Antagonistic Properties of Novel Arylpiperazine Derivatives of Pyrrolidin-2-one.
In an effort to develop α-adrenoceptor antagonists with antiarrhythmic activity, we designed a series of pyrrolidin-2-one derivatives. The α1- and α2-adrenorecepor affinities of the new pyrrolidin-2-one derivatives were determined using a radioligand binding assay. The most active compound was then tested in vitro for intrinsic activity toward α(1A)- and α(1B)-adrenoceptors and in vitro for antiarrhythmic activity in epinephrine-induced arrhythmia in rats. The highest affinity for the α1-adrenoceptor (pK(i) = 7.01) was displayed by 1-{4-[4-(2-methoxy-5-chlorophenyl)-piperazin-1-yl]-methyl}-pyrrolidin-2-one (9). 1-[4-(2-Fluorophenyl)-piperazin-1-yl]-methyl-pyrrolidin-2-one (7) showed the highest affinity toward the α2-adrenoceptor (pK(i) = 6.52). Intrinsic activity studies of compound 9 showed that this compound is an antagonist of both α(1A)- (EC50 = 0.5 nM) and α(1B)- (EC50 = 51.0 nM) adrenoceptors. Compound 9 displayed antiarrhythmic activity in rats (ED50 = 5.0 mg/kg (3.13-7.99)). New derivatives of pyrrolidin-2-one with α1 -adrenoceptor affinity were identified. We propose that the antiarrhythmic activity of compound 9 is related to its antagonism of α(1A)- and α(1B)-adrenoceptors.

α-Adrenoceptor antagonistic and hypotensive properties of novel arylpiperazine derivatives of pyrrolidin-2-one.
This study focused on a series of pyrrolidin-2-one derivatives connected via two or four methylene units to arylpiperazine fragment. The compounds obtained for α_1- and α_2-adrenoceptors were assessed. The compound with highest affinity for the α_1-adrenoceptors was 1-{4-[4-(2-chloro-phenyl)-piperazin-1-yl]-butyl}-pyrrolidin-2-one (10 h) with pKi=7.30. Compound with pKi (α_1) $\geqslant$6.44 were evaluated in functional bioassays for intrinsic activity at α_1A- and α_1B-adrenoceptors. All compounds tested were antagonists of the α_1B-adrenoceptors. Additionally, compounds 10e and 10h were α_1A-adrenoceptors antagonist. The dual α_1A-/α_1B-adrenoceptors antagonists, compounds 10e and 10h were also tested in vivo for their hypotensive activity in rats. These compounds, when dosed of 1.0 mg/kg iv in normotensive, anesthetized rats, significantly decreased systolic and diastolic pressure and their hypotensive effects lasted for longer than one hour.

METABOLISM AS AN ORIGIN OF SEXUAL DIMORPHISM IN MORPHINE-INDUCED ANALGESIA BUT NOT IN THE SETTING OF ANALGESIC TOLERANCE IN MICE

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Yannick Goumon, Florian Gabel, Volodya Hovhannisyan, Virginie Andry
CNRS UPR3212 INCI, Nociception And Pain, Strasbourg, France

Aims- In humans and rodents, sex influences morphine analgesia. In the liver and brain, morphine is metabolized into proalgic morphine-3-glucuronide (M3G). We have hypothesized that sexual dimorphism in morphine metabolism and differential metabolic modulation during the setting of analgesic tolerance might contribute to behavioural differences. Thus, we have studied if differences in peripheral and central morphine metabolism exist after acute and chronic morphine treatments in male and female mice. **Methods-** Sexual dimorphism in morphine analgesia and tolerance were studied using the tail-immersion test. Morphine and M3G metabolic kinetics in the blood after acute and chronic morphine treatments were determined using LC-MS/MS. Morphine and M3G were also quantified in several central nervous system (CNS) regions. **Results –** Our results indicate that female mice display weaker morphine analgesia and faster tolerance setting compared to males. In addition, female mice have higher concentrations of proalgic M3G in the blood and several pain-related CNS regions (PAG, amygdala…) than male mice. At the opposite, lower concentrations of morphine were found in these regions. These major differences reflect a major imbalance in the pronociceptive/antinociceptive balance within the CNS. **Conclusion-** Sex differences in morphine analgesic effects were mainly attributable to morphine central metabolism in pain-related CNS regions, consistent with weaker morphine analgesic effects in females. However, the implication of morphine metabolism in analgesic tolerance appeared to be limited.

EFFICACY OF A SELECTIVE 5-HT6R ANTAGONIST IN AN INNOVATIVE 2-HIT MOUSE MODEL OF SCHIZOPHRENIA

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Caroline Lahogue, Jean-Marie Billard, Valentine Bouet
Caen-Normandy University, Calvados, CAEN Cedex, France

Schizophrenic patients are mainly treated with antipsychotic drugs, which efficiently improve positive symptoms (delirium, hallucination…). However, negative symptoms (avolition, anhedonia, social withdrawal…) and cognitive deficits (memory impairment…) remain resistant. The modulation of 5-HT6 receptors appears as a new promising therapeutic strategy since it was shown to improve memory deficits in several preclinical investigations. Our project aims to characterize the efficacy of pharmacological modulation of 5-HT6R in a new animal model of schizophrenia constructed on the combination between two factors (2-hit) including a genetic factor (deletion of serine racemase that synthesizes the NMDA receptor co-agonist D-serine) and an environmental factor (maternal separation for 24h at post-natal day 9). To characterize the new mouse model and assess the efficacy of 5-HT6R modulation, behavioural experiments and electrophysiological recordings in the CA1 region of hippocampus were performed. The 2-hit combination increases spontaneous activity and anxiety-like behaviour, and impairs memory performances (recognition, spatial and working memory). A disruption of synaptic plasticity (long-term potentiation), a mechanism involved in memory processes that requires a strong activation of NMDA receptors, was found in the 2-hit model. Interestingly, the 5-HT6R antagonist SB-271046 facilitates NMDA activation in both control and 2-hit groups. We are now investigating whether this antagonist could restore the expression of synaptic plasticity and counterbalance the memory deficits in the 2-hit model. Thus, our work underlines the interest of targeting 5-HT6R for the treatment of schizophrenia-related negative and cognitive symptoms.

Frontoparietal anodal tDCS reduces ketamine-induced oscillopathies.
During the prodromal phase of schizophrenia with its complex and insidious clinical picture, electroencephalographic recordings detect widespread oscillation disturbances (or oscillopathies) during the wake-sleep cycle. Neural oscillations are electrobiomarkers of the connectivity state within systems. A single-systemic administration of ketamine, a non-competitive NMDA glutamate receptor antagonist, transiently reproduces the oscillopathies with a clinical picture reminiscent of the psychosis prodrome. This acute pharmacological model may help the research and development of innovative treatments against psychotic transition. Transcranial electrical stimulation is recognized as an appropriate non-invasive therapeutic modality since it can increase cognitive performance and modulate neural oscillations with little or no side effects. Therefore, our objective was to set up, in the sedated adult rat, a stimulation method that is able to normalize ketamine-induced increase in gamma-frequency (30-80 Hz) oscillations and decrease in sigma-frequency (10-17 Hz) oscillations. Unilateral and bipolar frontoparietal (FP), transcranial anodal stimulation by direct current (<+1 mA) was applied in ketamine-treated rats. A concomitant bilateral electroencephalographic recording of the parietal cortex measured the stimulation effects on its spontaneously occurring oscillations. A 5 min FP anodal tDCS immediately and quickly reduced, significantly with an intensity-effect relationship, the ketamine-induced gamma hyperactivity, and sigma hypoactivity at least in the bilateral parietal cortex. A duration effect was also recorded. The tDCS also tended to diminish the ketamine-induced delta hypoactivity. These preliminary neurophysiological findings are promising for developing a therapeutic proof-of-concept against neuropsychiatric disorders.

EFFECTS OF L-DOPA, SKF-38393, AND QUINPIROLE ON EXPLORATORY, ANXIETY- AND DEPRESSIVE-LIKE BEHAVIORS IN PUBERTAL FEMALE AND MALE MICE

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Muiara Moraes, Laila Árabe, Bruna Resende, Beatriz Codo, Ana Luiza Reis, Bruno Souza
Federal University of Minas Gerais, Physiology And Biophysics, Belo Horizonte, Brazil

Puberty is a period of broad morphological, functional, and chemical reorganization of the brain with significant changes in the emergence of behavior, cognition, and emotions. For example, the dopaminergic system, which is involved in several neuropsychiatric disorders, is overactive during adolescence. However, very little is known regarding the role of dopaminergic receptors in prepubertal behavior. In this study, we investigated the behavioral effects of a single i.p. administration of L-Dopa, SKF-38393 (D1 receptor agonist), and Quinpirole (D2 receptor agonist) in 4 weeks old female and male C57BL/6 mice. We observed that both L-Dopa and Quinpirole decreased exploratory/motor behavior (total distance and number of rearings) and risk assessment/anxiety-like behavior (number of rearings, head dippings, and stretchings) only in females in the open field test (OFT) and elevated plus-maze (EPM) respectively. Males injected with Quinpirole also showed a decrease in risk assessment/anxiety-like behavior (number of rearings, head dippings, and stretchings) in EPM but only L-Dopa injected males showed an increase in behavioral despair/depressive-like behavior in forced swimming test (FST). Our results showed that distinct dopaminergic receptors modulate prepubertal mice behavior in a sex-specific manner, which provides insights into the dynamic of dopaminergic system development in puberty.

THE BUTYRIC ACID PRECURSOR TRIBUTYRIN MODULATES HIPPOCAMPAL SYNAPTIC PLASTICITY AND PREVENTS SPATIAL MEMORY DEFICITS: ROLE OF PPARγ AND AMPK

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Short chain fatty acids (SCFA), derived from the intestinal fermentation of dietary fiber and contained in dairy products, are gaining interest in relation to their possible beneficial effects on neuropsychological disorders. Specifically, butyric acid (BA), a SCFA, has been shown to reverse certain memory impairments. In order to investigate the impact of this fatty acid on spatial memory process, we have investigated the effect of tributyrin (TB), a prodrug of BA, on i) hippocampus-dependent spatial memory, ii) hippocampal synaptic transmission and plasticity mechanisms, and iii) the expression of genes and proteins relevant to hipocampal glutamatergic transmission. Adolescent male C57BL/6J mice were fed diets with different doses of TB (0.5%, 1% and 3%) acutely (48 h) and chronically (20 weeks). We found that free-feeding intake during 48 h of a diet containing 1% TB prevented, in adolescent but not in adult mice, scopolamine (SCOP)-induced impairment of hippocampus-dependent spatial memory. Moreover, TB treatment up-regulated, within the adolescent hippocampus, gene expression of *Pparg*, leptin and adiponectin receptors, and glutamate receptor subunits (AMPA-2, NMDA-1, NMDA-2A and NMDA-2B). On the other hand, in vitro studies carried out in hippocampal slices, revealed that TB was able to transform early-LTP (e-LTP) into late-LTP (l-LTP) and rescued LTP-inhibition induced by SCOP. TB-induced facilitation of l-LTP was blocked by GW9662 (PPARγ antagonist) and Compound C (AMPK inhibitor). In conclusion, our study suggests that TB has a positive influence on the processes of hippocampal transmission and synaptic plasticity suggesting the involvement of both PPARγ and AMPK on TB-mediated effects.

Saturated and unsaturated fat diets impair hippocampal glutamatergic transmission in adolescent mice.
Consumption of high-fat diets (HFD) has been associated with neuronal plasticity deficits and cognitive disorders linked to the alteration of glutamatergic disorders in the hippocampus. As young individuals are especially vulnerable to the effects of nutrients and xenobiotics on cognition, we studied the effect of chronic consumption of saturated (SOLF) and unsaturated oil-enriched foods (UOLF) on: i) spatial memory; ii) hippocampal synaptic transmission and plasticity; and iii) gene expression of glutamatergic receptors and hormone receptors in the hippocampus of adolescent and adult mice. Our results show that both SOLF and UOLF impair spatial short-term memory. Accordingly, hippocampal synaptic plasticity mechanisms underlying memory, and gene expression of NMDA receptor subunits are modulated by both diets. On the other hand, PPARγ gene expression is specifically down-regulated in adolescent SOLF individuals and up-regulated in adult UOLF mice.

Identification by proximity labeling of novel lipidic and proteinaceous potential partners of the dopamine transporter.
Dopamine (DA) transporters (DATs) are regulated by trafficking and modulatory processes that probably rely on stable and transient interactions with neighboring proteins and lipids. Using proximity-dependent biotin identification (BioID), we found

novel potential partners for DAT, including several membrane proteins, such as the transmembrane chaperone 4F2hc, the proteolipid M6a and a potential membrane receptor for progesterone (PGRMC2). We also detected two cytoplasmic proteins: a component of the Cullin1-dependent ubiquitination machinery termed F-box/LRR-repeat protein 2 (FBXL2), and the enzyme inositol 5-phosphatase 2 (SHIP2). Immunoprecipitation (IP) and immunofluorescence studies confirmed either a physical association or a close spatial proximity between these proteins and DAT. M6a, SHIP2 and the Cullin1 system were shown to increase DAT activity in coexpression experiments, suggesting a functional role for their association. Deeper analysis revealed that M6a, which is enriched in neuronal protrusions (filopodia or dendritic spines), colocalized with DAT in these structures. In addition, the product of SHIP2 enzymatic activity (phosphatidylinositol 3,4-bisphosphate [PI(3,4)P]) was tightly associated with DAT, as shown by co-IP and by colocalization of mCherry-DAT with a specific biosensor for this phospholipid. PI(3,4)P strongly stimulated transport activity in electrophysiological recordings, and conversely, inhibition of SHIP2 reduced DA uptake in several experimental systems including striatal synaptosomes and the dopaminergic cell line SH-SY5Y. In summary, here we report several potential new partners for DAT and a novel regulatory lipid, which may represent new pharmacological targets for DAT, a pivotal protein in dopaminergic function of the brain.

GALANIN(1-15) ENHANCED THE ANTIDEPRESSANT-LIKE EFFECTS OF ESCITALOPRAM IN THE OLFACTORY BULBECTOMY RATS IN THE FORCED SWIMMING TEST THROUGH 5-HT1A RECEPTORS.

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Laura García-Durán[1], Antonio Flores-Burgess[1], Noelia Cantero-García[1], Araceli Puigcerver[2], José Ángel Narváez[1], Kjell Fuxe[3], Luis Santín[2], Carmelo Millón[1], Zaida Díaz-Cabiale[1]

We previously described that Galanin (1-15) [GAL(1-15)] enhances the antidepressant-like effects induced by the SSRI Fluoxetine in the forced swimming test (FST) in naïve rats. In this work, we have analyzed in olfactory bulbectomy rats (OBX) the effect of GAL(1-15)-Escitalopram (ESC) combination in the FST and the involvement of GALR and 5-HT1A receptors in these effects. In the first set of experiments, OBX rats received three injections of ESC (10mg/Kg) (23, 5 and 1 hour) and a single injection of a threshold dose of GAL(1-15) (1nmol) and GALR2 antagonist M871 (3nmol) alone or in combination 15 minutes before the FST. Secondly, we have generated siRNA 5HT1A knockdown rats, and we have evaluated the effects of ESC and GAL(1-15) administration in the FST. One-way ANOVA followed by Fisher´s least significant difference test was used. In the FST, GAL(1-15) (1nmol) enhanced the antidepressant-like effects of ESC, reducing immobility ($p<0.05$) and increasing the swimming time ($p<0.05$). M871 blocked the behavioural effects of GAL(1-15) in the immobility time ($p<0.001$) and in the swimming time ($p<0.05$) in the FST. Moreover, the decrease in 5-HT1AR was sufficient to block GAL(1-15) enhancement of the antidepressant-like effects mediated by ESC. Our results indicate a potent effect of the combination GAL(1-15) with SSRIs in reversed depressive symptoms in the animal model of chronic depression OBX. The results open up the possibility of using GAL(1-15) in combination with SSRIs as a novel strategy for treating depression. Recently, we described that Galanin(1-15)[GAL(1-15)] enhanced Escitalopram(ESC) effectiveness in depression symptoms. Moreover GAL(1-15) induces a substantial reduction in alcohol consumption. To investigate the effect of GAL(1-15) on ESC-activity in depression-alcoholism comorbidity, we used the ethanol self-administration test and the forced swimming test(FST) in rats, after a chronic alcohol consumption. Also to study if GAL(1-15)+ESC modulate the reward system induced by different reinforcers we have analyzed this combination in the saccharine self-administration test. Groups of rats received three times intraperitoneal injections of ESC (2.5mg/Kg or 7.5mg/Kg) 23, 5 and 1h before the test and one icv injection of GAL(1-15) (0.3nmol or 1nmol) 15 minutes before the test. One-way ANOVA followed by Fisher´s least significant difference test was used. In the saccharin self-administration, the coadministration GAL(1-15)(1nmol) and ESC (2.5mg/Kg) induced a strong reduction in the number of reinforcements of saccharine ($p<0.05$) and in number of active lever presses ($p<0.05$). In the ethanol Self-Administration, GAL(1-15)(0.3nmol) enhanced the reduction of alcohol intake mediated by ESC (2.5mg/Kg). GAL(1-15) decreased the number of alcohol reinforcements ($p<0.01$) and the number of active levers pressed ($p<0.01$) by around 50% induced by ESC. In FST, in rats under a chronic alcohol consumption, GAL(1-15) reversed adverse ESC-mediated effects. Coadministration of GAL(1-15)(1nmol) and ESC (7.5mg/Kg) showed a significant decrease in immobility ($p<0.05$) and an increase in swimming ($p<0.05$) compared with ESC group. The results open up the possibility to use GAL(1-15) in combination with Escitalopram as a novel strategy in AUD comorbidity with depression. Supported by PID2020-114392RB-100, PDC2021-121566-100, P20-00026-R, PI-0083-2019.

DELETION OF BETA2 NICOTINIC SUBUNIT IN SPECIFIC TYPES OF CORTICAL GABAERGIC NEURONS CHANGES SOCIAL AND ANXIETY-LIKE BEHAVIOR

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Helena Janickova[1], Alice Abbondanza[2,3], Jan Elias[4], Sylvie Dumas[5], Véronique Bernard[2]
[1]Institute of Physiology of the Czech Academy of Sciences, Laboratory Of Neurochemistry, Prague , Czech Republic, [2]Neuroscience Paris Seine - Institut de Biologie Paris Seine (NPS - IBPS), INSERM, CNRS, Sorbonne Universite, Paris, France, [3]Institute of Physiology of the Czech Academy of Sciences, Laboratory Of Neurochemistry, Prague, Czech Republic, [4]Institute of Molecular Genetics of the Czech Academy of Sciences, Czech Centre For Phenogenomics, Vestec, Czech Republic, [5]Oramacell, Oramacell, PARIS, France

Nicotinic acetylcholine receptors (nAChRs) containing beta2 nicotinic subunit are widely expressed throughout the brain and they have been implicated in the control of various behavioral processes. The widespread expression makes them an important therapeutic target; however, it also poses a requirement for a more precise targeting of nAChRs in specific locations. Until today, tools available for a targeted inhibition or activation of nAChRs remain limited. In the present study, we used a CRISPR/Cas9-based approach to induce a deletion of beta2 nicotinic subunit in the mouse prefrontal cortex in neuropeptide Y- (NPY) and serotonin receptor 5HT3A-expressing neurons. We crossed a mouse line with Cre-inducible expression of Cas9 with respective Cre-drivers and injected the offspring with an AAV vector carrying gRNA targeting CHRNB2 gene. First, we used FISH to characterize beta2 expression in NPY- and 5HT3A-expressing neurons. To analyze the efficiency of the CRISPR/Cas9 indels, we used the fluorescence activated cell sorting (FACS) followed by DNA isolation and sequencing. Then we used a comprehensive behavioral testing to identify domains affected by the beta2 deletion in the targeted neuronal populations. Interestingly, the deletion in either NPY- or 5HT3A-expressing neurons led to an increase in social interactions. In contrast, beta2 deletion in NPY- but not the 5HT3A-expressing neurons decreased anxiety-like behavior during the elevated plus maze. In conclusion, selective deletion of nAChRs in distinct populations of cortical neurons can be achieved by CRISPR/Cas9-based approach and it has different effects on behavior based on the neurons targeted.

We aim to compare α5IA and Basmisanil efficacy on α5-$GABA_AR$-mediated synaptic inhibition, as well as on rescuing cognitive deficits in a Down syndrome (DS) mouse model. They are negative allosteric modulators of α5-$GABA_ARs$ and have been proposed as cognitive-enhancing drugs. Inhibitory postsynaptic currents (IPSCs) evoked on pyramidal neurons (PNs) in L2/L3 by extracellular stimulation on L1 in the somatosensory cortex were recorded by whole-cell patch clamp. In the hippocampus, we recorded IPSCs evoked on CA1 PNs by optogenetic activation of SST axons in the stratum lacunosum moleculare. We also quantified α5IA and Basmisanil concentrations in blood samples from mice following single intraperitoneal administrations of increasing doses of these drugs by LC-MS. Brain samples collected from treated mice were used for ex vivo receptor occupancy measurements. We found a decrease in IPSCs amplitudes recorded from PNs in L2/L3; however, there was a significant variability in drug effect using this approach. Light-evoked IPSCs recorded in hippocampal CA1 PNs were found to be preferentially mediated by α5-$GABA_ARs$, as well as sensitive to α5IA, which corroborates with previous findings. Dose-dependent increase in plasma concentrations was observed for both, although the occupancy at α5-containing $GABA_AR$ was higher for α5IA (~80-100%) than for Basmisanil (~15-30%). Our data suggest that α5IA and Basmisanil have different receptor-binding properties. Next steps will be the study of the effects of these drugs on behavioural phenotypes of a DS mouse model. Optogenetically evoked IPSCs in CA1 PNs seems to be a feasible approach to compare drug efficacy on α5-$GABA_AR$-mediated synaptic inhibition.

THE INFLUENCE OF G PROTEIN-BIASED AGONISTS OF THE μ-OPIOID RECEPTOR ON ADDICTION-LIKE SYMPTOMS AND BEHAVIOURAL EFFECTS OF MORPHINE IN MICE

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Lucja Kudla[1], Ryszard Bugno[2], Sabina Podlewska[2], Lukasz Szumiec[1], Andrzej Bojarski[2], Ryszard Przewlocki[1]

Aims: G protein-biased agonists of the μ-opioid receptor are promising opioid therapeutics, proposed to have diminished side effects and addictive potential. Using animal models, we aimed to assess the addiction-like effects of compounds presenting high G protein bias – PZM21, SR-14968 and SR-17018. We further assessed the impact of these compounds on morphine-induced addictive-like behaviour. **Methods:** Using C57BL/6J mice we determined the effects of these compounds on locomotion, tolerance, physical dependence and reward. Those effects were also tested in mice cotreated with novel agonists and morphine. **Results:** The tested compounds differently affected addictive-like behaviour. PZM21 and SR-17018 did not change animals' locomotion, whereas the treatment with SR-14968 resulted in enhancement of locomotor activity, tolerance of this effect during repeated treatment, and high expression after the incubation period. While PZM21 caused rapid development of antinociceptive tolerance, this effect was delayed in SR-compounds-treated mice. In terms of physical dependence, PZM21 induced low effect, but SR-compounds were highly physically addictive. Both SR-compounds also had rewarding properties, albeit PZM21 was nonrewarding. Finally, the compounds turned out to influence symptoms of morphine addiction, i.e. all the compounds attenuated some symptoms of morphine withdrawal and PZM21 diminished morphine reward. **Conclusions:** Our results suggest that different classes of G protein-biased μ-opioid receptor agonists vary in terms of euphorigenic effects and severity of physical dependence. However, these agonists diminish some symptoms of morphine addiction, thus may be useful in opioid use disorder pharmacotherapy. **Acknowledgments:** The studies were funded by the Polish National Science Centre grants: 2018/31/B/NZ7/03954 and 2019/33/N/NZ7/02378.

Comparison of an Addictive Potential of μ-Opioid Receptor Agonists with G Protein Bias: Behavioral and Molecular Modeling Studies.
Among different approaches to the search for novel-safer and less addictive-opioid analgesics, biased agonism has received the most attention in recent years. Some μ-opioid receptor agonists with G protein bias, including SR compounds, were proposed to induce diminished side effects. However, in many aspects, behavioral effects of those compounds, as well as the mechanisms underlying differences in their action, remain unexplored. Here, we aimed to evaluate the effects of SR-14968 and SR-17018, highly G protein-biased opioid agonists, on antinociception, motor activity and addiction-like behaviors in C57BL/6J mice. The obtained results showed that the compounds induce strong and dose-dependent antinociception. SR-14968 causes high, and SR-17018 much lower, locomotor activity. Both agonists develop reward-associated behavior and physical dependence. The compounds also cause antinociceptive tolerance, however, developing more slowly when compared to morphine. Interestingly, SR compounds, in particular SR-17018, slow down the development of antinociceptive tolerance to morphine and inhibit some symptoms of morphine withdrawal. Therefore, our results indicate that SR agonists possess rewarding and addictive properties, but can positively modulate some symptoms of morphine dependence. Next, we have compared behavioral effects of SR-compounds and PZM21 and searched for a relationship to the substantial differences in molecular interactions that these compounds form with the μ-opioid receptor.
Pharmaceutics, 2021; 14

Influence of G protein-biased agonists of μ-opioid receptor on addiction-related behaviors.
Opioid analgesics remain a gold standard for the treatment of moderate to severe pain. However, their clinical utility is seriously limited by a range of adverse effects. Among them, their high-addictive potential appears as very important, especially in the context of the opioid epidemic. Therefore, the development of safer opioid analgesics with low abuse

potential appears as a challenging problem for opioid research. Among the last few decades, different approaches to the discovery of novel opioid drugs have been assessed. One of the most promising is the development of G protein-biased opioid agonists, which can activate only selected intracellular signaling pathways. To date, discoveries of several biased agonists acting via μ-opioid receptor were reported. According to the experimental data, such ligands may be devoid of at least some of the opioid side effects, such as respiratory depression or constipation. Nevertheless, most data regarding the addictive properties of biased μ-opioid receptor agonists are inconsistent. A global problem connected with opioid abuse also requires the search for effective pharmacotherapy for opioid addiction, which is another potential application of biased compounds. This review discusses the state-of-the-art on addictive properties of G protein-biased μ-opioid receptor agonists as well as we analyze whether these compounds can diminish any symptoms of opioid addiction. Finally, we provide a critical view on recent data connected with biased signaling and its implications to in vivo manifestations of addiction.

Astroglial Knockout of Glucocorticoid Receptor Attenuates Morphine Withdrawal Symptoms, but Not Antinociception and Tolerance in Mice.
The development of tolerance and drug dependence limit the clinical application of opioids for the treatment of severe pain. Glucocorticoid receptors (GRs) are among molecular substrates involved in these processes. Most studies focus on the role of neuronal GR, while the involvement of GR on glial cells is not fully understood. To address this issue, we used a transgenic model of conditional GR knockout mice, targeted to connexin 30-expressing astrocytes, treated with repeated doses of morphine. We observed no difference between control mice and astrocytic GR knockouts in the development of antinociceptive tolerance. Nevertheless, when animals were subjected to precipitated withdrawal, knockouts presented some attenuated symptoms, including jumping. Taken together, our data suggest that hippocampal and spinal astrocytic GRs appear to be involved in opioid withdrawal, and drugs targeting the GR may relieve some symptoms of morphine withdrawal without influencing its antinociceptive properties.

Knockdown of the astrocytic glucocorticoid receptor in the central nucleus of the amygdala diminishes conditioned fear expression and anxiety.
The amygdala is a key structure involved in both physiological and behavioural effects of fearful and stressful stimuli. The central stress response is controlled by the activity of the hypothalamic-pituitary-adrenal (HPA) axis via glucocorticoid hormones, acting mainly through glucocorticoid receptors (GR), widely expressed among different brain regions, including the central nucleus of the amygdala (CeA). Although to date, neuronal GR was postulated to be involved in the mediating stress effects, increasing evidence points to the vital role of glial GR. Here, we aimed to evaluate the role of astrocytic GR in CeA in various aspects of the stress response. We used a lentiviral vector to disrupt an astrocytic GR in the CeA of Aldh1l1-Cre transgenic mice. Astrocytic GR knockdown mice (GR KD) exhibited an attenuated expression of fear-related memory in the fear conditioning paradigm. Interestingly, the consolidation of non-stressful memory in the novel object recognition test remained unchanged. Moreover, GR KD group presented reduced anxiety, measured in the open field test. However, knockdown of astrocytic GR in the CeA did not affect an acute response to stress in the tail suspension test. Taken together, obtained results suggest that astrocytic GR in the CeA promotes aversive memory consolidation and some aspects of anxiety behaviour.

Molecular Modeling of μ Opioid Receptor Ligands with Various Functional Properties: PZM21, SR-17018, Morphine, and Fentanyl-Simulated Interaction Patterns Confronted with Experimental Data.
Molecular modeling approaches are an indispensable part of the drug design process. They not only support the process of searching for new ligands of a given receptor, but they also play an important role in explaining particular activity pathways of a compound. In this study, a comprehensive molecular modeling protocol was developed to explain the observed activity profiles of selected μ opioid receptor agents: two G protein-biased μ opioid receptor agonists(PZM21 and SR-17018), unbiased morphine, and the β-arrestin-2-biased agonist,fentanyl. The study involved docking and molecular dynamics simulations carried out for three crystal structures of the target at a microsecond scale, followed by the statistical analysis of ligand-protein contacts. The interaction frequency between the modeled compounds and the subsequent residues of a protein during the simulation was also correlated with the output of in vitro and in vivo tests, resulting in the set of amino acids with the highest Pearson correlation coefficient values. Such indicated positions may serve as a guide for designing new G protein-biased ligands of the μ opioid receptor.

Functional characterization of a novel opioid, PZM21, and its effects on the behavioural responses to morphine.
The concept of opioid ligands biased towards the G protein pathway with minimal recruitment of β-arrestin-2 is a promising approach for the development of novel, efficient, and potentially nonaddictive opioid therapeutics. A recently discovered biased μ-opioid receptor agonist, PZM21, showed analgesic effects with reduced side effects. Here, we aimed to further investigate the behavioural and biochemical properties of PZM21.

Astrocytes determine conditioned response to morphine via glucocorticoid receptor-dependent regulation of lactate release.
To date, neurons have been the primary focus of research on the role of glucocorticoids in the regulation of brain function and pathological behaviors, such as addiction. Astrocytes, which are also glucocorticoid-responsive, have been recently implicated in the development of drug abuse, albeit through as yet undefined mechanisms. Here, using a spectrum of tools (whole-transcriptome profiling, viral-mediated RNA interference in vitro and in vivo, behavioral pharmacology and electrophysiology), we demonstrate that astrocytes in the nucleus accumbens (NAc) are an important locus of glucocorticoid receptor (GR)-dependent transcriptional changes that regulate rewarding effects of morphine. Specifically, we show that targeted knockdown of the GR in the NAc astrocytes enhanced conditioned responses to morphine, with a concomitant inhibition of morphine-induced neuronal excitability and plasticity. Interestingly, GR knockdown did not influence sensitivity to cocaine. Further analyses revealed GR-dependent regulation of astroglial metabolism. Notably, GR knockdown inhibited induced by glucocorticoids lactate release in astrocytes. Finally, lactate administration outbalanced conditioned responses to morphine in astroglial GR knockdown mice. These findings demonstrate a role of GR-dependent regulation of astrocytic metabolism in the NAc and a key role of GR-expressing astrocytes in opioid reward processing.

30487639: Tertil M, Skupio U, Barut J, Dubovyk V, Wawrzczak-Bargiela A, Soltys Z, Golda S, Kudla L, Wiktorowska L, Szklarczyk K, Korostynski M, Przewlocki R, Slezak M
Glucocorticoid receptor signaling in astrocytes is required for aversive memory formation.
Stress elicits the release of glucocorticoids (GCs) that regulate energy metabolism and play a role in emotional memory. Astrocytes express glucocorticoid receptors (GR), but their contribution to cognitive effects of GC's action in the brain is unknown. To address this question, we studied how astrocyte-specific elimination of GR affects animal behavior known to be regulated by stress. Mice with astrocyte-specific ablation of GR presented impaired aversive memory expression in two different paradigms of Pavlovian learning: contextual fear conditioning and conditioned place aversion. These mice also displayed compromised regulation of genes encoding key elements of the glucose metabolism pathway upon GR stimulation. In particular, we identified that the glial, but not the neuronal isoform of a crucial stress-response molecule, Sgk1, undergoes GR-dependent regulation in vivo and demonstrated the involvement of SGK1 in regulation of glucose uptake in astrocytes. Together, our results reveal astrocytes as a central element in GC-dependent formation of aversive memory and suggest their relevance for stress-induced alteration of brain glucose metabolism. Consequently, astrocytes should be considered as a cellular target of therapies of stress-induced brain diseases.

INFLAMMATORY SIGNALLING IN AMPHETAMINE-INDUCED MOUSE MANIA MODEL, THE ROLE OF P2X7 RECEPTOR

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Flora Goloncser, Maria Baranyi, Pál Tod, Fruzsina Maácz, Beata Sperlagh
Institute of Experimental Medicine, Laboratory Of Molecular Pharmacology, Budapest, Hungary

Background: Purinergic dysfunctions play a role in the pathological process of mania and depression, but the essential relationship is not fully understood. Activation of the purinergic P2X7 receptor (P2X7R) plays a central role in inflammation, microglia activation, and IL-1β release, and activates NLRP3 inflammasome. We investigated whether d-amphetamine (AMPH) has an inflammatory profile andwhether P2X7R has an effect through IL-1β in this model. **Methods**: We analysed the modulatory effects of the P2X7R antagonist JNJ 47965567 on behaviour, tissue cytokines, monoamines, brain-derived neurotrophic factor (BDNF), and plasma purine levels in a subchronic d-amphetamine-induced mania model in wild-type and IL-1αβ-double knockout (IL-1αβKO) mice. **Results**: 7-day AMPH treatment caused a significant increase in locomotion of wild-type and IL-1αβKO mice, which was abolished by JNJ 47965567 in both genotype. AMPH mostly did not affect cytokine levels in the prefrontal cortex (PFC), striatum (STR), and hippocampus (HP), and it also increased serotonin content in IL-1αβKO mice only in STR and HP. JNJ 47965567 significantly reduced AMPH-induced dopamine release from STR, while it was not affected by genotype. Changes in purine levels were not affected by AMPH, only by JNJ 47965567. **Conclusion**: Although JNJ 47965567 had an effect on cytokine and purine levels as well as monoamines content, the potencial inflammatory effects of AMPH were contradictory in this model.

COMPARING THE ANTIDEPRESSANT-LIKE EFFECTS AND NEUROCHEMICAL CORRELATES OF DESIPRAMINE IN MALE AND FEMALE ADULT RATS

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Jordi Jornet-Plaza, Sandra Ledesma-Corvi, M. Julia García-Fuster
University of the Balearic Islands and IdISBa, Iunics, Palma, Spain

Major depression is one of the most common mental disorders in females, however preclinical studies investigating changes in antidepressant-like efficacy that include this variable are scarce. In this context, the present study compared the antidepressant-like potential and neurochemical correlates of desipramine, a typical tricyclic antidepressant, in female vs. male adult rats. Adult Sprague-Dawley rats (52 females and 89 males) were exposed to the forced-swim test (FST) for 15 min (pre-test) and then treated (i.p.) with 3 pulses of desipramine (5, 10 or 20 mg/kg) or vehicle (0.9% NaCl, 1 ml/kg) administered 23, 5 and 1 h prior to the FST (5-min test). Probable persistent effects were re-evaluated 1 and 3 days post-treatment in the FST. Hippocampal samples were collected 1 h, and 1- and 5-days post-treatment to evaluate cell proliferation (Ki-67+cells) and key neuroplasticity markers (FADD, Cdk-5, p35-p25). Desipramine exerted antidepressant-like effects both in male and female rats by decreasing immobility time in the FST 1 h and 1-day post-treatment. The main molecular results showed that desipramine increased hippocampal cell proliferation 1 h post-treatment both in male and female rats, but regulated some neuroplasticity markers (i.e., decreased FADD, p35/p25 and Cdk-5 protein content) exclusively in male rats. The results demonstrate that although desipramine is capable of inducing a similar antidepressant-like response in male and female rats, there are some sex differences in the mechanisms behind its actions that deserve further studies. PID2020-118582RB-I00 (MCIN/AEI/10.13039/501100011033) and PDR2020-14 (CAIB) to MJG-F; “JUNIOR” program to SL-C (IdISBa).

EVALUATION OF NEUROTRANSMITTERS (SEROTONIN AND NORADRENALINE) MODULATION IN MICE BRAIN VIA QUERCETIN MEDIATED MONOAMINE OXIDASE INHIBITION IN DEPRESSED MICE

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Sara Zeeshan
Quaid I Azam University, Biological Sciences, Gloucestershire, United Kingdom

The potential of antioxidants defenses against depression were evaluated by this study. The standardized methanolic extract of the vine of C. reflexa was assessed for antidepressant action using various behavioural paradigms such as tail suspension test (TST), forced swim test (FST) and locomotor activity test along with biochemical markers. HPLC fingerprints were obtained. The key constituent of C. reflexa is quercetin which belongs to flavonoids class that are good antioxidants. As per this potential, this natural moiety showed positive activity towards reducing stress mediated depression and showed to have better antidepressant potential. The serotonergic and noradrenergic changes were evaluated using 5-hydroxytryptophan (5-HTP) induced head twitches and yohimbine potentiation tests, respectively. The fluoxetine and phenelzine were used as positive control in the study. The test moeity significantly declined the immobility time in TST (IC50 ~ 50mg/kg) and FST while no significant increase in locomotor count was observed. The extract also significantly increased the 5-HTP induced head twitches and yohimbine induced lethality. The aforesaid results were similar to that caused by standard phenelzine. Furthermore the cortisol and BDNF levels were also determined in the prefrontal cortex as well and the level of certain monoamines and their metabolites was evaluated by using high performance liquid chromatography test. In the mice hippocampus, the C. reflexa extract caused significant elevation of serotonin & noradrenaline compared with the control. Histopathological data also supported the findings. The C. reflexa extract demonstrated antidepressant activity can be attributed to rise in serotonin and noradrenaline levels in the brain via MAO inhibition.

Anti-epileptic activity of daidzin in PTZ-induced mice model by targeting oxidative stress and BDNF/VEGF signaling.
Epilepsy is a complex and multifactorial neurodegenerative disease described by recurrent seizures. Oxidative stress and dysregulation of brain-derived neurotrophic factor (BDNF) and vascular endothelial growth factor (VEGF) are critical factors for the development of epilepsy. Daidzin is well-known for its effective anti-inflammatory and antioxidant potential for centuries. The present study was focused on exploring the anti-epileptic potential of daidzin in the pentylenetetrazole-induced mice model. Daidzin (1, 5, and 10 mg/kg) was administered in the acute study and the dose was optimized. Pretreatment with daidzin remarkably reduced the severity of epileptogenesis in a dose-dependent manner. Moreover, chronic epilepsy was induced in mice by administration of PTZ (35 mg/kg, i.p) every alternative day for 21 days. Results demonstrated that daidzin significantly prevented epileptogenesis and reversed histopathological changes in the hippocampus. It remarkably improved antioxidant (glutathione, glutathione sulfotransferase, superoxide dismutase, and catalase) levels while decreased MDA (malondialdehyde) and nitrite production in the brain. It remarkably improved the expressions of heme oxygenase-1 (HO-1) and BDNF while reduced the expression of VEGF. It remarkably prevented the neuronal apoptosis in the brain tissue. Additionally, spectroscopic analysis such as FTIR (Fourier transform infrared spectroscopy) and DSC (differential scanning calorimetry) revealed that daidzin remarkably prevented PTZ-induced protein damage. HPLC-UV spectrophotometry results demonstrated that there was no peak of aglycone daidzin (metabolite) in the brain sample which specify that the anticonvulsant effect of the compound is due to its direct entry into the brain tissue. Moreover, the molecular docking results showed that daidzin possesses a better binding affinity for ALDH2, estrogen receptor-β, P13k, AKT2, mTORC1, and HIF-1-α proteins. Taken together, the results of the present study showed that daidzin has remarkable neuroprotective and anti-epileptic properties through modulation of oxidative stress, BDNF/VEGF, and apoptotic signaling in the brain tissue of PTZ-kindled mice.

N-Pyrazoloyl and N-thiopheneacetyl hydrazone of isatin exhibited potent anti-inflammatory and anti-nociceptive properties

through suppression of NF-κB, MAPK and oxidative stress signaling in animal models of inflammation.
Hydrazide derivatives constitute an important class of compounds for new drug development as they are reported to possess good anti-inflammatory and analgesic activity. The present study was aimed to investigate the role of newly synthesized hydrazide derivatives N-pyrazoloyl hydrazone of isatin (PHI) and N-thiopheneacetyl hydrazone of isatin (THI) in acute and chronic inflammatory pain models induced by carrageenan and complete Freud's adjuvant (CFA).

Diadzein ameliorates 5-fluorouracil-induced intestinal mucositis by suppressing oxidative stress and inflammatory mediators in rodents.
5-Fluorouracil (5-FU) is one of the most commonly prescribed anti-cancer agent. However, its use is associated with several debilitating adverse effects such as intestinal mucositis (IM) and myelosuppression. Oxidative stress and inflammation are major contributors in the development of mucositis. Diadzein is known for its potent anti-inflammatory and anti-oxidative activities from decades. The present study focused on investigating the effects of diadzein on intestinal mucositis induced by 5-FU by mainly focusing on oxidative stress and inflammatory markers in mice. Mucositis was induced in mice by administration of 5-FU (50 mg/kg, i.p.), once daily for three days and diadzein (1, 5, 10 mg/kg) was administered once daily for seven days. Diadzein pretreatment was found to reduce the severity of mucosal injury in a dose-dependent manner. Diadzein significantly reversed weight loss, relieved diarrhea, and improved histopathological deformities associated with inflammation. Moreover, diadzein remarkably improved the intestinal wall histopathology by reducing inflammatory mediators infiltration and prevented suppression of antioxidants (glutathione, glutathione sulfo-transferase, and catalase) by 5-FU administration. Furthermore, nitrite production in intestinal tissue was reduced by diadzein consistent with the observed modulation of inflammatory markers. Additionally, diadzein also improved the amended microflora profile, by reducing the number of pathogenic bacteria and increasing the abundance of probiotics. Taken together, the behavioral, biochemical and histological outcomes of the present study demonstrates that diadzein has significant anti-mucositis properties in 5-FU induced mucositis model, and the attenuative potential of diadzein might be due to inhibition of oxidative stress and inflammatory mediators.

Cinnamomum cassia: an implication of serotonin reuptake inhibition in animal models of depression.
The aim of the study was to explore the traditional use of Cinnamomum cassia against depression. The standardised methanolic extract of the bark of C. cassia was evaluated for antidepressant activity using various behavioural tests, i.e. tail suspension test (TST), forced swim test (FST) and locomotor activity test. The serotonergic and noradrenergic modulation was assessed using 5-hydroxytryptophan (5-HTP)-induced head twitches and yohimbine potentiation tests, respectively. The fluoxetine and phenelzine were used as positive controls in the study. The C. cassia extract significantly decreased the immobility time in TST (maximum effective dose tested was 50 mg/kg) while no effect was observed in FST and locomotor activity test. The extract significantly increased the 5-HTP-induced head twitches while yohimbine-induced lethality remained unaltered. The aforementioned results are similar to that caused by fluoxetine. The standardised methanolic extract of C. cassia demonstrated antidepressant activity that can be attributed to rise in serotonin levels.

A new cationic palladium(II) dithiocarbamate exhibits anti-inflammatory, analgesic, and antipyretic activities through inhibition of inflammatory mediators in in vivo models.
Inflammation is being a protective mechanism of the body towards the injury. However, chronic and progressive inflammation may lead to some chronic diseases. Due to the serious unwanted effects associated with available drugs, new and safe anti-inflammatory agents are still required. Therefore, the present study was designed to investigate the anti-inflammatory, analgesics, and antipyretic properties of a new compound (4-benzylpiperidine-1-carbodithioato-κS,S')(1,4-bis-(diphenylphosphino)butane)palladium(II)chloride monohydrate (compound-1) in albino mice models. Compound-1 was characterized by elemental analysis, FT-IR, and multinuclear NMR spectroscopy. Initially, compound-1 was evaluated for cytotoxicity, anti-inflammatory, and analgesic activities by performing MTT assay, carrageenan-, histamine-, serotonin-, and CFA-induced paw edema, mechanical hyperalgesia, thermal hyperalgesia, and mechanical allodynia (0.1, 1, and 10 mg/kg, b.w). Antipyretic activity was evaluated in brewer's yeast-induced model. The pro-inflammatory cytokines were measured by using commercially available ELISA kits. Additionally, nitrite production, antioxidant enzymes, H&E staining, muscle activity and motor coordination, and kidney and liver function tests were also determined. The results demonstrated that compound-1 significantly inhibited inflammation, pain, and febrile responses in all models at a dose of 10 mg/kg without effecting viability of cells in vitro at concentrations up to 100 μM. Similarly, the data clearly demonstrated significant reduction in the pro-inflammatory cytokines and nitrite production while enhancing antioxidant enzymes. Furthermore, pretreatment with

compound-1 did not produce any prominent side effect on kidney, liver, stomach, and muscles. These findings suggest that compound-1 has potent anti-inflammatory-, pain-, and pyrexia-relieving properties. Hence, compound-1 might be a potential candidate for the therapeutic management of chronic inflammation and pain.

NEUROBEHAVIORAL DEVELOPMENT OF HETEROZYGOUS DAT (DAT-HET) RATS

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Dmitrii Traktirov, Nina Pestereva, Marina Karpenko
FSBSI «Institute of Experimental Medicine», I.p. Pavlov Department Of Physiology, Petersburg, Russian Federation

Introduction
Among neuropsychiatric disorders in children, attention deficit hyperactivity disorder (ADHD) is one of the most common, difficult to diagnose and treat early. The etiology of this disorder has not yet been established. Rats with a genetically determined dopamine metabolism disorder can probably be used to study the impact of the genetic factor in ADHD pathogenesis. The aim of this work was to study the effect of partial knockout of dopamine transporter (DAT) gene on the neurobehavioral development of rat pups. Methods
Rats were bred following a HET–HET breeding scheme. A total of 18 animals were tested, 4 DAT WT and 12 DAT HET. We analyzed their behavior in 5 tests: surface righting, negative geotaxis, cliff aversion, pendular reflex, grip strength. All experiments were conducted every day starting from 3-rd postnatal day (PND) and performed until the reflex appeared. Genotyping was performed by PCR followed by enzymatic digestion with BtsI MutI NEB.
Results & Discussion
In the surface righting test DAT-HET rats were able to flip onto their feet at 5-th PND on average, which is a day later than DAT-WT (two-tailed Fisher's exact test, p=0.0379). This may be the result of postural imbalances due to deficits in their core. In negative geotaxis, pendular reflex and cliff aversion tests there were no differences between groups. Reflexes appeared in 7th, 8th and 9th PND, respectively.
There were no statistically significant differences between groups in the grip strength test. Research support
The reported study was funded by RSF, project number 22-25-00124.

Calpain activity in plasma of patients with essential tremor and Parkinson's disease: a pilot study.
: Essential tremor (ET) and Parkinson's disease (PD) are the two most common movement disorders in adults with similar clinical symptoms, which is hinting towards existence of coincident pathogenesis steps.: The objective of this report is to characterize the relationship between ET and PD severity and the activity of calcium-dependent proteases calpain in plasma.: The study enrolled 12 volunteers for each condition: ET, PD, healthy. We evaluated the stage of PD on the H&Y scale in patients with PD, and the severity of tremor in patients with ET on the FTMS scale. IL-1β, TNFα, IL6, IL10 were determined in plasma using ELISA. Calpain activity was measured using fluorescent substrate and zymography methods.: We demonstrated that the activity of calpains in plasma of patients with PD and ET increased 5.1 and 4.3 times, respectively. The increase of calpain activity in plasma of PD patients correlated with the content of IL-1β, for ET such a connection was not found. At the advanced stages of PD calpain activity in plasma was significantly higher than that of the PD group at the early stage, and this increase was mediated by the increase in m-calpain activity. The increase in the tremor severity in ET did not lead to an increase in the activity of calpains in plasma.: We observed general increase in the activity of calpains in plasma of both PD and ET patients that hints towards presence of the common steps in the pathogenesis of these diseases.

The relationship between serum interleukin-1β, interleukin-6, interleukin-8, interleukin-10, tumor necrosis factor-α levels and clinical features in essential tremor.
In recent years, there has been discussion that essential tremor (ET) might be a neurodegenerative disease. Indicators of inflammation are considered as possible biomarkers of neurodegeneration. In this connection, the aim of our study was to identify the relationship between serum inflammation markers and clinical features in ET, including the severity of tremor, cognitive decline, depression.

BEHAVIOURAL MARKERS OF RESILIENCE AND SUSCEPTIBILITY IN A NEURODEVELOPMENTAL TWO-HIT MODEL OF SCHIZOPHRENIA

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Jarred Lorusso[1], Rebecca Woods[2], Mike Harte[3], Reinmar Hager[2], Jocelyn Glazier[2]
[1]University of Manchester, Division Of Evolution, Infection, And Genomics, Manchester, United Kingdom, [2]University of Manchester, Division Of Evolution, Infection And Genomics, Manchester, United Kingdom, [3]University of Manchester, Division Of Pharmacy And Optometry, Manchester, United Kingdom

Aims: Maternal immune activation (MIA) and postnatal stress are risk factors for neurodevelopmental disorders (NDDs) such as schizophrenia. The current research aimed to characterize the phenotypes resulting from both risk factors in isolation and together. Furthermore, the research aims to identify any putative markers of resilience to either insult. **Method:** A two-hit model for schizophrenia is presented combining MIA via poly(I:C) administration at gestational day 15 and limited bedding and nesting (LBN) from postnatal days 1-10. **Results:** We showed that MIA resulted in cognitive deficits in adolescence and adulthood, with LBN resulting in increased anxiety and cognitive deficits in adolescence. Cognition was used to stratify offspring irrespective of treatment. In adolescence, this resulted in three clusters of typical and deficient cognition as well as one cluster of intermediary performance. This intermediary cluster exhibited recognition memory but at a significantly lower level than typically-performing animals. In adulthood, the procedure resulted in a typical and a deficited group. In adolescence, there was a relationship between MIA and cluster membership in the absence of stress. When offspring were stressed, the relationship was attenuated. In adulthood, MIA offspring were more likely than vehicle offspring to be clustered into the low cognition group. **Conclusions:** Both models result in phenotypes of relevance to NDDs. Unbiased clustering presents the opportunity to identify responders and non-responders for use in subsequent analysis.

MATERNAL IMMUNE ACTIVATION WITH POLY(I:C) MAY PRODUCE VARIABLE OUTCOMES: COMPARISON OF RESULTS FROM TWO INDEPENDENT EXPERIMENTS AND DIFFERENT CAGING SYSTEMS

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Martina Janíková, Kristyna Maleninska, Dominika Radostová, Iveta Vojtěchová, Jan Svoboda, Ales Stuchlik
the Czech Academy of Sciences, Institute Of Physiology, Prague, Czech Republic

Maternal immune activation has been identified as a significant risk factor for onset of schizophrenia in offspring. We applied 5 mg/kg of poly(I:C) on gestation day 9 to pregnant mouse dams, whose offspring were then stressed during puberty. The experiment was performed twice with two consequential runs of animals, who were housed in different caging systems. The first run was housed in individually ventilated cages (IVC) and we showed impairments in attentional set-shifting in a T-maze and a decreased number of parvalbumin-positive interneurons in the hippocampus as a result of peripubertal stress specifically in females. The second run was housed in open cages, and we found a between-group differences in set-shifting, prepulse inhibition and sensitivity to amphetamine in the open field. However, surprisingly, the poly(I:C) group had less impaired prepulse inhibition and lower sensitivity to amphetamine. There was no between-group difference in these behavioral tasks in the first run of mice housed in IVC. It is therefore possible that caging system has impact on behavioral profile of mice prenatally treated with poly(I:C). This work was supported by Czech Science Foundation (GACR) grants 20-00939S and 21-16667K.

Selective deficits in attentional set-shifting in mice induced by maternal immune activation with poly(I:C).
Maternal immune activation has been identified as a significant risk factor for schizophrenia. Using rodent models, past work has demonstrated various behavioral and brain impairments in offspring after immune-activating events. We applied 5 mg/kg of poly(I:C) on gestation day 9 to pregnant mouse dams, whose offspring were then stressed during puberty. We show impairments in attentional set-shifting in a T-maze, and a decreased number of parvalbumin-positive interneurons in the hippocampus as a result of peripubertal stress specifically in females.

Memantine and Riluzole Exacerbate, Rather Than Ameliorate Behavioral Deficits Induced by 8-OH-DPAT Sensitization in a Spatial Task.
Chronic sensitization to serotonin 1A and 7 receptors agonist 8-OH-DPAT induces compulsive checking and perseverative behavior. As such, it has been used to model obsessive-compulsive disorder (OCD)-like behavior in mice and rats. In this study, we tested spatial learning in the 8-OH-DPAT model of OCD and the effect of co-administration of memantine and riluzole-glutamate-modulating agents that have been shown to be effective in several clinical trials. Rats were tested in the active place avoidance task in the Carousel maze, where they learned to avoid the visually imperceptible shock sector. All rats were subcutaneously injected with 8-OH-DPAT (0.25 mg/kg) or saline (control group) during habituation. During acquisition, they were pretreated with riluzole (1 mg/kg), memantine (1 mg/kg), or saline solution 30 min before each session and injected with 8-OH-DPAT ("OH" groups) or saline ("saline" groups) right before the experiment. We found that repeated application of 8-OH-DPAT during both habituation and acquisition significantly increased locomotion, but it impaired the ability to avoid the shock sector. However, the application of 8-OH-DPAT in habituation had no impact on the learning process if discontinued in acquisition. Similarly, memantine and riluzole did not affect the measured parameters in the "saline" groups, but in the "OH" groups, they significantly increased locomotion. In addition, riluzole increased the number of entrances and decreased the maximum time avoided of the shock sector. We conclude that monotherapy with glutamate-modulating agents does not reduce but exacerbates cognitive symptoms in the animal model of OCD.

Plasticity-Related Activity in the Hippocampus, Anterior Cingulate, Orbitofrontal, and Prefrontal Cortex Following a Repeated Treatment with D/D Agonist Quinpirole.
Quinpirole (QNP) sensitization is a well-established model of stereotypical checking relevant to obsessive-compulsive disorder. Previously, we found that QNP-treated rats display deficits in hippocampus-dependent tasks. The present study explores the expression of immediate early genes (IEG) during QNP-induced stereotypical checking in the hippocampus, anterior cingulate cortex (ACC), orbitofrontal cortex (OFC), and medial prefrontal cortex (mPFC). Adult male rats were injected with QNP (0.5 mg/mL/kg; = 15) or saline (= 14) daily for 10 days and exposed to an arena enriched with two objects. Visits to the objects and the corners of the arena were recorded. QNP-treated rats developed an idiosyncratic pattern of visits that persisted across experimental days. On day 11, rats were exposed to the arena twice for 5 min and sacrificed. The expression of IEGs and was determined using cellular compartment analysis of temporal activity by fluorescence in situ hybridization. IEG-positive nuclei were counted in the CA1 area of the hippocampus, ACC, OFC, and mPFC. We found significantly fewer IEG-positive nuclei in the CA1 in QNP-treated rats compared to controls. The overlap between IEG expressing neurons was comparable between the groups. We did not observe significant differences in IEG expression between QNP treated and control rats in ACC, OFC, and mPFC. In conclusion, treatment of rats with quinpirole decreases plasticity-related activity in the hippocampus during stereotypical checking.

CRMP2 mediates Sema3F-dependent axon pruning and dendritic spine remodeling.
Regulation of axon guidance and pruning of inappropriate synapses by class 3 semaphorins are key to the development of neural circuits. Collapsin response mediator protein 2 (CRMP2) has been shown to regulate axon guidance by mediating semaphorin 3A (Sema3A) signaling; however, nothing is known about its role in synapse pruning. Here, using newly generated crmp2 mice we demonstrate that CRMP2 has a moderate effect on Sema3A-dependent axon guidance in vivo, and its deficiency leads to a mild defect in axon guidance in peripheral nerves and the corpus callosum. Surprisingly, crmp2 mice display prominent defects in stereotyped axon pruning in hippocampus and visual cortex and altered dendritic spine remodeling, which is consistent with impaired Sema3F signaling and with models of autism spectrum disorder (ASD). We demonstrate that CRMP2 mediates Sema3F signaling in primary neurons and that crmp2 mice display ASD-related social behavior changes in the early postnatal period as well as in adults. Together, we demonstrate that CRMP2 mediates Sema3F-dependent synapse pruning and its dysfunction shares histological and behavioral features of ASD.

The McGill Transgenic Rat Model of Alzheimer's Disease Displays Cognitive and Motor Impairments, Changes in Anxiety and Social Behavior, and Altered Circadian Activity.
The McGill-R-Thy1-APP transgenic rat is an animal model of the familial form of Alzheimer's disease (AD). This model mirrors several neuropathological hallmarks of the disease, including the accumulation of beta-amyloid and the formation of amyloid plaques (in homozygous animals only), neuroinflammation and the gradual deterioration of cognitive functions even prior to plaque formation, although it lacks the tauopathy observed in human victims of AD. The goal of the present study was a thorough characterization of the homozygous model with emphasis on its face validity in several domains of behavior known to be affected in AD patients, including cognitive functions, motor coordination, emotionality, sociability, and circadian activity patterns. On the behavioral level, we found normal locomotor activity in spontaneous exploration, but problems with balance and gait coordination, increased anxiety and severely impaired spatial cognition in 4-7 month old homozygous animals. The profile of social behavior and ultrasonic communication was altered in the McGill rats, without a general social withdrawal. McGill rats also exhibited changes in circadian profile, with a shorter free-running period and increased total activity during the subjective night, without signs of sleep disturbances during the inactive phase. Expression of circadian clock gene was found to be increased in the parietal cortex and cerebellum, while expression was not changed. The clock-controlled gene expression was found to be elevated in the parietal cortex and hippocampus, which might have contributed to the observed changes in circadian phenotype. We conclude that the phenotype in the McGill rat model is not restricted to the

cognitive domain, but also includes gait problems, changes in emotionality, social behavior, and circadian profiles. Our findings show that the model should be useful for the development of new therapeutic approaches targeting not only memory decline but also other symptoms decreasing the quality of life of AD patients.

Recent studies suggest that schizophrenia treatment may benefit from a combination of antipsychotic administration with neurosteroids in some cases. As a pilot experiment for a subsequent study of co-application with neurosteroids, we evaluated the efficacy of three widely used antipsychotics (haloperidol, risperidone, and clozapine) in the acute MK-801 model of schizophrenia. Three-month-old males of Wistar rats were trained in the Carousel maze paradigm, a sensitive tool for detecting schizophrenia-like symptoms. This task requires rats to avoid an unmarked section on a slowly rotating arena in four daily sessions (20 minutes each). Prior to each session, rats were administered two i.p. injections. First, they were injected with one of the antipsychotics (haloperidol, risperidone, clozapine) or saline. Second, they received MK-801 (0.2 mg/kg) or saline. In the MK-801 injected animals, none of the antipsychotics reversed the cognitive deficit. In terms of positive symptoms, clozapine attenuated hyperactivity while haloperidol almost blocked the locomotion even in rats without MK-801. These data suggest that clozapine seems to be the most suitable molecule for the follow-up studies aimed at co-administration with neurosteroids. The study was supported by the Czech Health Research Council grant NU20-04-00389.

During normal brain aging, neurons of the hippocampus, a key structure for learning and memory, present defects in their autophagy machinery which contribute to age-related cognitive decline. Osteocalcin (OCN), a youth-associated hormone, is a direct inducer of autophagy in hippocampal neurons and its administration to aged mice improved memory in an autophagy-dependent manner. Recently, it was shown that the autophagy machinery can be mobilized in response to systemic stimuli by a direct or indirect connection with the primary cilium, an extracellular organelle that acts as a cellular antenna sensing systemic signals, such as hormones. Here we explore the role of the primary cilium as mediator of OCN signaling to modulate autophagy and cognitive fitness. We found that alteration of core ciliary proteins selectively in the hippocampus impaired autophagy machinery, reduced calcium signaling, and led to severe memory deficits. During aging, we found abnormal primary cilia morphology associated with a reduction of major ciliary proteins and restoration of IFT20 ameliorated age-impaired autophagic machinery and memory functions. Lastly, we found that GPR158 (OCN's receptor), is highly present in hippocampal neuronal primary cilia and IFT20 is required to integrate the beneficial effects of OCN on autophagy and memory. These data demonstrate that primary cilia are essential for hippocampal neurons ability to sense the systemic milieu and provide an adaptive response by modulating the autophagic machinery.

Introduction: Inflammation seems to be involved in the pathophysiology of depression, while autophagy is essential in the regulation of immunity and inflammation. Autophagy is a lysosome-based degradative pathway whose pathway alterations could lead to other processes hindrance, as membrane dynamics (controlled by the endosomal sorting complex required for transport, ESCRT) or waste products removal by lysosomes. **Aims**: To characterize autophagy markers, ESCRT machinery effectors, and possible lysosomal alterations in frontal cortex (FC) and hippocampus (Hp) of rats exposed to Chronic Mild Stress (CMS). **Methods**: mTOR, ULK1, beclin1, Atgs, SQSTM1, Hrs, STAM2, CHMP6 (among others) were evaluated in FC and Hp by western blot (WB). Fractions of purified lysosomes were tested for lysosomal markers (LAMPs) and proteins (cathepsins, cystatins) by WB. Immunofluorescence approaches were used to study colocalization events between autophagy and lysosomal proteins with neuron and glial cells. **Results**: FC and Hp displayed autophagy and ESCRT imbalances, being FC the most affected by CMS. Several steps of the autophagy pathway were impeded in a region-specific manner. ESCRT proteins were mainly downregulated in FC. CMS increased lysosomal presence in FC and Hp, oppositely modulating proteins in lysosomal fractions of FC and Hp. Astrocytes seemed to exert a chief role in SQSTM1 regulation, while neurons and microglia were the main orchestrators for LAMP2A CMS-derived modifications. **Conclusions**: CMS-induced alterations derived in lysosomal damage in both brain areas, and to the impairment of autophagy and ESCRT components mainly in FC. Autophagy seems to play a concrete role in brain homeostasis according to location.

Stress-Induced Depressive Behaviors Require a Functional NLRP3 Inflammasome.
Depression is a major public health concern in modern society, yet little is known about the molecular link between this condition and neuroinflammation. The inflammasome complex was recently shown to be implicated in depression. The present study shows the implication of NLRP3 inflammasome in animal model of stress-induced depression. Accordingly, we show here that in the absence of a NLRP3 inflammasome, prolonged stress does not provoke depressive behaviors or microglial activation in mice or dampen hippocampal neurogenesis. Indeed, NLRP3 deletion or inhibition of microglial activation impairs the stress-induced alterations associated with depression. According to these findings in animal model, the inflammasome could be a target for new therapeutic interventions to prevent depression in patients.

Paliperidone attenuates chronic stress-induced changes in the expression of inflammasomes-related protein in the frontal cortex of male rats.
Several stress-related neuropsychiatric diseases are related to inflammatory phenomena. Thus, a better understanding of stress-induced immune responses could lead to enhanced treatment alternatives. Little is known about the possible involvement of inflammasomes in the stress-induced proinflammatory response. Antipsychotics have anti-inflammatory effects, but the possible antipsychotic treatment actions on inflammasomes remain unexplored. Our aim was to study whether inflammasomes are involved in the neuroinflammation induced by a paradigmatic model of chronic stress and whether the monoamine receptor antagonist paliperidone can modulate the possible stress-induced inflammasomes activation in the

frontal cortex (FC). Thus, the effects of paliperidone (1 mg/Kg, oral gavage) administered during a chronic restraint stress protocol (6 h/day for 21 days) on the possible stress-related inflammasomes protein induction were evaluated through Western blot in the FC of male Wistar rats. Stress increased protein expression levels of the inflammasome complexes NALP1, NLRP3 and AIM2 and augmented caspase-1 and mature interleukin (IL)-1β protein levels. Paliperidone pre-treatment normalized the protein expression of the inflammasome pathway. In conclusion, our data indicate an induction of inflammasome complexes by chronic restraint stress in the FC of rats. The antipsychotic paliperidone has an inhibitory action on some of the stress-induced inflammasomes stimulation trying to normalize the neuroinflammatory scenario caused by stress. Considering the emerging role of inflammation in neuropsychiatric diseases, the development of new drugs targeting inflammasome pathways is a promising approach for future therapeutic interventions.

CD163 overexpression using a macrophage-directed gene therapy approach improves wound healing in ex vivo and in vivo human skin models.
Large tissue damage or wounds cause serious comorbidities and represent a major burden for patients, families, and health systems. Due to the pivotal role of immune cells in the proper resolution of inflammation and tissue repair, we focus our current study on the interaction of macrophages with skin cells, and specifically on the effects of CD163 gene induction in macrophages in wound healing. We hypothesize that the over-expression of the scavenger receptor gene CD163 in human macrophages would result in a more efficient wound healing process. Using 3D human wounded skin organotypic tissues, we observed that CD163 overexpression in THP-1 and human primary macrophages induced a more efficient re-epithelization when compared to control cells. Using human primary skin cells and an in vitro scratch assay we observed that CD163 overexpression in THP-1 macrophages promoted a more rapid and efficient wound healing process through a unique interaction with fibroblasts. The addition of CD163-blocking antibody, but not isotype control, blocked the efficient wound healing process induced by CD163 overexpression in macrophages. We found that the co-culture of skin cells and CD163 overexpressing macrophages reduced monocyte chemoattractant protein (MCP)-1 and enhanced tumor growth factor (TGF)-α, without altering interleukin (IL)-6 or TGF-β. Our findings show that CD163 induces a more efficient wound healing and seems to promote a wound milieu with a pro-resolution molecular profile. Our studies set the foundation to study this approach in in vivo clinically relevant settings to test its effects in wound healing processes such as acute major injuries, large surgeries, or chronic ulcers.

Evaluation of a nanotechnology-based approach to induce gene-expression in human THP-1 macrophages under inflammatory conditions.
Macrophages orchestrate the initiation and resolution of inflammation by producing pro- and anti-inflammatory products. An imbalance in these mediators may originate from a deficient or excessive immune response. Therefore, macrophages are valid therapeutic targets to restore homeostasis under inflammatory conditions. We hypothesize that a specific mannosylated nanoparticle effectively induces gene expression in human macrophages under inflammatory conditions without undesirable immunogenic responses. THP-1 macrophages were challenged with lipopolysaccharide (LPS, 5μg/mL). Polyethylenimine (PEI) nanoparticles grafted with a mannose receptor ligand (Man-PEI) were used as a gene delivery method. Nanoparticle toxicity, Man-PEI cellular uptake rate and gene induction efficiency (GFP, CD14 or CD68) were studied. Potential immunogenic responses were evaluated by measuring the production of tumor necrosis factor-alpha (TNF-α), Interleukin (IL)-6 and IL-10. Man-PEI did not produce cytotoxicity, and it was effectively up-taken by THP-1 macrophages (69%). This approach produced a significant expression of GFP (mRNA and protein), CD14 and CD68 (mRNA), and transiently and mildly reduced IL-6 and IL-10 levels in LPS-challenged macrophages. Our results indicate that Man-PEI is suitable for inducing an efficient gene overexpression in human macrophages under inflammatory conditions with limited immunogenic responses. Our promising results set the foundation to test this technology to induce functional anti-inflammatory genes.
Immunobiology, 2017; 222

Macrophage-specific nanotechnology-driven CD163 overexpression in human macrophages results in an M2 phenotype under inflammatory conditions.
M1 macrophages release proinflammatory factors during inflammation. They transit to an M2 phenotype and release anti-inflammatory factors to resolve inflammation. An imbalance in the transition from M1 to M2 phenotype in macrophages contributes to the development of persistent inflammation. CD163, a member of the scavenger receptor cysteine-rich family, is an M2 macrophage marker. The functional role of CD163 during the resolution of inflammation is not completely known.

We postulate that CD163 contributes to the transition from M1 to M2 phenotype in macrophages. We induced CD163 gene in THP-1 and primary human macrophages using polyethylenimine nanoparticles grafted with a mannose ligand (Man-PEI). This nanoparticle specifically targets cells of monocytic origin via mannose receptors. Cells were challenged with a single or a double stimulation of lipopolysaccharide (LPS). A CD163 or empty plasmid was complexed with Man-PEI nanoparticles for cell transfections. Quantitative RT-PCR, immunocytochemistry, and ELISAs were used for molecular assessments. CD163-overexpressing macrophages displayed reduced levels of tumor necrosis factor-alpha (TNF)-α and monocytes chemoattractant protein (MCP)-1 after a single stimulation with LPS. Following a double stimulation paradigm, CD163-overexpressing macrophages showed an increase of interleukin (IL)-10 and IL-1ra and a reduction of MCP-1. This anti-inflammatory phenotype was partially blocked by an anti-CD163 antibody (effects on IL-10 and IL-1ra). A decrease in the release of TNF-α, IL-1β, and IL-6 was observed in CD163-overexpressing human primary macrophages. The release of IL-6 was blocked by an anti-CD163 antibody in the CD163-overexpressing group. Our data show that the induction of the CD163 gene in human macrophages under inflammatory conditions produces changes in cytokine secretion in favor of an anti-inflammatory phenotype. Targeting macrophages to induce CD163 using cell-directed nanotechnology is an attractive and practical approach for inflammatory conditions that could lead to persistent pain, i.e. major surgeries, burns, rheumatoid arthritis, etc.

Antidepressants are the first-line pharmacological treatment for stress-related psychiatric disorders. However, their late-onset of action, frequent side effects and the significant percentage of treatment-resistant patients are important limitations. Cannabidiol (CBD) is a non-psychotomimetic phytocannabinoid and preliminary data showed that CBD (30mg/kg) is faster than the antidepressant escitalopram (ESC; 20mg/kg) to induce an anti-stress effect in mice. We hypothesized that CBD could be beneficial as an add-on therapy to enhance the action of antidepressants. We found that in male mice submitted to either of two different repeated stress protocols, the combination of ESC (10mg/kg) with a low dose of CBD (7.5mg/kg) accelerated the anxiolytic-like effect of the treatment. The anti-stress effect of ESC+CBD, however, was absent in mice in which the expression of the N-acyl phosphatidylethanolamine phospholipase D (NAPE-PLD, responsible for synthesizing N-acyl ethanolamines) was deleted in the medial prefrontal cortex (mPFC) using a CRISPR-Cas9-mediated approach. The CRISPR-Cas9-mediated deletion of diacylglycerol lipase, on the other hand, did not prevent the behavioral effect of ESC+CBD in stressed mice. Additionally, in three patients with treatment-resistant depression, after 12 weeks of treatment with CBD as add-on therapy, two patients were considered depression remitted (MADRS Score <10) while one patient successfully responded to CBD adjuvant treatment (>50% improved MADRS score). Our results suggest that CBD might be useful as an add-on therapy for optimizing the action of antidepressants. They also suggest that CBD's beneficial actions depend on the activity of NAPE-PLD in the mPFC. (CEUA: 032/2015-1 / 047/2019). Financial Support: FAPESP, CNPq, L'Oreal-UNESCO.

ABLATION OF NECROPTOSIS PROTECTS DIABETES ASSOCIATED COGNITIVE DEFICITS & LIPOTOXICITY INDUCED NEURO-GLIA CHANGES

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Kumari Preeti
LAB 70, Cellular and Molecular Neuroscience lab, NIPER Hyderabad, Department Of Pharmacology & Toxicology, HYDERABAD, India

Aims: Type-2 diabetes (T2DM), and obesity are associated with neuroinflammation and cognitive decline. Necroptosis and programmed necrosis is the major contributing factor to neuroinflammation, neurodegeneration, and metabolic disorder. Necroptosis is best characterized by relative upregulation of phosphorylated-MLKL (mixed-lineage kinase domain-like protein). The present study aims to evaluate the necrostatin (Nec-1) effect on cognitive decline in the experimental T2DM model in C57BL6/J mice and lipotoxicity induced neuro-glia changes in neuro2a and BV2 cells. **Methods:** T2DM was induced in mice by keeping them on a high-fat diet (HFD) for 16 weeks and injecting a single dose of streptozotocin (100 mg/kg,*i.p*) at the 12th week. Nec-1 was administered for 3 weeks at (10 mg/kg, i.p) once every 3-day. Lipotoxicity was induced in neuro2a, and BV2 cells by 200µM palmitate/BSA conjugate, and 50µM of Nec-1 is used to assess their inhibitory effect. neurobehavioral studies, plasma biochemical parameter level was analysed to assess cognitive performances, inflammatory characteristics, and type2 DM. Further, western blot, immunofluorescence, and staining were performed to evaluate the relative protein expression, their cellular localization, amyloid deposit, and neurodegenerative changes. **Results**: Nec-1 improved the cognitive performance of mice and reduced the p-RIPK3-p-MLKL mediated neuroglia changes in the brain tissue, and cells. Nec-1 also reduced the tau and, amyloid-beta load.it has alleviated the p-MLKL mediated mitochondrial and autophagy functionality. **Conclusions:** Necroptosis, a major contributing factor to neuroinflammation and gliosis, is responsible for cognitive decline. The above findings emphasises the central impact of metabolic stress and open the horizon for the need for the development of newer therapies targeting necroptosis.

EFFECTS OF S-KETAMINE ON COCAINE-SEEKING BEHAVIOR IN RATS

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Karolina Wydra, Kacper Witek, Agata Suder, Małgorzata Filip
Maj Institute of Pharmacology Polish Academy of Sciences, Drug Addiction Pharmacology, Krakow, Poland

Cocaine use disorder is a chronic brain disease characterized by compulsive drug-taking and drug-seeking despite harmful consequences. Recent observations suggest glutamatergic transmission and its N-methyl-D-aspartate (NMDA) receptors are implicated in different environmental conditions of cocaine forced abstinence in animals. The aim of this study was to examine the effects of S-ketamine a noncompetitive antagonist of NMDA receptor on cocaine-seeking behavior in rats with a history of cocaine (0.5 mg/kg/infusion) self-administration and different abstinence (condition housing in an enriched or in an isolated environment) and withdrawal with extinction training. S-ketamine was administered acutely (2.5-10 mg/kg, *i.p*.) before exposure to cocaine (10 mg/kg, *i.p*.) or a drug-associated conditional stimulus (a cue) in male male Wistar rats. Our results showed that exposure to different conditions of cocaine abstinence evoked increased active lever presses during cocaine- and cue-induced drug-seeking behavior. S-ketamine (2.5-10 mg/kg, *i.p.*) significantly reduced the effect of the priming dose of cocaine or cue in all conditions of abstinence and withdrawal with extinction training. S-ketamine in investigated doses did not alter locomotor activity in naive rats. Our findings indicate that S-ketamine may have the potential as a novel pharmacotherapies for cocaine addiction to be linked with reduction of relapse. Supported by the statutory funds of the Maj Institute of Pharmacology PAS (Kraków, Poland). We declare no conflict of interest.

ELEVATION OF ANANDAMIDE BY URB597 MITIGATES COCAINE-SEEKING BEHAVIOUR DURING ABSTINENCE

POSTER SESSION 05 - SECTION: ANIMAL MODELS OF PSYCHIATRIC DISORDERS AND PRECLINICAL PHARMACOLOGY

Laia Alegre Zurano[1], Alba García-Baos[1], Adriana Castro-Zavala[1], Olga Valverde[1,2]
[1]Universitat Pompeu Fabra, Department Of Medicine And Life Sciences, Barcelona, Spain, [2]IMIM-Hospital del Mar Research Institute, Neurosciences Programme, Barcelona, Spain

Aim: cue-induced cocaine-craving is one of the main factors contributing to relapse in abstinent addicts. The endocannabinoid system represents a potential therapeutic target for the cocaine-related maladaptative alterations that drive drug-seeking behaviour during protracted abstinence. Among them, endocannabinoid mediated long-term depression (eCB-LTD) in the nucleus accumbens is lost after cocaine exposure. However, how this alteration could add to the seeking behaviour in abstinent mice has never been explored. **Methods:** mice underwent an intravenous cocaine (0,75 mg/kg/infusion) self-administration. Afterwards, a group of mice was tested on withdrawal day 1 for cue-induced drug-seeking behaviour. The other groups were treated daily in their home cages with vehicle, the fatty acid amide hydrolase inhibitor URB597 (1 mg/kg ip) or the monoacylglycerol lipase inhibitor MJN110 (5 mg/kg ip) and, on withdrawal day 30, they were tested for cue-induced cocaine-seeking behaviour. Immediately after the test, we dissected or perfused the brains to evaluate the levels of different components of the endocannabinoid system using qPCR and the levels of c-Fos using free-floating immunochemistry in the nucleus accumbens. **Results:** our results show that URB597, but not MJN110, decreased drug-seeking behaviour during abstinence. URB597 also modulated the expression of c-Fos and components of the endocannabinoid system in the nucleus accumbens. **Conclusions:** these results support the therapeutic potential of the cannabinoid-targeted strategies for the treatment of cocaine craving during protracted abstinence from cocaine use. Lastly, the present study suggests that anandamide might constitute the main endocannabinoid involved in the regulation of cue-induced drug-seeking behaviour during withdrawal.

Amyloid beta (Aβ) accumulation is known to be a major risk factor of Alzheimer's disease. Protaetia brevitarsis larvae, a kind of edible insect, have been used as a traditional medicine. Now, it approved by the Ministry of Food and Drug Safety as food resources in Republic of Korea. In this study, we examined whether P. brevitarsis larvae improved cognitive decline under Aβ-induced mice model. Ethanol extracts of P. brevitarsis larvae is administred to Aβ-induced mice at doses of 100 and 200 mg/kg/day for 14 days. The protective effect of P. brevitarsis larvae from Aβ was determined by behavioral tests using T-maze test, novel object recognition test and water maze test. The Aβ-injected control group showed disorders in both spatial memory and novel object cognitive abilities. However, P. brevitarsis treated groups increased exploration of novel route and novel object, and it also decreased latencies and travelling distances to find the invisible platform in water maze. Therefore, our study demonstrated that administration of P. brevitarsis larvae improved Aβ-induced cognitive decline.

Alzheimer's disease (AD) is a progressive neurodegenerative disease characterized by cognitive decline and dementia with no effective treatment. As we know, neuroinflammation plays key role during AD life, Here, we investigated a novel compound from oats named avenanthramide-C (Avn-C), on AD-related memory impairment and behavioral deficits in transgenic mouse models. Avn-C, a polyphenol compound found predominantly in oats, has a range of biological properties. Acute hippocampal slices of wild-type or AD transgenic mice were treated with Avn-C in the presence or absence of oligomeric Aβ42. LTP analyses and immunoblotting were performed to assess the effect of Avn-C on Aβ-induced memory impairment. To further investigate the effect of Avn-C on impaired memory and Aβ pathology, two different AD transgenic mice (Tg2576 and 5XFAD) models were orally treated with either Avn-C or vehicle for 2 weeks. They were then assessed for the effect of the treatment on neuropathologies and behavioral impairments. Avn-C reversed impaired LTP in both ex vivo- and in vivo-treated AD mice hippocampus. Oral administration (6 mg/kg per day) for 2 weeks in AD mice leads to improved recognition and spatial memory, reduced caspase-3 cleavage, reversed neuroinflammation, and to accelerated glycogen synthase kinase-3β (pS9GSK-3β) and interleukin (IL-10) levels. Our findings provide evidence, for the first time, that oats' Avn-C reverses the AD-related memory and behavioral impairments, and establish it as a potential candidate for Alzheimer's disease drug development (This work was supported by NRF-2019R1A2C1089108 and the Commercializations Promotion Agency for R&D Outcomes(COMPA) grant funded by the Korea government(MSIT) (2021C100)

Alzheimer's disease (AD) is a complex disorder and multiple cellular and molecular mechanisms are involved in AD onset and progression. Recent evidences have suggested that metabolic alterations are an important pathological feature in disease progression in AD. Likewise, diabetes and obesity, two mayor metabolic illnesses associated with white adipose tissue expansion, are risk factors for AD. Here, we hypothesize that the white adipose tissue may serve as a key communicator organ between the brain and peripheral metabolic illnesses. We used histological stains, immunohistochemistry and biochemical means to determine changes in the white adipose tissue from WT and db/db mice. Moreover, similar techniques were used in the brain of 3xTg-AD mice that received white fat pads from WT and db/db donors to determine any changes in amyloid and tau pathology. Our study shows that recipient 3xTg-AD mice from db/db fat pads mice develop profound changes in tau pathology due to increased CDK5/p25 expression compared to 3xTg-AD mice that received fad pads from WT mice. This increment in tau level was associated with elevated levels in IL-1β and microglial activation. However, we found that Aβ levels were reduced in recipient 3xTg-AD mice from db/db fat pads compared to 3xTg-AD mice that received fad pads from WT mice. These reduction in Aβ levels were correlated with an increment in microglia phagocytic capacity. Overall, our study demonstrates a novel important crosstalk between AD and diabetes type II through white adipose cells and a differential effect on tau and Aβ pathology.

Aging is the major risk factor for Alzheimer's disease (AD). Hallmarks of cellular senescence have been detected in aging brain and recently in brain from AD patients and AD mice models. In the absence of effective treatment, identifying and treating comorbidities is an interesting treatment strategy. Sleep apnea syndrome (SAS) is common in elderly subjects and is accompanied by intermittent hypoxia (IH). IH may cause stress-induced premature aging and cognitive decline, but the role of cellular senescence in these mechanisms remains largely unknown. To determine whether IH causes premature brain aging and accelerates neurodegeneration, 3-month-old wild-type (WT) and AD transgenic mice (PS1M146Vki; PS1Ki) were exposed to IH or normoxia for 6 weeks (8h/day). We assessed behavioral as well as markers of cellular senescence in the brain. Our results indicate that IH exposure induced a cognitive impairment in WT mice similar to that observed in PS1Ki mice exposed to normoxia. Moreover, we found that IH induced an increase in the expression of markers of cellular senescence in the hippocampus and entorhinal cortex of WT mice. These first data indicate that cellular senescence mediated by SAS could be a potential target for AD prevention.

Alzheimer´s disease (AD) is one of the main neurodegenerative disorders of the 21stcentury involving declining cognitive function characterized by a difficulty in learning new information and memory loss. Currently, AD is considered incurable and barely treatable. This results in an increasing need for patient care, posing enormous social and economic challenges to society and healthcare systems worldwide. Adult neurogenesis, the process by which new neurons arise from neural stem cells (NSCs) in the dentate gyrus of the adult hippocampus, is known to be important for memory formation and learning. Current research of our group suggests that NSCs are affected in their fate decisions by AD. We observed an increased proliferation of NSCs in the pre-plaque phase which is followed by a strong decline in the number of stem cells and adult neurogenesis. The fate of these overactivated cells has not yet been fully elucidated. The aim of the present work was to evaluate the early-onset changes in the neurogenic niche in AD. For this, the fate of NSCs in the pre-plaque phase of AD was determined by *in vivo* fate mapping of individual stem cell clones using the NestinCreER^{T2}/tdTomato mouse model. The fate tracking of the tomato-positive stem cells over a period of 1 month shows increased proliferation of stem- and progenitor cells and the formation of mature astrocytes. Results suggest that increased astrogenesis due to direct differentiation of the NSCs ultimately leads to a decrease in the stem cell pool and consequently reduction of new neurons during AD.

VASCULAR ALTERATIONS IN MIXED MURINE MODELS OF METABOLIC DISORDERS AND ALZHEIMER´S DISEASE

POSTER SESSION 05 - SECTION: ALZHEIMER'S DISEASE: FROM NEUROINFLAMMATION TO NEUROPROTECTION

Maria Vargas-Soria, Carmen Infante-Garcia, Carmen Hierro-Bujalance, Angel Del Marco, Monica Garcia-Alloza
University of Cadiz, Division Of Physiology, Cádiz, Spain

Aims: While aging remains the main risk factor to suffer Alzheimer´s disease (AD), metabolic disorders, including prediabetes and type 2 diabetes (T2D) also increase the risk to develop dementia. Blood flow and vascular alterations might be one the linking mechanisms underlying the close relationship between AD and T2D. We have analyzed the presence of spontaneous hemorrhages in AD-prediabetes mice and AD-T2D animals. We have also analyzed alterations in brain vascular functionality. **Methods**: AD-prediabetes mice were generated by feeding a high-fat diet to APP/PS1 mice. AD-T2D mice resulted from crossing APP/PS1 and db/db animals. Amyloid-β (Aβ) levels were determined by ELISA. Spontaneous hemorrhages in the brain were quantified by Prussian blue staining. Vessel contractility and red blood cell (RBC) velocity were analyzed *in vivo* and in real time by multiphoton microscopy. **Results**: Soluble Aβ levels were higher in AD-prediabetes and AD-T2D mice. Spontaneous hemorrhages were increased in AD-T2D animals. Vessel contractility was impaired in AD-prediabetes animals and more severely in AD-T2D mice. Moreover, RBC velocity was significantly reduced in AD-T2D animals. **Conclusion**: Vascular complications are observed in AD-prediabetes mice and these effects are more severe in animals harboring AD and T2D, as regularly observed in the clinic, supporting a role for vascular alterations when AD and metabolic disorders coexist. **Funding:** Ministerio de Ciencia e Innovacion (PID2020-115499RB-I0). Aims: Based upon our previous experiments we aimed to investigate the neuroprotective effect of 17β-estradiol (E2) in a triple transgenic mouse model of Alzheimer's disorder (3xTg-AD) and to find new estrogen-like compounds (activators of non-genomic estrogen-like signaling – ANGELS) without classical side effects and with neuroprotective potential. **Methods:** The experiment was performed on 6-month-old genetically modified female 3xTg-AD mice. To eliminate the peripheral E2 synthesis ovaries were removed (OVX). After two-week recovery an acute subcutaneous (s.c.) treatment of vehicle, 33ng/g E2 or ANGELS was administered. Y-Maze and Forced Swim Test (FST) were performed 24 hours after treatment. The $A\beta_{1-42}$ plaques, Tau aggregates, and acetylcholinesterase (AChE) fiber loss in the brain were determined with quantitative immunohistochemistry. The uterus was dissected and weighted. **Results:** The uterus weight increased significantly after E2 but not after ANGELS treatment. Behavioural disturbances, both in cognitive (Y-Maze, testing working memory) and depressive-like domain (immobility in FST), were modified by our interventions. The hippocampal region of the 3xTg-AD mice showed the expected pathological hallmarks of AD ($A\beta_{1-42}$ plaques, Tau aggregates). Additionally, significant AChE fiber loss was found in the cortex of 3xTg-AD animals. Our treatments were effective. **Conclusions:** The tested ANGELS proved to lack estrogenic-like side effects *in vivo* and have protective properties in 3xTg-AD mice. We believe that these or similar compounds may provide a novel approach in AD therapy.

Effects of Chronic Cannabidiol Treatment in the Rat Chronic Unpredictable Mild Stress Model of Depression.
Several neuropharmacological actions of cannabidiol (CBD) due to the modulation of the endocannabinoid system as well as direct serotonergic and gamma-aminobutyric acidergic actions have recently been identified. The current study aimed to reveal the effect of a long-term CBD treatment in the chronic unpredictable mild stress (CUMS) model of depression. Adult male Wistar rats (n = 24) were exposed to various stressors on a daily basis in order to induce anhedonia and anxiety-like behaviors. CBD (10 mg/kg body weight) was administered by daily intraperitoneal injections for 28 days (n = 12). The effects of the treatment were assessed on body weight, sucrose preference, and exploratory and anxiety-related behavior in the open field (OF) and elevated plus maze (EPM) tests. Hair corticosterone was also assayed by liquid chromatography-mass spectrometry. At the end of the experiment, CBD-treated rats showed a higher rate of body weight gain (5.94% vs. 0.67%) and sucrose preference compared to controls. A significant increase in vertical exploration and a trend of increase in distance traveled in the OF test were observed in the CBD-treated group compared to the vehicle-treated group. The EPM test did not reveal any differences between the groups. Hair corticosterone levels increased in the CBD-treated group, while they decreased in controls compared to baseline (+36.01% vs. -45.91%). In conclusion, CBD exerted a prohedonic effect in rats subjected to CUMS, demonstrated by the increased sucrose preference after three weeks of treatment. The reversal of the effect of CUMS on hair corticosterone concentrations might also point toward an anxiolytic or antidepressant-like effect of CBD, but this needs further confirmation.

MODELLING SPORADIC AD IN MICE WITH RISK FACTORS APOE4 AND NEUROINFLAMMATION

POSTER SESSION 05 - SECTION: ALZHEIMER'S DISEASE: FROM NEUROINFLAMMATION TO NEUROPROTECTION

Kiruthika Ganesan[1], Peggy Rentsch[2], Alexander Langdon[1], Bryce Vissel[2]
[1]University of Technology Sydney, School Of Life Sciences, Sydney, Australia, [2]Centre for Applied Medical Research, Clinical Neuroscience And Regenerative Medicine, Sydney, Australia

Developing effective treatment for Alzheimer's disease (AD) remains a challenge. This can be partially attributed to the fact that the mouse models used in preclinical research largely replicate familial form of AD, while majority of human cases are sporadic; both forms differ widely in the onset and origin of pathology, therefore requiring specific/targeted treatments. In this study, we attempted to model sporadic AD in mice by combining two of the many risk factors that are strongly implicated in AD: ApoE4, a major genetic risk factor, together with neuro-inflammation which plays a pivotal role in AD. We gave ApoE4 knock in (KI) mice, expressing humanized ApoE4, low doses of Lipopolysaccharide (LPS) injections (weekly, for four months) to model chronic neuro-inflammation. We checked these animals for behavioral impairments at 6 months age using Open Field, Y-maze and Barnes Maze Test. LPS induced hypoactivity was observed in the Open Field and Y-maze test in these mice, however spatial learning and memory was intact. We then checked for differences in dendritic spine density, which is a strong correlate of AD, alongside microglia and astrocyte activation. ApoE4 KI mice showed a significant reduction in the number of spines after treatment with LPS, whereas there were no differences in the number of activated microglia and astrocytes. To conclude, although the spine loss observed in this model may indicate an early stage of a sporadic AD phenotype, further studies at later time points are required to see if these mice will also develop a convincing behavioral phenotype.

The 4-(Phenylsulfanyl) butan-2-one Improves Impaired Fear Memory Retrieval and Reduces Excessive Inflammatory Response in Triple Transgenic Alzheimer's Disease Mice.
Alzheimer's disease (AD) is a neurodegenerative disease characterized by an excessive inflammatory response and impaired memory retrieval, including spatial memory, recognition memory, and emotional memory. Acquisition and retrieval of fear memory help one avoid dangers and natural threats. Thus, it is crucial for survival. AD patients with impaired retrieval of fear memory are vulnerable to dangerous conditions. Excessive expression of inflammatory markers is known to impede synaptic transmission and reduce the efficiency of memory retrieval. In wild-type mice, reducing inflammation response can improve fear memory retrieval; however, this effect of this approach is not yet investigated in 3xTg-AD model mice. To date, no satisfactory drug or treatment can attenuate the symptoms of AD despite numerous efforts. In the past few years, the direction of therapeutic drug development for AD has been shifted to natural compounds with anti-inflammatory effect. In the present study, we demonstrate that the compound 4-(phenylsulfanyl) butan-2-one (4-PSB-2) is effective in enhancing fear memory retrieval of wild-type and 3xTg-AD mice by reducing the expression of TNF-α, COX-2, and iNOS. We also found that 4-PSB-2 helps increase dendritic spine density, postsynaptic density protein-95 (PSD-95) expression, and long-term potentiation (LTP) in the hippocampus of 3xTg-AD mice. Our study indicates that 4-PSB-2 may be developed as a promising therapeutic compound for treating fear memory impairment of AD patients.

TDP-43 interacts with amyloid-β, inhibits fibrillization, and worsens pathology in a model of Alzheimer's disease.
TDP-43 inclusions are found in many Alzheimer's disease (AD) patients presenting faster disease progression and greater brain atrophy. Previously, we showed full-length TDP-43 forms spherical oligomers and perturbs amyloid-β (Aβ) fibrillization. To elucidate the role of TDP-43 in AD, here, we examined the effect of TDP-43 in Aβ aggregation and the attributed toxicity in mouse models. We found TDP-43 inhibited Aβ fibrillization at initial and oligomeric stages. Aβ fibrillization was delayed specifically in the presence of N-terminal domain containing TDP-43 variants, while C-terminal TDP-43 was not essential for Aβ interaction. TDP-43 significantly enhanced Aβ's ability to impair long-term potentiation and, upon intrahippocampal injection, caused spatial memory deficit. Following injection to AD transgenic mice, TDP-43 induced inflammation, interacted

with Aβ, and exacerbated AD-like pathology. TDP-43 oligomers mostly colocalized with intracellular Aβ in the brain of AD patients. We conclude that TDP-43 inhibits Aβ fibrillization through its interaction with Aβ and exacerbates AD pathology.

TRANSFER OF A PHARMACOLOGICAL NEUROVASCULAR UNCOUPLING MODEL FROM MICE TO RATS

POSTER SESSION 05 - SECTION: ALZHEIMER'S DISEASE: FROM NEUROINFLAMMATION TO NEUROPROTECTION

Bence Varga, Attila Gáspár, Ernyey Aliz, Barbara Hutka, Brigitta Tajti, Zoltán Zádori, István Gyertyán
Semmewleis University, Department Of Pharmacology And Pharmacotherapy, Budapest, Hungary

Present study's aim was to establish a pharmacologically induced neurovascular uncoupling (NVU) method in rats as a translational animal model of human cognitive decline. Pharmacologically induced NVU with subsequent neurological and cognitive defects was described in mice (Tarantini, 2015), however, no similar procedure has been reported so far in rats. We used 32 male Hannover Wistar rats. NVU was induced by intraperitoneal administration of a pharmacological "cocktail" consisting of MSPPOH (5 mg/kg), L-NAME (10 mg/kg) and indomethacin (1 mg/kg), injected twice daily for 8 consecutive days. Animals were tested in Morris water-maze and fear-conditioning assays. Blood pressure of the animals was also monitored during the treatment. NVU was characterized by the decrease in whisker pad stimulation-induced hyperaemia in the barrel cortex, measured by laser-Doppler probe. Surgery was followed by euthanasia, and brain and small intestine tissue samples were collected for prostaglandin E_2 (PGE2) level measurements. The animals treated with the "cocktail" showed no impairment in their performance in any of the cognitive tasks. However, we observed an overall higher blood pressure in these rats. They also showed a greater than 50 % decrease in CBF. Intestinal bleeding and ulcers were found in some of the treated animals and ELISA assays of the tissue samples revealed significantly decreased levels of PGE2 in both areas. Although we could evoke NVU by the applied mixture of pharmacons, it also induced adverse side effects. Furthermore, the treatment did not cause cognitive impairment. Additional refinements are still required for the development of an applicable model.

Intracerebroventricularly Injected Streptozotocin Exerts Subtle Effects on the Cognitive Performance of Long-Evans Rats.
Intracerebroventricularly injected streptozotocin (STZ)-induced learning impairment has been an increasingly used rat model of Alzheimer disease. The evoked pathological changes involve many symptoms of the human disease (cognitive decline, increase in β-amyloid and phospho-tau level, amyloid plaque-like deposits). However, the model has predominantly been used with Wistar rats in the literature. The objective of the current study was to transfer it to Long-Evans rats with the ulterior aim to integrate it in a complex cognitive test battery where we use this strain because of its superior cognitive capabilities. We performed two experiments (EXP1, EXP2) with three months old male animals. At EXP1, rats were treated with 2 × 1.5 mg/kg STZ (based on the literature) or citrate buffer vehicle injected bilaterally into the lateral ventricles on days 1 and 3. At EXP2 animals were treated with 3 × 1.5 mg/kg STZ or citrate buffer vehicle injected in the same way as in EXP1 at days 1, 3, and 5. Learning and memory capabilities of the rats were then tested in the following paradigms: five choice serial reaction time test (daily training, started from week 2 or 8 post surgery in Exp1 or Exp2, respectively, and lasting until the end of the experiment); novel object recognition (NOR) test (at week 8 or 14), passive avoidance (at week 11 or 6) and Morris water-maze (at week 14 or 6). 15 or 14 weeks after the STZ treatment animals were sacrificed and brain phospho-tau/tau protein ratio and β -amyloid level were determined by western blot technique. In EXP1 we could not find any significant difference between the treated and the control groups in any of the assays. In EXP2 we found significant impairment in the NOR test and elevated β-amyloid level in the STZ treated group in addition to slower learning of the five-choice paradigm and a trend for increased phospho-tau/tau ratio. Altogether our findings suggest that the Long-Evans strain may be less sensitive to the STZ treatment than the Wistar rats and higher doses may be needed to trigger pathological changes in these animals. The results also highlight the importance of strain diversity in modelling human diseases.

Aims: The blood-brain barrier restricts penetration of many pharmaceutical agents to the brain leading to low drug accumulation and inadequate targeting of neurons. In this study we tried to investigate the efficacy of a novel carbon nanomolecule in targeting neurons and transferring pharmacologic agents to them. **Methods:** First, we aimed to develop nanoparticles that can successfully absorb and carry galantamine (Gal), an Alzheimer's disease (AD) treating agent, to their final target neurons. For this, hierarchical porous carbon (HPCs) nanoparticles, carrying Gal, were labeled with rhodamine-b and encapsuled in poly-lactic-co-glycolic acid (PLGA) by solid-oil-water modified double emulsification method. Then we elucidated the neuronal uptake of HPC-PLGA-Gal nanoparticles over time and their exact intra-neuronal localization by performing in-vitro experiments on primary neuronal cell cultures, deriving from wild type animals. Neuronal uptake of HPC-PLGA-Gal nanoparticles was also evaluated in vivo, after their intranasal administration to rats. **Results:** Our in-vitro results revealed a rapid, over the first two minutes, neuronal uptake of HPC-PGLA-Gal nanoparticles. Nanoparticles were localized in the cell body and proximal dendrites of neurons on primary neuronal cell cultures. In vivo experimentation confirmed the presence of HPC-PLGA-Gal nanoparticles in neurons of various brain regions within the first hour after a single intranasal administration. **Conclusion:** Conclusively, HPC-PGLA-Gal nanoparticles are capable to efficiently deliver Gal to neurons. Their possible therapeutic potential in the AD brain is under further evaluation on primary neuronal cultures and AD-transgenic rats.

New treatment approaches for Alzheimer's disease: preclinical studies and clinical trials centered on antidiabetic drugs.
Alzheimer's disease (AD) and type 2 diabetes mellitus (T2DM) represent two major chronic diseases that affect a large percentage of the population and share common pathogenetic mechanisms, including oxidative stress and inflammation. Considering their common mechanistic aspects, and given the current lack of effective therapies for AD, accumulating research has focused on the therapeutic potential of antidiabetic drugs in the treatment or prevention of AD.

Aims: Alzheimer's disease (AD) is an age-related neurodegenerative disease with progressive memory decline that may be related with the impairment of fine motor skills. The transgenic mouse models of AD are promising tools in understanding the underlying mechanisms. We hypothesized that this early event may be due to an alteration in cerebellar mitochondrial function. **Methods:** Male, 6-8-month-old triple transgenic (3xTg-AD) mice were investigated replicating some pathological hallmarks of the disorder. First, gross motor skills were tested in open field and grip tests. Next, fine motoric ability were checked by food-motivated tests (single pellett retrieval, staircase tests). To confirm that cerebellum was damaged we detected β-Amyloid (Aβ) and tau fibrillary tangels by immunohistochemistry and Western blot (WB). For evaluation of mitochondrial function the cerebellar levels of citochrom C IV subunits mRNA, as well as Bcl2, Bcl-xL and Bax protein levels changes were identified by qPCR and Western blot. **Results:** 3xTg-AD mice has decreased physical activity, muscle strenght and fine motoric. In the cerebellum AD-related deposits were detected. Mitochondrial pathways genes and proteins also showed alterations. **Conclusion:** These results support that the impaired gross and fine motor skills of 3xTg-AD mice are related to cerebellar changes both at the level of AD-related aggregations, as well as at mitochondrial level. We assume that cerebellar changes might be an early sign preceeding cognitive decline in AD.

A New Player in the Hippocampus: A Review on VGLUT3+ Neurons and Their Role in the Regulation of Hippocampal Activity and Behaviour.
Glutamate is the most abundant excitatory amino acid in the central nervous system. Neurons using glutamate as a neurotransmitter can be characterised by vesicular glutamate transporters (VGLUTs). Among the three subtypes, VGLUT3 is unique, co-localising with other "classical" neurotransmitters, such as the inhibitory GABA. Glutamate, manipulated by VGLUT3, can modulate the packaging as well as the release of other neurotransmitters and serve as a retrograde signal through its release from the somata and dendrites. Its contribution to sensory processes (including seeing, hearing, and mechanosensation) is well characterised. However, its involvement in learning and memory can only be assumed based on its prominent hippocampal presence. Although VGLUT3-expressing neurons are detectable in the hippocampus, most of the hippocampal VGLUT3 positivity can be found on nerve terminals, presumably coming from the median raphe. This hippocampal glutamatergic network plays a pivotal role in several important processes (e.g., learning and memory, emotions, epilepsy, cardiovascular regulation). Indirect information from anatomical studies and KO mice strains suggests the contribution of local VGLUT3-positive hippocampal neurons as well as afferentations in these events. However, further studies making use of more specific tools (e.g., Cre-mice, opto- and chemogenetics) are needed to confirm these assumptions.

Epigenetic Modulation of Vasopressin Expression in Health and Disease.
Vasopressin is a ubiquitous molecule playing an important role in a wide range of physiological processes thereby implicated in the pathomechanism of many disorders. Its effect is well characterized through V2 receptors, which regulates the water resorption in kidney, while its vasoconstrictory effect through V1a receptor also received a lot of attention in the maintenance of blood pressure during shock. However, the most striking is its central effect both through the V1b receptors in stress-axis regulation as well as through V1a receptors regulating many aspects of our behavior (e.g., social behavior, learning and memory). Vasopressin has been implicated in the development of depression, due to its connection with chronic stress, as

well as schizophrenia because of its involvement in social interactions and memory processes. Epigenetic changes may also play a role in the development of these disorders. The possible mechanism includes DNA methylation, histone modification and/or micro RNAs, and these possible regulations will be in the focus of our present review.

Conventional measures of intrinsic excitability are poor estimators of neuronal activity under realistic synaptic inputs. Activity-dependent regulation of intrinsic excitability has been shown to greatly contribute to the overall plasticity of neuronal circuits. Such neuroadaptations are commonly investigated in patch clamp experiments using current step stimulation and the resulting input-output functions are analyzed to quantify alterations in intrinsic excitability. However, it is rarely addressed, how such changes translate to the function of neurons when they operate under natural synaptic inputs. Still, it is reasonable to expect that a strong correlation and near proportional relationship exist between static firing responses and those evoked by synaptic drive. We challenge this view by performing a high-yield electrophysiological analysis of cultured mouse hippocampal neurons using both standard protocols and simulated synaptic inputs via dynamic clamp. We find that under these conditions the neurons exhibit vastly different firing responses with surprisingly weak correlation between static and dynamic firing intensities. These contrasting responses are regulated by two intrinsic K-currents mediated by Kv1 and Kir channels, respectively. Pharmacological manipulation of the K-currents produces differential regulation of the firing output of neurons. Static firing responses are greatly increased in stuttering type neurons under blocking their Kv1 channels, while the synaptic responses of the same neurons are less affected. Pharmacological blocking of Kir-channels in delayed firing type neurons, on the other hand, exhibit the opposite effects. Our subsequent computational model simulations confirm the findings in the electrophysiological experiments and also show that adaptive changes in the kinetic properties of such currents can even produce paradoxical regulation of the firing output.

Stress Adaptation and the Brainstem with Focus on Corticotropin-Releasing Hormone.
Stress adaptation is of utmost importance for the maintenance of homeostasis and, therefore, of life itself. The prevalence of stress-related disorders is increasing, emphasizing the importance of exploratory research on stress adaptation. Two major regulatory pathways exist: the hypothalamic-pituitary-adrenocortical axis and the sympathetic adrenomedullary axis. They act in unison, ensured by the enormous bidirectional connection between their centers, the paraventricular nucleus of the hypothalamus (PVN), and the brainstem monoaminergic cell groups, respectively. PVN and especially their corticotropin-releasing hormone (CRH) producing neurons are considered to be the centrum of stress regulation. However, the brainstem seems to be equally important. Therefore, we aimed to summarize the present knowledge on the role of classical neurotransmitters of the brainstem (GABA, glutamate as well as serotonin, noradrenaline, adrenaline, and dopamine) in stress adaptation. Neuropeptides, including CRH, might be co-localized in the brainstem nuclei. Here we focused on CRH as its role in stress regulation is well-known and widely accepted and other CRH neurons scattered along the brain may also complement the function of the PVN. Although CRH-positive cells are present on some parts of the brainstem, sometimes even in comparable amounts as in the PVN, not much is known about their contribution to stress adaptation. Based on the role of the Barrington's nucleus in micturition and the inferior olivary complex in the regulation of fine motoric-as the main CRH-containing brainstem areas-we might assume that these areas regulate stress-induced urination and locomotion, respectively. Further studies are necessary for the field.

MULTIMODAL ASSESSMENT OF AGING IN THE WILD-TYPE MICE

POSTER SESSION 05 - SECTION: ALZHEIMER'S DISEASE: FROM NEUROINFLAMMATION TO NEUROPROTECTION

Rie Ryoke, Hiroi Nonaka, Ryuta Kawashima
Tohoku University, Dept. Functional Brain Imaging, Sendai, Japan

Aging varies the phenotype of cognitive, physical and organ functions. In order to correctly interpret the mouse model of age-related disorders, it is necessary to clarify the aspects affected by aging in mice. In this study, we performed multimodal experiment combined with behavioral test, magnetic resonance imaging (MRI) and histological study using wild-type mice for comprehensive understanding of aging effect. We conducted behavioral batteries assessing motor, mood, cognitive functions in 3-month-old male C57BL/6J mice and 24-month-old. For the MRI experiment, we used voxel-based morphometry (VBM) to examine the changes of regional brain volumes. For the histological study, we conducted immunohistochemistry in brain decapitated after MRI. 24-month-old mice showed lower muscle strength and open-field activity than 3-month-old mice. Although 24-month-old mice had lower long-term object memory, aversive memory did not impair in both groups. The VBM analysis showed that several cortices, putamen and substantia nigra were larger in 3-month-old mice. On the other hand, 24-month-old mice had bigger anterior commissure, lateral olfactory tract, and corticospinal tract. In the histological results, Iba1-positive cells in white matter was increased in 24-month-old mice. Regression analysis between behavior and regional white matter volume revealed that lateral lemniscus was negatively correlated with open-field activity. Inflammation of lemniscus might affect activity in open-field. According to gray matter analysis, sensory system could be associated with the locomotor behavior. In conclusion, the effects of aging on physical aspects were simple in mice, while cognitive and neurological aspects likely to require consideration of mouse characteristics.

EFFECT OF BACOPA MONNIERI ON AMYLOID-BETA INDUCED ALZHEIMER'S DISEASE-LIKE PATHOLOGICAL CHANGES

POSTER SESSION 05 - SECTION: ALZHEIMER'S DISEASE: FROM NEUROINFLAMMATION TO NEUROPROTECTION

Sushma Kumari, Amal Mondal
Jawaharlal Nehru University, School Of Life Sciences, Delhi, India

Background: Alzheimer's disease (AD) is a late-onset neurodegenerative disorder characterized by loss of memory, disordered cognitive function, and caused by the accumulation of amyloid-beta peptide plaque and neurofibrillary tangles of hyperphosphorylated tau. Molecular pathological cause of AD includes oxidative stress, mitochondrial dysfunction, apoptosis, and dysregulation of calcium signaling. Only a few therapeutic drugs are available that intercept the symptoms, besides manifest side effects. *Bacopa monnieri* (BM) is an herb used as neuro-protectant. Several studies have shown its anti-oxidant, anti-cholinesterase, anti-apoptotic, and anti-inflammatory properties. It was also found to prevent neurodegeneration by upregulating BDNF. **Aim:** To explore the effect of BM on Amyloid-beta induced pathological changes in cellular and animal model of AD. **Methodology**: We examined the effect of BM ethanolic extract on cytotoxicity caused by aggregated amyloid-beta using SHSY-5Y cells. In the animal model, anxious behavior was examined in the Open field arena. Furthermore, memory deficits were examined using MWM and NORT tests. Neuronal density was evaluated by cresyl violet stain. **Results**: In this study, the protective effect of BM was found on cell viability. In addition, it has shown the ameliorative effect on the memory deficits and anxious symptoms caused by aggregated Aβ in rats. BM significantly increased neuronal density in hippocampal areas of the rat brain. **Conclusion**: Ethanolic extract of BM has been shown to prevent Amyloid-beta induced cellular toxicity in SHSY-5Y cells. Additionally, BM reverted the memory deficits and also ameliorated neurodegeneration caused by Amyloid-beta in animal models and a further molecular mechanism is needed to explore.

Immunotherapeutic Approaches for the Treatment of Neurodegenerative Diseases: Challenges and Outcomes.
Neurodegenerative diseases, being rapidly increasing disorders and the seventh leading cause of death worldwide, have been a great challenge for researchers, affecting cognition, motor activity and other body functioning due to neurodegeneration. Several neurodegenerative diseases are caused by aggregation of proteins which induce the alteration of neuronal function leading to cell death. These proteins are amyloid-β peptide, tau, α-synuclein, and mHTT, which cause Alzheimer's disease, Frontotemporal dementia, Corticobasal degeneration, Progressive supranuclear palsy, Parkinson's disease, Multiple system atrophy, Dementia with Lewy-body and Huntington's disease. Currently available treatments only reduce symptoms and increase life sustainability; however, they possess side effects and are ineffective in curing the diseases.

Role of GPCR signaling and calcium dysregulation in Alzheimer's disease.
Alzheimer's disease (AD), a late onset neurodegenerative disorder is characterized by the loss of memory, disordered cognitive function, caused by accumulation of amyloid-β (Aβ) peptide and neurofibrillary tangles (NFTs) in the neocortex and hippocampal brain area. Extensive research has been done on the findings of the disease etiology or pathological causes of aggregation of Aβ and hyperphosphorylation of tau protein without much promising results. Recently, calcium dysregulation has been reported to play an important role in the pathophysiology of AD. Calcium ion acts as one of the major secondary messengers, regulates many signaling pathways involved in cell survival, proliferation, differentiation, transcription and apoptosis. Calcium signaling is one of the major signaling pathways involved in the formation of memory, generation of energy and other physiological functions. It also can modulate function of many proteins upon binding. Dysregulation in calcium homeostasis leads to many physiological changes leading to neurodegenerative diseases including AD. In AD, GPCRs generate secondary messengers which regulate calcium homeostasis inside the cell and is reported to be disturbed in the pathological condition. Calcium channels and receptors present on the plasma membrane and intracellular organelle maintain calcium homeostasis through different signaling mechanisms. In this review, we have summarized the different

calcium channels and receptors involved in calcium dysregulation which in turn play a critical role in the pathogenesis of AD. Understanding the role of calcium channels and GPCRs to maintain calcium homeostasis is an attempt to develop effective AD treatments.

COMBINATION THERAPY OF DONEPEZIL AND ENVIRONMENTAL ENRICHMENT ON MEMORY DEFICITS IN AMYLOID-BETA-INDUCED ALZHEIMER'S DISEASE RATS

POSTER SESSION 05 - SECTION: ALZHEIMER'S DISEASE: FROM NEUROINFLAMMATION TO NEUROPROTECTION

Vahid Hajali, Sajad Sahab Negah, Jamileh Gholami
Mashhad University of Medical Science, Neuroscience, Mashhad, Iran

Alzheimer's disease (AD) is progressive neurodegeneration known as the most common cause of dementia and it is the sixth leading cause of death in elderly people. Given the promising data on the additive effect of combination therapy with donepezil (Aricept), an acetylcholinesterase inhibitor (AChEI), and regarding the similar neuronal mechanisms through them donepezil and environmental enrichment (EE) exert their enhancing effects on cognition, we asked whether simultaneous treatment with two paradigms in amyloid-beta-induced AD rats may lead to greater cognitive improvements than either treatment individually. AD was induced by intrahippocampal injection of amyloid-beta (1-42, 6 µg) and donepezil was orally administrated (4 mg/kg) for 21 days. Environmental enrichment consisted of housing animals in large cages (50× 50× 50 cm) containing a running wheel and differently shaped objects for 21 days. Spatial learning and memory were assessed in the Morris water maze (MWM) and Real-time PCR was performed to assess the expression of brain-derived neurotrophic factor (BDNF) and M1 muscarinic acetylcholine receptor (AchM1R) within the hippocampus. Spatial memory was impaired in AD animals and while neither pretreatment with donepezil nor EE alone could significantly restore spatial memory scores in AD rats, combination therapy was effective. BDNF expression was suppressed in AD rats and pretreatment with donepezil plus EE could increase it to the saline levels. The data suggest that a cholinesterase inhibitor and cognitive stimulation can be used effectively in combination to improve cognitive loss in an AD rat model.

The beneficial effects of green tea on sleep deprivation-induced cognitive deficits in rats: the involvement of hippocampal antioxidant defense.
The weight of evidence suggests that sleep is essential for the processes of memory consolidation and sleep deprivation (SD) impairs the retention of long-term memory in both humans and experimental animals, which is associated with oxidative stress damage within the brain. Green tea polyphenols have revealed carcinogenic, antioxidant, anti-, and anti-mutagenic properties. We aimed to investigate the possible protective effect of green tea extract (GTE) and its main active catechin, epigallocatechin-3-gallate (EGCG), on post-training total sleep deprivation (TSD) -induced spatial memory deficits and oxidative stress profile in the hippocampus of the rat.

Combination effect of exercise and environmental enrichment on cognitive functions and hippocampal neurogenesis markers of rat.
Cognitive decline is one of the most prevalent health problems and is associated with increased healthcare utilization and economic burden. Physical and cognitive training both have positive effects on cognition but have been less applied in combination. We hypothesized that simultaneous cognitive-physical components would yield greater cognitive benefits than single-domain interventions in rats.

The next step of neurogenesis in the context of Alzheimer's disease.
Among different pathological mechanisms, neuronal loss and neurogenesis impairment in the hippocampus play important roles in cognitive decline in Alzheimer's disease (AD). AD is a progressive and complex neurodegenerative diseases, which is very debilitating. The purpose of this paper is to review recent research into neurogenesis and AD and discuss how pharmacological drugs and herbal active components have impacts on neurogenesis and consequently improve cognitive functions. To date, despite huge research, no effective treatment has been approved for AD. Therefore, an avenue for future research and drug discovery is stimulating adult hippocampal neurogenesis (AHN). Evidence suggests that neurogenesis is

regulated by the pharmacological treatment that may be recommended as a part of prophylaxis and therapeutic options for AD. However, the underlying mechanisms of regulating neurogenesis in AD are not well understood. To this point, we highlight to achieve an efficient treatment in AD by manipulating neurogenesis, it's necessary to target all steps of neurogenesis.

The Impact of Estradiol on Neurogenesis and Cognitive Functions in Alzheimer's Disease.
Alzheimer's disease (AD) is described as cognitive and memory impairments with a sex-related epidemiological profile, affecting two times more women than men. There is emerging evidence that alternations in the hippocampal neurogenesis occur at the early stage of AD. Therapies that may effectively slow, stop, or regenerate the dying neurons in AD are being extensively investigated in the last few decades, but none has yet been found to be effective. The regulation of endogenous neurogenesis is one of the main therapeutic targets for AD. Mounting evidence indicates that the neurosteroid estradiol (17β-estradiol) plays a supporting role in neurogenesis, neuronal activity, and synaptic plasticity of AD. This effect may provide preventive and/or therapeutic approaches for AD. In this article, we discuss the molecular mechanism of potential estradiol modulatory action on endogenous neurogenesis, synaptic plasticity, and cognitive function in AD.

Progesterone modulates post-traumatic epileptogenesis through regulation of BDNF-TrkB signaling and cell survival-related pathways in the rat hippocampus.
Female sex hormone, progesterone, in addition to seizure modifying activity is also known as a potential protective agent against various brain injury conditions. Considering the predisposal role of traumatic brain injury (TBI) on developing post-traumatic epilepsy (PTE), the effect of progesterone on post-traumatic epileptogenesis is not investigated yet. Male Wistar rats were given a moderate focal weight drop injury (500 gr) or sham surgery and then progesterone (16 and 32mg/kg) was given daily for two consecutive weeks. On day 15 of injury, seizures were induced by administration of a GABAA receptor antagonist, pentylenetetrazole (PTZ, 30 mg/kg). Seizures were then assessed over a 1-h period using the Racine clinical rating scale. Traumatized animals that received 32 mg/kg progesterone had reduced score, duration of seizures and almost did not show tonic-clonic seizures during 60 min versus the untreated trauma group. In line with behavioral alterations, 32 mg/kg progesterone enhanced the amount of Nrf2 and HO-1 proteins and decreased the level of NF-kB, BDNF, Caspase 3 and ratio of Bax/Bcl-2 in the ipsilateral hippocampus. Additionally, the number of TUNEL-positive apoptotic cells, as well as injured dark neurons in the parietal cortex and hippocampal CA1 of 32 mg/kg-treated animals showed a significant reduction. Administration of 16 mg/kg progesterone elevated production of BDNF, Bax and Caspase 3 and decreased anti-apoptotic Bcl-2 protein. Taken together, an early administration of 32 mg/kg of progesterone after TBI for two weeks post-injury modified seizure activity. Our findings suggest that post-traumatic anti-epileptogenesis property of a high dose of progesterone partly occurs through the manipulation of BDNF-TrkB axis along with control of cell survival pathways.

Sex differences in sleep and sleep loss-induced cognitive deficits: The influence of gonadal hormones.
Males and females can respond differentially to the same environmental stimuli and experimental conditions. Chronic sleep loss is a frequent and growing problem in many modern societies and has a broad variety of negative outcomes for health

and well-being. While much has been done to explore the deleterious effects of sleep deprivation (SD) on cognition in both human and animal studies over the last few decades, very little attention has been paid to the part played by sex differences and gonadal steroids in respect of changes in cognitive functions caused by sleep loss. The effects of gonadal hormones on sleep regulation and cognitive performances are well established. Reduced gonadal function in menopausal women and elderly men is associated with sleep disturbances and cognitive decline as well as dementia, which suggests that sex steroids play a key role in modulating these conditions. Finding out whether there are sex differences in respect of the effect of insufficient sleep on cognition, and how neuroendocrine mediators influence cognitive impairment induced by SD could provide valuable insights into the best therapies for each sex. In this review, we aim to highlight the involvement of sex differences and gonadal hormone status on the severity of cognitive deficits induced by sleep deficiency in both human and animal studies.

Peroxisome proliferator-activated receptor-γ activation attenuates harmaline-induced cognitive impairments in rats.
Cognitive and motor disturbances are serious concerns of the tremors induced by motor disorders. Despite the lack of effective clinical treatment, some potential therapeutic agents have been used to alleviate the cognitive symptoms in the animal models of tremor. Recent studies have shown that PPAR-γ agonists have neuroprotective effects. In the current study, the effects of pioglitazone (PIO), a peroxisome proliferator-activated receptor gamma agonist, on harmaline-induced motor and cognitive impairment were studied. Male Wistar rats were divided into vehicle (normal saline), PIO (20 mg/kg i.p.), harmaline (10 mg/kg, i.p.) and PIO + harmaline (PIO injected 2 h before harmaline) groups. Open field, rotarod, wire grip, foot print and Morris water maze tests were used to evaluate the motor and cognitive performance. The results indicated that administration of PIO attenuated harmaline-induced locomotor, anxiety-like behaviors, and spatial learning and memory impairments, but it partially decreased the tremor score. The neuroprotective and anxiolytic effects of PIO demonstrated in the current study can offer the PPAR-γ receptor agonism as a potential therapeutic agent in the treatment of patients with tremor that manifest mental dysfunction.

Alterations in the intrinsic electrophysiological properties of Purkinje neurons in a rat model of hepatic encephalopathy: Relative preventing effect of PPARγ agonist.
Patients suffering from hepatic cirrhosis (HC) have been shown to have motor and cognitive impairments. The cerebellum, which controls coordinated and rapid movements, is a potential target for the deleterious effects of hyperammonemia induced by bile duct ligation. Therefore, the aim of this study was to determine the mechanisms of motor impairments observed in a rat model of HC and second objective of the current study was to evaluate the possible protective effect of pioglitazone (PIO) on these impairments. Male Wistar rats were used in the current study. Bile duct ligation (BDL) surgery was performed and pioglitazone administration was started two weeks after the surgery for the next four weeks. The effects of pioglitazone on BDL-induced electrophysiological changes of the Purkinje cerebellum neurons were evaluated by Whole-cell patch clamp recordings. Purkinje neurons from the BDL group exhibited significant changes in a number of electrophysiological properties and some alterations partially were counteracted by activation of peroxisome proliferator-activated receptor-γ. Purkinje cells from BDL groups showed a significant increase in the spontaneous firing frequency followed by a decrease in the action potential duration of half-amplitude and spike interval. Chronic administration of pioglitazone could contract this effect of BDL on event frequency and interevent interval, though the difference with the sham group was still significant in the duration of action potential. Results of the current study raise the possibility that BDL may profoundly affect the intrinsic membrane properties of the cerebellar Purkinje neurons and PIO administration can counteract some of these effects.

NLRP3 inflammasome is an essential component of innate immunity and its activation leads to the production of interleukin (IL)-1β and IL-18, and promotes inflammatory cell death. Recent studies have indicated a critical role for the dysregulation of NLRP3 inflammasome in the pathogenesis of Alzheimer's disease (AD), where neuroinflammation has been recognized as an essential player. Thus, novel NLRP3 selective inhibitors (NSIs) represent a promising approach to develop AD therapeutics. Our laboratory has recently successfully developed a sulfonamide-containing scaffold into a series of NSIs. Through medicinal chemistry campaign, two generations of compounds have been designed and biologically characterized, and several lead NSIs were identified. Based on the accumulated SAR information, we have designed a new scaffold with improved solubility and drug-like properties to develop NSIs with therapeutic potentials. Through itinerary optimizations, a new lead NSI was identified to bind to the recombinant NLRP3 with a K_D of 10 nM and to inhibit the release of IL-1β from J774A.1 cells with an IC_{50} of 200 nM. Further studies in mice using a PET radiotracer based on this lead structure also demonstrated its brain penetration and selective labeling of the NLRP3 inflammasome in the brain. Our studies also confirmed its in vivo target engagement and selectivity. Collectively, the results strongly encourage developing new analogs based on this novel chemical scaffold as novel NSIs and potential AD therapeutics.

Alzheimer's disease (AD) is a complex neurodegenerative disorder associated with normal aging that is more prevalent in women. Cholinergic neurotransmission is decreased in patients with AD. It has previously shown that mice with decreased VAChT expression (Knockdown, VAChT KD), a protein necessary for acetylcholine uptake into vesicles, show decreased cholinergic signaling. VAChT KD^{HOM} and VAChT KD^{HET} mice show 65% and 45% decrease in VAChT expression when compared to WT. These mutant mice showed learning and memory impairments, suggesting that they could be used to screen for potential therapeutic drugs to alleviate cognitive deficits in AD. Previous data from our group showed that standardized extract of *Ginkgo biloba* (EGb) improved fear memory retention as well as object recognition memory (ORM) in rats. In this study, we aimed to evaluate whether EGb improves memory in VAChT KD animals. Three-month-old female VAChT KD^{HOM}, VAChT KD^{HET} and WT mice were treated with EGb (250, 500 and 1000 mg/Kg) or vehicle for 30 days and subjected to memory testing and immunohistochemistry for VAChT expression in CA1, CA3 and dentate gyrus of dorsal hippocampal formation. All genotypes treated with EGb showed improved object recognition memory. Further, KD^{HOM} + EGb showed higher expression of VAChT in dentate gyrus. Together, our data suggest that EGb might be used as an alternative for treatment of AD.

BDNF as a Putative Target for Standardized Extract of -Induced Persistence of Object Recognition Memory.
Despite considerable progress on the study of the effect of standardized extract of (EGb) on memory processes, our understanding of its role in the persistence of long-term memory (LTM) and the molecular mechanism underlying its effect, particularly episodic-like memory, is limited. We here investigated the effects of EGb on the long-term retention of recognition memory and its persistence and BDNF expression levels in the dorsal hippocampal formation (DHF). Adult male Wistar rats (n = 10/group) were handled for 10 min/5 day. On day 6, the animals were treated with vehicle or 0.4 mg/kg diazepam (control groups) or with EGb (250, 500 or 100 mg/kg) 30 min before the training session (TR1), in which the animals were exposed to two sample objects. On day 7, all rats underwent a second training session (TR2) as described in the TR1 but without drug treatment. Object recognition memory (ORM) was evaluated on day 8 (retention test, T1) and day 9 (persistence test, T2). At the end of T1or T2, animals were decapitated, and DHF samples were frozen at -80 °C for analyses of the differential expression of BDNF by Western blotting. EGb-treated groups spent more time exploring the novel object in T2 and showed the highest recognition index (RI) values during the T1 and T2, which was associated with upregulation of BDNF expression in the DHF in a dose-and session-dependent manner. Our data reveal, for the first time, that EGb treatment before acquisition of ORM promotes persistence of LTM by BDNF differential expression.

THE PROTECTIVE ACTIONS OF DHEA/S AND BDNF AGAINST OXIDATIVE STRESS IN AN IN VITRO MODEL OF VASCULAR DEMENTIA

POSTER SESSION 05 - SECTION: ALZHEIMER'S DISEASE: FROM NEUROINFLAMMATION TO NEUROPROTECTION

Barbara Vuić[1], Matea Nikolac Perkovic[1], Gordana Nedic Erjavec[1], Lucija Tudor[1], Tina Milos[2], Nela Pivac[2], Marcela Konjevod[2], Dubravka Svob Strac[1]

Vascular dementia (VaD), the second most common form of dementia, is generally underrecognized and still poorly understood disease. It develops when the brain´s blood supply is blocked or reduced, causing deprivation of oxygen and nutrients and resulting in damage and death of neurons. The brain is highly susceptible to oxidative stress, due to its richness in fatty acids sensitive to peroxidation, as well as due to high oxygen consumption and free radicals accumulation. Oxidative stress in VaD, characterized by the exacerbated production of reactive oxygen species and insufficient antioxidant defense system, increases neuronal cell abnormalities and triggers apoptosis, leading to cognitive dysfunction and dementia. Neurosteroids dehydroepiandrosterone and dehydroepiandrosterone sulfate (DHEA/S) and neurotrophin brain-derived neurotrophic factor (BDNF) have attracted the attention of researchers investigating their involvement in various brain functions such as neural survival, plasticity, cognition and behavior. The aim of this study was to investigate the protective potential of DHEA/S and BDNF in promoting neuronal survival and preventing oxidative stress caused by brain ischemia, a common characteristic of VaD. Oxygen-glucose deprivation (OGD) was performed in primary mouse neurons derived from C57BL/6 mice, and human SH-SY5Y neuroblastoma cells as *in vitro* model of VaD. The cells were cultured in glucose- and serum-free medium in a modular incubator chamber filled with N_2. Before or after OGD, cells were treated with DHEA/S and BDNF and cell viability and oxidative stress parameters were determined. Our results suggested protective effects of DHEA/S and BDNF against oxidative damage induced by the ischemic injury in neuronal cells.

Personalizing the Care and Treatment of Alzheimer's Disease: An Overview.
Alzheimer's disease (AD) is a progressive, complex, and multifactorial neurodegenerative disorder, still without effective and stable therapeutic strategies. Currently, available medications for AD are based on symptomatic therapy, which include acetylcholinesterase (AChE) inhibitors and N-methyl-D-aspartate (NMDA) receptor antagonist. Additionally, medications such as antipsychotic drugs, antidepressants, sedative, and hypnotic agents, and mood stabilizers are used for the management of behavioral and psychological symptoms of dementia (BPSD). Clinical research has been extensively investigated treatments focusing on the hallmark pathology of AD, including the amyloid deposition, tau hyperphosphorylation, neuroinflammation, and vascular changes; however, so far without success, as all new potential drugs failed to show significant clinical benefit. The underlying heterogeneous etiology and diverse symptoms of AD suggest that a precision medicine strategy is required, which would take into account the complex genetic, epigenetic, and environmental landscape of each AD patient. The article provides a comprehensive overview of the literature on AD, the current and potential therapy of both cognitive symptoms as well as BPSD, with a special focus on gut microbiota and epigenetic modifications as new emerging drug targets. Their specific patterns could represent the basis for novel individually tailored approaches aimed to optimize precision medicine strategies for AD prevention and treatment. However, the successful application of precision medicine to AD demands a further extensive research of underlying pathological processes, as well as clinical and biological complexity of this multifactorial neurodegenerative disorder.

Background: A series of recent observations are shedding light on the involvement of brain carbonic anhydrases (CAs) in neurodegenerative disorders. For instance, a higher expression of the CAII isoform was found in the plasma of Alzheimer's Disease (AD) patients when compared to age-matched control subjects. Moreover, two CA inhibitors (CAIs) prevented Aβ-induced mitochondrial toxicity and cell death in vitro. Despite these encouraging findings, the impact of CAIs in AD animal models were not yet investigated. Aims: To evaluate the efficacy of a pharmacological intervention with acetazolamide (ACTZ), a well-known CAI, against the cognitive impairments and neuropathological alterations observed in TgCRND8 mice. Methods: TgCNRD8 mice (expressing the human amyloid precursor protein carrying the Swedish and Indiana *mutations*) were fed with control or ACTZ-enriched diets (100 and 200 ppm) starting at 6 weeks of age. After 6 or 12 weeks of treatment, animals' cognitive function was evaluated in the social discrimination paradigm. Then, their brains were collected for neurochemical analysis. Results: Chronic ACTZ treatment prevented the cognitive deficits observed in TgCNRD8 mice at both ages. A reduction in the number of β-amyloid plaques (Aβ1-42), in the expression of the β-amyloid pyroglutamic derivative (Aβ N3pE) and in Tau phosphorylation (AT8) were also observed in ACTZ-fed animals compared to the animals fed with control diet. Chronic ACTZ treatment also reduced the levels of caspase-3 in the same areas. Conclusions: Chronic CAIs prevented both behavioral and neuropathological alterations observed in TgCNRD8 animals, suggesting their role as innovative compounds for AD treatment.

Short- and Long-Term Social Recognition Memory Are Differentially Modulated by Neuronal Histamine.
The ability of recognizing familiar conspecifics is essential for many forms of social interaction including reproduction, establishment of dominance hierarchies, and pair bond formation in monogamous species. Many hormones and neurotransmitters have been suggested to play key roles in social discrimination. Here we demonstrate that disruption or potentiation of histaminergic neurotransmission differentially affects short (STM) and long-term (LTM) social recognition memory. Impairments of LTM, but not STM, were observed in histamine-deprived animals, either chronically (mice lacking the histamine-synthesizing enzyme histidine decarboxylase) or acutely (mice treated with the HDC irreversible inhibitor α-fluoromethylhistidine). On the contrary, restriction of histamine release induced by stimulation of the HR agonist (VUF16839) impaired both STM and LTM. HR agonism-induced amnesic effect was prevented by pre-treatment with donepezil, an acetylcholinesterase inhibitor. The blockade of the HR with ciproxifan, which in turn augmented histamine release, resulted in a procognitive effect. In keeping with this hypothesis, the procognitive effect of ciproxifan was absent in both and αFMH-treated mice. Our results suggest that brain histamine is essential for the consolidation of LTM but not STM in the social recognition test. STM impairments observed after HR stimulation are probably related to their function as heteroreceptors on cholinergic neurons.

The role of carbonic anhydrases in extinction of contextual fear memory.
Carbonic anhydrases (CAs; EC 4.2.1.1) are metalloenzymes present in mammals with 16 isoforms that differ in terms of catalytic activity as well as cellular and tissue distribution. CAs catalyze the conversion of CO to bicarbonate and protons and are involved in various physiological processes, including learning and memory. Here we report that the integrity of CA activity in the brain is necessary for the consolidation of fear extinction memory. We found that systemic administration of

acetazolamide, a CA inhibitor, immediately after the extinction session dose-dependently impaired the consolidation of fear extinction memory of rats trained in contextual fear conditioning. d-phenylalanine, a CA activator, displayed an opposite action, whereas C18, a membrane-impermeable CA inhibitor that is unable to reach the brain tissue, had no effect. Simultaneous administration of acetazolamide fully prevented the procognitive effects of d-phenylalanine. Whereas d-phenylalanine potentiated extinction, acetazolamide impaired extinction also when infused locally into the ventromedial prefrontal cortex, basolateral amygdala, or hippocampal CA1 region. No effects were observed when acetazolamide or d-phenylalanine was infused locally into the substantia nigra pars compacta. Moreover, systemic administration of acetazolamide immediately after the extinction training session modulated c-Fos expression on a retention test in the ventromedial prefrontal cortex of rats trained in contextual fear conditioning. These findings reveal that the engagement of CAs in some brain regions is essential for providing the brain with the resilience necessary to ensure the consolidation of extinction of emotionally salient events.

A New Kid on the Block? Carbonic Anhydrases as Possible New Targets in Alzheimer's Disease.
The increase in the incidence of neurodegenerative diseases, in particular Alzheimer's Disease (AD), is a consequence of the world's population aging but unfortunately, existing treatments are only effective at delaying some of the symptoms and for a limited time. Despite huge efforts by both academic researchers and pharmaceutical companies, no disease-modifying drugs have been brought to the market in the last decades. Recently, several studies shed light on Carbonic Anhydrases (CAs, EC 4.2.1.1) as possible new targets for AD treatment. In the present review we summarized preclinical and clinical findings regarding the role of CAs and their inhibitors/activators on cognition, aging and neurodegeneration and we discuss future challenges and opportunities in the field.

Preventing adolescent stress-induced cognitive and microbiome changes by diet.
Psychological stress during adolescence may cause enduring cognitive deficits and anxiety in both humans and animals, accompanied by rearrangement of numerous brain structures and functions. A healthy diet is essential for proper brain development and maintenance of optimal cognitive functions during adulthood. Furthermore, nutritional components profoundly affect the intestinal community of microbes that may affect gut-brain communication. We adopted a relatively mild stress protocol, social instability stress, which when repeatedly administered to juvenile rats modifies cognitive behaviors and plasticity markers in the brain. We then tested the preventive effect of a prolonged diet enriched with the ω-3 polyunsaturated fatty acids eicosapentaenoic acid, docosahexaenoic acid, and docosapentaenoic acid and vitamin A. Our findings highlight the beneficial effects of this enriched diet on cognitive memory impairment induced by social instability stress, as stressed rats fed the enriched diet exhibited performance undistinguishable from that of nonstressed rats on both emotional and reference memory tests. Furthermore, in stressed rats, the decline in brain-derived neurotrophic factor expression in the hippocampus and shifts in the microbiota composition were normalized by the enriched diet. The detrimental behavioral and neurochemical effects of adolescent stress, as well as the protective effect of the enriched diet, were maintained throughout adulthood, long after the exposure to the stressful environment was terminated. Taken together, our results strongly suggest a beneficial role of nutritional components in ameliorating stress-related behaviors and associated neurochemical and microbiota changes, opening possible new venues in the field of nutritional neuropsychopharmacology.

Mast Cell-Derived Histamine Regulates Liver Ketogenesis via Oleoylethanolamide Signaling.
The conversion of lipolysis-derived fatty acids into ketone bodies (ketogenesis) is a crucial metabolic adaptation to prolonged periods of food scarcity. The process occurs primarily in liver mitochondria and is initiated by fatty-acid-mediated stimulation of the ligand-operated transcription factor, peroxisome proliferator-activated receptor-α (PPAR-α). Here, we present evidence that mast cells contribute to the control of fasting-induced ketogenesis via a paracrine mechanism that involves secretion of histamine into the hepatic portal circulation, stimulation of liver H receptors, and local biosynthesis of the high-affinity PPAR-α agonist, oleoylethanolamide (OEA). Genetic or pharmacological interventions that disable any one of these events, including mast cell elimination, deletion of histamine- or OEA-synthesizing enzymes, and H blockade, blunt ketogenesis without affecting lipolysis. The results reveal an unexpected role for mast cells in the regulation of systemic fatty-acid homeostasis, and suggest that OEA may act in concert with lipolysis-derived fatty acids to activate liver PPAR-α and promote ketogenesis.

Neuronal histamine and the memory of emotionally salient events.

In this review, we describe the experimental paradigms used in preclinical studies to unravel the histaminergic brain circuits that modulate the formation and retrieval of memories associated with aversive events. Emotionally arousing events, especially bad ones, are remembered more accurately, clearly and for longer periods of time than neutral ones. Maladaptive elaborations of these memories may eventually constitute the basis of psychiatric disorders such as generalized anxiety, obsessive-compulsive disorders and post-traumatic stress disorder. A better understanding of the role of the histaminergic system in learning and memory has not only a theoretical significance but also a translational value. Ligands of histamine receptors are among the most used drugs worldwide; hence, understanding the impact of these compounds on learning and memory may help improve their pharmacological profile and unravel unexplored therapeutic applications. Histamine-deficient mice do not respond to the antidepressant-like effects of oleoylethanolamide.
It has been suggested that the bioactive lipid mediator oleoylethanolamide (OEA), a potent agonist of the peroxisome proliferator-activated receptor-alpha (PPAR-α) possesses anti-depressant-like effects in several preclinical models. We recently demonstrated that several of OEA's behavioural actions require the integrity of the brain histaminergic system, and that an intact histaminergic neurotransmission is specifically required for selective serotonin re-uptake inhibitors to exert their anti-depressant-like effect. The purpose of our study was to test if OEA requires the integrity of the histaminergic neurotransmission to exert its antidepressant-like effects. Immobility time in the tail suspension test was measured to assess OEA's potential (10 mg/kg i.p.) as an antidepressant drug in histidine decarboxylase null (HDC) mice and HDC littermates, as well as in PPAR-α and PPAR-α mice. CREB phosphorylation was evaluated using Western blot analysis in hippocampal and cortical homogenates, as pCREB is considered partially responsible for the efficacy of antidepressants. Serotonin release from ventral hippocampi of HDC and HDC mice was measured with in-vivo microdialysis, following OEA administration. OEA decreased immobility time and increased brain pCREB levels in HDC mice, whereas it was ineffective in HDC mice. Comparable results were obtained in PPAR-α and PPAR-α mice. Microdialysis revealed a dysregulation of serotonin release induced by OEA in HDC mice. Our observations corroborate our hypothesis that brain histamine and signals transmitted by OEA interact to elaborate appropriate behaviours and may be the basis for the efficacy of OEA as an antidepressant-like compound.

Histaminergic Neurotransmission as a Gateway for the Cognitive Effect of Oleoylethanolamide in Contextual Fear Conditioning.
The integrity of the brain histaminergic system is necessary for the unfolding of homeostatic and cognitive processes through the recruitment of alternative circuits with distinct temporal patterns. We recently demonstrated that the fat-sensing lipid mediator oleoylethanolamide indirectly activates histaminergic neurons to exerts its hypophagic effects. The present experiments investigated whether histaminergic neurotransmission is necessary also for the modulation of emotional memory induced by oleoylethanolamide in a contextual fear conditioning paradigm.

Donepezil, an acetylcholine esterase inhibitor, and ABT-239, a histamine H3 receptor antagonist/inverse agonist, require the integrity of brain histamine system to exert biochemical and procognitive effects in the mouse.
Histaminergic H3 receptors (H3R) antagonists enhance cognition in preclinical models and modulate neurotransmission, in particular acetylcholine (ACh) release in the cortex and hippocampus, two brain areas involved in memory processing. The cognitive deficits seen in aging and Alzheimer's disease have been associated with brain cholinergic deficits. Donepezil is one of the acetylcholinesterase (AChE) inhibitor approved for use across the full spectrum of these cognitive disorders. We addressed the question if H3R antagonists and donepezil require an intact histamine neuronal system to exert their procognitive effects. The effect of the H3R antagonist ABT-239 and donepezil were evaluated in the object recognition test (ORT), and on the level of glycogen synthase kinase 3 beta (GSK-3β) phosphorylation in normal and histamine-depleted mice. Systemic administration of ABT-239 or donepezil ameliorated the cognitive performance in the ORT. However, these compounds were ineffective in either genetically (histidine decarboxylase knock-out, HDC-KO) or pharmacologically, by means of intracerebroventricular (i.c.v.) injections of the HDC irreversible inhibitor a-fluoromethylhistidine (a-FMHis), histamine-deficient mice. Western blot analysis revealed that ABT-239 or donepezil systemic treatments increased GSK-3β phosphorylation in cortical and hippocampal homogenates of normal, but not of histamine-depleted mice. Furthermore, administration of the PI3K inhibitor LY294002 that blocks GSK-3β phosphorylation, prevented the procognitive effects of both

drugs in normal mice. Our results indicate that both donepezil and ABT-239 require the integrity of the brain histaminergic system to exert their procognitive effects and strongly suggest that impairments of PI3K/AKT/GSK-3β intracellular pathway activation is responsible for the inefficacy of both drugs in histamine-deficient animals.

Satiety factor oleoylethanolamide recruits the brain histaminergic system to inhibit food intake.
Key factors driving eating behavior are hunger and satiety, which are controlled by a complex interplay of central neurotransmitter systems and peripheral stimuli. The lipid-derived messenger oleoylethanolamide (OEA) is released by enterocytes in response to fat intake and indirectly signals satiety to hypothalamic nuclei. Brain histamine is released during the appetitive phase to provide a high level of arousal in anticipation of feeding, and mediates satiety. However, despite the possible functional overlap of satiety signals, it is not known whether histamine participates in OEA-induced hypophagia. Using different experimental settings and diets, we report that the anorexiant effect of OEA is significantly attenuated in mice deficient in the histamine-synthesizing enzyme histidine decarboxylase (HDC-KO) or acutely depleted of histamine via interocerebroventricular infusion of the HDC blocker α-fluoromethylhistidine (α-FMH). α-FMH abolished OEA-induced early occurrence of satiety onset while increasing histamine release in the CNS with an H3 receptor antagonist-increased hypophagia. OEA augmented histamine release in the cortex of fasted mice within a time window compatible to its anorexic effects. OEA also increased c-Fos expression in the oxytocin neurons of the paraventricular nuclei of WT but not HDC-KO mice. The density of c-Fos immunoreactive neurons in other brain regions that receive histaminergic innervation and participate in the expression of feeding behavior was comparable in OEA-treated WT and HDC-KO mice. Our results demonstrate that OEA requires the integrity of the brain histamine system to fully exert its hypophagic effect and that the oxytocin neuron-rich nuclei are the likely hypothalamic area where brain histamine influences the central effects of OEA.

Iron dyshomeostasis is one of the pathological features of Alzheimer's disease (AD). Excess iron is involved in amyloid beta (Aβ) production and glial cell activation. Moreover, in response to inflammation and iron overload, astrocytes express hepcidin, a main regulator of iron metabolism, and this expression depends on the interleukin-6 (IL-6)/STAT3 pathway. Physical exercise has been demonstrated to have positive effects on cognition, Aβ load, inflammation, and glial activation. Moreover, iron is crucial in oxygen transport and regular exercise may positively affect iron homeostasis, but the underlying mechanisms are still unclear, especially in the context of AD. The aim of this study was to investigate how voluntary physical exercise modulates iron metabolism in the brain and periphery of the 5xFAD mouse model of AD. The 5xFAD male mice and their wild-type (WT) littermates were subjected to voluntary running for 6 months from 1.5 months of age. We measured total iron levels and changes in expression of proteins involved in iron homeostasis in the brain and plasma samples via a variety of biochemical techniques. Our results demonstrate an exercise-induced reduction of Aβ load and an alteration in iron metabolism in the cortex of 5xFAD mice. We show that exercise has an effect on iron metabolism, reducing iron storage protein and hepcidin possibly via an attenuation of the IL-6/STAT3 pathway. Taken together, these findings suggest that voluntary physical exercise modulates iron homeostasis in both WT and AD mice. The molecular pathways involved in this modulation could be possible therapeutic targets against AD.

PARP MUTATIONS PROTECT FROM MITOCHONDRIAL TOXICITY IN ALZHEIMER'S DISEASE

POSTER SESSION 05 - SECTION: ALZHEIMER'S DISEASE: FROM NEUROINFLAMMATION TO NEUROPROTECTION

Yizhou Yu[1], Giorgio Fedele[1], Ivana Celardo[1], Samantha Loh[2], L. Miguel Martins[1]

Alzheimer's disease is the most common age-related neurodegenerative disorder. Familial forms of Alzheimer's disease associated with the accumulation of a toxic form of amyloid-β (Aβ) peptides are linked to mitochondrial impairment. The coenzyme nicotinamide adenine dinucleotide (NAD^+) is essential for both mitochondrial bioenergetics and nuclear DNA repair through NAD^+-consuming poly (ADP-ribose) polymerases (PARPs). Here we analysed the metabolomic changes in flies overexpressing Aβ and showed a decrease of metabolites associated with nicotinate and nicotinamide metabolism, which is critical for mitochondrial function in neurons. We show that increasing the bioavailability of NAD^+ protects against Aβ toxicity. Pharmacological supplementation using NAM, a form of vitamin B that acts as a precursor for NAD^+ or a genetic mutation of PARP rescues mitochondrial defects, protects neurons against degeneration and reduces behavioural impairments in a fly model of Alzheimer's disease. Next, we looked at links between PARP polymorphisms and vitamin B intake in patients with Alzheimer's disease. We show that polymorphisms in the human *PARP1* gene or the intake of vitamin B are associated with a decrease in the risk and severity of Alzheimer's disease. We suggest that enhancing the availability of NAD^+ by either vitamin B supplements or the inhibition of NAD^+-dependent enzymes such as PARPs are potential therapies for Alzheimer's disease.

Links between air pollution and COVID-19 in England.
In December 2019, a novel disease, coronavirus disease 19 (COVID-19), emerged in Wuhan, People's Republic of China. COVID-19 is caused by a novel coronavirus (SARS-CoV-2) presumed to have jumped species from another mammal to humans. This virus has caused a rapidly spreading global pandemic. To date, over 300,000 cases of COVID-19 have been reported in England and over 40,000 patients have died. While progress has been achieved in managing this disease, the factors in addition to age that affect the severity and mortality of COVID-19 have not been clearly identified. Recent studies of COVID-19 in several countries identified links between air pollution and death rates. Here, we explored potential links between major fossil fuel-related air pollutants and SARS-CoV-2 mortality in England. We compared current SARS-CoV-2 cases and deaths from public databases to both regional and subregional air pollution data monitored at multiple sites across England. After controlling for population density, age and median income, we show positive relationships between air pollutant concentrations, particularly nitrogen oxides, and COVID-19 mortality and infectivity. Using detailed UK Biobank data, we further show that PM was a major contributor to COVID-19 cases in England, as an increase of 1 m in the long-term average of PM was associated with a 12% increase in COVID-19 cases. The relationship between air pollution and COVID-19 withstands variations in the temporal scale of assessments (single-year vs 5-year average) and remains significant after adjusting for socioeconomic, demographic and health-related variables. We conclude that a small increase in air pollution leads to a large increase in the COVID-19 infectivity and mortality rate in England. This study provides a framework to guide both health and emissions policies in countries affected by this pandemic.

Combined Transcriptomic and Proteomic Analysis of Perk Toxicity Pathways.
In , endoplasmic reticulum (ER) stress activates the protein kinase R-like endoplasmic reticulum kinase (dPerk). dPerk can also be activated by defective mitochondria in fly models of Parkinson's disease caused by mutations in or . The Perk branch of the unfolded protein response (UPR) has emerged as a major toxic process in neurodegenerative disorders causing a chronic reduction in vital proteins and neuronal death. In this study, we combined microarray analysis and quantitative proteomics analysis in adult flies overexpressing dPerk to investigate the relationship between the transcriptional and translational response to dPerk activation. We identified and as two novel activating transcription factor 4 (dAtf4) regulated

transcripts. Using a combined bioinformatics tool kit, we demonstrated that the activation of dPerk leads to translational repression of mitochondrial proteins associated with glutathione and nucleotide metabolism, calcium signalling and iron-sulphur cluster biosynthesis. Further efforts to enhance these translationally repressed dPerk targets might offer protection against Perk toxicity.

Alzheimer's and Parkinson's Diseases Predict Different COVID-19 Outcomes: A UK Biobank Study.
In December 2019, a coronavirus, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), began infecting humans, causing a novel disease, coronavirus disease 19 (COVID-19). This was first described in the Wuhan province of the People's Republic of China. SARS-CoV-2 has spread throughout the world, causing a global pandemic. To date, thousands of cases of COVID-19 have been reported in the United Kingdom, and over 45,000 patients have died. Some progress has been achieved in managing this disease, but the biological determinants of health, in addition to age, that affect SARS-CoV-2 infectivity and mortality are under scrutiny. Recent studies show that several medical conditions, including diabetes and hypertension, increase the risk of COVID-19 and death. The increased vulnerability of elderly individuals and those with comorbidities, together with the prevalence of neurodegenerative diseases with advanced age, led us to investigate the links between neurodegeneration and COVID-19. We analysed the primary health records of 13,338 UK individuals tested for COVID-19 between March and July 2020. We show that a pre-existing diagnosis of Alzheimer's disease predicts the highest risk of COVID-19 and mortality among elderly individuals. In contrast, Parkinson's disease patients were found to have a higher risk of SARS-CoV-2 infection but not mortality from COVID-19. We conclude that there are disease-specific differences in COVID-19 susceptibility among patients affected by neurodegenerative disorders.

Introduction: To date, almost no disease-modifying therapeutics have proven efficacy in Alzheimer's disease. One reason may be the difficulty for drugs to cross the blood-brain barrier (BBB). It has been previously showed that the BBB can be opened safely, transiently and repeatedly, with the application of low-intensity pulsed ultrasound associated to microbubbles (LIPU-MB). Previous studies have also shown that BBB opening by ultrasounds and microbubbles may have beneficial effects on amyloid burden, neurogenesis and neuroinflammation. **Aims**: This study aimed at evaluating the effect of LIPU-MB BBB opening in P301S mice model of tauopathy on neurofibrillary tangles burden. Its secondary aims were to evaluate the effects of LIPU-MB BBB opening on neurogenesis and neuroinflammation. **Methods**: Five sessions (one per week) of LIPU-MB were administered to P301S mice (sonicated group). Sonicated and non-sonicated mice were sacrificed one week after the last session. Immunostaining of neurofibrillary tangles (AT8), neurogenesis (doublecortin) and neuroinflammation (Iba-1) were compared between the sonicated and non-sonicated groups. **Results**: There was a trend for a decrease of cortical neurofibrillary tangles in the sonicated group ($p<.06$). Interestingly, microglial densities were drastically decreased in different brain areas in sonicated mice, when compared to non-sonicated animals ($p<.0001$). Neurogenesis was not significantly different between the two groups in the hippocampus. **Conclusions**: Our results show that LIPU-MB BBB opening decreases microglial cells loads in P301S mice and may impact on tangles pathology. These results could have therapeutical impact for Alzheimer's disease but need to be confirmed in larger cohorts of mice.

NEUROPROTECTION, ANTIOXIDANT, AND ANTI-EXCITOTOXICITY ACTIVITIES OF ACAI BERRY (EUTERPE SP.) POWDER

POSTER SESSION 05 - SECTION: ALZHEIMER'S DISEASE: FROM NEUROINFLAMMATION TO NEUROPROTECTION

Maryam Alnasser[1], Ian Mellor[1], Wayne Carter[2]
[1]University of Nottingham, School Of Life Sciences, Notttingham, United Kingdom, [2]University of Nottingham, School Of Medicine, Derby, United Kingdom

Alzheimer's disease (AD) is characterized by progressive neuronal degeneration and is caused by a variety of pathomechanisms. The existing AD treatments are symptomatic and cause side effects, necessitating the development of more effective medicines. The native South American palm acai berry (*Euterpe sp.*) is a potential source of health-promoting dietary phytochemicals. The dibutyryl cyclic adenosine monophosphate differentiated human cell line TE671 was used to investigate the potential neurotoxicity of acai aqueous extract and neuroprotective ability to reduce the neurotoxicity of L-glutamate (L-Glu). L-Glu, which occurs naturally or as a food additive, can act as an excitotoxin and has been linked to AD development. Cell viability assay using 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) showed that acai extract had no toxic effects on neurons at concentrations ranging from 0.001-1000 µg/mL after a 24-hour exposure. Whereas L-Glu concentrations (0.137-100 mM) caused a significant reduction in cell viability after a 24-hour exposure. Acai extract showed significant neuroprotection against L-Glu at 0.137 mM. A 6 hours exposure of L-Glu caused a concentration-dependent increase in reactive oxygen species (ROS) measured via a 2',7'-dichlorofluorescein diacetate (DCFDA) assay. Acai aqueous extract significantly reduced ROS production induced by L-Glu. Whole-cell patch-clamp recordings at a membrane potential of −50 mV showed that acai extract (1000 µg/mL) significantly inhibited L-Glu (300 µM) and glycine (10 µM) activated currents in TE671 cells. In summary, this study demonstrates that acai berry contains nutraceutical components with antioxidant and anti-excitotoxicity activities that may be a beneficial dietary component to limit pathological deficits evidenced in AD.

TREATMENT WITH NOVEL HIPPO SIGNALING INHIBITOR, XMU-MP-1, AMELIORATES COGNITIVE IMPAIRMENT AND NEURODEGENERATION IN RAT MODEL OF SPORADIC ALZHEIMER'S DISEASE

POSTER SESSION 05 - SECTION: ALZHEIMER'S DISEASE: FROM NEUROINFLAMMATION TO NEUROPROTECTION

Manas Ranjan Sahu[1], Amal Mondal[2]
[1]Jawaharlal Nehru University, Lab No. 215, School Of Life Sciences,, New Delhi, India, [2]Jawaharlal Nehru University, School Of Life Sciences,, New Delhi, India

Alzheimer's disease (AD), is a form of dementia and a progressive neurodegenerative disorder often accompanied by aging. Neurodegeneration during the disease progression is majorly driven by cellular apoptosis. Recently, the Hippo signaling pathway has emerged as a key pathway influencing cell survival, proliferation, and apoptotic-related pathophysiological conditions. Several previous studies have demonstrated the contributions of a hyper-activated Hippo signaling pathway in executing cellular death in various neurodegenerative disorders, including AD. However, it remains unknown whether inhibiting Hippo pathway can diminish neurodegeneration and related pathophysiological changes in AD. **Aim:** In this study, our aim was to investigate the beneficial role of Hippo signaling inhibition via a chemical inhibitor, Xmu-mp-1, in the rat model of sporadic AD. **Methods:** Streptozotocin (STZ) was administered intracerebroventricularly via stereotactic surgery in the rat brain to develop AD model. Intraperitoneal administration of Xmu-mp-1 was performed at a dose of 0.5mg/kg body weight for two weeks 7 days post-STZ administration. At 3-week post-surgery, cognitive changes were assessed by behavioural test called Morris Water Maze Test. At the end of behaviour tests, histopathological examination of the rat brain tissue was performed to evaluate changes in the level of Tau phosphorylation and neurodegeneration. **Results:** Xmu-mp-1 treated AD rats exhibit improvement in cognitive deficits. At the tissue level, treatment with Xmu-mp-1 reduced the level of p-Tau and neurodegeneration compared to AD treated with only vehicle. **Conclusion:** These findings indicate a potential therapeutic ability of Hippo pathway inhibition in the management of AD pathophysiology, which needs to be further explored in detail.

The emerging role of Hippo signaling in neurodegeneration.
Neurodegeneration refers to the complex process of progressive degeneration or neuronal apoptosis leading to a set of incurable and debilitating conditions. Physiologically, apoptosis is important in proper growth and development. However, aberrant and unrestricted apoptosis can lead to a variety of degenerative conditions including neurodegenerative diseases. Although dysregulated apoptosis has been implicated in various neurodegenerative disorders, the triggers and molecular mechanisms underlying such untimely and faulty apoptosis are still unknown. Hippo signaling pathway is one such apoptosis-regulating mechanism that has remained evolutionarily conserved from Drosophila to mammals. This pathway has gained a lot of attention for its tumor-suppressing task, but recent studies have emphasized the soaring role of this pathway in inflaming neurodegeneration. In addition, strategies promoting inactivation of this pathway have aided in the rescue of neurons from anomalous apoptosis. So, a thorough understanding of the relationship between the Hippo pathway and neurodegeneration may serve as a guide for the development of therapy for various degenerative diseases. The current review focuses on the mechanism of the Hippo signaling pathway, its upstream and downstream regulatory molecules, and its role in the genesis of numerous neurodegenerative diseases. The recent efforts employing the Hippo pathway components as targets for checking neurodegeneration have also been highlighted.

Neuronal Hippo signaling: From development to diseases.
Hippo signaling pathway is a highly conserved and familiar tissue growth regulator, primarily dealing with cell survival, cell proliferation, and apoptosis. The Yes-associated protein (YAP) is the key transcriptional effector molecule, which is under negative regulation of the Hippo pathway. Wealth of studies have identified crucial roles of Hippo/YAP signaling pathway during the process of development, including the development of neuronal system. We provide here, an overview of the contributions of this signaling pathway at multiple stages of neuronal development including, proliferation of neural stem cells (NSCs), migration of NSCs toward their destined niche, maintaining NSCs in the quiescent state, differentiation of NSCs into

neurons, neuritogenesis, synaptogenesis, brain development, and in neuronal apoptosis. Hyperactivation of the neuronal Hippo pathway can also lead to a variety of devastating neurodegenerative diseases. Instances of aberrant Hippo pathway leading to neurodegenerative diseases along with the approaches utilizing this pathway as molecular targets for therapeutics has been highlighted in this review. Recent evidences suggesting neuronal repair and regenerative potential of this pathway has also been pointed out, that will shed light on a novel aspect of Hippo pathway in regenerative medicine. Our review provides a better understanding of the significance of Hippo pathway in the journey of neuronal system from development to diseases as a whole.

Induction of oxidative stress and apoptosis in the injured brain: potential relevance to brain regeneration in zebrafish.
Recent findings suggest a significant role of the brain-derived neurotrophic factor (BDNF) as a mediator of brain regeneration following a stab injury in zebrafish. Since BDNF has been implicated in many physiological processes, we hypothesized that these processes are affected by brain injury in zebrafish. Hence, we examined the impact of stab injury on oxidative stress and apoptosis in the adult zebrafish brain. Stab wound injury (SWI) was induced in the right telencephalic hemisphere of the adult zebrafish brain and examined at different time points. The biochemical variables of oxidative stress insult and transcript levels of antioxidant genes were assessed to reflect upon the oxidative stress levels in the brain. Immunohistochemistry was performed to detect the levels of early apoptotic marker protein cleaved caspase-3, and the transcript levels of pro-apoptotic and anti-apoptotic genes were examined to determine the effect of SWI on apoptosis. The activity of antioxidant enzymes, the level of lipid peroxidation (LPO) and reduced glutathione (GSH) were significantly increased in the injured fish brain. SWI also enhanced the expression of cleaved caspase-3 protein and apoptosis-related gene transcripts. Our results indicate induction of oxidative stress and apoptosis in the telencephalon of adult zebrafish brain by SWI. These findings contribute to the overall understanding of the pathophysiology of traumatic brain injury and adult neurogenesis in the zebrafish model and raise new questions about the compensatory physiological mechanisms in response to traumatic brain injury in the adult zebrafish brain.

Bacopaside-I Alleviates the Detrimental Effects of Acute Paraquat Intoxication in the Adult Zebrafish Brain.
Paraquat (PQ), an environmental neurotoxicant, causes acute fatal poisoning upon accidental or intentional ingestion (suicidal cases) worldwide. To date, an effective remedy for PQ toxicity is not available. In this study, we have evaluated the therapeutic efficacy of Bacopaside-I (BS-I), an active compound found in the plant extract of Bacopa monnieri (Brahmi), against acute PQ intoxication using zebrafish as a model organism. Adult zebrafish were injected with a dose of either 30 mg/kg or 50 mg/kg PQ. PQ-intoxicated zebrafish showed an increased rate of mortality and oxidative imbalance in their brain. Also, the proliferation of neural cells in the adult zebrafish brain was inhibited. However, when BS-I pretreated zebrafish were intoxicated with PQ, the toxic effects of PQ were ameliorated. PQ treatment also affected the expression of particular genes concerned with the apoptosis and dopamine signaling, which was not altered by BS-I administration. Our results highlight the efficiency of BS-I as a novel therapeutic agent for PQ intoxication. It further compels us to search and evaluate the molecular mechanisms targeted by BS-I to develop a potent therapy for acute PQ intoxication.

MITOCHONDRIAL PRIMING RESCUES MOLECULAR, PHYSIOLOGICAL AND BEHAVIORAL PATHOLOGICAL OUTCOMES IN A MOUSE MODEL OF ALZHEIMER'S DISEASE

POSTER SESSION 05 - SECTION: ALZHEIMER'S DISEASE: FROM NEUROINFLAMMATION TO NEUROPROTECTION

De Veij Mestdagh
Alzheimercentrum Amsterdam, Neurology, Amsterdam, Netherlands

Alzheimer’s disease (AD) is the most prevalent neurodegenerative disease worldwide and remains without effective cure. Increasing evidence is supporting the mitochondrial cascade hypothesis, proposing loss of mitochondrial fitness and subsequent ROS and ATP imbalance, as the foundation of AD pathophysiological outcomes. As such, mitochondria should be seriously considered as pharmacological targets. In this study we tested the effect of SUL-138, a small molecule that preserves mitochondrial network structure and supports mitochondrial bioenergetics via complex I/IV activation, on physiological and behavioural outcomes in APP/PS1 and Wildtype (WT) mice. Subsequently, we investigated the molecular background of SUL-138 treatment using mass-spectrometry and assessed the effect of SUL-138 on A-beta pathology, a key pathological hallmark of AD. 3 month SUL-138 treatment rescued impaired long-term potentiation and hippocampus dependent memory, which was paralleled by a rescue of AD associated and APP/PS1 affected proteins. Consistent with these findings, a decrease in plaque load in SUL-138 treated APP/PS1 mice was observed. In addition, SUL-138 increased synaptic plasticity in WT’s and proteomic analysis showed a genotype unspecific effect of SUL-138 on postsynaptic cytoskeleton proteins and specific proteins involved in metabolism. Taken together, our study points to a shift in metabolic efficiency and postsynaptic organisation as drivers of plasticity enhancement and it demonstrates that targeting mitochondrial bioenergetics by increasing mitochondrial complex I and IV activity is a promising new druggable target for the treatment of Alzheimer's disease.

Torpor enhances synaptic strength and restores memory performance in a mouse model of Alzheimer's disease.
Hibernation induces neurodegeneration-like changes in the brain, which are completely reversed upon arousal. Hibernation-induced plasticity may therefore be of great relevance for the treatment of neurodegenerative diseases, but remains largely unexplored. Here we show that a single torpor and arousal sequence in mice does not induce dendrite retraction and synapse loss as observed in seasonal hibernators. Instead, it increases hippocampal long-term potentiation and contextual fear memory. This is accompanied by increased levels of key postsynaptic proteins and mitochondrial complex I and IV proteins, indicating mitochondrial reactivation and enhanced synaptic plasticity upon arousal. Interestingly, a single torpor and arousal sequence was also sufficient to restore contextual fear memory in an APP/PS1 mouse model of Alzheimer's disease. Our study demonstrates that torpor in mice evokes an exceptional state of hippocampal plasticity and that naturally occurring plasticity mechanisms during torpor provide an opportunity to identify unique druggable targets for the treatment of cognitive impairment.

Neuroprotective hypothermia - Why keep your head cool during ischemia and reperfusion.
Targeted temperature management (TTM) is the induced cooling of the entire body or specific organs to help prevent ischemia and reperfusion (I/R) injury, as may occur during major surgery, cardiac resuscitation, traumatic brain injury and stroke. Ischemia and reperfusion induce neuronal damage by mitochondrial dysfunction and oxidative injury, ER stress, neuronal excitotoxicity, and a neuroinflammatory response, which may lead to activation of apoptosis pathways.

Aims: The effects of exposure to low-dose ionizing radiation (LDIR<1Gy) on the brain are not well established. There are increasing evidence to show that LDIR may exert beneficial actions through a radiological hormesis, especially in pathological conditions. Thereby we hypothesized that LDIR could be a therapeutic intervention in some neurological diseases. In this longitudinal study, we characterized the LDIR's effects on brain tissue damage and cognitive decline mediated by chronic cerebral hypoperfusion (HCC) in the rat. **Methods**: HCC was induced on Wistar rats by bilateral and permanent occlusion of the common carotid arteries. The entire brain was irradiated with 0.3 Gy X-rays at one- or seven-days post-occlusion. To assess the effects of LDIR on the hypoperfused brain, behavioral testing (Morris water maze, novel object recognition) and *ex-vivo* analyses evaluating blood brain-barrier permeability (BBB) (Evans blue injection) and neuronal damage (immunohistological studies) were performed. **Results**: LDIR exposure attenuated alterations of spatial learning and spatial reference memory induced by HCC. The working memory deficit driven by brain hypoperfusion was also reduced by irradiation treatment since the recognition index was 0.59±0.08, 0.44±0.24 and 0.56±0.07 for Sham, hypoperfused (HCC) and irradiated hypoperfused (HCC+LDIR) rats respectively. Interestingly, LDIR mitigated BBB permeability since Evans blue concentration in hippocampus was 28±6 µg/L in Sham rats, 51±8 µg/L in HCC rats and 24±2 µg/L in HCC+LDIR rats. **Conclusions**: LDIR modulates the events involved in the development of HCC and improves the cognitive decline in this preclinical model. The LDIR therapy could be promising for cerebrovascular and neurodegenerative diseases.

Aims Astrocytes support neuronal function and guarantee neuronal health by handling of glio/neurotransmitters, including ATP and glutamate at the synaptic cleft. Indeed, astrocytic malfunction is associated with synaptic dysregulation and underlies cognitive decline in neurodegenerative diseases, such as tauopathies. Aim of this work was to check whether extracellular tau oligomers (ex-oTau) impair neuronal function specifically targeting astrocytes, reducing gliotransmitter release, and affecting glutamate-dependent synaptic transmission. **Methods** Primary cultures of hippocampal astrocytes, neurons and organotypic brain slices were exposed to ex-oTau (200 nM) for 1 hour. Gliotransmitter handling by astrocytes and synaptic function were studied by Ca^{2+}, Na^{+} and FM1-43 imaging; electrophysiological recordings; high-performance liquid chromatography; Western blot and immunofluorescence. Experimental paradigms avoiding ex-oTau internalization were used to dissect intracellular vs. extracellular effects of oTau. **Results** Ex-oTau uploading in astrocytes led to alteration of intracellular Ca2+ waves and downregulation of glutamate-transporter-1 expression. Uploading-independent Na-K-ATPase mislocalization on plasma membrane was also observed, causing Na^{+} overload in astrocytes. All these actions affected uptake and release of gliotransmitters by astrocytes, including glutamate and ATP, that negatively influenced synaptic function. Notably, we identified glypican 4 as a membrane receptor for oTau internalization and a potential target against tau-induced synaptotoxicity. **Conclusions** We demonstrated that ex-oTau affect synaptic transmission by exerting a complex action on astrocytes, at both intracellular and extracellular levels. The net effect was a dysregulated gliotransmitter signaling that relied on altered intracellular Ca^{2+} signals, reduced expression of glutamate-transporter-1, along with altered function and localization of Na-K-ATPase affecting Na^{+} gradients and Na^{+}-dependent transports.

Increasing evidence implicates astrocytes in Alzheimer's disease (AD), a neurodegenerative disorder characterized by memory loss that parallels extracellular accumulation of amyloid-beta peptides (Aβ). Aβ can affect astrocytes function, mainly their ability to uptake and release neuroactive molecules. Astrocytes release ATP, which can be metabolized into adenosine by ecto-5'-nucleotidase, CD73, resulting in adenosine A_{2A} receptors ($A_{2A}R$) activation that in turn bolsters neurodegeneration. AD's brains exhibit increased levels of $A_{2A}R$ and connexins 43 (Cx43), which form astrocytic hemichannels (Cx43-HC) that mediate gliosignals release. **Aims:** investigate a possible association between Cx43-HC and $A_{2A}R$ in astrocytes exposed to Aβ peptides. **Methods:** We used mature primary cultures of cortical astrocytes from Wistar rats exposed to $Aβ_{1-42}$ (1 μM) to mimic pathological conditions of AD. ATP release and HC permeability were evaluated by luciferin-luciferase and ethidium bromide uptake assays, respectively. **Results:** Our results revealed an enhancement in ATP release (180.4±21.5%, $p<0.001$), HC activity (129.7±4.4%, $p<0.001$) and Cx43 total levels (148.9±14.0%, $p<0.05$) and phosphorylation (140.2±5.4%, $p<0.001$) in astrocytes exposed to $Aβ_{1-42}$ relatively to control cells (100%); these effects were mimicked by $A_{2A}R$ activation and counteracted by $A_{2A}R$ antagonism or CD73 blockade. Moreover, proximity ligation assay and co-immunoprecipitation revealed a physical association between $A_{2A}R$ and Cx43. **Conclusions:** Our data identified a feed-forward loop involving $A_{2A}R$ and Cx43-HC in astrocytes, whereby $A_{2A}R$ overfunction increases Cx43-HC activity and ATP release that is converted into adenosine by CD73, to sustain increased $A_{2A}R$ activity in AD-like conditions. **Fundings:** La Caixa Foundation (HP17/00523), Centro2020 (CENTRO-01-0145-FEDER-000008:BrainHealth2020 and CENTRO-01-0246-FEDER-000010) and FCT (FCT,PTDC/NEU-NMC/4154/2014-POCI-01-0145-FEDER-016684 and PTDC/MED-NEU/31274/2017 and UIDB/04539/2020). Alzheimer's disease (AD) is the most common form of dementia and is characterized by a progressive loss of memory and other mental abilities. Current therapies against AD are not totally effective, which highlights the need for new therapeutic strategies. Previous results from our group demonstrated that a combination of non-psychoactive doses of the natural cannabinoids ∆9-tetrahydrocannabinol (THC) and cannabidiol (CBD), the main components of the first cannabis-based medicine approved in many countries, reduces cognitive decline in a mouse model of AD, the APP/PS1 mice. However, the molecular mechanisms underlying this therapeutic effect are not completely understood. Here, we studied the effects of THC and CBD on the glutamate homeostasis and on synaptic plasticity in the hippocampus of APP/PS1 mice because these two processes are known to be altered in AD. Thus, by using in vivo microdialysis and HPLC techniques, we have quantified the glutamate levels in the hippocampus of wild-type and APP/PS1 animals in response to veratridine and the glutamate transporter-1 inhibitor dihydrokainate (DHK) after a chronic treatment with THC and/or CBD. Interestingly, THC+CBD treatment reduced the veratridine-evoked glutamate release in both genotypes and attenuated the enhanced glutamate levels observed in DHK-treated APP/PS1 mice. In contrast, our results by using ballistic labelling demonstrated that THC+CBD chronic treatment does not significantly impact on dendritic spine density and morphology in the hippocampus of APP/PS1 mice. These results suggest that cognitive improvement after THC+CBD treatment could be related with a reduction of the excitotoxicity occurring in our AD model.

AMPAR/TARP stoichiometry differentially modulates channel properties.
AMPARs control fast synaptic communication between neurons and their function relies on auxiliary subunits, which importantly modulate channel properties. Although it has been suggested that AMPARs can bind to TARPs with variable stoichiometry, little is known about the effect that this stoichiometry exerts on certain AMPAR properties. Here we have found that AMPARs show a clear stoichiometry-dependent modulation by the prototypical TARP γ2 although the receptor still needs to be fully saturated with γ2 to show some typical TARP-induced characteristics (i.e. an increase in channel conductance). We also uncovered important differences in the stoichiometric modulation between calcium-permeable and calcium-impermeable AMPARs. Moreover, in heteromeric AMPARs, γ2 positioning in the complex is important to exert certain TARP-dependent features. Finally, by comparing data from recombinant receptors with endogenous AMPAR currents from mouse cerebellar granule cells, we have determined a likely presence of two γ2 molecules at somatic receptors in this cell type. Elife, 2020; 9

Mechanisms of CPT1C-Dependent AMPAR Trafficking Enhancement.
In neurons, AMPA receptor (AMPAR) function depends essentially on their constituent components:the ion channel forming subunits and ion channel associated proteins. On the other hand, AMPAR trafficking is tightly regulated by a vast number of intracellular neuronal proteins that bind to AMPAR subunits. It has been recently shown that the interaction between the GluA1 subunit of AMPARs and carnitine palmitoyltransferase 1C (CPT1C), a novel protein partner of AMPARs, is important in modulating surface expression of these ionotropic glutamate receptors. Indeed, synaptic transmission in CPT1C knockout (KO) mice is diminished supporting a positive trafficking role for that protein. However, the molecular mechanisms of such

modulation remain unknown although a putative role of CPT1C in depalmitoylating GluA1 has been hypothesized. Here, we explore that possibility and show that CPT1C effect on AMPARs is likely due to changes in the palmitoylation state of GluA1. Based on analysis, Ser 252, His 470 and Asp 474 are predicted to be the catalytic triad responsible for CPT1C palmitoyl thioesterase (PTE) activity. When these residues are mutated or when PTE activity is inhibited, the CPT1C effect on AMPAR trafficking is abolished, validating the CPT1C catalytic triad as being responsible for PTE activity on AMPAR. Moreover, the histidine residue (His 470) of CPT1C is crucial for the increase in GluA1 surface expression in neurons and the H470A mutation impairs the depalmitoylating catalytic activity of CPT1C. Finally, we show that CPT1C effect seems to be specific for this CPT1 isoform and it takes place solely at endoplasmic reticulum (ER). This work adds another facet to the impressive degree of molecular mechanisms regulating AMPAR physiology.

RTP801 regulates motor cortex synaptic transmission and learning.
RTP801/REDD1 is a stress-regulated protein whose upregulation is necessary and sufficient to trigger neuronal death in in vitro and in vivo models of Parkinson's and Huntington's diseases and is up regulated in compromised neurons in human postmortem brains of both neurodegenerative disorders. Indeed, in both Parkinson's and Huntington's disease mouse models, RTP801 knockdown alleviates motor-learning deficits.

Alzheimer's disease is an age-related neurodegenerative condition characterized by progressive memory loss and other cognitive functions. The pathological hallmarks of this disease are the extracellular deposition of amyloid-β protein and intracellular accumulated hyperphosphorylated protein tau. Gliosis involving the activation of astrocytes and microglia is a crucial outcome of Aβ deposition leading to neuroinflammation. Sinomenine is an alkaloid found in a Chinese medicinal plant, Sinomenium acutum. We found that Sinomenine protects neurons against amyloid-beta-induced indirect toxicity by inhibiting astrocytic activation. It inhibits the release of toxic factors such as reactive oxygen species, nitric oxide, and inflammatory molecules from oligomeric amyloid-beta-treated astrocytes. In addition, Sinomenine protects neurons from toxicity caused by the conditioned medium from oligomeric amyloid-beta-treated astrocytes. Another natural compound, Safranal, isolated from Crocus sativus, has been examined for its efficacy against amyloid-beta-induced toxicity. Safranal prevents amyloid-beta-induced direct toxicity by reducing the levels of toxic factors and caspase-3 activation. Considerable studies have suggested that the enhancement of autophagy could be a therapeutic intervention in AD pathogenesis. The effects of autophagy modulators on amyloid-beta-induced toxic factors, and on proteins specific to different stages of autophagy, is under exploration.

EVIDENCE FOR PRODROMAL NEUROINFLAMMATION IN A RODENT MODEL OF ALPHA- SYNUCLEINOPATHY

POSTER SESSION 05 - SECTION: ALZHEIMER'S DISEASE: FROM NEUROINFLAMMATION TO NEUROPROTECTION

Ibtisam Al-Musawi, Gavin Clowry, Fiona Lebeau
Bioscience, Newcastle University, Newcastle upon Tyne, United Kingdom

Toxic aggregation of alpha-synuclein is a key feature of alpha-synucleinopathies, including dementia with Lewy bodies and Parkinson's disease dementia. Early neuroinflammation, mitochondrial dysfunction, and neuronal excitability changes could all be hallmarks of the progression of alpha-synucleinopathy in patients. In addition, transgenic mice expressing human alpha-synuclein exhibit hippocampal and neocortical network hyperexcitability. The current study investigated the early changes caused by abnormal alpha-synuclein in the prefrontal cortex and hippocampus of mice aged 2-4 months expressing human mutant (A30P) alpha-synuclein. We focused on early evidence for neuroinflammation, quantifying changes in astrocytic and microglial activation using immunohistochemistry. Fixed, frozen sections were prepared from the hippocampus and prefrontal cortex of male A30P and age-matched control mice. Immunofluorescence was conducted against GFAP (reactive astrocytes) and Iba-1 (reactive microglia). Sections were imaged using a Nikon N-1 microscope and analysed using the FIJI program. Results showed a significant increase in the percentage area of the CA3 region of hippocampus occupied by reactive astrocyte and microglia cell bodies and their processes (astrocytes; n=3 sections/4 mice, P = <0.033) and Iba-1 (microglia; n=3 sections/4 mice, P = 0.001) in A30P compared to control mice. Morphological changes in glial cells consistent with neuroinflammation were also identified. We aim to establish if these neuroinflammatory changes persist during disease progression in aged A30P mice. We will assess cytokine levels and mitochondrial function in young and old A30P versus control mice. Furthermore, we will determine whether metformin, an anti-hyperglycemic drug with known anti-inflammatory effects, has a neuroprotective role in A30P mice.

EFFECT OF REPAGLINIDE ON SYMPTOMS ASSOCIATED WITH AGING AND NEURODEGENERATION IN C.ELEGANS AND MUS MUSCULUS

POSTER SESSION 05 - SECTION: ALZHEIMER'S DISEASE: FROM NEUROINFLAMMATION TO NEUROPROTECTION

Inés Sánchez Romero
Universidad Pablo de Olavide, Department Of Anatomy, Physiology And Cell Biology, Seville, Spain

The aging process is associated with cognitive decline and an increased risk of suffering neurodegenerative diseases. DREAM is a calcium sensing protein, whose blockade delays the onset of cognitive decline associated with age in mice. One of the drugs capable of blocking DREAM activity is repaglinide (RPG), an antidiabetic drug used clinically. To determine if RPG treatment is capable of delaying the symptoms associated with neurodegeneration, experiments were carried out in two animal models, *C. elegans* and *Mus musculus*. These experiments include thrashing and paralysis assays in worms and behavioral tests, such as open field, object recognition and passive avoidance test in mice. Our results show that chronic treatment with RPG is capable of reducing motor symptoms in models of Parkinson's and Alzheimer's diseases in *C. elegans*, as well as of reversing cognitive deficits in aged mice injected with amyloid oligomers. Taken together, our results suggest that RPG could be an anti-aging drug and a potential treatment for neurodegenerative diseases in humans.

Introduction: The signalling pathways mediated by the brain-derived neurotrophic factor (BDNF) are strongly impaired in Alzheimer's disease (AD) due to the cleavage of its Tropomyosin-related kinase B-full-length (TrkB-FL) receptor. This cleavage generates an intracellular fragment (TrkB-ICD) with tyrosine kinase activity and accumulates into the nucleus over time, leading to modifications in gene expression and culminating in cognitive impairments. Considering the lack of an effective treatment for AD, our laboratory designed a new peptide, TAT-TrkB, capable of preventing TrkB-FL cleavage and assayed its usefulness for AD-pathology amelioration. Aim: This project aimed to assess the *in vivo* efficacy of TAT-TrkB peptide. Methods: 5xFAD, an AD mouse model and wild-type (wt) mice, with 4 months old, were treated intraperitoneally, with saline solution or TAT-TrkB (25 mg/kg), 5 times a week for 2 months. At 5.5 months old, mice were submitted to several behavioural tests and at 6 months the animals were sacrificed for cellular and molecular analysis. Results: The behavioural tests exposed the capacity of TAT-TrkB to prevent learning and memory impairments observed in vehicle-treated 5xFAD mice (assessed by Morris Water Maze test). Additionality, this compound did not induce anxiety-like behaviours or locomotor deficits in both wt nor 5xFAD mice (assessed by Open Field and Elevated Plus Maze tests). 5xFAD animals showed molecular alterations, including Aβ accumulation and gliosis. The ratio TrkB-ICD/-FL, altered in 5xFAD animals, was re-established by TAT-TrkB administration. Conclusion: The collected results suggest that TAT-TrkB could be a promising therapeutical strategy to prevent/recover the typical cognitive deficits of AD patients.

Aims: Metabolic neuronal pathways and their effect on the central nervous system (CNS) play a key role in neuronal degeneration and death. Considerable number of drugs modulating these pathways have been tested so far. Empagliflozin, a drug initially used for glucose management of type 2 diabetes, comprises a promising novel therapeutic approach tested against neurodegenerative disorders. Methods: Primary neuronal cell cultures were developed from wild type Sprague Dawley rats and neurons were exposed to different concentrations of empagliflozin for 48 hours, during either their early development in the first week, or after two weeks *in vitro*. Neuronal survival was evaluated by MTT assay and development of the dendritic tree was assessed under immunofluorescent microscopy after impregnation of neurons with CM-DiI. A morphometric comparative study was also performed with the ImageJ software and NeuronJ plug-in. Results: Empagliflozin at a concentration between 0,001μM and 8μM didn't significantly alter the survival of the neurons and the development of their dendritic field. However, as expected, higher concentrations resulted in a reduction of total dendritic tree length, branching, and number of spines. Conclusions: Our results show that low and medium concentrations of empagliflozin on neurons do not exert any toxic effect. It is thus appropriate for further *in vitro* and *in vivo* testing as neuroprotective agent against degenerative disorders. However, higher concentrations of empagliflozin in the CNS may cause neurotoxicity, due to glucose deprivation on neurons.

Brain-derived neurotrophic factor (BDNF) is a neurotrophin which regulates neuronal growth and differentiation, along with its receptor tyrosine receptor kinase B (TrkB)[1]. Neurotrophins show promise as therapeutics for neurodegeneration, but they cannot penetrate the blood-brain barrier. Instead, small neurotrophin mimetics could circumvent this obstacle. Here, we present new small BDNF mimetics [steroidal Dehydroepiandrosterone (DHEA) derivatives], with neuroprotective and neurogenic properties. First, we show compounds activate the TrkB pathway, using western blot in primary adult hippocampal neural stem cells (NSCs), showing phosphorylation of TrkB and its downstream targets. What is more, compounds increase proliferation, as assessed via BRDU integration, in absence of EGF/FGF. Strikingly, compounds also reduce cell death after Amyloid-β treatment, assessed through the celltox and MTT assays in hippocampal NSCs. In addition, we show that this effect is specifically carried via TrkB, as treatment with TrkB inhibitor ANA-12 abolishes compound action. Similar to NSCs, compounds also protect hippocampal neurons from Aβ toxicity, tested through tunnel assay and prevent synapse loss after Aβ treatment. To translate this work on a human relevant system, we use neural progenitor cells differentiated from 3 human induced pluripotent stem cell lines and show compounds successfully induce proliferation and prevent Aβ42 induced toxicity. Our work characterises novel BDNF mimetics that show ability to promote neurogenesis and neuroprotection *in vitro* and paves the way for follow up *in vivo* experiments. [1]J. Allen, S., J. The hydrobioid freshwater gastropods (Caenogastropoda, Truncatelloidea) of Greece: new records, taxonomic re-assessments using DNA sequence data and an update of the IUCN Red List Categories.
Hydrobioid freshwater gastropods were collected from mainland and insular Greece. Several threatened taxa, such as Graecoanatolica vegorriticola, Pseudamnicola negropontina, Pseudamnicola pieperi, Pseudobithynia eubooensis and Pseudoislamia balcanica, were recorded from new localities. Trichonia trichonica, which has been considered extinct from its type locality for the last twenty eight years, was re-discovered, whereas the presence of Daphniola exigua, G. vegorriticola, Marstoniopsis graeca, P. pieperi and Pseudobithynia trichonis in their type localities was verified. The taxonomic status of P. negropontina and the newly discovered populations of G. vegorriticola was elucidated using COI sequence data. The new data recorded during this survey indicate that the IUCN status of some Greek endemic hydrobioids needs to be updated. Zookeys, 2013;

DEPRESSION-INDUCED EARLY ONSET OF ALZHEIMER'S DISEASE IS ASSOCIATED WITH GUT MICROBIOTA IN MICE

POSTER SESSION 05 - SECTION: ALZHEIMER'S DISEASE: FROM NEUROINFLAMMATION TO NEUROPROTECTION

Yunjung Choi, Jinhee Bae, Heh-In Im
Korea Institute of Science and Technology, Brain Science Institute, Seoul, Korea, Republic of

Alzheimer's disease (AD) is the most prevalent form of dementia, yet the current pharmacologic treatments cannot slow or stop the pathology of AD. Interestingly, studies have shown that depression is associated with a greatly increased risk of developing dementia. Moreover, recent studies revealed that a bidirectional communication between the gut microbiota and the brain could play an important in various mental illnesses. In this study, we focused on the effect of depression on the onset of AD and gut microbiota profile in adult mice. 4-months-old APP/PS1 mice and their wild type (WT) littermates were exposed to social defeat-based chronic mild stress to induce depression-like behavior. Interestingly, the "depressed" APP/PS1 mice exhibited earlier onset of cognitive symptoms at 5-6 months, but the age-matched WT mouse model of depression did not develop cognitive impairment until 11 months. Shotgun metagenomic sequencing revealed various taxonomic and metabolic alterations in the gut microbiota of the depressed APP/PS1 mice. Collectively, our data imply that depression in young adulthood is an important risk factor of AD, and that gut microbiota composition and the associated metabolic pathway could be novel therapeutic targets of AD.

Dysfunction of striatal MeCP2 is associated with cognitive decline in a mouse model of Alzheimer's disease.
Cerebral Methyl-CpG binding Protein 2 (MeCP2) is involved in several psychiatric disorders that are concomitant with cognitive dysfunction. However, the regulatory function of striatal MeCP2 and its association with Alzheimer's disease (AD) has been largely neglected due to the absence of amyloid plaque accumulation in the striatal region until the later stages of AD progression. Considerable evidence indicates that neuropsychiatric symptoms related to cognitive decline are involved with striatal dysfunction. To this respect, we investigated the epigenetic function of striatal MeCP2 paralleling the pathogenesis of AD. We investigated the brain from amyloid precursor protein (APP)/presenilin1 (PS1) transgenic mice and postmortem brain samples from normal subjects and AD patients. The molecular changes in the brain, particularly in the striatal regions, were analyzed with thioflavin S staining, immunohistochemistry, immunoblotting, and MeCP2 chromatin immunoprecipitation sequencing (ChIP-seq). The cognitive function of APP/PS1 mice was assessed via three behavioral tests: 3-chamber test (3CT), Y-maze test (YMT), and passive avoidance test (PA). A multi-electrode array (MEA) was performed to analyze the neuronal activity of the striatum in APP/PS1 mice. Striatal MeCP2 expression was increased in the younger (6 months) and older (10 months) ages of APP/PS1 mice, and the genome-wide occupancy of MeCP2 in the younger APP/PS1 showed dysregulated binding patterns in the striatum. Additionally, we confirmed that APP/PS1 mice showed behavioral deficits in multiple cognitive behaviors. Notably, defective cognitive phenotypes and abnormal neuronal activity in old APP/PS1 mice were rescued through the knock-down of striatal MeCP2. We found that the MeCP2-mediated dysregulation of the epigenome in the striatum is linked to the defects in cognitive behavior and neuronal activity in the AD animal model, and that this alteration is initiated even in the very early stages of AD pathogenesis. Together, our data indicates that MeCP2 may be a potential target for the diagnosis and treatment of AD at asymptomatic and symptomatic stages.

Modulation of Neuroinflammation by Low-Dose Radiation Therapy in an Animal Model of Alzheimer's Disease.
Recently, several studies have reported that low-dose radiation therapy (RT) suppresses the release of proinflammatory cytokines in inflammatory-degenerative disorders, including Alzheimer disease (AD). AD is the most common cause of dementia, and neuroinflammation is one of the major contributing factors in AD pathogenesis. Therefore, low-dose RT may be used clinically for treating AD. However, the appropriate doses, effects, and underlying mechanisms of RT in AD have not been determined. In this study, we aimed to determine the appropriate RT dose and schedule for AD treatment and to

investigate the therapeutic effects and mechanisms of low-dose RT in AD.

Subanesthetic ketamine rapidly alters medial prefrontal miRNAs involved in ubiquitin-mediated proteolysis.
Ketamine is a dissociative anesthetic and a non-competitive NMDAR antagonist. At subanesthetic dose, ketamine can relieve pain and work as a fast-acting antidepressant, but the underlying molecular mechanism remains elusive. This study aimed to investigate the mode of action underlying the effects of acute subanesthetic ketamine treatment by bioinformatics analyses of miRNAs in the medial prefrontal cortex of male C57BL/6J mice. Gene Ontology and KEGG pathway analyses of the genes putatively targeted by ketamine-responsive prefrontal miRNAs revealed that acute subanesthetic ketamine modifies ubiquitin-mediated proteolysis. Validation analysis suggested that miR-148a-3p and miR-128-3p are the main players responsible for the subanesthetic ketamine-mediated alteration of ubiquitin-mediated proteolysis through varied regulation of ubiquitin ligases E2 and E3. Collectively, our data imply that the prefrontal miRNA-dependent modulation of ubiquitin-mediated proteolysis is at least partially involved in the mode of action by acute subanesthetic ketamine treatment.

Methyl-CpG Binding Protein 2 in Alzheimer Dementia.
Despite decades of research on Alzheimer disease, understanding the complexity of the genetic and molecular interactions involved in its pathogenesis remains far from our grasp. Methyl-CpG Binding Protein 2 (MeCP2) is an important epigenetic regulator enriched in the brain, and recent findings have implicated MeCP2 as a crucial player in Alzheimer disease. Here, we provide comprehensive insights into the pathophysiological roles of MeCP2 in Alzheimer disease. In particular, we focus on how the alteration of MeCP2 expression can impact Alzheimer disease through risk genes, amyloid-β and tau pathology, cell death and neurodegeneration, and cellular senescence. We suggest that Alzheimer disease can be adversely affected by upregulated MeCP2-dependent repression of risk genes (MEF2C, ADAM10, and PM20D1), increased tau accumulation, and neurodegeneration through neuronal cell death (excitotoxicity and apoptosis). In addition, we propose that the progression of Alzheimer disease could be caused by reduced MeCP2-mediated enhancement of astrocytic and microglial senescence and consequent glial SASP (senescence-associated secretory phenotype)-dependent neuroinflammation. We surmise that any imbalance in MeCP2 function would accelerate or cause Alzheimer disease pathogenesis, implying that MeCP2 may be a potential drug target for the treatment and prevention of Alzheimer disease.

Fetal neural stem cells from a mouse model of 15q11-13 duplication syndrome exhibit altered differentiation into neurons and astrocytes.
The duplication of human chromosome 15q11-13 is known to be associated with an estimated 1.1% of autism cases. Here, we investigated whether differentiation into neurons and astrocytes is altered in fetal neural stem cells (FNSCs) isolated from the mouse model of 15q11-13 duplication syndrome (patDp/+ mice). In patDp/+ mice-derived FNSCs, multipotency was maintained for a longer period, the population of neurons was downregulated, and that of astrocytes was upregulated significantly after differentiation induction. These results suggest that the dysregulation of FNSCs differentiation could affect cortical development and behavioral deficits in the early postnatal stage shown in the patDp/+ mice.

Phloroglucinol ameliorates cognitive impairments by reducing the amyloid β peptide burden and pro-inflammatory cytokines in the hippocampus of 5XFAD mice.
Among the various causative factors involved in the pathogenesis of Alzheimer's disease (AD), oxidative stress has emerged as an important factor. Phloroglucinol is a polyphenol component of phlorotannin, which is found at sufficient levels in Ecklonia cava (E. cava). Phloroglucinol has been reported to exert antioxidant activities in various tissues. Previously, we reported that the stereotaxic injection of phloroglucinol regulated synaptic plasticity in an AD mouse model. In this study, we aimed to investigate the effects of oral administration of phloroglucinol in AD. The oral administration of phloroglucinol for 2 months attenuated the impairments in cognitive function observed in 6-month-old 5X familial AD (5XFAD) mice, as assessed with the T-maze and Y-maze tests. The administration of phloroglucinol for 2 months in 5XFAD mice caused a reduction in the number of amyloid plaques and in the protein level of BACE1, a major amyloid precursor protein cleavage enzyme, together with γ-secretase. Phloroglucinol also restored the reduction in dendritic spine density and the number of mature spines in the hippocampi of 5XFAD mice. In addition, phloroglucinol-administered 5XFAD mice displayed lower protein levels of GFAP and Iba-1 and mRNA levels of TNF-α and IL-6 compared with vehicle-administered 5XFAD mice. These results demonstrated that phloroglucinol alleviated the neuropathological features and behavioral phenotypes in the 5XFAD mouse model. Taken together, our results suggest that phloroglucinol has therapeutic potential for AD treatment.

Alterations in protein phosphorylation in the amygdala of the 5XFamilial Alzheimer's disease animal model.
Alzheimer's disease is the most common disease underlying dementia in humans. Two major neuropathological hallmarks of AD are neuritic plaques primarily composed of amyloid beta peptide and neurofibrillary tangles primarily composed of hyperphosphorylated tau. In addition to impaired memory function, AD patients often display neuropsychiatric symptoms and abnormal emotional states such as confusion, delusion, manic/depressive episodes and altered fear status. Brains from AD patients show atrophy of the amygdala which is involved in fear expression and emotional processing as well as hippocampal atrophy. However, which molecular changes are responsible for the altered emotional states observed in AD remains to be elucidated. Here, we observed that the fear response as assessed by evaluating fear memory via a cued fear conditioning test was impaired in 5XFamilial AD (5XFAD) mice, an animal model of AD. Compared to wild-type mice, 5XFAD mice showed changes in the phosphorylation of twelve proteins in the amygdala. Thus, our study provides twelve potential protein targets in the amygdala that may be responsible for the impairment in fear memory in AD.

Institute of Neurosciences, Autonomous University of Barcelona, Department Of Biochemistry And Molecular Biology, Barcelona, Spain

The activation of presynaptic D2 autoreceptors in the striatum inhibits dopamine synthesis. This effect has been associated to changes in phosphorylation of tyrosine hydroxylase (TH) -the rate-limiting enzyme of brain dopamine biosynthesis-but the signaling mechanisms involved are not yet fully understood. We hypothesize that glycogen synthase kinase-3 (GSK-3) plays a key role in the presynaptic D2 autoreceptor signal transduction pathway, which could be of interest as an alternative target for schizophrenia treatment. We tested the effect of GSK-3 inhibitors CHIR-99021 and SB-216763 on dopamine synthesis and accumulation in rat striatum slices *ex vivo*. We also compared their effects with lithium chloride (LiCl), which is known to have antipsychotic properties and inhibit GSK-3, as well as with UNC9994, a β-arrestin biased D2 receptor agonist. HPLC-EC was used to assess dopamine accumulation, while dopamine synthesis was measured using radioisotopic HPLC-UV method. We have found that CHIR, SB, LiCl and UNC were all able to significantly decrease dopamine accumulation in rat striatum slices ex vivo. Further testing on CHIR revealed that it also significantly decreases dopamine synthesis. We also tested the amount of L-DOPA, given that this metabolite is an indicator of TH activity, and significant decrease in L-DOPA levels was found after CHIR treatment. Our results show that GSK-3 plays an important role in the dopamine synthesis pathway, by affecting the activity of TH. Since GSK-3 is part of the β-arrestin pathway, controlling dopamine hyperactivity through selective targeting could control psychotic symptoms without the adverse effects associated with conventional antipsychotics.

Background: The functional integrity of the brain relies on prompt delivery of metabolic substrates (via local hemodynamic changes) matching the increase in neuronal activity – neurovascular coupling (NVC). Microvascular alterations negatively impact NVC, which contributes to neurodegeneration and cognitive decline, as observed in type 2 Diabetes mellitus (T2DM). **Aim:** We aimed to assess 1) the functionality of NVC in a rodent model of T2DM in connection with cognitive function and 2) if dietary nitrate, a metabolic precursor of the key mediator of NVC – nitric oxide (•NO) – would improve NVC and counteract the cognitive decline in diabetes. **Method:** The functionality of NVC was assessed by laser Doppler flowmetry in the hippocampus of Goto-Kakizaki (GK) rats, an animal model of T2DM. The glycemic profile (glucose tolerance test) and spatial learning and memory (Barnes maze) were also evaluated. The effect of dietary nitrate was assessed via oral supplementation of sodium nitrate for 12 weeks. Age-matched Wistar rats were used as controls. **Results/Conclusions:** Four months old GK rats displayed a significantly impaired spatial learning and memory performance along with a dysregulated glucose tolerance. Additionally, the hemodynamic response to glutamatergic activation (NVC) was lower in GK rats as compared to controls. Dietary nitrate intervention, shown to increase both plasma nitrate and nitrite concentration, abrogated the NVC impairment and improved the spatial memory in GK rats, without changing the glycemic profile. This data supports the potential of dietary nitrate as a therapeutic approach to mitigate cognitive decline in T2DM. **Funding:** COMPETE/FCT-POCI-01-0145-FEDER-000012-HealthyAging2020 and POCI-01-0145-FEDER-029099

Dietary nitrite induces occludin nitration in the stomach.
The clinical implications of the nitrate-nitrite-nitric oxide pathway have been extensively studied in recent years. However, the physiological impact of bioactive nitrogen oxides produced from dietary nitrate has remained largely elusive. Here, we report a hitherto unrecognized nitrite-dependent nitrating pathway that targets tight junction proteins in the stomach. Inorganic nitrate, nitrite or saliva obtained after the consumption of lettuce were administered by oral gavage to Wistar rats. The enterosalivary circulation of nitrate was allowed to occur for 4 h after which the animals were euthanized and the stomach collected. Nitrated occludin was detected by immunoprecipitation in the gastric epithelium upon inorganic nitrite administration ($p < .05$) but was not observed in the case of inorganic nitrate or human saliva administration. This observation, along with differences in NO production rates from inorganic and salivary nitrite under simulated gastric conditions, suggests that competing reactions at acidic pH determine the production of nitrating agents (NO) or other, more stable, oxides. Accordingly, it is shown in vitro that salivary nitrite yields higher steady state concentrations of NO (0.37 ± 0.01 μM) than sodium nitrite (0.12 ± 0.03 μM). Dietary-dependent reactions involving the production of nitrogen oxides should be further investigated as, in the context of occludin nitration, the consumption of green leafy vegetables (with high nitrate content), if able to modulate gut barrier function, may have important implications in the context of leaky gut disorders.

The susceptibility of aged brain to Alzheimer's disease (AD) development is related with several risk factors, including hyperglycemia and amyloid beta (Aβ) accumulation. *Cuscuta chinensis* (*C. chinensis*) Lam. has been reported to display pharmacological effects on the neuronal system and diabetic disorders. Thus, the aim of this study was to investigate whether the *C. chinensis* water extract (CCWE) protects the neuronal damage under the hyperglycemia risk factor model of AD (i.e. the hyperglycemic-Aβ toxic *in vivo* model). Hyperglycemia was induced in male C57BL/6N mice by intraperitoneal (IP) injection of streptozotocin (STZ, 50 mg/kg) for consecutive 3 days and verified by measuring fasting blood glucose levels. And then, a single intracerebroventricular (ICV) injection of $A\beta_{25-35}$ at does of 25 nM was performed. The $A\beta_{25-35}$-injected hyperglycemic mice were administered with 100, 200 mg/kg/day of CCWE for 14 days. The administration of CCWE reduced the levels of lipid peroxidation, reactive oxygen species generation, and nitrite oxide production in brain. Moreover, in association with the modulatory effect on the amyloidogenic pathway, the treatment of CCWE down-regulated the amyloidogenic pathway by declining amyloid precursor protein, presenilin 1, presenilin 2, and beta-secretase. Therefore, the CCWE could not only ameliorate oxidative stress, but also inhibit the amyloidogenic pathway in STZ/$A\beta_{25-35}$-injected mice. Our findings suggest that *C. chinensis* might be a potential candidate for the treatment in hyperglycemic-Alzheimer's disease-like pathological features.

Alzheimer's disease (AD) is a progressive neurodegenerative disorder leading to major cognitive and behavioural dysfunctions. Available drugs do not cure AD but only temporarily improve symptoms. *Guiera senegalensis* (GS) is a plant used in traditional medicine in Africa for the treatment of epilepsy and depression. However, the anti-amnesic property of GS has not yet been evaluated. Here we investigated whether GS leaves hydroethanolic extract prevents scopolamine-induced memory impairment and brain oxidative stress in zebrafish model. Sixty adults zebrafish were divided into six groups: normal control group which received distilled water, negative control group which received scopolamine, positive control group which received galantamine and scopolamine, and test groups which received different doses of GS and scopolamine. Memory was assessed using the Y-maze and novel object recognition (NOR). Acetylcholinesterase (AChE), superoxide dismutase (SOD), Glutathion peroxidase (GPX) and Catalase (CAT) activities, malondialdehyde (MDA), Glutathione (GSH) and protein carbonyl levels were also evaluated. In Y-maze, plant extract resulted in a significant increase of the time spent in the novel arm, total distance travelled, and turn angle. In NOR, preference percentage for the novel object significantly increased in test groups compared to negative control group. Moreover, GS significantly reduced brain AChE activity and significantly suppressed scopolamine-induced oxidative damage by decreasing MDA level, protein carbonyl level and increasing GSH level, SOD, CAT and GPX activities. These findings provide further relevance for the potential use of GS as a natural, alternative treatment against cognitive disorders associated to AD. **Key words:** *Guiera senegalensis*, scopolamine, Alzheimer's disease, memory, acetylcholinesterase.

DIFFERENTIAL ENTRAINMENT OF PREFRONTAL NEURONAL ACTIVITY BY RESPIRATION-RELATED RHYTHMS ACROSS EMOTIONAL STATES

POSTER SESSION 05 - SECTION: ALZHEIMER'S DISEASE: FROM NEUROINFLAMMATION TO NEUROPROTECTION

Shani Folschweiller[1,2], Jonas-Frederic Sauer[1]
[1]University of Freiburg, Medical Faculty, Institute For Physiologie I, Freiburg, Germany, [2]University of Freiburg, Faculty Of Biology, Freiburg, Germany

At each respiratory cycle, airflow in the nasal cavity induces respiration related oscillations (RR) in the olfactory bulb. These slow oscillations propagate broadly in the neocortex, and have recently been shown to play a role in cognitive function that are independent of olfaction. Among the forebrain areas displaying prominent RR is the medial prefrontal cortex (mPFC), a neocortical region extensively connected with the basal ganglia and the limbic sytsem, and involved in the regulation of emotions. To understand the role that RR might play in emotional control, we recorded single-unit activity in the mPFC of freely behaving mice while simultaneously monitoring respiration by electrophysiological recording from the nasal epithelium. We compared the neuronal activity during spontaneous immobility in the home cage, as a neutral state, to immobility induced by an intense stressor, namely tail suspension. First, we established that intense emotions changed the respiratory pattern and increased the entrainment of the mPFC local field potential by the RR. Secondly, we found that subjecting mice to intense stress shifted the preferred respiratory phase of mPFC single units from inspiration to late expiration with a differential effect on putative interneurons and pyramidal cells. Finally, the proportion of cells modulated by the respiration was changing depending on their laminar location and emotional state of the mice, which might reflect the recruitment of different long-range connections by the RR during stress. Overall, these observations suggest a functional role of the RR in the synchronization of PFC neuronal activity for the processing of emotions.

Topographically organized representation of space and context in the medial prefrontal cortex.
Spatial tuning of neocortical pyramidal cells has been observed in diverse cortical regions and is thought to rely primarily on input from the hippocampal formation. Despite the well-studied hippocampal place code, many properties of the neocortical spatial tuning system are still insufficiently understood. In particular, it has remained unclear how the topography of direct anatomical connections from hippocampus to neocortex affects spatial tuning depth, and whether the dynamics of spatial coding in the hippocampal output region CA1, such as remapping in novel environments, is transmitted to the neocortex. Using mice navigating through virtual environments, we addressed these questions in the mouse medial prefrontal cortex, which receives direct input from the hippocampus. We found a rapidly emerging prefrontal representation of space in the absence of task rules, which discriminates familiar from novel environments and is reinstated upon reexposure to the same familiar environment. Topographical analysis revealed a dorsoventral gradient in the representation of the own position, which runs opposite to the innervation density of hippocampal inputs. Jointly, these results reveal a dynamically emerging and topographically organized prefrontal place code during spontaneous locomotion.

Respiration-Driven Brain Oscillations in Emotional Cognition.
Respiration paces brain oscillations and the firing of individual neurons, revealing a profound impact of rhythmic breathing on brain activity. Intriguingly, respiration-driven entrainment of neural activity occurs in a variety of cortical areas, including those involved in higher cognitive functions such as associative neocortical regions and the hippocampus. Here we review recent findings of respiration-entrained brain activity with a particular focus on emotional cognition. We summarize studies from different brain areas involved in emotional behavior such as fear, despair, and motivation, and compile findings of respiration-driven activities across species. Furthermore, we discuss the proposed cellular and network mechanisms by which cortical circuits are entrained by respiration. The emerging synthesis from a large body of literature suggests that the impact of respiration on brain function is widespread across the brain and highly relevant for distinct cognitive functions. These intricate links between respiration and cognitive processes call for mechanistic studies of the role of rhythmic breathing as a timing

signal for brain activity.

COGNITIVE PHENOTYPES AFTER LEFT AND RIGHT HEMISPHERIC STROKE: A LATENT CLASS ANALYSIS

POSTER SESSION 05 - SECTION: ALZHEIMER'S DISEASE: FROM NEUROINFLAMMATION TO NEUROPROTECTION

Hanne Huygelier[1], Annick Odom[1], Hella Thielen[1], Mauro Mancuso[2], Céline Gillebert[1], Nele Demeyere[3]

Aims. Although cognitive impairment after stroke is highly prevalent, most research has not investigated patterns of comorbidity. In this study, we aimed to identify separable cognitive profiles after stroke. **Methods.** We retrospectively analysed data of 2,172 stroke patients (43% left hemisphere, 50% right hemisphere; 81% ischemic; tested on average 19 days post-stroke) across three countries. All patients completed the Oxford Cognitive Screen in their native language, which screens for impairments in language, memory, number, praxis, executive function and attention. To identify cognitive profiles within this cohort, latent class models were estimated. The best model was selected based on three fit indices, the certainty of class assignments and interpretability of classes. **Results.** The best model suggested 13 distinguishable cognitive profiles. The largest group demonstrated no cognitive impairment (30.2%). Five right-lateralized profiles were identified, of which three were characterized by left-sided neglect (neglect without comorbidity, neglect with comorbidity, and neglect with signs of hemianopia). The two other right-lateralized profiles were characterized by non-spatial attention impairments and executive impairment, respectively. Four left-lateralized profiles occurred, of which two were characterized by language impairments (with impaired versus intact praxis and numerical abilities). Four other profiles occurred equally often after left- and right-hemispheric stroke. Age, country, gender and time since stroke did not predict the cognitive profiles. **Conclusions.** A simple distinction of right- and left-lateralized cognitive profiles after stroke does not capture the heterogeneity of post-stroke cognitive comorbidities. Our study presents a big step towards an empirically validated taxonomy of post-stroke cognitive profiles.

IMPULSIVE BEHAVIOR ASSESSMENT IN A PRECLINICAL MODEL OF STROKE

POSTER SESSION 05 - SECTION: ALZHEIMER'S DISEASE: FROM NEUROINFLAMMATION TO NEUROPROTECTION

Natalia De Las Heras[1], Antonio Rodriguez[2], Manuela Olmedo-Córdoba[1], Elena Martín González[1], Ángeles Prados-Pardo[1], Patricia Martinez-Sanchez[3], Margarita Moreno[1]

Clinical stroke patients show relevant cognitive impairments including inhibitory control deficit; however, preclinical research has focused almost exclusively on motor deficits. In the present work we assess impulsive decision making in a preclinical model of stroke. Male Wistar rats underwent focal ischemia induced in the medial Prefrontal Cortex (mPFC) using bilateral intracerebral injections of endothelin-1, or sham surgery. We evaluated impulsive decision making by the Rodent Gambling task (RGT). The results will be discussed in terms of the effects of stroke on prefrontal cortex damage and the long term alterations of impulsive behaviors such as impulsive risky decision making, perseverative responses and cognitive inflexibility. Preclinical models of focal stroke in the mPFC could help to understand the cognitive impairments and the association with the neuroplastic changes after damage. **Funded by Gobierno de España MCIN/ AEI /10.13039/501100011033/ grant number PGC2018-099117-B-C21, UAL2020-CTSD2068 FEDER I+D+i "Una manera de hacer Europa" and Redes de Investigación Cooperativa Orientadas a Resultados en Salud RICORS-ICTUS RD21/0006/0010.**

The rapid decline in cognition is a major component of many neurodegenerative disorders with the most common type being Alzheimer's disease (AD), as it poses a global challenge both in terms of mortality and exerting pressure on the healthcare system. Delayed disease diagnosis along with the lack of disease modifying treatments mean there is an urgent need to decipher its pathogenesis and underlying biochemistry. It is hypothesised that AD leaves a metabolic signature which can be detectected in the pre-clinical stage. Using an untargeted metabolic profiling approach, metabonomic data acquired from biofluids and tissue samples from AD patients were compared to non-disease controls. In the first study, the relationship between potential metabolites found in human serum and urine and previously recorded cogntive function scores via AD Assessment Scale-Cognition (ADAS-Cog) subset were assessed in training (n = 62; AD patients on donepezil) and validation (n = 75; combination of subgroups e.g., AD) sets. The cohort consisited of controls, stable mild cogntive impairment (MCI), converting MCI and AD subgroups and the feauture exhibiting significant association with cogntition was annotated to be theophylline. Also, to further probe potential mechanisms associated with AD, lipid profiling analysis of tissue samples acquired from AD (n = 102) and control (n = 39) post-mortem human brain expressing triggering recpetor expressed on myeloid cells 2 (*TREM2*; AD risk gene) variants. Preliminary multivariate statistical models (OPLS-DA) for the somatosensory cortex showed lipid features driving separation between sex, group (AD vs. control) and *TREM2* variants.

PATHOGENIC EFFECTS OF GABAB RECEPTOR ANTIBODIES FROM PATIENTS WITH AUTOIMMUNE ENCEPHALITIS ON SYNAPTIC STRUCTURE AND MEMORY

POSTER SESSION 05 - SECTION: NEUROINFLAMMATION AND AUTOIMMUNITY

Eleonora Anna Loi[1], Josefine Sell[1], Christian Geis[1,2]
[1]Jena University Hospital, Section Translational Neuroimmunology, Jena, Germany, [2]University of Jena, Department Of Neurology, Jena, Germany

Aims: $GABA_B$ receptor ($GABA_BR$) are dimeric G-protein coupled receptors regulating presynaptic neurotransmitter release and postsynaptic excitability. In $GABA_BR$ autoimmune encephalitis IgG antibodies target the B1 subunit of $GABA_BR$ leading to various symptoms, including epilepsy, cognitive disorders and short-term memory loss. Here we aimed to investigate the pathophysiological effect of human serum antibodies on synaptic structure and memory, using staining protocols and behavioral paradigms. Methods: Purified patient-derived immunoglobulin G antibodies (control- and anti-$GABA_BR$-IgG) were used in a mouse model of continuous 14-day cerebroventricular infusion via osmotic pumps. The IgG influence on memory and cognition was examined via novel object recognition test (NOR) and novel object location test (NOL), performed with a retention time of either 3 hours or 24 hours. We preincubated cultivated neurons with control and $GABA_BR$ IgG and co-stained with commercial $GABA_BR$ antibodies and pre- and post-synaptic markers to evaluate preferential IgG binding sites and structural changes in the synaptic area. Results: Evaluation of cognitive function trough behavioral paradigm suggest an influence of the anti-$GABA_BR$-IgG on the consolidation and maintenance of contextually precise memory, but not for the initial encoding of the memory. Super resolution imaging gave further insights on changes in peri-synaptic structure and $GABA_BR$ localization mediated by patients' IgG treatment. Conclusions:
Our results provide insight on differential action of patient IgG on pre- and post-synaptic $GABA_BR$, and elucidated potential mechanism involved in cognitive impairment in this subtype of autoimmune encephalitis. Further experiments will evaluate the influence of patient IgG on $GABA_BR$ B1 subunit localization.

[1]Institute of Human Genetics, University of Münster, Department Of Genetic Epidemiology, Münster, Germany, [2]University of Münster, Department Of Neurology With Institute Of Translational Neurology, Münster, Germany, [3]Christian-Albrechts-University of Kiel, Institute Of Clinical Molecular Biology, Kiel, Germany, [4]Heinrich-Heine University Düsseldorf, Department Of Neurology, Düsseldorf, Germany, [5]University of Kiel, Department Of Neurology, Kiel, Germany, [6]University Hospital Schleswig-Holstein, Neuroimmunology, Institute Of Clinical Chemistry, Kiel, Germany

Aims: Autoimmune neurological syndromes (AINS) with autoantibodies against the 65 kDa isoform of the glutamic acid decarboxylase (GAD65) present with limbic encephalitis, cerebellitis and stiff-person-syndrome, or overlap forms. Here, we investigated the genetic predisposition to anti-GAD65 AINS. **Methods:** We performed the first genome-wide association study (GWAS) for anti-GAD65 AINS in a large German cohort of 167 patients and 1,047 population-based controls (N=1,214). GWAS findings were further explored in the cerebrospinal fluid (CSF) proteome of a small and virtually independent cohort of 10 patients and 10 controls. **Results:** Our GWAS identified 16 genome-wide significant ($p<5x10^{-8}$) loci for the susceptibility to anti-GAD65 AINS. The great majority of variants in loci (>90%) mapped to non-coding regions of the genome. Over 40% of the variants are documented regulators of a total of 48 genes in disease relevant cells and tissues, mainly $CD4^+$ T cells and the cerebral cortex. The annotation of epigenomic marks suggested specificity for neurons, monocytes, T cells as well as neural and hematopoietic progenitor cells. A network analysis of the implicated protein-coding genes uncovered a role of protein kinase C beta (*PRKCB* on chr16*)* in the pathophysiology of anti-GAD65 AINS. The larger and stronger locus spanned the human leukocyte antigen (HLA) region (chr6:29488249-31105310, 244 variants, 3 lead variants), implicating mainly non-classical HLA molecules. In the CSF proteome, we found support for this locus through differential levels of HLA-A/B and C4A. **Conclusions:** These findings suggest a strong genetic predisposition with direct functional implications for immunity and neural function in anti-GAD65 AINS.

Background: Chronic fatigue syndrome or myalgic encephalomyelitis (CFS/ME) is often preceded by viral or bacterial infection. Symptoms include pronounced fatigue, post-exertional malaise, autonomic dysregulation, myalgia, and cognitive deficits. Similar symptoms are often present in “long-COVID”, a sequela of infection with the SARS-CoV-2 virus. Available evidence suggests CFS/ME pathology may be linked to neuroinflammation and oxidative stress, resulting in impaired mitochondrial function and energy metabolism. There is a need to understand the pathogenesis of both conditions, particularly given their individual and societal symptomatic burden and the paucity of pharmacological treatment options. **Aims:** Using high-field magnetic resonance spectroscopy (MRS), we aimed to examine central and peripheral symptoms of CFS/ME and long-COVID by measuring biochemical concentrations in the anterior cingulate cortex (ACC) and peripheral muscle. Previous CFS/ME data revealed neurochemical abnormalities in the ACC, which is associated with cognitive, emotional, and pain processing, and autonomic function. Metabolites of interest were markers of energy metabolism (creatine and phosphocreatine); neurotransmitters (glutamate, glutamine and GABA); and glutathione, a marker of oxidative stress. A secondary aim was to determine how neurochemical concentrations relate to symptoms and cognitive performance. **Methods:** 20 CFS/ME (13 tested, recruitment ongoing), 20 long-COVID, and 20 healthy participants underwent MRS scans of the brain and leg at 7 Tesla. Voxels were placed in the pregenual and dorsal ACC, and the right calf muscle. Participants also completed a battery of cognitive tests and questionnaires assessing their symptoms and psychological wellbeing. **Results:** Data analysis is in-progress. Results and conclusions will be presented in the final poster.

ELECTROPHYSIOLOGICAL CHARACTERISATION OF HIPPOCAMPAL NETWORKS IN ANTI-NMDA RECEPTOR ENCEPHALITIS: FROM SYNAPSE TO CIRCUIT

POSTER SESSION 05 - SECTION: NEUROINFLAMMATION AND AUTOIMMUNITY

Daniel Hunter[1], Mar Petit-Pedrol[1], Harald Pruss[2], Laurent Groc[1]
[1]The University of Bordeaux, Interdisciplinary Institute For Neuroscience (cnrs), Bordeaux, France, [2]Charité-Universitätsmedizin Berlin, Department Of Neurology And Experimental Neurology, Berlin, Germany

Introduction NMDAR-encephalitis is an autoantibody-mediated psychiatric syndrome, presenting with seizure and psychosis. Molecular investigations have delineated a pathway of action of these autoantibodies, whereby NMDARs are translocated out of synaptic compartments and subsequently internalised. This depletion of surface NMDAR expression results in an excitatory hypofunction on hippocampal neurons. **Aims** We aim to characterise a broader-scale functional impact of antibody action, at synaptic-, cellular- and circuit-levels, to finely elucidate the mechanisms by which NMDAR-autoantibodies elicit a hyper-excitable seizure phenotype in clinical settings. **Methods** Using a range of patch-clamp electrophysiological techniques, we examined the synaptic disturbance induced by indirect actions of NMDAR-autoantibodies, encompassing dysfunction at both excitatory and inhibitory inputs to hippocampal cells. **Results** We have identified alterations to the synaptic phenotype of hippocampal neurons, which are compounded by a shift in intrinsic excitability at the cellular- and network-scales. We have further demonstrated a divergence in the pathogenicity of NMDAR-autoantibodies on discrete subpopulations of hippocampal neurons. **Conclusions** Overall, we have characterised an additional disease pathway in NMDAR-encephalitis, whereby alterations in synaptic and cellular functional properties, induced by autoantibodies, are identified at the synaptic and cellular level.

IMPACT OF AUTOANTIBODIES FROM PATIENTS WITH NMDAR-ENCEPHALITIS ON THE GABAERGIC SYNAPSES

POSTER SESSION 05 - SECTION: NEUROINFLAMMATION AND AUTOIMMUNITY

Mar Petit-Pedrol[1], Daniel Hunter[1], Harald Prüß[2], Laurent Groc[1]
[1]Université of Bordeaux, CNRS, Institute For Interdisciplinary Neurosciences, Umr 5297, Bordeaux, France, [2]Charité University Medicine Berlin, Department Of Neurology, Berlin, Germany

Autoantibodies targeting the NMDA receptor (NMDAR) have been associated to neuropsychiatric disorders together with memory problems, movement disorders, and epileptic seizures. These autoantibodies cause the internalization of receptors, leading to NMDAR hypofunction. Whether this major dysfunction alter other neurotransmitter systems, such as the GABAergic one, remains an open question. Aim: Here, we aimed to tackle this question and the putative mechanism by which NMDAR autoantibodies could alter the inhibitory transmission. Methods: Monoclonal NMDAR autoantibodies from patients with NMDAR encephalitis or control non-reactive human monoclonal antibody antibodies were used in hippocampal cultured neurons. We performed single nanoparticle tracking and immunofluorescence assays to assess changes in the diffusion and density of the receptors at the GABAergic synapses. Results: We report alteration of the synaptic material at the inhibitory as well as at the excitatory synapse upon exposure to NMDAR autoantibodies. These changes take place at the single receptor level dynamics and at the macroscopic level. Conclusions: Together, our results demonstrate that NMDAR autoantibodies not only affect the target antigen, but also cause alterations in the trafficking and surface distribution of receptors at the inhibitory synapse, providing evidence of the interplay between glutamatergic and GABAergic synapses.

HUMAN ANTI-GLUN1 AUTOANTIBODIES INDUCE DEFECTIVE SYNAPTIC PLASTICITY DEPENDENT ON CAMKII AND DAPK1 PATHWAYS AS INVESTIGATED BY SUPER-RESOLUTION MICROSCOPY

POSTER SESSION 05 - SECTION: NEUROINFLAMMATION AND AUTOIMMUNITY

Marin Kempfer[1], Lars Schmidl[1], Holger Haselmann[1], Harald Prüß[2], Christian Geis[3]
[1]University Hospital Jena, Section Translational Neuroimmunology, Jena, Germany, [2]Charité University Medicine Berlin, Department Of Neurology, Berlin, Germany, [3]University of Jena, Department Of Neurology, Jena, Germany

Aims: The anti-N-methyl-D-aspartate receptor (NMDAR) encephalitis is an autoimmune disorder characterized by specific autoantibodies targeting the GluN1 subunit of postsynaptic NMDARs. We investigated the effect of patient monoclonal anti-GluN1 antibodies on important pathways for synaptic plasticity and function, e.g. synaptic signalling events involving the antagonistic molecules CaMKII and DAPK1. **Methods:** We incubated primary hippocampal cell cultures (div 20) with patient-derived monoclonal anti-GluN1 or control antibodies. Afterwards, we performed additional incubation with the DAPK1 inhibitor TC-DAPK6 and/or LTP induction. We analysed the localization and distribution of the NMDAR GluN1 subunit and the GluA1 subunit of the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPAR) and correlated their expression to a postsynaptic marker with direct stochastic reconstruction microscopy (*d*STORM). Furthermore, we investigated the localisation of CaMKII and DAPK1 compared to a postsynaptic marker using structured illumination microscopy (SIM). **Results:** We established a stable LTP and immunostaining protocol for postsynaptic markers, CaMKII and DAPK1 in primary neuronal cultures for *d*STORM and SIM imaging. We established TC-DAPK6 treatment to inhibit co-localisation of DAPK1 within synapses. Furthermore, we investigated the combined application of LTP, human GluN1 antibodies, and/or TC-DAPK6 on the localisation of GluN1/GluA1 and CaMKII/DAPK1 compared to synaptic markers, thus providing evidence for antibody-induced and CaMKII/DAPK1-dependent synaptic remodelling. **Conclusions:** We observed defective cellular NMDA receptor dependent LTP upon highly specific, patient-derived autoantibodies. Interfering with CaMKII/DAPK1-dependent plasticity pathways by inhibiting DAPK1 function and translocation to extrasynaptic compartments might be beneficial for GluN1 antibody-induced defective LTP.

PATHOGENIC EFFECTS OF GABAB RECEPTOR ANTIBODIES FROM PATIENTS WITH AUTOIMMUNE ENCEPHALITIS ON NEURONAL SIGNALING AND NETWORK EXCITABILITY

POSTER SESSION 05 - SECTION: NEUROINFLAMMATION AND AUTOIMMUNITY

Josefine Sell, Eleonora Anna Loi, Vahid Rahmati, Christian Geis
Jena University Hospital, Section Translational Neuroimmunology, Jena, Germany

Aims:
$GABA_B$ receptor ($GABA_BR$) encephalitis is an autoimmune disorder with immunoglobulin G (IgG) antibodies targeting pre- and postsynaptic $GABA_B$Rs. Patients suffer from severe memory dysfunction and epileptic seizures. $GABA_B$Rs are G-protein coupled receptors and mediate complex synaptic signaling in glutamatergic as well as GABAergic neurons by regulating presynaptic neurotransmitter release and postsynaptic excitability. Here we aimed at investigating the pathophysiological effect of human serum antibodies on neuronal synaptic transmission. Methods:
Purified patient-derived IgG antibodies were used in a mouse model of continuous 14-day cerebroventricular infusion via osmotic pumps. To investigate $GABA_BR$ mediated regulation of synaptic transmission, somatic patch-clamp recordings of CA1 pyramidal neurons were performed and special stimulation protocols were applied on afferent fibers. To reveal IgG-effects on $GABA_BR$ function, either the $GABA_BR$ agonist baclofen or the antagonist CGP55845 was applied by bath perfusion. Results:
$GABA_BR$ antibodies affected excitatory synaptic transmission and short-term plasticity of heteroreceptors, as they reduced eEPSC amplitudes and the agonist effect of baclofen onto paired pulse ratios. Furthermore, they block presynaptic autoreceptors on inhibitory synapses, leading to less depression during repetitive IPSC stimulation. In contrast, postsynaptic $GABA_BR$-activated K^+-currents and action potential firing is not influenced by patient's IgGs. Conclusions:
Our results provide evidence that $GABA_BR$ antibodies antagonize the receptor preferably on presynaptic auto- and heteroreceptors, but have less direct pathogenic effect on postsynaptic $GABA_BR$-downstream signaling. These changes may contribute to severe neuronal dysfunction as the basis of memory dysfunction and increased seizure susceptibility.

ACUTE EFFECTS OF HUMAN MONOCLONAL ANTI-GLUN1 AUTOANTIBODIES ON NMDA-RECEPTOR CHANNEL FUNCTION

POSTER SESSION 05 - SECTION: NEUROINFLAMMATION AND AUTOIMMUNITY

Abdulla Taha[1], Holger Haselmann[1], Harald Prüß[2], Christian Geis[1]
[1]University hospital of Jena, Section For Translational Neuroimmunology, Fzl, Jena, Germany, [2]Charité University Medicine Berlin, Department Of Neurology, Berlin, Germany

Aim: NMDAR encephalitis is an autoimmune disorder characterized by specific autoantibodies to the aminoterminal domain of the NMDAR GluN1 subunit. This project aims at understanding the acute effects of human monoclonal autoantibodies on NMDA-receptor channel function in detail. **Methods:** To identify changes in glutamate–evoked NMDAR channel responses, a non-host cell line NG108-15 was transfected with NR1/NR2A subunits of NMDARs. We developed a transfection protocol for lower cytotoxicity and optimized membrane integrity. For the fast application of various NMDAR-modulators (including ligands and pathogenic antibodies), a fast solution exchange system was applied, which is able to switch between multiple solutions with a controllable flow rate. To measure the effect of human pathogenic antibodies on acute NMDAR responses, whole-cell patch recordings were applied in both, NR1/NR2A transfected NG108-15 cells and cultured neurons. Moreover, immunostaining followed by imaging using confocal microscopy was performed to evaluate the antibodies' binding kinetics to NMDARs during fast perfusion. **Results:** We established a fast-perfusion antibody-application scheme based on immunostainings. We assessed the influence of monoclonal antibodies on the steady-state and peak amplitude of NMDAR-current in NG108-15 and cultured neurons. At low antibody concentration (10 µg/ml), we found no significant change in the steady-state of NMDAR-current. Furthermore, the influence of these antibodies on the peak-amplitude of NDMAR-currents elucidated the change in the simultaneous opening of NDMARs. **Conclusion:** Human pathogenic antibodies to the NMDAR GluN1 subunit may influence NMDAR channel function. These direct effects may contribute to NMDAR-directed pathology and the development of disease symptoms in patients.

PATHOPHYSIOLOGICAL RELEVANCE OF NMDAR1-AUTOANTIBODIES DURING GRAY MATTER INFLAMMATION

POSTER SESSION 05 - SECTION: NEUROINFLAMMATION AND AUTOIMMUNITY

Justus Wilke[1], Martin Hindermann[1], Sahab Arinrad[1], Anja Ronnenberg[1], Nadine Barnkothe[1], Fred Lühder[2], Hannelore Ehrenreich[1]
[1]Max Planck Institute for Multidisciplinary Sciences, Clinical Neuroscience, Göttingen, Germany, [2]University Medical Center Göttingen, Institute For Neuroimmunology And Multiple Sclerosis Research, Göttingen, Germany

After the discovery of an encephalitis associated with autoantibodies directed against the NMDAR1 subunit of N-methyl-D-aspartate receptors (NMDAR), a vast amount of studies investigated the pathogenicity of these autoantibodies, resulting in some understanding of their function and mode of action. Prior work has shown, that NMDAR are internalized upon binding of NMDAR1-autoantibodies (NMDAR1-AB) resulting in NMDAR-hypofunction. This decrease in surface NMDAR expression potentially explains some psychiatric and neurological symptoms observed in patients with the so-called anti-NMDAR encephalitis. However, the actual pathomechanism(s) that induce encephalitis and drive neuroinflammation are understudied and few studies investigated the pathophysiological relevance of NMDAR1-AB in a neuroinflammatory context. To investigate the effects of NMDAR1-AB during gray matter inflammation, we immunized transgenic (Neurod6$^{tm2.1(cre/ERT2)Kan}$ x Gt(ROSA)26Sor$^{tm1(DTA)Jpmb}$; 'DTA') mice against a cocktail of four NMDAR1-specific peptides and subsequently induced a spatiotemporally defined sterile encephalitis by tamoxifen-dependent ablation of pyramidal neurons. Upon DTA induction, mice developed lasting blood-brain barrier dysfunction, gray matter inflammation and neurodegeneration, particularly in the hippocampus and cortex. Behavioral phenotyping revealed typical hippocampal learning/memory deficits, prefrontal cortical network-dysfunction and hyperlocomotion in DTA mice. Compared to ovalbumin-immunized control mice, mice carrying NMDAR1-AB displayed increased hyperlocomotion, reminiscent of mice injected with the NMDAR antagonist MK-801. Importantly, the presence of NMDAR1-AB did not aggravate the neuroinflammation in DTA mice and immunized non-DTA mice were free of any signs of neuroinflammation. To conclude, while the encephalitic potential of NMDAR1-AB remains to be proven, NMDAR1-AB can modulate the behavioral phenotype of an underlying gray matter inflammation (reference: doi.org/10.1038/s41380-021-01238-3).

FUNCTIONAL EFFECTS OF HUMAN LGI1 AUTOANTIBODIES ON CA3 PYRAMIDAL NEURONS: A SPECIES-SPECIFIC IN VITRO STUDY IN HUMAN HIPPOCAMPAL SLICE CULTURES

POSTER SESSION 05 - SECTION: NEUROINFLAMMATION AND AUTOIMMUNITY

Laura Monni[1,2], Hans-Christian Kornau[2,3], Dietmar Schmitz[2,3], Martin Holtkamp[1,4], Pawel Fidzinski[1,2]
[1]Charité – Universitätsmedizin Berlin, Experimental Neurology, Berlin, Germany, [2]Charité – Universitätsmedizin Berlin, Neuroscience Research Center, Cluster Neurocure, Berlin, Germany, [3]German Center for Neurodegenerative Diseases, Dzne, Berlin, Germany, [4]Epilepsy-Center Berlin-Brandenburg, Institute For Diagnostics Of Epilepsy, Berlin, Germany

Leucine-rich glioma-inactivated 1 (LGI1) is a neuronal protein that modulates axonal $K_v1.1$ channels density. $K_v1.1$ channels mediate the dendrotoxin (DTX)-sensitive D-type potassium current, which regulates neuronal action potential firing and excitability. Human autoantibodies against LGI1 are associated with the second most common autoimmune encephalitis characterized by faciobrachial dystonic seizures, memory impairment, and, in some cases, severe uncontrolled seizures. Recently, LGI1 autoantibodies cloned from cerebrospinal fluid of patients with LGI1 encephalitis have been shown to increase neuronal excitability and glutamatergic synaptic transmission of hippocampal CA3 pyramidal neurons in mouse brain slice cultures. The aim of the current study was to investigate the functional effects of human LGI1 autoantibodies in a species-specific manner, namely on human hippocampal tissue derived from epilepsy surgical resections. Upon resection, human hippocampal tissue was sliced and the slices were cultured for 24h in the absence or presence of LGI1 autoantibodies. Next, excitability of CA3 pyramidal neurons was assessed by whole-cell patch clamp experiments together with extracellular recordings of antidromically-evoked population spikes (PS) of CA3 axons. DTX-K was applied as pharmacological control. We found that LGI1 autoantibodies increased human CA3 neuronal excitability and spike latency. In addition, LGI1 increased the amplitude of the antidromic PS, in contrast to the DTX-K effect, which slightly decreased the amplitude, while increasing its delay. We thus confirm that LGI1 autoantibodies increase neuronal excitability underlying seizure generation in human tissue. Further investigation is necessary to understand target specificity of LGI1 autoantibodies at the axonal level.

CASPR2 AUTOANTIBODIES ELICIT CONCENTRATION-DEPENDENT PERTURBATIONS IN THE REGULATION OF AMPA RECEPTOR TRAFFICKING AND SYNAPTIC PLASTICITY

POSTER SESSION 05 - SECTION: NEUROINFLAMMATION AND AUTOIMMUNITY

Dominique Fernandes[1], Ana Vasconcelos[1], Sandra Santos[1], Ester Coutinho[1,2,3], Jessica Whitt[4], Hey-Kyoung Lee[4], Ana Luisa Carvalho[5]
[1]University of Coimbra, Center For Neuroscience And Cell Biology, Coimbra, Portugal, [2]King's College Hospital, King's College Hospital, London, United Kingdom, [3]MRC Centre for Neurodevelopmental Disorders, King's College, London, United Kingdom, [4]Johns Hopkins University, The Zanvyl Krieger Mind/brain Institute & The Solomon Snyder Department Of Neurosciences, Baltimore, United States of America, [5]CNC-Centro de Neurociências e Biologia Celular, Departamento De Ciências Da Vida, Coimbra, Portugal

Antibodies targeting the cell-adhesion protein CASPR2 have been found in patients with autoimmune synaptic encephalitis, which can present peripheral nerve hyperexcitability, memory loss, cognitive impairments, and seizures. Despite the clear implication of CASPR2 autoantibodies (CASPR2-Abs) in disease, the pathogenic mechanisms ensuing from antibody-mediated perturbations in CASPR2 function are still unclear. Our laboratory recently described a novel role for CASPR2 in the regulation of glutamate AMPA receptors (AMPAR) and cortical excitatory synaptic transmission. Herein, we explored whether patient CASPR2-Abs disrupt excitatory synapse function. To achieve this, we incubated primary cultured neurons with a range of concentrations (0.2, 5, 20 or 50 µg/mL) of purified IgGs from a patient with anti-CASPR2 synaptic encephalitis. We found that CASPR2-Abs alter the synaptic expression of Caspr2 and induce a dose-dependent perturbation in AMPAR trafficking. At lower concentrations, CASPR2-Abs decrease synaptic AMPARs by increasing their internalization from the cell surface. Conversely, endocytosis of AMPARs is hampered at higher CASPR2-Ab concentrations, resulting in a striking synaptic accumulation of surface AMPARs. Moreover, we show that CASPR2-Abs at lower concentrations prevent the synaptic incorporation of AMPARs following chemically-induced long-term potentiation; whereas higher CASPR2-Ab concentrations occlude this effect. Finally, we find that CASPR2-Abs disrupt AMPAR function, since excitatory synaptic transmission in the mouse visual cortex is perturbed following *in vivo* incubation with CASPR2-Abs. Overall, our results suggest that CASPR2-Abs elicit concentration-dependent effects that distinctively perturb the function of CASPR2 in regulating AMPAR trafficking and synaptic plasticity, thus pinpointing the glutamatergic system as a target for pathogenesis in CASPR2 synaptic encephalitis.

Mechanisms of homeostatic plasticity in the excitatory synapse.
Brain development, sensory information processing, and learning and memory processes depend on Hebbian forms of synaptic plasticity, and on the remodeling and pruning of synaptic connections. Neurons in networks implicated in these processes carry out their functions while facing constant perturbation; homeostatic responses are therefore required to maintain neuronal activity within functional ranges for proper brain function. Here, we will review in vitro and in vivo studies demonstrating that several mechanisms underlie homeostatic plasticity of excitatory synapses, and identifying participant molecular players. Emerging evidence suggests a link between disrupted homeostatic synaptic plasticity and neuropsychiatric and neurologic disorders. Hebbian forms of synaptic plasticity, such as long-term potentiation (LTP), induce long-lasting changes in synaptic strength, which can be destabilizing and drive activity to saturation. Conversely, homeostatic plasticity operates to compensate for prolonged activity changes, stabilizing neuronal firing within a dynamic physiological range. We review mechanisms underlying homeostatic plasticity, and address how neurons integrate distinct forms of plasticity for proper brain function. This article is part of a mini review series: "Synaptic Function and Dysfunction in Brain Diseases".

Disrupted AMPA Receptor Function upon Genetic- or Antibody-Mediated Loss of Autism-Associated CASPR2.
Neuropsychiatric disorders share susceptibility genes, suggesting a common origin. One such gene is CNTNAP2 encoding contactin-associated protein 2 (CASPR2), which harbours mutations associated to autism, schizophrenia, and intellectual disability. Antibodies targeting CASPR2 have also been recently described in patients with several neurological disorders, such as neuromyotonia, Morvan's syndrome, and limbic encephalitis. Despite the clear implication of CNTNAP2 and CASPR2 in neuropsychiatric disorders, the pathogenic mechanisms associated with alterations in CASPR2 function are unknown. Here, we show that Caspr2 is expressed in excitatory synapses in the cortex, and that silencing its expression in vitro or in vivo decreases the synaptic expression of α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors and the amplitude of AMPA receptor-mediated currents. Furthermore, Caspr2 loss of function blocks synaptic scaling in vitro and experience-dependent homoeostatic synaptic plasticity in the visual cortex. Patient CASPR2 antibodies decrease the dendritic levels of Caspr2 and synaptic AMPA receptor trafficking, and perturb excitatory transmission in the visual cortex. These results suggest that mutations in CNTNAP2 may contribute to alterations in AMPA receptor function and homoeostatic plasticity, and indicate that antibodies from anti-CASPR2 encephalitis patients affect cortical excitatory transmission.

LONG-LASTING DEGRADATION OF HIPPOCAMPAL SPATIAL REPRESENTATION AND MEMORY, IN THE MOUSE MODEL OF ANTI-NMDAR ENCEPHALITIS

POSTER SESSION 05 - SECTION: NEUROINFLAMMATION AND AUTOIMMUNITY

Amirpasha Zamani[1], David Tomàs[2], Paula Peixoto Moledo[1], Josep Dalmau[1], Pablo Jercog[1]

Anti-NMDA receptor encephalitis is the most frequent antibody-mediated encephalitis, in which patients' autoantibodies are directed against subunits of N-methyl-D-aspartate receptors (NMDARs). Patients with this disorder suffer a prolonged recovery process, bearing severe deficits of episodic long-term memory. In an animal model of 14-day continuous cerebroventricular intracranial transfer of antibodies, a decrease of performance in a memory task, along with reduction of synaptic NMDARs, has been reported. Here, we have used the same mouse model to investigate hippocampal neural activity over a period of 80 days. We recorded functional calcium imaging of CA1 neuronal population activity of mice that were freely moving and performing 2 distinct behavioral tasks. The tasks were designed to assess animals' abilities in either a) forming new memories or b) recalling old memories. We found that the CA1 neuronal population's firing activity increased significantly as a result of human NMDAR-antibodies. This high activity state lasted beyond 4 weeks after the infusion stopped. In addition, the decrease of behavioral performance in both memory tasks, as a result of NMDAR-antibodies, was accompanied by the decrease in the amount of spatial information encoded in neural activities and the reduction of place cells' stability over the duration of the experiment.
Our data support a novel methodology to create an amnesic state by using highly specific antibodies for blocking NMDAR function. More importantly, our results can explain the long-term effects of antibody-mediated dysfunction of NMDAR-related circuitry and the slow recovery period in patients with this disease.

HUMAN CASPR2 ANTIBODIES REVERSIBLY ALTER MEMORY AND THE CASPR2 PROTEIN COMPLEX

POSTER SESSION 05 - SECTION: NEUROINFLAMMATION AND AUTOIMMUNITY

Jesús Planagumà, Bastien Joubert, Mar Petit-Pedrol
IDIBAPS, Neuroimmunology, Barcelona, Spain

Aims: The encephalitis associated with antibodies against contactin-associated protein-like 2 (CASPR2) is presumably antibody-mediated but the antibody effects and whether they cause behavioral alterations are not well-known. Here, we used a mouse model of patients' IgG transfer and super-resolution microscopy to demonstrate the antibody pathogenicity. **Methods:** IgG from patients with anti-CASPR2 encephalitis or healthy controls were infused into the cerebroventricular system of mice. The levels and colocalization of CASPR2 with transient axonal glycoprotein-1 (TAG1) were determined with Stimulated Emission Depletion (STED) microscopy (40-70nm lateral resolution). Hippocampal clusters of Kv1.1 voltage-gated potassium channels (VGKC) and GluA1-containing AMPA receptors were quantified with confocal microscopy. Behavioral alterations were assessed with standard behavioral paradigms. Cultured neurons were used to determine the levels of intracellular CASPR2 and TAG1 after exposure to patients' IgG. **Results:** Infusion of patients' IgG, but not control IgG, caused memory impairment along with hippocampal reduction of surface CASPR2 clusters and decreased CASPR2/TAG1 colocalization. In cultured neurons, patients' IgG led to an increase of intracellular CASPR2 without affecting TAG1, suggesting selective CASPR2 internalization. Additionally, mice infused with patients' IgG showed decreased levels of Kv1.1 and GluA1 (two CASPR2 regulated proteins). All these alterations and the memory deficit reverted to normal after removing patients' IgG. **Conclusions:** IgG from patients with anti-CASPR2 encephalitis cause reversible memory impairment, inhibit the interaction of CASPR2/TAG1, and decrease the levels of CASPR2 and related proteins (VGKC, AMPAR). These findings demonstrate that patients CASPR2 antibodies are pathogenic and provide support to the use of antibody-removing treatment approaches.

CHIMERIC AUTOANTIBODY RECEPTOR T CELLS TARGETING AUTOREACTIVE B CELLS IN N-METHYL-D-ASPARTATE (NMDA) RECEPTOR ENCEPHALITIS

POSTER SESSION 05 - SECTION: NEUROINFLAMMATION AND AUTOIMMUNITY

Momsen Reincke[1], Niels Von Wardenburg[1], Marie Alice Homeyer[1], Hans-Christian Kornau[2], Dietmar Schmitz[2], Inan Edes[2], Harald Pruss[3]

NMDA receptor (NMDAR) encephalitis is the most common autoimmune encephalitis causing psychosis, epileptic seizures and cognitive impairment. Current treatment options are based on broad immunosuppression or non-selective antibody removal, resulting in often treatment-limiting side effects or insufficient responses. Disease-defining pathogenic autoantibodies bind the NMDAR leading to its internalization and subsequent synaptic alterations. Here, we developed NMDAR-specific Chimeric autoantibody receptor (NMDAR-CAAR) T cells to selectively target the source of disease-causing autoantibodies, anti-NMDAR-specific B cells. NMDAR-CAARs consist of an extracellular NMDAR autoantigen fused to intracellular 4-1BB/CD3ζ domains. After coculture with Nalm6 or K562 cells expressing anti-NMDAR-specific B cell receptors (BCRs), human NMDAR-CAAR T cells released interferon-gamma and granzyme B as markers of T cell effector function and killed target cells in an antigen-specific manner with high specificity. Furthermore, target cell encounter *in vitro* induced proliferation of NMDAR-CAAR T cells. In a NOD/Shi-*scid*/IL-2Rγ^{null} (NOG) mouse model, treatment with NMDAR-CAAR T cells led to depletion of Nalm6 B cells expressing an anti-NMDAR BCR and sustained reduction of autoantibody levels with no notable off-target toxicity. For the first time, this strategy could provide a highly selective treatment of a severe neurological autoimmune disease with reduced side effects, faster remission and better long-term prognosis. These results will the pave the way for clinical trials of CAAR-T cells in patients with antibody-mediated neurological disorders and can be expanded to a broader spectrum of antibody-mediated diseases.

SARS-CoV-2 Beta variant infection elicits potent lineage-specific and cross-reactive antibodies.
Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) Beta variant of concern (VOC) resists neutralization by major classes of antibodies from COVID-19 patients and vaccinated individuals. In this study, serum of Beta-infected patients revealed reduced cross-neutralization of wild-type virus. From these patients, we isolated Beta-specific and cross-reactive receptor-binding domain (RBD) antibodies. The Beta-specificity results from recruitment of VOC-specific clonotypes and accommodation of mutations present in Beta and Omicron into a major antibody class that is normally sensitive to these mutations. The Beta-elicited cross-reactive antibodies share genetic and structural features with wild type-elicited antibodies, including a public VH1-58 clonotype that targets the RBD ridge. These findings advance our understanding of the antibody response to SARS-CoV-2 shaped by antigenic drift, with implications for design of next-generation vaccines and therapeutics. Science, 2022; 375

Encephalitis patient-derived monoclonal GABAA receptor antibodies cause epileptic seizures.
Autoantibodies targeting the GABAA receptor (GABAAR) hallmark an autoimmune encephalitis presenting with frequent seizures and psychomotor abnormalities. Their pathogenic role is still not well-defined, given the common overlap with further autoantibodies and the lack of patient-derived mAbs. Five GABAAR mAbs from cerebrospinal fluid cells bound to various epitopes involving the α1 and γ2 receptor subunits, with variable binding strength and partial competition. mAbs selectively

reduced GABAergic currents in neuronal cultures without causing receptor internalization. Cerebroventricular infusion of GABAAR mAbs and Fab fragments into rodents induced a severe phenotype with seizures and increased mortality, reminiscent of encephalitis patients' symptoms. Our results demonstrate direct pathogenicity of autoantibodies on GABAARs independent of Fc-mediated effector functions and provide an animal model for GABAAR encephalitis. They further provide the scientific rationale for clinical treatments using antibody depletion and can serve as tools for the development of antibody-selective immunotherapies.

Structural and functional ramifications of antigenic drift in recent SARS-CoV-2 variants.
Neutralizing antibodies (nAbs) elicited against the receptor binding site (RBS) of the spike protein of wild-type severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) are generally less effective against recent variants of concern. RBS residues Glu, Lys, and Asn are mutated in variants first described in South Africa (B.1.351) and Brazil (P.1). We analyzed their effects on angiotensin-converting enzyme 2 binding, as well as the effects of two of these mutations (K417N and E484K) on nAbs isolated from COVID-19 patients. Binding and neutralization of the two most frequently elicited antibody families (IGHV3-53/3-66 and IGHV1-2), which can both bind the RBS in alternative binding modes, are abrogated by K417N, E484K, or both. These effects can be structurally explained by their extensive interactions with RBS nAbs. However, nAbs to the more conserved, cross-neutralizing CR3022 and S309 sites were largely unaffected. The results have implications for next-generation vaccines and antibody therapies.

A Therapeutic Non-self-reactive SARS-CoV-2 Antibody Protects from Lung Pathology in a COVID-19 Hamster Model.
The emergence of SARS-CoV-2 led to pandemic spread of coronavirus disease 2019 (COVID-19), manifesting with respiratory symptoms and multi-organ dysfunction. Detailed characterization of virus-neutralizing antibodies and target epitopes is needed to understand COVID-19 pathophysiology and guide immunization strategies. Among 598 human monoclonal antibodies (mAbs) from 10 COVID-19 patients, we identified 40 strongly neutralizing mAbs. The most potent mAb, CV07-209, neutralized authentic SARS-CoV-2 with an IC value of 3.1 ng/mL. Crystal structures of two mAbs in complex with the SARS-CoV-2 receptor-binding domain at 2.55 and 2.70 Å revealed a direct block of ACE2 attachment. Interestingly, some of the near-germline SARS-CoV-2-neutralizing mAbs reacted with mammalian self-antigens. Prophylactic and therapeutic application of CV07-209 protected hamsters from SARS-CoV-2 infection, weight loss, and lung pathology. Our results show that non-self-reactive virus-neutralizing mAbs elicited during SARS-CoV-2 infection are a promising therapeutic strategy.

N-methyl-D-aspartate receptor dysfunction by unmutated human antibodies against the NR1 subunit.
Anti-N-methyl-D-aspartate receptor (NMDAR) encephalitis is the most common autoimmune encephalitis related to autoantibody-mediated synaptic dysfunction. Cerebrospinal fluid-derived human monoclonal NR1 autoantibodies showed low numbers of somatic hypermutations or were unmutated. These unexpected germline-configured antibodies showed weaker binding to the NMDAR than matured antibodies from the same patient. In primary hippocampal neurons, germline NR1 autoantibodies strongly and specifically reduced total and synaptic NMDAR currents in a dose- and time-dependent manner. The findings suggest that functional NMDAR antibodies are part of the human naïve B cell repertoire. Given their effects on synaptic function, they might contribute to a broad spectrum of neuropsychiatric symptoms. Ann Neurol 2019;85:771-776.

Inactivation and Anion Selectivity of Volume-regulated Anion Channels (VRACs) Depend on C-terminal Residues of the First Extracellular Loop.
Canonical volume-regulated anion channels (VRACs) are crucial for cell volume regulation and have many other important roles, including tumor drug resistance and release of neurotransmitters. Although VRAC-mediated swelling-activated chloride currents (ICl,vol) have been studied for decades, exploration of the structure-function relationship of VRAC has become possible only after the recent discovery that VRACs are formed by differently composed heteromers of LRRC8 proteins. Inactivation of ICl,vol at positive potentials, a typical hallmark of VRACs, strongly varies between native cell types. Exploiting the large differences in inactivation between different LRRC8 heteromers, we now used chimeras assembled from isoforms LRRC8C and LRRC8E to uncover a highly conserved extracellular region preceding the second LRRC8 transmembrane domain as a major determinant of ICl,vol inactivation. Point mutations identified two amino acids (Lys-98 and Asp-100 in LRRC8A and equivalent residues in LRRC8C and -E), which upon charge reversal strongly altered the kinetics and voltage dependence of inactivation. Importantly, charge reversal at the first position also reduced the iodide > chloride permeability of ICl,vol This change in selectivity was stronger when both the obligatory LRRC8A subunit and the other co-expressed isoform (LRR8C or -E) carried such mutations. Hence, the C-terminal part of the first extracellular loop not only determines VRAC inactivation but might also participate in forming its outer pore. Inactivation of VRACs may involve a closure of the extracellular mouth of the permeation pathway.

AGE-DEPENDENT ROLE OF NMDA RECEPTORS IN EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

POSTER SESSION 05 - SECTION: NEUROINFLAMMATION AND AUTOIMMUNITY

Ivana Ćuruvija[1], Biljana Bufan[2], Emilija Đorović[3], Veljko Blagojević[1], Jelica Grujić-Milanović[4], Milica Marković[3], Jasmina Djuretić[3]
[1]Institute of Virology, Vaccines and Sera "Torlak", Immunology Research Centre "branislav Janković", Belgrade, Serbia, [2]University of Belgrade - Faculty of Pharmacy, Department Of Microbiology And Immunology, Belgrade, Serbia, [3]University of Belgrade - Faculty of Pharmacy, Department Of Pathobiology, Belgrade, Serbia, [4]Institute for Medical Research, National Institute of Republic of Serbia, Department For Cardiovascular Research, Laboratory For Experimental Hypertension, Belgrade, Serbia

Aims Ageing affects *N*-methyl-D-aspartate receptors (NMDARs), their expression and function in neuronal and non-neuronal cells. Contribution of NMDARs to pathogenesis of experimental autoimmune encephalomyelitis (EAE) has been investigated but further study is still needed. The aim of this study was to determine whether ageing affects the role of NMDARs in EAE. Methods Memantine, a non-competitive NMDAR antagonist which limits pathological activity of NMDARs while sparing normal synaptic activity, was administered orally from day 7 after immunization to 3- and 24-month-old female Dark Agouti rats. The animals were sacrificed at the peak of the disease. Spinal cord mononuclear cells were analyzed by flow cytometry. Brain tissue was collected for biochemical analysis of redox status and RT-qPCR. Results Semiprophylactic administration of memantine ameliorated clinical disease course, with greater effect in aged rats. Memantine reduced the number, frequency, and reactivation of CD4+ T lymphocytes and increased the relative percentage of CX3CR1-expressing microglia in spinal cord, but to a greater extent in aged rats. Additionally, analysis of brain redox status parameters showed that memantine was more effective in reducing superoxide anion radical, malondialdehyde and advanced oxidation protein products in aged rats than in young ones. In accordance with previous findings, NMDAR inhibition by memantine decreased NADPH oxidase and IL-1β expression and increased the nuclear factor erythroid 2-related factor 2 and heme oxygenase-1 expression, to a greater extent in aged rats. Conclusions The involvement of NMDARs in the pathogenesis of EAE was age-dependent, being more pronounced in aged than in young rats.

Exercise is reported to induce neuroplasticity and to modulate immune response. Both effects may be involved in the benefits of exercise for people with Multiple Sclerosis (MS), a neuroinflammatory disorder characterized by accumulating motor disability. An inflammatory synaptopathy has been shown to contribute to excitotoxicity and neurodegeneration in MS and in mice with experimental autoimmune encephalomyelitis (EAE), animal model of MS. We investigated the effects of preventive voluntary running wheel (exercise) on motor function and EAE-induced alterations of the glutamatergic transmission in the striatum, a subcortical area involved in motor control, by performing behavioral tests, electrophysiology, and biochemical studies. Compared to sedentary-EAE mice, exercise-EAE mice showed reduced clinical deficits and performed better at Rotarod test and grip strength test, suggesting improved motor coordination and neuromuscular function. Exercise prevented myelin loss in spinal cord lysates, consistently with the reduced neurological symptoms. On reverse, in the striatum exercise did not significantly ameliorate demyelination but attenuated both microglia activation and glutamatergic excitotoxicity with a specific effect on the presynaptic compartment. Indeed, the frequency of the spontaneous excitatory postsynaptic events (sEPSCs) was normalized in the EAE-exercise striatum, while the sEPSC kinetics were unaffected. The two main vesicular glutamate transporters (VGLUT-1 and VGLUT-2) that regulate glutamate load into presynaptic vesicles were increased in EAE-striatal protein lysates, but only VGLUT-1 was reduced by exercise. These data suggest that exercise attenuates microglia activation and limits glutamate excitotoxicity in the striatum of EAE mice, by modulating the glutamate release at cortico-striatal synapses, likely contributing to improved motor performance.

ACTIVATION OF COMPLEMENT C3 IN THE COURSE OF RAT EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

POSTER SESSION 05 - SECTION: NEUROINFLAMMATION AND AUTOIMMUNITY

Sungmoo Hong[1], Taekyun Shin[2]
[1]Jeju National University, Department Of Veterinary Medicine, Jeju, Korea, Republic of, [2]College of Veterinary Medicine, Jeju National Univeristy, Department Of Veterinary Medicine, Jeju, Korea, Republic of

Experimental autoimmune encephalomyelitis (EAE) is an animal model for the human demyelinating disease of the central nervous system, such as multiple sclerosis (MS). It is characterized by the infiltration of autoimmune T cells, activation of microglia and astrocytes, and chronic demyelination. It has recently been reported that complement system genes, including complement component C3, are overexpressed in various neuroinflammatory diseases, with complement C3 occasionally being regarded as a marker for toxic astrocytes. The study aims to localize complement C3 in the course of rat EAE immunohistochemically. Complement C3 was found in some glial cells and neurons in control spinal cords. In EAE, increased immunoreactivity of complement C3 was recognized in reactive astrocytes, but not in Iba-1-positive cells in the spinal cord during the peak and recovery stages of EAE. Collectively, this finding suggests that complement C3 from astrocytes activates microglia and macrophages in demyelinating lesions of EAE, resulting in chronic demyelination.

Work over the last decade demonstrates that the myelin sheaths enwrapping axons, classically seen as static insulators, are highly dynamic and respond to axonal activity and experience. This phenomenon, called “myelin plasticity”, goes beyond postnatal stages into adulthood and plays key roles in remodeling neuronal circuits to support adaptive behavior or functional recovery upon injury. Here we show that NMDA receptors containing GluN3A subunits (GluN3A-NMDARs) are expressed by oligodendrocyte progenitor cells (OPCs) and required for activity-dependent myelin plasticity. Specifically, we find that genetic removal of GluN3A from young brains accelerates the differentiation of OPCs into oligodendrocytes (OLs) in a variety of brain areas, yielding an upregulation of multiple markers of OL differentiation and myelination that resembles gene expression programs typical of aged OPCs. Functional assays in conditional, OPC-restricted *Grin3a* knockouts further showed that OPCs-lacking GluN3A fail to differentiate in response to chemo-genetic stimulation of callosal axons, and exhibit altered proliferation and differentiation responses to white matter injury. Our study opens an opportunity to develop strategies to re-express GluN3A and boost myelin plasticity that declines during aging and neurodegenerative diseases.

CDKL5 deficiency disorder (CDD) is a rare neurodevelopmental condition without a cure caused by mutations in cyclin-dependent kinase-like 5 (*CDKL5*) gene and characterized by early-onset epilepsy, severe cognitive dysfunctions, sensorimotor and intellectual disabilities. CDKL5 is a serine/threonine kinase that is expressed early during postnatal development in neurons where it phosphorylates epigenetic factors, elements of both axonal and dendritic compartment and microtubule associated proteins (MAP1S, EB2) which are crucial in nucleation and assembly of microtubules. Along with neurons, CDKL5 is also expressed in oligodendroglia, underlying myelination process. Although growing evidence indicates that the organization of myelin sheath is severely compromised in autism spectrum disorders and other neurodevelopmental diseases, whether *CDKL5* mutation affects myelin is still unknown. We here evaluated both extent and developmental trajectory of myelination, and the expression of molecules modified by myelin deposition or axonal injury – i.e.: Myelin basic protein (MBP) and neurofilaments (NF)– in both young (PND15) and adult (PND56) *Cdkl5*-KO mice. This analysis showed reduction of both MBP and phospho-NFs expression in both S1 and V1 cortices of *Cdkl5*-KO mice. The g-ratio analysis of myelinated axons investigated by electron microscopy revealed that myelin sheath thickness is decreased in mutant mice. Finally, the density of mature oligodendrocytes was reduced in adult mutant mice whereas oligodendrocyte precursor cells were not affected. In conclusion, our data indicate that primary cortical areas in CDD animals exhibit a global reduction/distortion of myelination process and disclose a novel consequence of CDKL5 loss, likely of pivotal importance for CDD.

Microglia are corresponding macrophages of Central Nervous System with phagocytic activity; also involved in developmental stages, including neural differentiation. Depending on extracellular signals, microglia polarize into distinctive M1 and M2 phenotypes. The aim of the study is to determine the differential miRNA content of M1 and M2 microglia-derived exosomes, demonstrate exosome uptake and investigate the effects of M1 and M2 microglial exosome on neural differentiation. Assuming that effect of polarized microglia is mediated through miRNAs transported via exosomes; exosomes were isolated from polarized microglia and miRNA contents of exosomes were designated via qPCR panel. Statistically significant upregulation of 6 miRNAs and downregulation 9 miRNAs were determined in M1; while upregulation of 12 miRNAs and downregulation 13 miRNAs were determined in M2 phenotypes. To investigate the effect of exosomes *in vitro*, we used neural stem cells (NSCs) that were differentiated from CGR8 mouse embryonic-stem cells and microglial exosomes. NSCs were cultured with exosomes within 3D-culture that was used to mimic microenvironment within the brain. We visualized exosome uptake by NSCs. The effects of M1 and M2 exosomes on NSCs was investigated via qPCR and immunocytochemistry methods. An increasing trend in neural markers were determined via M2 exosome treatment. Additionally, treatment has been determined to increase neurite outgrowth of NSCs. The observation of altered neural differentiation through microglial exosomes is promising to highlight the pathogenesis of several inflammation-related disorders and will eventually provide a new approach in terms of diagnosis and treatment. This study is supported by TUBITAK (Project no: 218S527)

Inhibitory effects of sulforaphane on NLRP3 inflammasome activation.
SFN, a dietary phytochemical, is a significant member of isothiocyanates present in cruciferous vegetables at high levels in broccoli. It is a well-known activator of the Nrf2/ARE antioxidant pathway. Long since, the therapeutic effects of SFN have been widely studied in several different diseases. Other than the antioxidant effect, SFN also exhibits an anti-inflammatory effect through suppression of various mechanisms, including inflammasome activation. Considerably, SFN has been demonstrated to inhibit multiple inflammasomes, including NLRP3 inflammasome. NLRP3 inflammasome induces secretion of pro-inflammatory cytokines and promotes inflammatory cell death. The release of pro-inflammatory cytokines enhances the inflammatory response, in turn leading to tissue damage. These self-propelling inflammatory responses would need modulation with exogenous therapeutic agents to suppress them. SFN is a promising candidate molecule for the mitigation of NLRP3 inflammasome activation, which has been related to the pathogenesis of numerous disorders. In this review, we have provided fundamental knowledge about Sulforaphane, elaborated its characteristics, and evidentially focused on its mechanisms of action with regard to its anti-inflammatory, anti-oxidative, and neuroprotective features. Thereafter, we have summarized both in vitro and in vivo studies regarding SFN effect on NLRP3 inflammasome activation.

Microglial NLRP3 inflammasome activation in multiple sclerosis.
Multiple sclerosis (MS) is a chronic, autoimmune and neuroinflammatory disease of the central nervous system (CNS) mediated by autoreactive T cells directed against myelin antigens. Although the crucial role of adaptive immunity is well established in MS, the contribution of innate immunity has only recently been appreciated. Microglia are the main innate immune cells of the CNS. Similar to other myeloid cells, microglia recognize both exogenous and host-derived endogenous

danger signals through pattern recognition receptors (PRRs) localized on their cell surface such as Toll Like receptor 4, or in the cytosol such as NLRP3. The second one is the sensor protein of the multi-molecular NLRP3 inflammasome complex in activated microglia that promotes the maturation and secretion of proinflammatory cytokines, interleukin-1β and interleukin-18. Overactivation of microglia and aberrant activation of the NLRP3 inflammasome have been implicated in the pathogenesis of MS. Indeed, experimental data, together with post-mortem and clinical studies have revealed an increased expression of NLRP3 inflammasome complex elements in microglia and other immune cells. In this review, we focus on microglial NLRP3 inflammasome activation in MS. First, we overview the basic knowledge about MS, microglia and the NLRP3 inflammasome. Then, we summarize studies about microglial NLRP3 inflammasome activation in MS and its animal models. We also highlight experimental therapeutic approaches that target different steps of NLRP inflammasome activation. Finally, we discuss future research avenues and new methods in this rapidly evolving area.

Cannabinoids are known to modulate oligodendrogenesis and developmental CNS myelination. However, the cell-autonomous action of these compounds on oligodendroglial cells *in vivo*, and the molecular mechanisms underlying these effects have not yet been studied. Here, by using oligodendroglial precursor cell (OPC)-targeted genetic mouse models, we show that cannabinoid CB_1 receptors exert an essential role in modulating OPC differentiation at the critical periods of postnatal myelination. We found that selective genetic inactivation of CB_1 receptors in OPCs *in vivo* perturbs oligodendrogenesis and postnatal myelination by altering the RhoA/ROCK signaling pathway, leading to hypomyelination, and motor and cognitive alterations in young adult mice. Conversely, pharmacological CB_1 receptor activation, by inducing E3 ubiquitin ligase-dependent RhoA proteasomal degradation, promotes oligodendrocyte development and CNS myelination in OPCs, an effect that was not evident in OPC-specific CB_1 receptor-deficient mice. Moreover, pharmacological inactivation of ROCK *in vivo* overcame the defects in oligodendrogenesis and CNS myelination, and behavioral alterations found in OPC-specific CB_1 receptor-deficient mice. Overall, this study supports a cell-autonomous role for CB_1 receptors in modulating oligodendrogenesis *in vivo*, which may have a profound impact on the scientific knowledge and therapeutic manipulation of CNS myelination by cannabinoids.

Astrocytes represent major glial population contacting vasculature in CNS, however subpopulations of cells lining ventricular system may be attached to blood vessels too, including ependymal cells (EC) of spinal cord (SC). Immunofluorescent labelling of vimentin revealed that EC in SC of adult rat form basal processes, which are directed toward laminin positive vasculature surrounding the central canal lining. Role of ependymo-vascular connection is not clear yet and only little information is known about extracellular matrix termed fractone bulbs (FB), which develop in SC after birth. In this work we focused on identification of connections between EC, blood vessels and FB in SC using TEM and SBF-SEM. We identified that basal processes of EC form direct contacts to capillary basal lamina or may be attached to narrow extensions resembling to vascular fractones or stems, previously identified in rodent brain. Since no connections between FB and vasculature has been identified using SBF-SEM, we assume that FB are blood vessel independent structures. We observed that complexity of FB containing laminin vary from small to massively branched labyrinths located at interface between EC and neuropil. Electron-dense material was identified on inner membrane of EC contacting FB, with small vesicles present in EC cytoplasm. We also identified vesicles separating from FB indicating potential transport of molecules between these compartments. Our approaches proved that EC of SC contact vasculature, and that FB are organized in SC similarly as was observed in rodent brain. Keywords: fractone bulbs, ependymal cells, vasculature, spinal cord Acknowledgement: Czech-Bioimaging LM2018129, VEGA1/0760/20, APVV-19-0279

After demyelinating injury of the central nervous system, resolution of the mounting acute inflammation is crucial for the initiation of a regenerative response. Here, we aim to identify fatty acids and lipid mediators that govern the balance of inflammatory reactions within demyelinating lesions. Using lipidomics, we identify bioactive lipids in the resolution phase of inflammation with markedly elevated levels of n-3 polyunsaturated fatty acids. Using fat-1 transgenic mice, which convert n-6 fatty acids to n-3 fatty acids, we find that reduction of the n-6/n-3 ratio decreases the phagocytic infiltrate. In addition, we observe accelerated decline of microglia/macrophages and enhanced generation of oligodendrocytes in aged mice when n-3 fatty acids are shuttled to the brain. Thus, n-3 fatty acids enhance lesion recovery and may, therefore, provide the basis for pro-regenerative medicines of demyelinating diseases in the central nervous system.

INJURY-INDUCED UPREGULATION OF FIBRONECTIN AND BMP4 MODULATES THE DIFFERENTIATION OF OLIGODENDROCYTE PROGENITOR CELLS INTO SCHWANN CELLS

POSTER SESSION 05 - SECTION: GLIAL CELLS AND MYELINATION

Civia Chen[1], Björn Neumann[2], Chao Zhao[2], Myfanwy Hill[2], Juan Cubillos[2], Natalia Murphy[2], Robin Franklin[2]
[1]University of Cambridge, Stem Cell Institute, Cambridge, United Kingdom, [2]University of Cambridge, Stem Cell Institute, CAMBRIDGE, United Kingdom

Background: Under homeostatic conditions, axons of the CNS are myelinated by oligodendrocytes. However, in response to demyelinating insults, Schwann cells (SCs), the myelinating glia of the PNS can contribute to CNS remyelination. Although CNS SCs can migrate into the CNS from peripheral sources, lineage tracing studies demonstrated that adult CNS progenitors can also produce SCs *in vivo.* This OPC fate switch is surprising given the early phylogenetic and ontogenetic divergence of the peripheral and central components of the nervous system. **Aims:** We aimed to determine the mechanisms OPCs reprogram towards a SC fate. **Results:** Using single-cell RNA-sequencing we identified a subpopulation of OPCs within experimental demyelinating lesions that co-express SC markers 5 days after injury. Within this SC-primed OPC cluster, differential gene analysis revealed a significant upregulation of genes involved with integrin signalling and bone morphogenetic protein (BMP) activation. We found that OPCs can be differentiated *in vitro* into SCs by exposing OPCs to fibronectin and BMP4, or by directly modulating the expression levels of *OLIG2* and *SOX10*. OPC-derived SCs transcriptionally resemble primary SCs, and when transplanted into the CNS can survive and myelinate host CNS axons with peripheral type myelin. **Conclusions:** These findings show that injury-related changes in the environment can destabilise oligodendroglial transcription factor networks, which enable alternative OPC fate choices. Together, this study reveals insight into the mechanisms underlying OPC cell fate decisions during CNS remyelination.

Schwann cell remyelination of the central nervous system: why does it happen and what are the benefits?
Myelin sheaths, by supporting axonal integrity and allowing rapid saltatory impulse conduction, are of fundamental importance for neuronal function. In response to demyelinating injuries in the central nervous system (CNS), oligodendrocyte progenitor cells (OPCs) migrate to the lesion area, proliferate and differentiate into new oligodendrocytes that make new myelin sheaths. This process is termed remyelination. Under specific conditions, demyelinated axons in the CNS can also be remyelinated by Schwann cells (SCs), the myelinating cell of the peripheral nervous system. OPCs can be a major source of these CNS-resident SCs-a surprising finding given the distinct embryonic origins, and physiological compartmentalization of the peripheral and central nervous system. Although the mechanisms and cues governing OPC-to-SC differentiation remain largely undiscovered, it might nevertheless be an attractive target for promoting endogenous remyelination. This article will (i) review current knowledge on the origins of SCs in the CNS, with a particular focus on OPC to SC differentiation, (ii) discuss the necessary criteria for SC myelination in the CNS and (iii) highlight the potential of using SCs for myelin regeneration in the CNS.

IMMUNOCOMPETENT CEREBRAL SPHEROIDS AS A MODEL SYSTEM TO EVALUATE DRUG-MEDIATED DEMYELINATION AND TO STUDY REMYELINATION

POSTER SESSION 05 - SECTION: GLIAL CELLS AND MYELINATION

Simona Lange[1], Jan Hoeber[1,2], Stefan Kustermann[1]
[1]F. Hoffmann-La Roche Ltd, Investigative And Immuno Safety - Neuroscience, Pharmaceutical Sciences, Pharmaceutical Research And Early Development, Roche Innovation Center Basel, Basel, Switzerland, [2]Roche Innovation Center Basel, Roche Institute For Translational Bioengineering, Basel, Germany

In the central nervous system (CNS), oligodendrocytes generate an axon wrapping lipid-rich substance known as myelin. Under certain inflammatory conditions such as Multiple Sclerosis or as a consequence of toxic drug side effects, myelin and/or oligodendrocytes may be destroyed in a process called demyelination.
Potential myelin and/or oligodendrocyte toxicity of new drugs as well as experimental demyelination and myelin repair are mainly evaluated using animal experiments. Due to species differences and the experimental setup these results can often not be translated to humans. The formation of proper myelin sheaths in 2D in vitro culture systems remains a challenge. Moreover, certain aspects such as indirect effects mediated by other CNS resident cell types may not be considered.
Being able to predict side effects of new drugs causing demyelination or neurotoxicity, or to evaluate compounds promoting remyelination in a human 3D in vitro system would not only facilitate safety assessments omitting interspecies differences, but also support efficacy assessment of novel compounds.
Here we show the generation of human iPSC-derived immunocompetent cerebral spheroids consisting of neurons, astrocytes, myelinating oligodendrocytes and microglia. Our data suggest that upon toxin-induced demyelination, the volume of myelin sheaths is decreased, but can efficiently be restored during remyelination and even enhanced by myelination promoting compounds.
These human immunocompetent cerebral spheroids show a high degree of physiological relevance as a tool for safety and efficacy assessment of new drugs. Furthermore, they may serve as a basis for the development of human disease models.

[1]Institut de Psychiatrie et Neurosciences de Paris, Umr 1266 Inserm, Paris, France, [2]Inovarion, Sas, PARIS, France

GABAergic inhibitory interneurons have a prominent role in the activity of cortical networks. They act as important regulators of the excitatory output and confer dynamic modulation to neuronal circuits and information processing. Moreover, we previously showed that parvalbumin (PV)-expressing interneurons, the largest proportion of GABAergic neurons of the cerebral cortex, represent the major synaptic input onto oligodendrocyte precursor cells (OPCs) during postnatal development (Orduz et al., 2015 & 2019).
Interestingly, the study of PV interneuron myelination did not attract attention until recently. Using a NG2creERT2;Gcamp3;γ2 (γ2f/f) mice line, we recently demonstrated that disruption of PV interneuron-OPC GABAergic synapses prior to myelination onset resulted in severe PV interneuron myelination defects, impacting inhibitory circuits of the somatosensory cortex as well as whisker-based texture discrimination behavior (Benamer et al., 2020).
Here, we hypothesize that PV interneuron myelination defects impair the function of the medial prefrontal cortex (mPFC), an area implicated in diverse neurodevelopmental disorders. We used a fear conditioning task and found that γ2f/f mice presented extinction retrieval deficits. Since the infralimbic (IL) region has been involved in this process, we evaluated the excitation-inhibition (E-I) balance of its layers 2/3 pyramidal neurons by recording postsynaptic currents in acute brain slices. We found a significant imbalance of the E-I ratio caused by a decreased inhibition. However, no changes in either cell density or distribution of IL PV interneurons were observed.
Taken together, our results show that early postnatal disruption of PV interneuron-OPC synaptic interactions causes deficits in cortical inhibitory circuit function and cognitive processes.

Differentiation of oligodendrocyte precursor cells (OPCs) into mature oligodendrocytes (OLs) is a key event for axonal myelination in the brain; this process fails during demyelinating pathologies, such as multiple sclerosis (MS). Adenosine is emerging as an important player in oligodendrogliogenesis, by activating its metabotropic receptors and by consequently modulating potassium currents. Moreover, 4-aminopyridine (4-AP), a broad-spectrum potassium channel blocker, can promote axonal conduction and remyelination and it was approved to improve motor skills in MS patients. **Aim:** We studied the functional role of A_{2B}Rs in modulating potassium currents and oligodendrogliogenesis in cultured OPCs and during myelination in dorsal root ganglion (DRG) neurons/OPC co-culture. **Methods:** Patch-clamp recordings coupled to quantitative Real-Time PCR, small-interference RNA techniques, and immunocytochemistry were used. **Results:** BAY60-6583 (1-30 µM), a selective A_{2B}R agonist, inhibited potassium currents in rat OPCs and reduced their differentiation, reported as the decrease in MBP/MAG gene expression. The A_{2B}R silencing or selective A_{2B}Rs antagonists prevented the BAY60-6583 effect on potassium currents and promoted OPC differentiation. Surprisingly, BAY60-6583 increased myelin deposition on DRG axons co-cultured with OPC and enhanced action potential firing in primary DRG culture. **Conclusions:** Our data show that A_{2B}R activation prevents OPC differentiation, by inhibiting potassium currents. However, in OPC-DRG co-cultures A_{2B}Rs increase myelin deposition, probably by enhancing action potential firing in DRG neurons. These results suggest that activation of A_{2B}Rs modulates different functions in oligodendrogliogenesis, depending on their cellular localization, and may represent a valuable target in demyelinating pathologies such as MS.

Ion Channels as New Attractive Targets to Improve Re-Myelination Processes in the Brain.
Multiple sclerosis (MS) is the most demyelinating disease of the central nervous system (CNS) characterized by neuroinflammation. Oligodendrocyte progenitor cells (OPCs) are cycling cells in the developing and adult CNS that, under demyelinating conditions, migrate to the site of lesions and differentiate into mature oligodendrocytes to remyelinate damaged axons. However, this process fails during disease chronicization due to impaired OPC differentiation. Moreover, OPCs are crucial players in neuro-glial communication as they receive synaptic inputs from neurons and express ion channels and neurotransmitter/neuromodulator receptors that control their maturation. Ion channels are recognized as attractive therapeutic targets, and indeed ligand-gated and voltage-gated channels can both be found among the top five pharmaceutical target groups of FDA-approved agents. Their modulation ameliorates some of the symptoms of MS and improves the outcome of related animal models. However, the exact mechanism of action of ion-channel targeting compounds is often still unclear due to the wide expression of these channels on neurons, glia, and infiltrating immune cells. The present review summarizes recent findings in the field to get further insights into physio-pathophysiological processes and possible therapeutic mechanisms of drug actions.

Oligodendrocyte precursor cell maturation: role of adenosine receptors.
Oligodendrocyte-formed myelin sheaths allow fast synaptic transmission in the brain and their degeneration leads to demyelinating diseases such as multiple sclerosis. Remyelination requires the differentiation of oligodendrocyte progenitor cells into mature oligodendrocytes but, in chronic neurodegenerative disorders, remyelination fails due to adverse environment. Therefore, a strategy to prompt oligodendrocyte progenitor cell differentiation towards myelinating oligodendrocytes is required. The neuromodulator adenosine, and its receptors (A, A, A and A receptors: AR, AR, AR and

AR), are crucial mediators in remyelination processes. It is known that ARs facilitate oligodendrocyte progenitor cell maturation and migration whereas the ARs initiates apoptosis in oligodendrocyte progenitor cells. Our group of research contributed to the field by demonstrating that AR and AR inhibit oligodendrocyte progenitor cell maturation by reducing voltage-dependent K currents necessary for cell differentiation. The present review summarizes the possible role of adenosine receptor ligands as potential therapeutic targets in demyelinating pathologies such as multiple sclerosis.

Adenosine A receptors inhibit K currents and cell differentiation in cultured oligodendrocyte precursor cells and modulate sphingosine-1-phosphate signaling pathway.
Oligodendrocytes are the only myelinating cells in the brain and differentiate from their progenitors (OPCs) throughout adult life. However, this process fails in demyelinating pathologies. Adenosine is emerging as an important player in OPC differentiation and we recently demonstrated that adenosine A receptors inhibit cell maturation by reducing voltage-dependent K currents. No data are available to date about the A receptor (AR) subtype. The bioactive lipid mediator sphingosine-1-phosphate (S1P) and its receptors (S1P) are also crucial modulators of OPC development. An interaction between this pathway and the AR is reported in peripheral cells. We studied the role of ARs in modulating K currents and cell differentiation in OPC cultures and we investigated a possible interplay with S1P signaling. Our data indicate that the AR agonist BAY60-6583 and its new analogue P453 inhibit K currents in cultured OPC and the effect was prevented by the AR antagonist MRS1706, by K channel blockers and was differently modulated by the S1P analogue FTY720-P. An acute (10 min) exposure of OPCs to BAY60-6583 also increased the phosphorylated form of sphingosine kinase 1 (SphK1). A chronic (7 days) treatment with the same agonist decreased OPC differentiation whereas SphK1/2 inhibition exerted the opposite effect. Furthermore, AR was overexpressed during OPC differentiation, an effect prevented by the pan SphK1/2 inhibitor VPC69047. Finally, AR silenced cells showed increased cell maturation, decreased SphK1 expression and enhanced S1P lyase levels. We conclude that ARs inhibit K currents and cell differentiation and positively modulate S1P synthesis in cultured OPCs.

The Selective Antagonism of Adenosine A Receptors Reduces the Synaptic Failure and Neuronal Death Induced by Oxygen and Glucose Deprivation in Rat CA1 Hippocampus .
Ischemia is a multifactorial pathology characterized by different events evolving in time. Immediately after the ischemic insult, primary brain damage is due to the massive increase of extracellular glutamate. Adenosine in the brain increases dramatically during ischemia in concentrations able to stimulate all its receptors, A, A, A, and A. Although adenosine exerts clear neuroprotective effects through A receptors during ischemia, the use of selective A receptor agonists is hampered by their undesirable peripheral side effects. So far, no evidence is available on the involvement of adenosine A receptors in cerebral ischemia. This study explored the role of adenosine A receptors on synaptic and cellular responses during oxygen and glucose deprivation (OGD) in the CA1 region of rat hippocampus . We conducted extracellular recordings of CA1 field excitatory post-synaptic potentials (fEPSPs); the extent of damage on neurons and glia was assessed by immunohistochemistry. Seven min OGD induced anoxic depolarization (AD) in all hippocampal slices tested and completely abolished fEPSPs that did not recover after return to normoxic condition. Seven minutes OGD was applied in the presence of the selective adenosine A receptor antagonists MRS1754 (500 nM) or PSB603 (50 nM), separately administered 15 min before, during and 5 min after OGD. Both antagonists were able to prevent or delay the appearance of AD and to modify synaptic responses after OGD, allowing significant recovery of neurotransmission. Adenosine A receptor antagonism also counteracted the reduction of neuronal density in CA1 stratum pyramidale, decreased apoptosis at least up to 3 h after the end of OGD, and maintained activated mTOR levels similar to those of controls, thus sparing neurons from the degenerative effects caused by the simil-ischemic conditions. Astrocytes significantly proliferated in CA1 stratum radiatum already 3 h after the end of OGD, possibly due to increased glutamate release. Areceptor antagonism significantly prevented astrocyte modifications. Both A receptor antagonists did not protect CA1 neurons from the neurodegeneration induced by glutamate application, indicating that the antagonistic effect is upstream of glutamate release. The selective antagonists of the adenosine A receptor subtype may thus represent a new class of neuroprotective drugs in ischemia.

Adenosine A3 receptor activation inhibits pronociceptive N-type Ca2+ currents and cell excitability in dorsal root ganglion neurons.

Recently, studies have focused on the antihyperalgesic activity of the A3 adenosine receptor (A3AR) in several chronic pain models, but the cellular and molecular basis of this effect is still unknown. Here, we investigated the expression and functional effects of A3AR on the excitability of small- to medium-sized, capsaicin-sensitive, dorsal root ganglion (DRG) neurons isolated from 3- to 4-week-old rats. Real-time quantitative polymerase chain reaction experiments and immunofluorescence analysis revealed A3AR expression in DRG neurons. Patch-clamp experiments demonstrated that 2 distinct A3AR agonists, Cl-IB-MECA and the highly selective MRS5980, inhibited Ca-activated K (KCa) currents evoked by a voltage-ramp protocol. This effect was dependent on a reduction in Ca influx via N-type voltage-dependent Ca channels, as Cl-IB-MECA-induced inhibition was sensitive to the N-type blocker PD173212 but not to the L-type blocker, lacidipine. The endogenous agonist adenosine also reduced N-type Ca currents, and its effect was inhibited by 56% in the presence of A3AR antagonist MRS1523, demonstrating that the majority of adenosine's effect is mediated by this receptor subtype. Current-clamp recordings demonstrated that neuronal firing of rat DRG neurons was also significantly reduced by A3AR activation in a MRS1523-sensitive but PD173212-insensitive manner. Intracellular Ca measurements confirmed the inhibitory role of A3AR on DRG neuronal firing. We conclude that pain-relieving effects observed on A3AR activation could be mediated through N-type Ca channel block and action potential inhibition as independent mechanisms in isolated rat DRG neurons. These findings support A3AR-based therapy as a viable approach to alleviate pain in different pathologies.

Acetylcholine modulates K and Na currents in human basal forebrain cholinergic neuroblasts through an autocrine/paracrine mechanism.
The Nucleus Basalis of Meynert (NBM) is the main source of cholinergic neurons in the basal forebrain to be crucially involved in cognitive functions and whose degeneration correlates with cognitive decline in major degenerative pathologies as Alzheimer's and Parkinson's diseases. However, knowledge concerning NBM neurons derived from human brain is very limited to date. We recently characterized a primary culture of proliferating neuroblasts isolated from the human fetal NBM (hfNBM) as immature cholinergic neurons expressing the machinery to synthetize and release acetylcholine. Here we studied in detail electrophysiological features and cholinergic effects in this cell culture by patch-clamp recordings. Our data demonstrate that atropine-blocked muscarinic receptor activation by acetylcholine or carbachol enhanced I and reduced I currents by stimulating G -coupled M2 or phospholipase C-coupled M3 receptors, respectively. Inhibition of acetylcholine esterase activity by neostigmine unveiled a spontaneous acetylcholine release from hfNBM neuroblasts that might account for an autocrine/paracrine signaling during human brain development. Present data provide the first description of cholinergic effects in human NBM neurons and point to a role of acetylcholine as an autocrine/paracrine modulator of voltage-dependent channels. Our research could be of relevance in understanding the mechanisms of cholinergic system development and functions in the human brain, either in health or disease.

Functional characterization of a novel adenosine A receptor agonist on short-term plasticity and synaptic inhibition during oxygen and glucose deprivation in the rat CA1 hippocampus.
Adenosine is an endogenous neuromodulator exerting its biological functions via four receptor subtypes, A, A, A, and A. A receptors (ARs) are expressed at hippocampal level where they are known to inhibit paired pulse facilitation (PPF), whose reduction reflects an increase in presynaptic glutamate release. The effect of ARs on PPF is known to be sensitive not only to AR blockade but also to the AR antagonist DPCPX, indicating that it involves AR activation. In this study we provide the first functional characterization of the newly synthesized non-nucleoside like AR agonist P453, belonging to the amino-3,5-dicyanopyridine series. By extracellular electrophysiological recordings, we demonstrated that P453 mimicked the effect of the prototypical AR agonist BAY60-6583 in decreasing PPF at Schaffer collateral-CA1 synapses in rat acute hippocampal slices. This effect was prevented by two different AR antagonists, PSB603 and MRS1754, and by the AR antagonist DPCPX. We also investigated the functional role of AR during a 2 min of oxygen and glucose deprivation (OGD) insult, known to produce a reversible fEPSP inhibition due to adenosine AR activation. We found that P453 and BAY60-6583 significantly delayed the onset of fEPSP reduction induced by OGD and the effect was blocked by PSB603. We conclude that P453 is a functional AR agonist whose activation decreases PPF by increasing glutamate release at presynaptic terminals and delays AR-mediated fEPSP inhibition during a 2-minute OGD insult.

Adenosine A3 agonists reverse neuropathic pain via T cell-mediated production of IL-10.
The A3 adenosine receptor (A3AR) has emerged as a therapeutic target with A3AR agonists to tackle the global challenge of

neuropathic pain, and investigation into its mode of action is essential for ongoing clinical development. Immune cell A3ARs, and their activation during pathology, modulate cytokine release. Thus, the use of immune cells as a cellular substrate for the pharmacological action of A3AR agonists is enticing, but unknown. The present study discovered that Rag-KO mice lacking T and B cells, as compared with WT mice, are insensitive to the anti-allodynic effects of A3AR agonists. Similar findings were observed in interleukin-10 and interleukin-10 receptor knockout mice. Adoptive transfer of CD4+ T cells from WT mice infiltrated the dorsal root ganglion (DRG) and restored A3AR agonist-mediated anti-allodynia in Rag-KO mice. CD4+ T cells from Adora3-KO or Il10-KO mice did not. Transfer of CD4+ T cells from WT mice, but not Il10-KO mice, into Il10-KO mice or Adora3-KO mice fully reinstated the anti-allodynic effects of A3AR activation. Notably, A3AR agonism reduced DRG neuron excitability when cocultured with CD4+ T cells in an IL-10-dependent manner. A3AR action on CD4+ T cells infiltrated in the DRG decreased phosphorylation of GluN2B-containing N-methyl-D-aspartate receptors at Tyr1472, a modification associated with regulating neuronal hypersensitivity. Our findings establish that activation of A3AR on CD4+ T cells to release IL-10 is required and sufficient evidence for the use of A3AR agonists as therapeutics.

Dexpramipexole enhances hippocampal synaptic plasticity and memory in the rat.

Even though pharmacological approaches able to counteract age-dependent cognitive impairment have been highly investigated, drugs improving cognition and memory are still an unmet need. It has been hypothesized that sustaining energy dynamics within the aged hippocampus can boost memory storage by sustaining synaptic functioning and long term potentiation (LTP). Dexpramipexole (DEX) is the first-in-class compound able to sustain neuronal bioenergetics by interacting with mitochondrial F1Fo-ATP synthase. In the present study, for the first time we evaluated the effects of DEX on synaptic fatigue, LTP induction, learning and memory retention. We report that DEX improved LTP maintenance in CA1 neurons of acute hippocampal slices from aged but not young rats. However, we found no evidence that DEX counteracted two classic parameters of synaptic fatigue such as fEPSP reduction or the train area during the high frequency stimulation adopted to induce LTP. Interestingly, patch-clamp recordings in rat hippocampal neurons revealed that DEX dose-dependently inhibited (IC 814 nM) the I current, a rapidly-inactivating K current that negatively regulates neuronal excitability as well as cognition and memory processes. In keeping with this, DEX counteracted both scopolamine-induced spatial memory loss in rats challenged in Morris Water Maze test and memory retention in rats undergoing Novel Object Recognition. Overall, the present study discloses the ability of DEX to boost hippocampal synaptic plasticity, learning and memory. In light of the good safety profile of DEX in humans, our findings may have a realistic translational potential to treatment of cognitive disorders.

A Adenosine Receptors: When Outsiders May Become an Attractive Target to Treat Brain Ischemia or Demyelination.

Adenosine is a signaling molecule, which, by activating its receptors, acts as an important player after cerebral ischemia. Here, we review data in the literature describing AR-mediated effects in models of cerebral ischemia obtained in vivo by the occlusion of the middle cerebral artery (MCAo) or in vitro by oxygen-glucose deprivation (OGD) in hippocampal slices. Adenosine plays an apparently contradictory role in this receptor subtype depending on whether it is activated on neuro-glial cells or peripheral blood vessels and/or inflammatory cells after ischemia. Indeed, ARs participate in the early glutamate-mediated excitotoxicity responsible for neuronal and synaptic loss in the CA1 hippocampus. On the contrary, later after ischemia, the same receptors have a protective role in tissue damage and functional impairments, reducing inflammatory cell infiltration and neuroinflammation by central and/or peripheral mechanisms. Of note, demyelination following brain ischemia, or autoimmune neuroinflammatory reactions, are also profoundly affected by ARs since they are expressed by oligodendroglia where their activation inhibits cell maturation and expression of myelin-related proteins. In conclusion, data in the literature indicate the ARs as putative therapeutic targets for the still unmet treatment of stroke or demyelinating diseases.

MYELINATION OF PARVALBUMIN INTERNEURONS IS CRITICAL TO MAINTAIN HIGH-FREQUENCY FIRING AND SELF-INHIBITORY NEUROTRANSMISSION

POSTER SESSION 05 - SECTION: GLIAL CELLS AND MYELINATION

Sara Hijazi, María Pascual García, Yara Nabawi, Steven Kushner
Erasmus MC, Psychiatry, Rotterdam, Netherlands

Parvalbumin-expressing (PV) interneurons are GABAergic cells that are characterized by their distinct ability to fire at high frequencies, due to a remarkably short action potential (AP) duration and refractory period. These unique firing properties are dependent on a unique complement of sodium and potassium channels with a distinct subcellular localization. Recent studies have highlighted another interesting feature of PV neurons, revealing their extensive myelination throughout the brain. However, the precise function of myelination in PV neurons remains to be elucidated. Here we utilize the cuprizone model of demyelination to investigate how PV interneuron myelination might influence their neuronal physiology. Using whole-cell patch-clamp recordings to examine intrinsic properties of PV neurons, we find that demyelination induces clear alterations in PV neuron firing patterns. Specifically, we find that demyelination causes an increase of AP duration and impairment in the ability of PV interneuron to sustain high frequency firing. Voltage-clamp recordings from PV interneurons confirmed a decrease in Kv-specific current in cuprizone-treated mice compared to control mice. We also found a substantial impairment in PV interneuron self-inhibitory transmission, a feature implicated in temporally coordinating PV neurons during cortical network activity, as well as a significant decrease in the number of PV interneuron autaptic contacts after demyelination. Together, our data provide insight into the importance of PV interneuron myelination, especially in their unique ability to fire at high frequency.

MYELINATION CLUSTERS MITOCHONDRIA TO PARVALBUMIN INTERNEURON AXONAL DOMAINS

POSTER SESSION 05 - SECTION: GLIAL CELLS AND MYELINATION

Koen Kole[1], Bas Voesenek[1], Maria Brinia[2], Maarten Kole[1,3]
[1]Netherlands Institute for Neuroscience, Axonal Signaling Group, Amsterdam, Netherlands, [2]National Kapodistrian University of Athens, Medical School, Athens, Greece, [3]Utrecht University, Cell Biology, Neurobiology And Biophysics, Department Of Biology, Utrecht, Netherlands

Parvalbumin-expressing (PV^+) interneurons are critical for cortical rhythms and a diverse range of important cognitive functions. Recent findings show that PV^+ interneurons require myelination in the proximal axonal arbors to produce fast inhibition and in vivo gamma rhythms. Here, we examined whether PV^+ axon myelination has a role in the metabolic support of axons. To examine such a cell type-specific role of myelination we developed a Cre-dependent AAV methodology to fluorescently label mitochondria specifically in PV^+ interneurons, using the PV-Cre driver line. Detailed anatomical reconstructions of myelinated and unmyelinated PV^+ axonal branches revealed that mitochondria are clustered at higher densities in myelinated internodes compared to unmyelinated branches within the same axon (P = 0.03). Furthermore, after demyelination, using the oligodendrocyte-selective toxin cuprizone, the mitochondrial density in the proximal axonal branches was reduced by ~20% (0.25 vs. 0.19 mitochondria/µm, P = 0.01), and resembled the mitochondrial density in unmyelinated control axons (0.16 mitochondria/µm). Finally, to examine whether myelin affects mitochondrial function of Ca^{2+} buffering (mt-Ca^{2+}) we used two-photon imaging of action-potential evoked mt-Ca^{2+} responses revealing that mitochondria at branch points display robust Ca^{2+} buffering, which was significantly reduced in amplitude upon demyelination (P = 0.01). Together, these findings indicate that in PV^+ interneurons myelination locally increases the mitochondrial content and increases branch point Ca^{2+} buffering, which may serve to orchestrate the local energy demands of the fast-spiking PV^+ axons.

OPTIMIZATION OF MYELINATION AT MID-AGE: INTERACTION ANALYSIS BETWEEN GREY MATTER AND WHITE MATTER COMPARTMENTS.

POSTER SESSION 05 - SECTION: GLIAL CELLS AND MYELINATION

Pratik Purohit[1], Vikas Pareek[2], Prasun Roy[1]
[1]Indian Institute of Technology (BHU), School Of Biomedical Engineering, Varanasi, India, [2]National Brain Research Centre, National Neuroimaging Facility, Manesar, India

Equal first-authors: PP, VP. **INTRODUCTION:** Brain-networks span grey-matter and white-matter, where myelination enables fast transmission of action-potential. An optimum level of myelination is crucial for constancy of spatiotemporal-perception with aging. Using MR-relaxometry, MRI-DTI, and tissue-histology, we estimated myelination-levels and we probed whether grey-matter exuberance influences white-matter integrity. **METHODS:** We use myelin-stained histology of different ages (5-94 years) to estimate myelin-level using Quantitative-histological analysis. Furthermore, we find myelination-levels using transverse-relaxation rates from MR-relaxometry analysis (252 normal-subjects, age:19-82; relaxametric scanning from Arch Neurol, 60(3):393-398,2003). We formulated optimality equation to account for MR-relaxometry and histology findings. Moreover, we assessed grey-matter-exuberance (volume), vis-a-vis white matter integrity (diffusion-parameters), utilizing MRI-DTI scans of separate 177 normal-subjects (age:20-85). **RESULTS:** We find that maximum myelination occurs at 47.3 and 45.1 years using MR-relaxometry and tissue-histology analysis, respectively. For analyzing white-matter and grey-matter interaction around mid-age(~50years), three age-groups were considered: 50±10 years (mid-age), 20-40 years (young), 60-80 years (old). In Males: we found that grey-matter-volume is stable in earlier-age, and this is followed by white-matter integrity being stable in later-age (diffusivities: $p<10^{-3}$). Contrastingly in Females: grey-matter-volume declines in earlier-age, and this is followed by white-matter integrity being impeded in later-age (diffusivities: $p=0.02$). **CONCLUSION:** For perceptual constancy, neuronal signal-velocity, as reflected by myelination-level, should be high across lifespan. As per the optimality principle, peak myelination at mid-age maintains a basal-level throughout aging. Neural activation transmits from dendrite/soma (cortical grey matter), into myelinated axons (white matter), as an efferent process. MR-relaxometery/MRI-DTI findings attest to this grey-matter effect on white-matter.

Neurodevelopmental disorders, including learning disabilities, attention deficits and autism spectrum disorders, are a major public health problem. Endocrine disruptors are incriminated in the growing frequency of these pathologies. Indeed, by mimicking or blocking the effects of hormones, endocrine disruptors can have harmful consequences on brain development. Among the compounds of high concern is bisphenol A (BPA), a ubiquitous environmental pollutant which contaminates the organism mainly through ingestion of contaminated water and food. From conception and then during pregnancy and lactation, fetuses and infants are exposed to BPA from their mother through the placenta and then breast milk. One of the crucial steps of brain development is the establishment of myelin sheaths around axons. Thanks to their high lipid content, myelin sheaths improve the transmission of action potentials and ensure optimal functioning of the brain. We hypothesized that BPA could disrupt myelin sheaths formation in the brain during development. By administering BPA to mice during pregnancy and lactation, we studied the impact of this endocrine disruptor on myelination by analyzing myelin lipid composition in male and female offspring. Two doses of BPA were administered in drinking water, 4 and 40 $\mu g.kg^{-1}$, and lipidomic analysis was performed at three postnatal stages: P15, P30 and P60 by UHPLC-HRMS. Our results suggest that BPA impacts the lipid composition of myelin and that this impact depends on the gender. Ultimately, our study will provide a better understanding of deleterious effects of this pollutant on neurodevelopment.

Background A recent clinical study demonstrated that white matter lesions (WML) seen in cerebral small vessel disease (cSVD) patients correlated with decreased cerebral blood flow (CBF). We thus hypothesize that cerebral hypoperfusion causes local hypoxia affecting the function of oligodendrocyte precursor cells (OPC), leading to the development of WML. **Methods** Male C57BL6/J male mice (11-week-old) underwent bilateral carotid artery stenosis (BCAS, n=10) or Sham surgery (Sham, n=7). CBF was measured before (at baseline) and after surgery (d0 and d7). At d7, mice were injected with pimonidazole (60mg/kg, IP), a hypoxic probe, prior to sacrifice. Myelin content, and hypoxic cell and OPC density were quantified by immunohistochemistry. Primary mouse OPC were exposed to hypoxic (2% O_2) or normoxic culturing conditions (21% O_2) for 24h. RNA sequencing was performed (Novaseq Illumina), data normalized and differentially expressed genes (DEG) were identified using DEseq2 and enrichment analyses. **Results** CBF was significantly reduced in BCAS at d0 (14,6±5,3%, p=0.02), and at d7 (27,2±3,6%, p<0.0001) compared to baseline. No difference in myelin content was observed. Hypoxic cells and hypoxic OPC in the deep cortical region were increased in BCAS vs Sham (12,9±1,3 vs 7,8±1,1 cells/mm^2, p=0.01, 17,9±2,3% vs 7,9±3,9% cells/mm^2, p=0.04, respectfully). There was no difference in OPC densities. *In vitro*, hypoxia led to 417 DEG in primary OPC, with genes involved in cell migration, differentiation, and angiogenesis. **Conclusion** Cerebral hypoperfusion induced hypoxia in OPC. Signaling pathways involved in myelination and vascularity were regulated in hypoxic OPC in vitro. OPC-vessel signaling pathways are being studied to understand the origin of WML in cSVD.

A Systematic Review of WNT Signaling in Endothelial Cell Oligodendrocyte Interactions: Potential Relevance to Cerebral Small Vessel Disease.
Key pathological features of cerebral small vessel disease (cSVD) include impairment of the blood brain barrier (BBB) and the progression of white matter lesions (WMLs) amongst other structural lesions, leading to the clinical manifestations of cSVD. The function of endothelial cells (ECs) is of major importance to maintain a proper BBB. ECs interact with several cell types to provide structural and functional support to the brain. Oligodendrocytes (OLs) myelinate axons in the central nervous system and are crucial in sustaining the integrity of white matter. The interplay between ECs and OLs and their precursor cells (OPCs) has received limited attention yet seems of relevance for the study of BBB dysfunction and white matter injury in cSVD. Emerging evidence shows a crosstalk between ECs and OPCs/OLs, mediated by signaling through the Wingless and Int-1 (WNT)/β-catenin pathway. As the latter is involved in EC function (e.g., angiogenesis) and oligodendrogenesis, we reviewed the role of WNT/β-catenin signaling for both cell types and performed a systematic search to identify studies describing a WNT-mediated interplay between ECs and OPCs/OLs. Dysregulation of this interaction may limit remyelination of WMLs and render the BBB leaky, thereby initiating a vicious neuroinflammatory cycle. A better understanding of the role of this signaling pathway in EC-OL crosstalk is essential in understanding cSVD development.

CNS MYELINATION: A ROLE FOR AUTOPHAGIC FUNCTION

POSTER SESSION 05 - SECTION: GLIAL CELLS AND MYELINATION

(Macro)autophagy comprises a major lysosome-dependent degradation mechanism which engulfs, removes, and recycles unwanted cytoplasmic material, including damaged organelles and toxic protein aggregates. Although a few studies implicate autophagy in CNS demyelinating pathologies, its role, particularly in oligodendrocytes and CNS myelin, remains poorly studied. We will present data on the significance of macroautophagy in the central nervous system, focusing on oligodendrocytes and myelin homeostasis. To this end, we have used both *in vitro* and *in vivo* approaches. *In vitro*, both pharmacological and genetic inhibition of autophagy have revealed severe defects in myelin sheet formation, delayed maturation and altered cellular distribution of major myelin protein constituents. *In vivo*, we have utilized a new conditional mutant mouse line that we have generated, in which a core gene of autophagic machinery (*atg5*) is specifically ablated in the myelinating glial cells after tamoxifen administration (*plp-Cre^{ERT2}; atg5$^{fl/fl}$*). Biochemical and ultrastructural analysis of this mouse line has revealed differences in myelin protein levels as well as morphological alterations in conditional mutant animals compared to age-matched controls. In summary, our data support the novel principle that the progression of myelination in the CNS requires the involvement of a fully functional autophagic machinery. We acknowledge funding from the Hellenic Foundation for Research and Innovation (HFRI grant agreement 1676), the National Multiple Sclerosis Society (NMSS, pilot Research Grant), the Hellenic Society for Neuroscience (travel Award to attend FENS Forum Paris 2022), and from The Company of Biologists (Travelling Fellowship).

FUNCTIONAL ALTERATION OF MYELINATED GABAERGIC NEURONS IN THE HIPPOCAMPUS OF CONTACTIN2- AND 4.1B-DEFICIENT MICE

POSTER SESSION 05 - SECTION: GLIAL CELLS AND MYELINATION

Delphine Pinatel[1], Edouard Pearlstein[1], Giulia Bonetto[1], Valérie Crépel[1], Laurence Goutebroze[2], Domna Karagogeos[3], Catherine Faivre-Sarrailh[1]
[1]INSERM, Umr1249, Marseille cedex, France, [2]Institut du fer à moulin, Umr-s 1270 / Inserm / Sorbonne Université, Paris, France, [3]University of Crete Medical School and IMBB-FORTH, Po Box 1385, Heraklion, Greece

A substantial fraction of myelin, both in mouse and human neocortex and hippocampus, belongs to inhibitory neurons (Micheva et al., 2016; Stedehouder et al., 2017). The role of myelination for axonal conduction is well-established in projection neurons but little is known about its significance in GABAergic interneurons. Myelination is discontinuous along interneuron axons and the mechanisms controlling myelin patterning and segregation of ion channels at the nodes of Ranvier require further investigations. We showed that the Kv1 channels, in complex with the cell adhesion molecules Caspr2, Contactin2/TAG-1, ADAM22, and the scaffolding protein 4.1B, exhibit high expression along the GABAergic axons before myelination and their clustering at juxtaparanodes in cultured hippocampal neurons (Pinatel and Faivre-Sarrailh, 2021; Bonetto et al., 2019). We used Contactin2- and 4.1B-deficient mice expressing tdTomato in parvalbumin and somatostatin Lhx6-expressing cells, two major classes of myelinated GABAergic neurons. Strikingly, the 4.1B-deficient hippocampal inhibitory neurons display a strong alteration of juxtaparanodal Kv1 and nodal Nav channels associated with selective loss of myelin. Using whole-cell patch-clamp recordings on acute slices, we showed that the neuronal excitability of somatostatin interneurons localized in stratum oriens is reduced both in Contactin2- and 4.1B-deficient mice. Finally, we found that the spatial working memory is altered in *4.1B* KO mice using the Y-maze test. In conclusion, we showed that dysmyelination and misdistribution of ion channels at the nodes of Ranvier of Contactin2- and 4.1B-deficient interneurons may induce a network inhibitory/excitatory imbalance.

PROLACTIN RECEPTOR DEFICIENCY PROMOTES HYPOMYELINATION IN THE CORPUS CALLOSUM OF SUCKLING MICE

POSTER SESSION 05 - SECTION: GLIAL CELLS AND MYELINATION

Oligodendrocytes (OLs) are responsible for myelination in the central nervous system. OLs extend their cell membrane surrounding neuronal axons and forming myelin, which accelerates action potential conduction and allow the assembly of complex neural circuits. In this fundamental phenomenon, there is evidence suggesting a regulatory role for the hormone prolactin (PRL). In pregnant mice lacking an allele of the PRL receptor (Prlr), there is a lower rate of oligodendrocyte precursor cell proliferation and decreased myelin production. Moreover, systemic PRL treatment promotes myelin repair in a model of spinal cord demyelination. Here, we explored the effect of Prlr deficiency during the early postnatal stage, a critical window in CNS development, where neonates are exposed to high concentrations of PRL through maternal milk. Using Prlr null mice (Prlr-KO) at postnatal day 12 and their wild type pairs (Prlr-WT), we evaluated myelination by Black Gold II (BGII) staining, immunofluorescence against Myelin Basic Protein (MBP), volumetric evaluation and rt-qPCR. In corpus callosum (CC) of Prlr-KO mice, BGII staining revealed a hypomyelinating phenotype, volumetric analysis showed less volume in this area, and immunofluorescence showed less MBP expression compared to Prlr-WT mice. In agreement, evaluation of the CC mRNA expression of some myelin proteins, showed a significant reduction in the expression of Myelin Proteolipid Protein (PLP) and Myelin Oligodendrocyte Glycoprotein (MOG) in Prlr-KO compared to Prlr-WT mice. Taken together, these data indicates that the lack of Prlr activity leads to hypomyelination in CC and disfavors myelin sheath transcriptional elements.

TILING THE GLIAL NETWORK: HOW INTERNODAL LENGTH CHANGES DURING DEVELOPMENT.

POSTER SESSION 05 - SECTION: GLIAL CELLS AND MYELINATION

Alexandra Beaudry-Richard[1,2], Makenna Chapman[2], Nour Jabassini[2], Christian Cordano[2], Jonah Chan[2], Ari Green[2]

The pattern of myelin internodes plays a crucial role in determining the speed of conduction of electrical signals in the nervous system. Yet, we are still debating whether this process of patterning is stochastic or dynamically responds to extrinsic cues. This project characterizes internodal length during development to assess how it is tuned over time. We precisely quantify internodal length in the corpus callosum and the optic nerve using a novel mouse model of stochastically sparse labeled oligodendrocytes PLP-CreER^{T};STARS. Preliminary results from these experiments reveal that each oligodendrocyte has a wide variety of internodal lengths during early development (postnatal day [P]14): internodes (reported as median [min-max]) are 33 µm long [12 to 89 µm] in the corpus callosum of mice (N=3) and are skewed to shorter internodes (Skewness: 1.22). In the optic nerve, internodes measured at P18 were 77 µm long [51 to 144 µm], while at 7 months old (mo) internodes measured 120 µm long [50 to 192 µm]. We noted a shift in the distribution of internodal length between early (P18) and late (7mo) development: most internodes in the optic nerve at P18 were skewed to shorter internodes (Skewness = 0.74). However, internodes at 7mo adopted a Gaussian distribution (Skewness = 0.07). Further experiments to study the impact of extrinsic cues on internodal length are ongoing. These approaches will not only establish that myelination during development is a dynamic process, but will also provide a model for internodal length determination.

Methods to Assess Ocular Motor Dysfunction in Multiple Sclerosis.
: BACKGROUND:: Multiple sclerosis (MS) is an inflammatory disease of the central nervous system causing the immune-mediated demyelination of the brain, optic nerve, and spinal cord and resulting in ultimate axonal loss and permanent neurological disability. Ocular motor dysfunction is commonly observed in MS but can be frequently overlooked or underappreciated by nonspecialists. Therefore, detailed and quantitative assessment of eye movement function has significant potential for optimization of patient care, especially for clinicians interested in treating visual symptoms or tracking disease progression. METHODS:: A brief history of eye tracking technology followed by a contextualized review of the methods that can be used to assess ocular motor dysfunction in MS-including a discussion of each method's strengths and limitations. We discuss the rationale for interest in this area and describe new tools capable of tracking eye movements as a possible means of monitoring disease. RESULTS/CONCLUSIONS:: This overview should inform clinicians working with patients with MS of how ocular motor deficits can best be assessed and monitored in this population. It also provides a rationale for interest in this field with insights regarding which techniques should be used for studying which classes of eye movements and related dysfunction in the disease.

Preterm Birth and Neonatal Injuries: Importance of Interleukin-1 and Potential of Interleukin-1 Receptor Antagonists.
Preterm birth (PTB) is a leading cause of neonatal mortality and morbidity worldwide, and surviving infants are at increased risks of lifelong complications. PTB has been firmly linked to inflammation regardless of infection, specific aetiology or timing of birth. Deleterious inflammation is observed in maternal and fetal tissue, and correlates with the severity of perinatal complications. At present, PTB is treated with tocolytics as though it is exclusively a myometrial contractile disorder. These agents do not address underlying inflammatory processes and are thus vastly ineffective at improving neonatal outcomes. Of all inflammatory mediators, IL-1 is central to the pathophysiology of PTB and most adverse neonatal outcomes. We thus present herein a review of the various effects of IL-1 in utero, with a brief overview of its mechanism of action. We then discuss the potential of different IL-1-targeting agents based on pre-clinical testing in relevant models of PTB and neonatal inflammatory injuries.

Retinopathy of prematurity: inflammation, choroidal degeneration, and novel promising therapeutic strategies.
Retinopathy of prematurity (ROP) is an important cause of childhood blindness globally, and the incidence is rising. The disease is characterized by initial arrested retinal vascularization followed by neovascularization and ensuing retinal detachment causing permanent visual loss. Although neovascularization can be effectively treated via retinal laser ablation, it is unknown which children are at risk of entering this vision-threatening phase of the disease. Laser ablation may itself induce visual field deficits, and there is therefore a need to identify targets for novel and less destructive treatments of ROP. Inflammation is considered a key contributor to the pathogenesis of ROP. A large proportion of preterm infants with ROP will have residual visual loss linked to loss of photoreceptor (PR) and the integrity of the retinal pigment epithelium (RPE) in the macular region. Recent studies using animal models of ROP suggest that choroidal degeneration may be associated with a loss of integrity of the outer retina, a phenomenon so far largely undescribed in ROP pathogenesis. In this review, we highlight inflammatory and neuron-derived factors related to ROP progression, as well, potential targets for new treatment strategies. We also introduce choroidal degeneration as a significant cause of residual visual loss following ROP. We propose that ROP should no longer be considered an inner retinal vasculopathy only, but also a disease of choroidal degeneration affecting both retinal pigment epithelium and photoreceptor integrity.

Antenatal IL-1-dependent inflammation persists postnatally and causes retinal and sub-retinal vasculopathy in progeny.
Antenatal inflammation as seen with chorioamnionitis is harmful to foetal/neonatal organ development including to eyes. Although the major pro-inflammatory cytokine IL-1β participates in retinopathy induced by hyperoxia (a predisposing factor to retinopathy of prematurity), the specific role of antenatal IL-1β associated with preterm birth (PTB) in retinal vasculopathy (independent of hyperoxia) is unknown. Using a murine model of PTB induced with IL-1β injection in utero, we studied consequent retinal and choroidal vascular development; in this process we evaluated the efficacy of IL-1R antagonists. Eyes of foetuses exposed only to IL-1β displayed high levels of pro-inflammatory genes, and a persistent postnatal infiltration of inflammatory cells. This prolonged inflammatory response was associated with: (1) a marked delay in retinal vessel growth; (2) long-lasting thinning of the choroid; and (3) long-term morphological and functional alterations of the retina. Antenatal administration of IL-1R antagonists - 101.10 (a modulator of IL-1R) more so than Kineret (competitive IL-1R antagonist) - prevented all deleterious effects of inflammation. This study unveils a key role for IL-1β, a major mediator of chorioamnionitis, in causing sustained ocular inflammation and perinatal vascular eye injury, and highlights the efficacy of antenatal 101.10 to suppress deleterious inflammation.

Antenatal Suppression of IL-1 Protects against Inflammation-Induced Fetal Injury and Improves Neonatal and Developmental Outcomes in Mice.
Preterm birth (PTB) is commonly accompanied by in utero fetal inflammation, and existing tocolytic drugs do not target fetal inflammatory injury. Of the candidate proinflammatory mediators, IL-1 appears central and is sufficient to trigger fetal loss. Therefore, we elucidated the effects of antenatal IL-1 exposure on postnatal development and investigated two IL-1 receptor

antagonists, the competitive inhibitor anakinra (Kineret) and a potent noncompetitive inhibitor 101.10, for efficacy in blocking IL-1 actions. Antenatal exposure to IL-1β induced , , , , and expression in placenta and fetal membranes, and it elevated amniotic fluid IL-1β, IL-6, IL-8, and PGF, resulting in PTB and marked neonatal mortality. Surviving neonates had increased , , , , , , and expression in WBCs, elevated plasma levels of IL-1β, IL-6, and IL-8, increased IL-1β, IL-6, and IL-8 in fetal lung, intestine, and brain, and morphological abnormalities: e.g., disrupted lung alveolarization, atrophy of intestinal villus and colon-resident lymphoid follicle, and degeneration and atrophy of brain microvasculature with visual evoked potential anomalies. Late gestation treatment with 101.10 abolished these adverse outcomes, whereas Kineret exerted only modest effects and no benefit for gestation length, neonatal mortality, or placental inflammation. In a LPS-induced model of infection-associated PTB, 101.10 prevented PTB, neonatal mortality, and fetal brain inflammation. There was no substantive deviation in postnatal growth trajectory or adult body morphometry after antenatal 101.10 treatment. The results implicate IL-1 as an important driver of neonatal morbidity in PTB and identify 101.10 as a safe and effective candidate therapeutic.

Choroidal Involution Is Associated with a Progressive Degeneration of the Outer Retinal Function in a Model of Retinopathy of Prematurity: Early Role for IL-1β.

Retinopathy of prematurity (ROP), the most common cause of blindness in premature infants, has long been associated with inner retinal alterations. However, recent studies reveal outer retinal dysfunctions in patients formerly afflicted with ROP. We have recently demonstrated that choroidal involution occurs early in retinopathy. Herein, we investigated the mechanisms underlying the choroidal involution and its long-term impact on retinal function. An oxygen-induced retinopathy (OIR) model was used. In vitro and ex vivo assays were applied to evaluate cytotoxic effects of IL-1β on choroidal endothelium. Electroretinogram was used to evaluate visual function. We found that proinflammatory IL-1β was markedly increased in retinal pigment epithelium (RPE)/choroid and positively correlated with choroidal degeneration in the early stages of retinopathy. IL-1β was found to be cytotoxic to choroid in vitro, ex vivo, and in vivo. Long-term effects on choroidal involution included a hypoxic outer neuroretina, associated with a progressive loss of RPE and photoreceptors, and visual deterioration. Early inhibition of IL-1β receptor preserved choroid, decreased subretinal hypoxia, and prevented RPE/photoreceptor death, resulting in life-long improved visual function in IL-1 receptor antagonist-treated OIR animals. Together, these findings suggest a critical role for IL-1β-induced choroidal degeneration in outer retinal dysfunction. Neonatal therapy using IL-1 receptor antagonist preserves choroid and prevents protracted outer neuroretinal anomalies in OIR, suggesting IL-1β as a potential therapeutic target in ROP.

Uterotonic Neuromedin U Receptor 2 and Its Ligands Are Upregulated by Inflammation in Mice and Humans, and Elicit Preterm Birth.

Uterine labor requires the conversion of a quiescent (propregnancy) uterus into an activated (prolabor) uterus, with increased sensitivity to endogenous uterotonic molecules. This activation is induced by stressors, particularly inflammation in term and preterm labor. Neuromedin U (NmU) is a neuropeptide known for its uterocontractile effects in rodents. The objective of the study was to assess the expression and function of neuromedin U receptor 2 (NmU-R2) and its ligands NmU and the more potent neuromedin S (NmS) in gestational tissues, and the possible implication of inflammatory stressors in triggering this system. Our data show that NmU and NmS are uterotonic ex vivo in murine tissue, and they dose-dependently trigger labor by acting specifically via NmU-R2. Expression of NmU-R2, NmU, and NmS is detected in murine and human gestational tissues by immunoblot, and the expression of NmS in placenta and of NmU-R2 in uterus increases considerably with gestation age and labor, which is associated with amplified NmU-induced uterocontractile response in mice. NmU- and NmS-induced contraction is associated with increased NmU-R2-coupled Ca transients, and Akt and Erk activation in murine primary myometrial smooth muscle cells (mSMCs), which are potentiated with gestational age. NmU-R2 is upregulated in vitro in mSMCs and in vivo in uterus in response to proinflammatory interleukin 1beta (IL1beta), which is associated with increased NmU-induced uterocontractile response and Ca transients in murine and human mSMCs; additionally, placental NmS is markedly upregulated in vivo in response to IL1beta. In human placenta at term, immunohistological analysis revealed NmS expression primarily in cytotrophoblasts; furthermore, stimulation with lipopolysaccharide (LPS; Gram-negative endotoxin) markedly upregulates NmS expression in primary human cytotrophoblasts isolated from term placentas. Correspondingly, decidua of women with clinical signs of infection who delivered preterm display significantly higher expression of NmS compared with those without infection. Importantly, in vivo knockdown of NmU-R2 prevents LPS-triggered preterm birth in mice and the associated neonatal mortality. Altogether, our data suggest a critical role for NmU-R2 and its ligands NmU and NmS in preterm labor triggered by infection. We hereby identify NmU-R2 as a relevant target for preterm

birth.

ANIMAL MODELS FOR DIABETIC PERIPHERAL NEUROPATHIES

POSTER SESSION 05 - SECTION: GLIAL CELLS AND MYELINATION

Anastasia Tsingotjidou[1], Rony Kalman[2]
[1]Aristotle University of Thessaloniki, Faculty Of Veterinary Medicine, Thessaloniki, Greece, [2]Hebrew University, Biological And Biomedical Models, Jerusalem, Israel

Peripheral neuropathy is one of most common complications in diabetes (1). It occurs in almost half the population with the disease and leads to a poor quality of the patients' life. For this reason, numerous animal models have been developed mimicking the human ailment, with rodents being the main players. Among the murine models of diabetic neuropathy (2) are conventional, streptozotocin-induced, genetically modified and/or high-fat diet-fed mice models, nonobese diabetic (NOD), spontaneously induced Ins2 Akita model, and the leptin-deficient (ob/ob) mice models. Rat models, on the other hand include the streptozotocin-induced diabetic rat models, spontaneously diabetic WBN/Kob rat model, L-fucose-induced neuropathic rat model, the partial sciatic nerve ligated rat model, Otsuka Long-Evans Tokushima Fatty (OLETF) rat model, surgically-induced neuropathic model, and genetically modified Spontaneously Diabetic Torii (SDT) rat model. Chinese hamsters, sand rats are also used for the same purpose. Lastly, non-human primates, play a role into the investigation of the disease. In this review we will present the plethora of animal studies existing today and discuss their efficacy for human study since there are advantages, disadvantages and limitations between the different species and the genetic and nongenetic animal models addressing acute and chronic events leading to diabetic neuropathy. Charcot-Marie-Tooth (CMT) is a genetically and clinically heterogenous group of inherited neuropathies. CMT affects peripheral nerves and patients typically experience progressive weakness and atrophy of distal muscles. *ATP1A1* is one of the genes that has been recently associated with axonal and intermediate CMT. *ATP1A1* encodes for the α-1 subunit of the Na^+, K^+ ATPase, an integral membrane protein responsible for establishing the electrochemical gradients of Na^+ and K^+ ions across the plasma membrane. Mutations in distinct protein domains affect tissues with high ion transport activity resulting in renal hypomagnesemia, aldosterone-producing adenoma, or neurodevelopmental delay. Using whole exome sequencing, we identified a novel c.1799C>G (p.P600R) missense variant in a Cypriot demyelinating CMT patient with severe sensorineural hearing loss. Functional studies indicated significant reduction of mRNA and protein expression of *ATP1A1* in the patient. In addition, the *ATP1A1*$^{p.P600R}$ transfected HEK cells displayed significant decrease in cell viability, further supporting the pathogenicity of this candidate variant. Thus, we show that *ATP1A1* can cause demyelinating phenotype through loss of function mechanism in addition to previously reported axonal and intermediate phenotypes. Our results further confirm the causative role of *ATP1A1* in peripheral neuropathy and broaden the mutational and phenotypic spectrum of *ATP1A1*-CMT.

NEURODEVELOPMENTAL ORIGIN OF CORTICAL SATELLITE CELLS

POSTER SESSION 05 - SECTION: GLIAL CELLS AND MYELINATION

Edson Rodrigues[1], Laura Dumas[2], Jason Durand[2], Karine Loulier[2]
[1]NSERM, Université de Montpellier, Institut Des Neurosciences De Montpellier, Montpellier, France, [2]INSERM, Université de Montpellier, Institut Des Neurosciences De Montpellier, Montpellier, France

Cortical satellites cells (CSC) are poorly explored members of the oligodendrocyte lineage that play a role in the regulation of neuronal activity. In the mammalian cerebral cortex, they are found affixed to the soma of pyramidal neurons and to blood vessels, and imbalanced in human pathological brain tissue. As key features of their cellular identity and molecular regulators remain controversial, further characterization of CSC development is essential to gain more insight into their functions during cerebral cortex maturation in physiological and pathological contexts. To probe the developmental origin of CSC and their mode of colonization of the cortical parenchyma, we used the MAGIC Markers multicolor fate mapping strategy and tracked cortical progenitors and all their progeny in the developing mouse brain. Our results show that CSC are generated from cortical progenitor and arrive at their final location after the first postnatal week. The deep cortical layers are colonized first, followed by the upper layers two weeks later. Then, CSC continue to spread in the cortical layers, increasing in numbers until the adult stage. Crossing MAGIC Markers mice with specific inducible Cre transgenic mice allows us to further characterize the progenitors that generate CSC, while tracking over time this poorly studied cell population for which no dedicated marker has been identified so far. Overall, our work contributes to elucidate an enigmatic cell population of the mammalian cerebral cortex by shedding new light on their developmental origin and heterogeneity, which will help us better understand their involvement in neurodevelopmental disorders.

FUNCTIONAL ROLE OF SATELLITE OLIGODENDROCYTES IN NEOCORTICAL CIRCUITS

POSTER SESSION 05 - SECTION: GLIAL CELLS AND MYELINATION

Maddalena Balia[1], Fernando Sanchez-Roman Teran[1], Vanessa Rouglan[2], Alexandre Favereaux[2], Arne Battefeld[1]
[1]University of Bordeaux, UMR 5293, Institute Of Neurodegenerative Diseases, Bordeaux, France, [2]Interdisciplinary Institute for Neuroscience, University Of Bordeaux, Cnrs Umr5297, Bordeaux Cedex, France

Oligodendrocytes were considered as a homogeneous population for a long time, however these cells display clear anatomical and transcriptomic heterogeneity. In the somatosensory cortex, oligodendrocytes can be found in direct perisomatic contact with pyramidal neurons. Earlier work established that these satellite oligodendrocytes can detect action potentials and contribute to potassium buffering, therefore modulating the associated neuron's activity. This functional role of satellite oligodendrocytes lead us to hypothesize more complex inter-somatic interactions with their associated neurons, *i.e.* the existence of a direct metabolic coupling. Furthermore, we also hypothesized that satellite oligodendrocytes positioning and function correlates with distinct transcriptional features.
We determined whether (i) satellite oligodendrocytes are specific for distinct cortical neuron populations, (ii) a direct metabolic support of the associated neuron exists, and (iii) a specific transcriptomic profile is associated with this anatomical position of oligodendrocytes.
Using immunohistochemical labelling of murine cortex, we show that satellite oligodendrocytes represent around half of the cortical oligodendrocyte population in layers II to IV. To target different cortical layer V projection neurons, we used a retrograde tracing strategy and found that neurons with different projection targets associate similarly with satellite oligodendrocytes. Electrophysiological recordings of satellite oligodendrocytes and their associated neuron were used to determine the extent of direct metabolic coupling. Targeted whole-cell recordings combined with subsequent single-cell sequencing were used to analyse the transcriptomic profiles of satellite oligodendrocyte - associated neuron pairs. We provide an extended analysis of satellite oligodendrocytes and conclude these cells are an integral part of neocortical circuits.

GENERATION OF DIFFERENT OLIGODENDROCYTE LINEAGE CELL STATES FOLLOWING DIRECT LINEAGE REPROGRAMMING OF GFAP+ ASTROCYTES

POSTER SESSION 05 - SECTION: GLIAL CELLS AND MYELINATION

Justine Bajohr[1], Hiba Taha[1], Arman Olfat[1], Erica Scott[1,2], Kevin Lee[1], Daniela Lozano-Casasbuenas[1,3], Scott Yuzwa[3], Maryam Faiz[1]

Oligodendrocyte (OL) loss or dysfunction is a hallmark of many central nervous system (CNS) conditions. Direct lineage reprogramming (DLR) is a new strategy for CNS repair, where a donor cell is converted into a target cell without a pluripotent intermediate. Here we show that astrocytes can be directly reprogrammed to different OL lineage cells *in vitro* using transcription factors (TFs) involved in different stages of OL fate determination. Postnatal cortical astrocytes were purified and transduced with lentiviruses containing three different GFAP-driven TFs. We found that ectopic expression of each of these single TFs produced different types of OL lineage cells. Ectopic expression of a TF important for late OL development resulted in the generation of MBP+ myelinating OLs (mOLs), while expression of an early OL fate determinant generated PDGFRα+ oligodendrocyte progenitor cells (OPCs). Finally, expression of a third TF, expressed throughout OL development, produced cells at various stages of OL lineage development (OPCs, newly forming OLs (nfOLs) and mOLs). Live cell imaging of the reprogramming process confirmed that reprogrammed OLs originate from S100β expressing astrocytes. Finally, single cell RNA sequencing revealed different iOL gene signatures depending on TF delivered. These findings suggest that ectopic expression of TFs in astrocytes results in the generation of OLs at different stages of maturity. These studies lay the groundwork for novel, DLR-based therapeutic strategies for diseases involving OL lineage cell loss with possibilities to tailor iOL production according to the OL type lost in disease.

Direct Lineage Reprogramming in the CNS.
Direct lineage reprogramming is the conversion of one specialized cell type to another without the need for a pluripotent intermediate. To date, a wide variety of cell types have been successfully generated using direct reprogramming, both in vitro and in vivo. These newly converted cells have the potential to replace cells that are lost to disease and/or injury. In this chapter, we will focus on direct reprogramming in the central nervous system. We will review current progress in the field with regards to all the major neural cell types and explore how cellular heterogeneity, both in the starter cell and target cell population, may have implications for direct reprogramming. Finally, we will discuss new technologies that will improve our understanding of the reprogramming process and aid the development of more specific and efficient future CNS-based reprogramming strategies.

A POPULATION OF GREY MATTER OLIGODENDROCYTES ASSOCIATES DIRECTLY WITH THE VASCULATURE

POSTER SESSION 05 - SECTION: GLIAL CELLS AND MYELINATION

Arne Battefeld[1], Justine Palhol[1], Maddalena Balia[1], Fernando Sanchez-Roman Teran[1], Mélody Labarchède[1], Etienne Gontier[2]
[1]Univ. Bordeaux, Institut Des Maladies Neurodégénératives (imn), Umr 5293, Bordeaux, France, [2]Univ. Bordeaux, CNRS, INSERM, Bordeaux Imaging Center, Bic, Uar3420, Bordeaux, France

Oligodendrocyte lineage cells are known to interact with the vasculature in the grey matter. During cortical development oligodendrocyte precursor cells (OPCs) migrate along the vasculature and subsequently detach. Signaling from OPCs influences angiogenesis during early development and release of transforming growth factor ß-1 by OPCs plays a role in maintenance of the blood brain barrier. There is evidence that mature oligodendrocytes continue to interact with the vasculature as they have been occasionally noted being close to blood vessels. In addition, endothelial cell signaling influences activity dependent myelination and early multiple sclerosis lesions can occur around blood vessels. To date, a systematic investigation of oligodendrocyte-vasculature interaction is missing. We studied in an oligodendrocyte reporter mouse line the occurrence and interaction of mature oligodendrocytes with the vasculature in the grey matter using immunohistochemistry, electron microscopy volume imaging coupled with 2-photon branding, and whole-cell electrophysiology. We found that mature oligodendrocytes are regularly closely linked with blood vessels in various brain areas. Correlated light and electron microscopy revealed that parts of the oligodendrocyte cell body is in direct contact with the endothelial basement membrane similar to astrocytic endfeet. Systematic analysis across all neocortical layers showed an increase in vascular associated oligodendrocytes following the overall increase of oligodendrocytes towards deeper cortical layers. We conclude that the association of mature oligodendrocytes with the vasculature is a common feature of all oligodendrocyte lineage cells. Additionally, oligodendrocytes could directly take up metabolites from the vasculature and deterioration of this contact might contribute to the alterations of oligodendrocytes in pathologies.

OPTICALLY RESOLVED MEMBRANE VOLTAGE CHANGES IN MYELIN

POSTER SESSION 05 - SECTION: GLIAL CELLS AND MYELINATION

Mélody Labarchède, Arne Battefeld
Univ. Bordeaux, Institut Des Maladies Neurodégénératives (imn), Umr 5293, Bordeaux, France

A number of ion channels including several potassium and calcium channels have been proposed to be localised in the myelin sheath, but their contribution to myelin membrane voltage changes have not been explored. Investigating spatial dynamics of membrane potential changes could help to understand ion homeostasis of myelin under physiological or pathophysiological conditions. For instance, the potassium inward rectifying channel Kir4.1 has been shown to locate to the inner node and compact myelin where it contributes to potassium buffering during action potentials. Technical limitations of electrode-based voltage measurements do not allow direct recordings of voltage changes at the oligodendrocyte myelin sheath. Therefore, we implemented an imaging strategy to optically measure voltage changes in the myelin membrane in response to neuronal activity with the aim to identify ion channels underlying these responses. We achieved in vivo transfection of oligodendrocytes with an adeno-associated virus expressing the genetically encoded voltage sensor ASAP3 under an oligodendrocyte specific promoter. Five weeks after stereotaxic injection of the virus we prepared acute brain slices of the mouse somatosensory cortex. Using a LED illumination-based epifluorescence live imaging approach, single oligodendrocytes were imaged at 192 Hz during extracellular stimulation of axons at 100 Hz. We recorded voltage responses in control and in the presence of pharmacological blockers at the oligodendrocyte cell body and myelin sheath in wild type and Kir4.1 knock out mice. Our results show that optical measurements of myelin voltage can be a useful tool to study voltage and underlying conductance directly in myelin.

DEVELOPMENTAL OLIGODENDROGENESIS AND MYELINATION : REVISITING CANONICAL AND NON-CANONICAL SHH SIGNALING

POSTER SESSION 05 - SECTION: GLIAL CELLS AND MYELINATION

Adil El Mesaoudi, Abdelmoumen Kassoussi, Amina Zahaf, Elisabeth Traiffort
INSERM, U1195, Kremlin-Bicêtre, France

During development, Hedgehog morphogens orchestrate morphogenesis by controlling cell growth, differentiation and migration (Briscoe & Small, 2015). The canonical signaling occurs when Hedgehog proteins bind the transmembrane protein Patched (Ptc), which relieves the repressive activity exerted by Ptc on the key mediator Smoothened (Smo) and leads to a complex downstream signaling cascade involving the transcription factors of the Gli family (Kong et al, 2019). The pathway has been previously involved in the perinatal wave of oligodendrocyte production arising from the germinative zone of the dorsal forebrain (Tong et al, 2015 ; Samanta et al, 2015 ; Winkler et al, 2018) where the canonical pathway has to be first activated and then blocked in order to promote OPC proliferation and differentiation, respectively. However, Shh transcription is maintained at a quite unchanged level during the process of oligodendrogenesis and myelination suggesting that the proteins may still act during myelination by triggering a non canonical pathway. We are currently using specific antibodies in order to characterize the expression of the pathway components in cells other than the neural stem cells where Shh signaling has been identified until now. Our data suggest the expression of the pathway in cells different from the neural stem cells that we are currently characterizing. The maintenance of Shh signals together with the severe downregulation of the main readout of the canonical pathway may likely mask the activity of a non-canonical Shh signaling during developmental myelination.

Oligodendrocytes form myelin and enable the efficient transmission of axon electric impulses in the central nervous system. Dysfunctions of oligodendrocyte and myelin are paralleled by pathological hallmarks such as axonal swellings and reactive gliosis in multiple sclerosis and leukodystrophies. How these pathological side-effects of oligodendrocyte dysfunction arise, however, is incompletely understood. Here, we performed single-nuclei transcriptome sequencing (snRNA-seq) of the cortex and underlying white matter from knockout mouse models of the three most abundant myelin proteins (PLP1, MBP, CNP) that present with subtle oligodendrocyte dysfunctions. We recovered astonishingly distinct oligodendrocyte RNA profiles upon knockout of CNP, PLP1, and MBP. Cell manifold reconstruction, as well as integrative analysis with previously defined cell subpopulations, revealed that mutant oligodendrocytes are mostly trapped at specific intermediate cell states. The imbalanced oligodendrocyte subtype proportions in the mutant brain potentially shift the crosstalk between oligodendrocytes and other cell populations. Our data, therefore, provide a single-cell perspective on the early stages of oligodendrocyte dysfunction with relevance to neurological disorders that present with myelin defects.

GBA1 INACTIVATION IN OLIGODENDROCYTES AFFECTS MYELINATION AND INDUCES NEURODEGENERATION AND LIPID DYSHOMEOSTASIS IN MICE

POSTER SESSION 05 - SECTION: GLIAL CELLS AND MYELINATION

Loris Russo[1], Ilaria Gregorio[1], Pietro Barbacini[2], Dario Bizzotto[1], Paola Braghetta[1], Enrico Moro[1], Cecilia Gelfi[2], Matilde Cescon[1]

Aims: GBA1 (Glucocerebrosidase 1) mutations are recognized as risk factors for Parkinson's disease (PD). Whilst substantial knowledge is available regarding GBA1 in neurons, the role of glial GBA1 has been mostly overlooked in oligodendrocytes (OL). Nonetheless, white matter alterations have been described in GBA1-linked PD patients. Our aim was to study the relevance of GBA1 in OLs *in vitro* and *in vivo*. Methods: We used *in vitro* models in which GBA1 was inactivated either chemically or genetically to study cell-specific alterations in differentiation and signaling pathways. We generated an OL specific conditional knockout mouse for GBA1. We characterized myelination *in vivo* by quantifying the levels of myelin-related proteins and measuring g-ratio on electron microscopy pictures. Brain lipidic species were quantified by lipidomic analysis. Behavioral tests were also performed. Results: GBA1 inhibition delayed myelination *in vitro* and led to the accumulation of α-synuclein in the Olineu cell line. GBA1 inactivation also altered intracellular cholesterol distribution. Consistently, genetic inactivation of GBA1 in primary cultures altered the maturation of OLs and caused aberrant expression of OL lineage specific markers. *In vivo*, 6-months-old GBA1 deficient mice showed decreased myelin thickness in the striatum and optic nerve, together with axonal degeneration. Quantitative lipidomic analysis of brain extracts showed global anomalies in lipidic species. Gait alterations were detectable at 6 months of age. Conclusions: This is the first demonstration of a contribution from OL dysfunction to GBA1-related neurodegenerative disorders. We showed that GBA1 deficiency leads to defective myelination inducing neuronal degeneration and altered lipid homeostasis.

EFFECTS OF CRMP2 KNOCKOUT ON MYELINATION IN A SCHIZOPHRENIA MOUSE MODEL

POSTER SESSION 05 - SECTION: GLIAL CELLS AND MYELINATION

Katarzyna Grycel[1], Jens Midtgaard[2], Zhiheng Xu[3], Stine Hasselholt[4], Jens Nyengaard[1]
[1]Aarhus University, Institute Of Clinical Medicine, Aarhus N, Denmark, [2]University of Copenhagen, Motor Control, Copenhagen N, Denmark, [3]Chinese Academy of Sciences, Institute Of Genetics And Developmental Biology, Beijing, China, [4]Aarhus University, Clinical Medicine, Center For Functional Integrative Neuroscience, Aarhus C, Denmark

Aims: Myelination is essential to keep signal transduction and communication within the brain at an optimal level. There is evidence for impaired myelination in several neuropsychiatric disorders including Schizophrenia (SZ). This project centers around CNS demyelination as a component of SZ, using a Collapsin Response Mediator Protein 2 (CRMP2) conditional knock out mouse (cKO) model. The aims are to investigate myelin at a functional, structural and ultrastructural levels to elucidate which myelin parameters might be mostly affected. **Methods**: We investigated potential changes in **function** of the largest white matter structure in the brain, corpus callosum (CC), with multielectrode electrophysiology of compound action potentials (CAPs). At the **structural** level, we looked at the volume of CC and number of oligodendrocytes. We examined the **ultrastructure** with 3D axonal and myelin reconstructions of image stacks acquired by Serial Block Face Scanning Electron Microscopy, implementing an image-segmentation pipeline. Several parameters of Nodes of Ranvier (volume, length, and myelin thickness) were manually quantified. **Results:** We saw indication of altered CAP signals and a reduction in CC volume, but not in the number of oligodendrocytes . Preliminary ultrastructural results suggest changes in node of Ranvier structure in CRMP2-cKO animals. **Conclusions:** Together our findings indicate that CRMP2 plays a role in white matter function in a SZ model. The mechanisms by which this happens are still uncertain. Our project has implemented analytic methods to shed light on the role of myelin defects in SZ. The analyses-pipelines can be used in future work on genetic models of neuropsychiatric disorders.

EXPRESSION OF THE SCHIZOPHRENIA SUSCEPTIBILITY GENE FEZ1 IN THE EARLY FETAL HUMAN FOREBRAIN

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Maznah Alhesain[1], Hannah Ronan[1], Fiona Lebeau[2], Gavin Clowry[2]
[1]Newcastle university, Bioscience, Newcastle upon Tyne, United Kingdom, [2]Newcastle University, Biosciences Institute, Newcastle upon Tyne, United Kingdom

The protein fasciculation and elongation zeta-1 (FEZ1) has been shown to be involved in axon outgrowth but potentially interacts with various proteins whose roles range from intracellular transport systems to transcription regulation. Genome-wide association studies have identified it as a schizophrenia susceptibility gene. To test whether it may play a role in early brain development, we mapped *FEZ1* expression by region and cell type in the normally developing human forebrain. **Methods:** All tissues were collected with appropriate maternal consent and ethical approval by the Human Developmental Biology Resource (HDBR.org). RNAseq data was obtained from previously published sources. Thin paraffin sections 8-21 post-conceptional weeks (PCW) were used to perform RNAScope in situ hybridization and immunohistochemistry against FEZ1 mRNA and protein and other marker proteins, sometimes in combination. **Results:** Tissue RNAseq data revealed that FEZ1 is highly expressed in the human cerebral cortex between 7 and 17 PCW (top 5% of protein coding genes), and single cell RNAseq at 17-18 PCW confirmed its high expression, predominantly in maturing excitatory neurons. In the cerebral cortex, strong expression of mRNA and protein appeared confined to post-mitotic neurons although low expression was seen in progenitor zones. Protein expression was observed in axon tracts and the subplate at older stages. In the ganglionic eminences and diencephalon, the opposite was observed, with FEZ1 highly expressed in progenitor zones, but largely absent from post-mitotic cells. **Conclusion:** FEZ1 has different expression patterns and potentially diverse functions in discrete forebrain regions during prenatal human development.

Amyotrophic lateral sclerosis (ALS) is a fatal, progressive neurodegenerative disease characterized by the loss of upper and lower motor neurons (MNs). Most ALS cases are sporadic, with no familial history or known genetic association. Therefore, a large collection of sporadic ALS models is required to identify common underlying mechanisms of pathology or develop new therapeutic interventions. Induced pluripotent stem cells (iPSCs) are a valuable tool for disease modelling, drug screening and cell therapy, especially for sporadic cases as there is no animal model. But the shortages of deriving enriched and functional MNs from iPSCs hinder the utility of the iPSCs model. In combination with small molecules cocktail, we established a rapid, simple, and efficient protocol of spinal MN differentiation. $CHAT^+$ and $MAP2^+$ MNs (90% and 98%) can be derived in 18 days, and they are functionally mature as evidenced by firing strong single action potentials, typical calcium transients in 18 days. And they also showed extensive network firing and responded to the agonists and antagonists of glutamate receptors in 28 days. Using this new protocol, we observed hyperexcitation in MNs derived from sporadic ALS on MEA recording. Above all, a rapid, simple, and efficient spinal MNs differentiation protocol was established and applied to a model of ALS. This protocol enables the generation of large quantities of MN with high purity and maturity, which will provide a basis for modelling ALS and other MN diseases, drug screening and cell therapy.

Generation of twelve induced pluripotent stem cell lines from two healthy controls and two patients with sporadic amyotrophic lateral sclerosis.
The majority of amyotrophic lateral sclerosis are sporadic (sALS) with no familial history or known genetic association, therefore a large cohort of disease models are required to identify common mechanisms or to test therapeutic interventions. Here we generated twelve induced pluripotent stem cell (iPSC) lines from human dermal fibroblasts of two healthy individuals and two sALS patients lacking common ALS mutations, using non-integrational Sendai virus expressing reprogramming factors OCT3/4, KLF4, SOX2 and c-MYC. The iPSC lines highly expressed pluripotency markers could be spontaneously differentiated into three embryonic germ layers, with no gross chromosomal aberrations or specific copy number variations.
Stem Cell Res, 2020; 44
31514057: Yang M, Liu M, Vajda A, O'Brien T, Henshall D, Hardiman O, Shen S
Generation of six induced pluripotent stem cell (iPSC) lines from two patients with amyotrophic lateral sclerosis (NUIGi043-A, NUIGi043-B, NUIGi043-C, NUIGi044-A, NUIGi044-B, NUIGi044-C).
In this study, we generated 6 induced pluripotent stem cell (iPSC) lines derived from dermal fibroblasts of patients with sporadic amyotrophic lateral sclerosis (sALS). The fibroblasts were reprogrammed using non-integrating Sendai viruses containing four reprogramming factors OCT3/4, SOX2, KLF4 and C-MYC. The iPSC lines displayed normal molecular karyotype, expressed pluripotency markers and were capable of differentiating into three embryonic germ layers.
Stem Cell Res, 2019; 40
33631419: Ding Y, O'Brien A, Marcó de la Cruz B, Yang M, Lu Y, Qian X, Yang G, McInerney V, Krawczyk J, Lynch SA, Howard L, Allen NM, O'Brien T, Gallagher L, Shen S
Derivation of four iPSC lines from a male ASD patient carrying a deletion in the middle coding region of NRXN1α gene

(NUIGi039-A and NUIGi039-B) and a male sibling control (NUIGi040-A and NUIGi040-B).
NRXN1 deletions are commonly found in autism spectrum disorder (ASD) and other neurodevelopmental/neuropsychiatric disorders. Derivation of induced pluripotent stem cells (iPSCs) from different diseases involving different deletion regions are essential, as NRXN1 may produce thousands of splicing variants. We report here the derivation of iPSCs from a sibling control and an ASD proband carrying de novo heterozygous deletions in the middle region of NRXN1, using a non-integrating Sendai viral kit. The genotype and karyotype of the iPSCs were validated by whole genome SNP array. All iPSC lines highly expressed pluripotency markers and could be differentiated into three germ layers.
Stem Cell Res, 2021; 53
33578364: Ding Y, O'Brien A, de la Cruz BM, Yang M, Fitzgerald J, Yang G, Li W, McInerney V, Krawczyk J, Lynch SA, Howard L, Allen NM, O'Brien T, Gallagher L, Shen S
Derivation of iPSC lines from two patients with autism spectrum disorder carrying NRXN1α deletion (NUIGi041-A, NUIG041-B; NUIGi045-A) and one sibling control (NUIGi042-A, NUIGi042-B).
NRXN1 encodes thousands of splicing variants categorized into long NRXN1α, short NRXN1β and extremely short NRXN1γ, which exert differential roles in neuronal excitation/inhibition. NRXN1α deletions are common in autism spectrum disorder (ASD) and other neurodevelopmental/neuropsychiatric disorders. We derived induced pluripotent stem cells (iPSCs) from one sibling control and two ASD probands carrying NRXN1α, using non-integrating Sendai viral method. All iPSCs highly expressed pluripotency markers and could be differentiated into ectodermal/mesodermal/endodermal cells. The genotype and karyotype of the iPSCs were validated by whole genome SNP array. The availability of the iPSCs offers an opportunity for understanding NRXN1α function in human neurons and in ASD.

Overexpression of the receptor-like protein kinase genes AtRPK1 and OsRPK1 reduces the salt tolerance of Arabidopsis thaliana.
AtRPK1 (AT1G69270) is a leucine-rich repeat receptor-like protein kinase (LRR-RLK) gene in Arabidopsis thaliana. The rice gene O

BOARD NUMBER: S07g0602700 (OsRPK1) is the homolog of AtRPK1. AtRPK1 and OsRPK1 were overexpressed and the expression of AtRPK1 was inhibited by RNAi in A. thaliana. The functional results showed that the degrees of salt tolerance of the 35S:RPK1 A. thaliana plants were significantly lower than that of the control plants. The AtRPK1-RNAi A. thaliana plants exhibited higher salt tolerance than the wild-type plants (Col). The subcellular localisation results showed that the RPK1 proteins were mainly distributed on the cell membrane and that the overexpressed AtRPK1 proteins exhibited a significantly clustered distribution. The physiological analyses revealed that the overexpression of the RPK1 genes increased the membrane permeability in the transgenic A. thaliana plants. In response to salt stress, these plants exhibited an increased Na(+) flux into the cell, which caused greater damage to the cell. The real-time quantitative PCR analysis showed that the expression of the P5CS1 gene was inhibited and the SOS signalling pathway was blocked in the 35S:AtRPK1 A. thaliana plants. These effects at least partially contribute to the salt-sensitive phenotype of the 35S:RPK1 plants.
Plant Sci, 2014; 217-218

SHORT- AND LONG-DISTANCE EXTRINSIC REGULATION OF INTERNEURON SPECIFICATION AND MIGRATION

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Fabrizia Pipicelli
Max Plank Institute of Psychiatry, Developmental Neurobiology, Munich, Germany

Imbalance between excitatory and inhibitory neurons in the human brain might lead to neurodevelopmental and neuropsychiatric disorders including cortical malformations epilepsy (EP), and autism spectrum disorders (ASD). Here, we propose that the extracellular environment regulates interneuron (IN) differentiation and migration during development, ultimately affecting the excitatory/inhibitory (E/I) balance. Using dorso-ventral cerebral assembloids (dvCAs) and ventral cerebral organoids (vCOs) with mutations in the extracellular matrix gene LGALS3BP, we show that composition of the extracellular medium regulates the migration and molecular differentiation of INs. To investigate how the extracellular environment affects neuronal specification and migration, we characterized the protein content of extracellular vesicles (EVs) secreted from COs carrying a mutation in *LGALS3BP* identified in individual with cortical malformation and neuropsychiatric disorders. These results revealed differences in protein composition. Interestingly, alteration of proteins associated with neuronal migration and ECM composition were altered in mutant EVs contained, suggesting an extrinsic role of LGALS3BP in these processes. Our results indicate that IN migration and molecular differentiation are regulated by short- and long-distance factors released into the extracellular environment.

CELL-TYPE AND BRAIN-REGION-SPECIFIC EXPRESSION OF PLPPRS AS A MOLECULAR CODE FOR DEVELOPMENTAL NEURON MORPHOGENESIS IN THE CNS

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Alexandra Polyzou[1], Joachim Fuchs[2], Fotini Delis[1], Katerina Antoniou[1,3], Androniki Kotoula[1], Georgia Louskou[1], Britta Eickholt[2], George Leondaritis[1,3]
[1]University of Ioannina, Laboratory Of Pharmacology, Department Of Medicine, Ioannina, Greece, [2]Institute of Biochemistry, Charite-universitatsmedizin-berlin, Berlin, Germany, [3]Institute of Biosciences, University Research Center Ioannina, University Of Ioannina, Ioannina, Greece

Phospholipid-phosphatase-related proteins (PLPPRs) are a family of neuron-enriched, developmentally expressed membrane proteins that control glutamatergic synapses, filopodia and branch formation, and growth cone navigation. PLPPRs may form heteromeric complexes suggesting diversified effects on bioactive lipid and small GTPase signaling. Studies have focused on hippocampus and cortex early postnatal development, but PLPPRs expression in subcortical brain tissues during development and adulthood is far from known. Furthermore, there are no studies on co-expression of PLPPRs or their neuron-type expression patterns. Aim: To explore which brain regions and cell types express PLPPRs during development and adulthood. Methods: We used qPCR for quantifying PLPPR mRNA in 5 tissues and 5 developmental stages and developed a custom computational screening tool to mine 4 publicly available mouse brain single-cell RNA-sequencing datasets. Results: Our qPCR analyses suggest ensuing expression of PLPPRs in subcortical brain areas, particularly in structures of the limbic system. Single neuron analysis suggests high PLPPR co-expression in specific adult GABAergic interneuron as well as in cortical and hippocampal glutamatergic subtypes. Conclusions: PLPPRs are expressed at high levels in the adult limbic system, while GABAergic neurons show the highest degree of PLPPR co-expression. This points to a possible regulatory role of PLPPR heteromeric complexes in GABAergic neuron morphogenesis and function. Lastly, our computational screening approach for single cell sequencing datasets provides a tool to collect information about any gene and neuron type of interest. Astrocytes are intimately linked with the brain vasculature, through structural and functional relationships that are critical for neuronal health. However, key molecular factors in astrocytes driving these physical and functional associations during development have not yet been identified. Here, we leveraged pan-astrocytic gene *Aldh1l1* as a molecular handle to unmask gliovascular dynamics in the postnatal mouse brain. Using mice with Green Fluorescent Protein expressed under the control of the *Aldh1l1* promoter, we found by immunofluorescence and electron microscopy that astrocytes undergo extensive maturation from postnatal day 5 (P5) and interact with blood vessels more closely from P7 (mostly evident at P14) via their endfeet. Astrocytic endfeet undergo refinement between P7 and P14, after which they exhibit a mature morphology, similar to those found at P21. To identify astrocyte genes critical for gliovascular development during postnatal brain growth, we utilised multiplex spatial RNA sequencing in the cerebral cortex from P0, P5 and P14 mice. We found that high-mobility group box 1 (*Hmgb1*), normally involved in vascular repair in the adult brain, was highly expressed in astrocytes at birth and decreased rapidly. Astrocyte-selective ablation of *Hmgb1* in newborn mice affected astrocytic endfoot placement and disturbed gap junction protein Connexin43 in the long-term. Early removal of astroglial *Hmgb1* also led to transcriptional changes mostly in microvessels and altered endothelial cell ultrastructure. While lack of astroglial *Hmgb1* did not affect vascular permeability or angiogenesis postnatally, it impaired neurovascular coupling in adults. These findings reveal a novel mechanism regulating gliovascular maturation during postnatal development.

Maternal high-fat diet in mice induces cerebrovascular, microglial and long-term behavioural alterations in offspring.
Various environmental exposures during pregnancy, like maternal diet, can compromise, at critical periods of development, the neurovascular maturation of the offspring. Foetal exposure to maternal high-fat diet (mHFD), common to Western societies, has been shown to disturb neurovascular development in neonates and long-term permeability of the neurovasculature. Nevertheless, the effects of mHFD on the offspring's cerebrovascular health remains largely elusive. Here, we sought to address this knowledge gap by using a translational mouse model of mHFD exposure. Three-dimensional and ultrastructure analysis of the neurovascular unit (vasculature and parenchymal cells) in mHFD-exposed offspring revealed major alterations of the neurovascular organization and metabolism. These alterations were accompanied by changes in the expression of genes involved in metabolism and immunity, indicating that neurovascular changes may result from abnormal brain metabolism and immune regulation. In addition, mHFD-exposed offspring showed persisting behavioural alterations reminiscent of neurodevelopmental disorders, specifically an increase in stereotyped and repetitive behaviours into adulthood.

Sex differences in developmental patterns of neocortical astroglia: A mouse translatome database.
Astroglial cells are key players in the development and maintenance of neurons and neuronal networks. Astroglia express

steroid hormone receptors and show rapid responses to hormonal manipulations. However, despite important sex differences in the cortex and hippocampus, few studies have examined sex differences in astroglial cells in telencephalic development. To characterize the cortical astroglial translatome in male and female mice across postnatal development, we use translating ribosome affinity purification together with RNA sequencing and immunohistochemistry to phenotype astroglia at six developmental time points. Overall, we find two distinct astroglial phenotypes between early (P1-P7) and late development (P14-adult), independent of sex. We also find sex differences in gene expression patterns across development that peak at P7 and appear to result from males reaching a mature astroglial phenotype earlier than females. These developmental sex differences could have an impact on the construction of neuronal networks and windows of vulnerability to perturbations and disease.

Structural and Functional Remodeling of the Brain Vasculature Following Stroke.
Maintenance of cerebral blood vessel integrity and regulation of cerebral blood flow ensure proper brain function. The adult human brain represents only a small portion of the body mass, yet about a quarter of the cardiac output is dedicated to energy consumption by brain cells at rest. Due to a low capacity to store energy, brain health is heavily reliant on a steady supply of oxygen and nutrients from the bloodstream, and is thus particularly vulnerable to stroke. Stroke is a leading cause of disability and mortality worldwide. By transiently or permanently limiting tissue perfusion, stroke alters vascular integrity and function, compromising brain homeostasis and leading to widespread consequences from early-onset motor deficits to long-term cognitive decline. While numerous lines of investigation have been undertaken to develop new pharmacological therapies for stroke, only few advances have been made and most clinical trials have failed. Overall, our understanding of the acute and chronic vascular responses to stroke is insufficient, yet a better comprehension of cerebrovascular remodeling following stroke is an essential prerequisite for developing novel therapeutic options. In this review, we present a comprehensive update on post-stroke cerebrovascular remodeling, an important and growing field in neuroscience, by discussing cellular and molecular mechanisms involved, sex differences, limitations of preclinical research design and future directions.

Vascular contributions to 16p11.2 deletion autism syndrome modeled in mice.
While the neuronal underpinnings of autism spectrum disorder (ASD) are being unraveled, vascular contributions to ASD remain elusive. Here, we investigated postnatal cerebrovascular development in the 16p11.2 mouse model of 16p11.2 deletion ASD syndrome. We discover that 16p11.2 hemizygosity leads to male-specific, endothelium-dependent structural and functional neurovascular abnormalities. In 16p11.2 mice, endothelial dysfunction results in impaired cerebral angiogenesis at postnatal day 14, and in altered neurovascular coupling and cerebrovascular reactivity at postnatal day 50. Moreover, we show that there is defective angiogenesis in primary 16p11.2 mouse brain endothelial cells and in induced-pluripotent-stem-cell-derived endothelial cells from human carriers of the 16p11.2 deletion. Finally, we find that mice with an endothelium-specific 16p11.2 deletion (16p11.2) partially recapitulate some of the behavioral changes seen in 16p11.2 syndrome, specifically hyperactivity and impaired motor learning. By showing that developmental 16p11.2 haploinsufficiency from endothelial cells results in neurovascular and behavioral changes in adults, our results point to a potential role for endothelial impairment in ASD.

Danegaptide Enhances Astrocyte Gap Junctional Coupling and Reduces Ischemic Reperfusion Brain Injury in Mice.
Ischemic stroke is a complex and devastating event characterized by cell death resulting from a transient or permanent arterial occlusion. Astrocytic connexin43 (Cx43) gap junction (GJ) proteins have been reported to impact neuronal survival in ischemic conditions. Consequently, Cx43 could be a potential target for therapeutic approaches to stroke. We examined the effect of danegaptide (ZP1609), an antiarrhythmic dipeptide that specifically enhances GJ conductance, in two different rodent stroke models. In this study, danegaptide increased astrocytic Cx43 coupling with no significant effects on Cx43 hemichannel activity, in vitro. Using matrix-assisted laser desorption ionization imaging mass spectrometry (MALDI IMS) the presence of danegaptide within brain tissue sections were detected one hour after reperfusion indicating successful transport of the dipeptide across the blood brain barrier. Furthermore, administration of danegaptide in a novel mouse brain ischemia/reperfusion model showed significant decrease in infarct volume. Taken together, this study provides evidence for the therapeutic potential of danegaptide in ischemia/reperfusion stroke.

Targeting MAPK phosphorylation of Connexin43 provides neuroprotection in stroke.
Connexin43 (Cx43) function is influenced by kinases that phosphorylate specific serine sites located near its C-terminus. Stroke is a powerful inducer of kinase activity, but its effect on Cx43 is unknown. We investigated the impact of wild-type (WT) and knock-in Cx43 with serine to alanine mutations at the protein kinase C (PKC) site Cx43, the casein kinase 1 (CK1) sites Cx43, and the mitogen-activated protein kinase (MAPK) sites Cx43 (MK4) on a permanent middle cerebral artery occlusion (pMCAO) stroke model. We demonstrate that MK4 transgenic animals exhibit a significant decrease in infarct volume that was associated with improvement in behavioral performance. An increase in astrocyte reactivity with a concomitant decrease in microglial reactivity was observed in MK4 mice. In contrast to WT, MK4 astrocytes displayed reduced Cx43 hemichannel activity. Pharmacological blockade of Cx43 hemichannels with TAT-Gap19 also significantly decreased infarct volume in WT animals. This study provides novel molecular insights and charts new avenues for therapeutic intervention associated with Cx43 function.

Acute connexin43 temporal and spatial expression in response to ischemic stroke.
Connexin43 (Cx43) gap junctions expressed in astrocytes can significantly impact neuronal survival in stroke. However, little is known regarding Cx43 spatial and temporal expression during the initial stages of brain ischemia. Using immunohistochemistry and Western blot analysis, we examined Cx43 spatial and temporal expression as a function of neuronal injury within the first 24 h after permanent middle cerebral artery occlusion (pMCAO). Western blot analysis showed a significant increase in Cx43 protein expression in the core ischemic area at 2 and 3 h after pMCAO. However, after 6 h of pMCAO Cx43 levels were significantly reduced. This reduction was due to cell death and concomitant Cx43 degradation in the expanding focal ischemic region, while the peri-infarct zone revealed intense Cx43 staining. The neuronal cell-death marker Fluoro-Jade C labeled injured neurons faintly at 1 h post-pMCAO with a time-dependent increase in both intensity and size of punctate staining. In addition, decreased microtubule-associated protein 2 (MAP2) immunoreactivity and thionin staining similarly indicated cell damage beginning at 1 h after pMCAO. Taken together, Cx43 expression is sensitive to neuronal injury and can be detected as early as 2 h post-pMCAO. These findings underscore Cx43 gap junction as a potential early target for therapeutic intervention in ischemic stroke.

Pannexin1 knockout and blockade reduces ischemic stroke injury in female, but not in male mice.
The membrane channel Pannexin 1 (Panx1) mediates apoptotic and inflammatory signaling cascades in injured neurons, responses previously shown to be sexually dimorphic under ischemic conditions. We tested the hypothesis that Panx1 plays an underlying role in mediating sex differences in stroke outcome responses. Middle-aged, 8-9 month old male and female wild type and Panx1 KO mice were subjected to permanent middle cerebral artery (MCA) occlusion, and infarct size and astrocyte and microglia activation were assessed 4 days later. The sexually dimorphic nature of Panx1 deletion was also explored by testing the effect of probenecid a known Panx1 blocker to alter stroke volume. Panx1 KO females displayed significantly smaller infarct volumes (~ 50 % reduction) compared to their wild-type counterparts, whereas no such KO effect occurred in males. This sex-specific effect of Panx1 KO was recapitulated by significant reductions in peri-infarct inflammation and astrocyte reactivity, as well as smaller infarct volumes in probenecid treated females, but not males. Finally, females showed overall, higher Panx1 protein levels than males under ischemic conditions. These findings unmask a deleterious role for Panx1 in response to permanent MCA occlusion, that is unique to females, and provide several new frameworks for understanding sex differences in stroke outcome.

Gap junctions and hemichannels: communicating cell death in neurodevelopment and disease.
Gap junctions are unique membrane channels that play a significant role in intercellular communication in the developing and mature central nervous system (CNS). These channels are composed of connexin proteins that oligomerize into hexamers to

form connexons or hemichannels. Many different connexins are expressed in the CNS, with some specificity with regard to the cell types in which distinct connexins are found, as well as the timepoints when they are expressed in the developing and mature CNS. Both the main neuronal Cx36 and glial Cx43 play critical roles in neurodevelopment. These connexins also mediate distinct aspects of the CNS response to pathological conditions. An imbalance in the expression, translation, trafficking and turnover of connexins, as well as mutations of connexins, can impact their function in the context of cell death in neurodevelopment and disease. With the ever-increasing understanding of connexins in the brain, therapeutic strategies could be developed to target these membrane channels in various neurological disorders.

REASSESSING THE CONTRIBUTIONS OF CAJAL-RETZIUS CELLS TO CORTICAL DEVELOPMENT

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Vicente Elorriaga[1,2], Matthieu Moreau[1,2], Alessandra Pierani[1,2], Frédéric Causeret[1,2]

In mammals, the cerebral cortex is the region of the brain in charge of motor, sensory and cognitive processing. The correct assembly of cortical architecture during embryogenesis is essential for its normal function and a key player in this process are Cajal-Retzius cells (CR), which are among the first-born pallial neurons. CR migrate tangentially over long distances in the embryonic telencephalon to cover its entire surface and disappear soon after birth. Historically, they have been mostly associated with controlling the radial migration of neocortical glutamatergic neurons and the layering pattern of the cortex. However, more recent work has shown that they also behave as "mobile signalling units, participating in other crucial aspects of cortical development such as patterning and size of functional areas or the establishment of cortical networks. Despite their importance, there is a limited availability of models to study the specific CR contributions to brain development. By using scRNAseq and mouse genetics we have recently developed a novel mouse model largely devoid of CR from early stages of embryogenesis. Our results further point to the critical function that these cells play in correctly shaping the developing brain.

DECIPHERING HOX TIMER MECHANISMS FOR HUMAN NEURONAL SUBTYPE ENGINEERING.

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Remi Robert[1], Célia Vaslin[1], Vincent Mouilleau[1], Jacques Van Helden[2], Stephane Nedelec[1]

HOX genes encode a large family of transcription factors that orchestrate neural diversification along the hindbrain and spinal cord. Their timely sequential activation during embryogenesis is essential to establish their stereotypical expression profiles and the formation of distinct locomotor circuits. Yet, the timer mechanisms that set the tempo of their activation remain unclear. We recently derived axial progenitors from human pluripotent stem cells in which *HOX* sequential activation is recapitulated. Using this model we demonstrated that the levels of FGF2 and GDF11, two extrinsic factors, are pacing *HOX* temporal induction leading to the efficient specification of distinct motor neuron subtypes found along the human embryonic spinal cord. Transcriptomics and pharmacological analysis indicated that the two cues activate distinct signaling pathways to rapidly and directly induce *HOX* genes together with transcription factors and signal transduction regulators. We are now investigating the role of these targets in the temporal dynamic of *HOX* sequential activation. We should be able to provide a breakthrough in *HOX* timer mechanisms and their links to the specification of neuronal diversity in the human spinal cord. Beside its fundamental biological relevance, considering the pleiotropic role of *HOX* genes decoding these mechanisms will favor *in vitro* human cell and tissue engineering within and beyond the nervous system.

Most of the studies on neurochemical mapping, connectivity and physiology in the hypothalamic region were carried out in rats and under the columnar morphologic paradigm. According to the columnar model, the entire hypothalamic region lies ventrally within the diencephalon, and includes preoptic, anterior, tuberal and mamillary anteroposterior regions. This model is weak in providing little or no experimentally corroborated causal explanation of such subdivisions. In contrast, the modern prosomeric model uses different axial assumptions based on the parallel courses of the brain floor, alar-basal boundary and brain roof (all causally explained), and postulates that the hypothalamus and telencephalon jointly form the secondary prosencephalon. The hypothalamus is divided into two neuromeric (transverse) parts called peduncular and terminal hypothalamus. The classic AP divisions of the columnar hypothalamus are rather seen as dorsoventral subdivisions of the hypothalamic alar and basal plates. We offer here a prosomeric immunohistochemical mapping in the rat of hypothalamic cells expressing tyrosine hydroxylase (TH). TH-positive cells are abundant within the periventricular stratum of the paraventricular and subparaventricular alar domains. In the tuberal region, most labelled cells are found in the acroterminal arcuate nucleus and in the terminal periventricular stratum. The dorsal retrotuberal region contains the A13 cell group of TH-positive cells. In addition, some TH cells appear in the perimamillary and retromamillary regions. The prosomeric model proved useful for determining the precise location of TH-positive cells relative to possible origins of morphogenetic signals, thus aiding potential causal explanation of position-related specification of this hypothalamic cell type.

NAVIGATING THE SPATIO-TEMPORAL PROGRAMS OF APICAL PROGENITORS ACROSS MOUSE EMBRYONIC DEVELOPMENT

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Natalia Baumann, Shingo Nakazawa, Sergi Roig Puiggros, Daniel Fuciec, Denis Jabaudon
University of Geneva, Neuroscience Fondamentale, Geneva, Switzerland

Along the developing neural tube, progenitor cells of the ventricular zone give rise to neurons populating the brain. The spatial location and temporal progression of these progenitors are critical determinants of the neuronal identities of their progenies, yet little is known about molecular patterning in progenitors. To address this question, we used single-cell RNA sequencing at several embryonic ages together with in silico spatial mapping of neuronal progenitors along the neural tube. We find that progenitors share a program encoding temporal progression regardless of their position and a common spatial program regardless of their age. Together, these results provide an integrative view of dynamic transcriptional programs in central nervous system progenitors.

PROSOMERIC CHARACTERIZATION OF CHICKEN TH POSITIVE CELLS DURING HYPOTHALAMIC DEVELOPMENT

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Marina Womack Reina[1], Paula Womack[1], Sylvia Bardet[2], Antonia Alonso[1], Ramón Pla[1], Daniel Garrigos[1], Yevheniy Kutsenko[1], Alberto Barreda[1], Bruno Ribeiro Do Couto[1], Luis Puelles[1], José Luis Ferrán[1]

The chicken secondary prosencephalon presents the telencephalon dorsally and the hypothalamus ventrally. The hypothalamic region is identified by two neuromeric parts defined in terms of peduncular and terminal hypothalamus, caudal and rostral respectively. Dorsoventrally, the hypothalamic region is characterized by the paraventricular and subparaventricular alar plate domains, and tuberal/retrotuberal, perimammillary/retroperimammillary and mammillary/retromammillary basal plate domains. Our aim was to determine the hypothalamic distribution of tyrosine hydroxylase (TH) during chicken hypothalamic development following prosomeric references. We performed prosomeric immunohistochemical mapping of TH from chicken developmental stages HH28 to HH46. This mapping was also combined with markers for various hypothalamic nuclei (*Avp*, *Mch*, *Oxt*, *Pomc*, *Sst*, and *Trh*). In stage HH28 TH-positive cells are observed in the mammillary, perimammillary, retromammillary and periretromammillary regions, but also in the caudal part of the retrotuberal domain (precursor of the A13 cell group?). Alar plate TH positive cells are observed as early as stage HH34 in the terminal and peduncular paraventricular alar plate domain. In addition, at this stage, TH-positive cells that are candidates for forming part of the anterobasal nucleus are observed. The prosomeric model provides the clues to pinpoint the location of TH-positive cells during chicken developmental stages, a descriptive framework that became suitable for accurate comparisons with mammals.

According to the prosomeric model, the hypothalamus is located in the ventral alar and basal plate domains of the secondary prosencephalon, rostral to the diencephalon proper. The hypothalamic region is identified by two neuromeric (transverse) parts called peduncular and terminal hypothalamus. Our recent prosomeric mapping during adolescence of rats identifies abundant TH-positive cells within the periventricular stratum of the paraventricular and subparaventricular alar domains. In addition, TH cells were observed in the periventricular stratum of the tuberal region, arcuate nucleus and A13 cell group. In order to identify early prenatal appearance of TH-positive cells, we performed a prosomeric immunohistochemical mapping of tyrosine hydroxylase (TH), from E12.5 to E21.5 developmental stages of the rat. This mapping was also combined with markers for diverse hypothalamic nuclei (*Avp*, *Mch*, *Oxt*, *Pomc*, *Sst*, and *Trh*). At E13.5, most TH positive cells are observed in the acroterminal alar plate domain with increasing numbers in the dorsal tuberal domain, with few of the A13 cell group precursors. At E15.5, *Mch* identifies the peduncular basal plate and the A13 cell group precursors in the same domain. Beginning at E17.5, most TH-positive cells are distributed in the same domains characterized during the adolescence in the rat. The prosomeric model helps to determine the location of prenatal TH-positive cells more precisely than in previous studies. We have an initial framework to begin work on characterizing the origin of each TH neuron in the hypothalamic region.

A CELL-AUTONOMOUS ROLE FOR PRIMARY CILIA IN LONG-RANGE COMMISSURAL AXON GUIDANCE

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Alexandre Dumoulin, Esther Stoeckli
University of Zurich, Department Of Molecular Life Sciences, Zurich, Switzerland

Ciliopathies are characterized by the absence or dysfunction of primary cilia. Patients exhibit a broad spectrum of symptoms, including kidney and liver problems, limb malformations, and very often cognitive impairments. Despite the fact that cognitive impairments are common, how cilia dysfunction affects neuronal development has not been characterized in detail. Here, we show that the primary cilium is required cell-autonomously by neurons during neural circuit formation. In particular, the primary cilium plays a crucial role during axonal pathfinding for the switch in responsiveness of axons at a choice point, or intermediate target. Utilizing animal models and in vivo, ex vivo as well as in vitro experiments, we provide evidences of a critical role played by the primary cilium at the soma level of commissural neurons in transducing long-range guidance signals sensed by axons navigating an intermediate target. In extension of our finding that Shh is required for the rostral turn of post-crossing commissural axons, we show here that the cilium is required for a change in the transcription of axon guidance receptors, which in turn mediate the repulsive response to floorplate-derived Shh shown by post-crossing commissural axons.

SINGLE-CELL RNA SEQUENCING IN MOUSE REVEALS THAT SCHWANN CELL PRECURSORS REPRESENT A NEURAL CREST-LIKE HUB STATE WITH BIASED MULTIPOTENCY

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Louis Faure[1], Maria Eleni Kastriti[1], François Lallemend[2], Saida Hadjab[2], Igor Adameyko[1]
[1]Medical University of Vienna - Center for Brain Research, Dpt. Of Neuroimmunology, Wien, Austria, [2]Karolinska Institute, Department Of Neuroscience, Stockholm, Sweden

For decades, Schwann cell precursors (SCPs) were considered embryonic nerve-associated progenitors generating myelinating and non-myelinating Schwann cells. It recently became evident that SCPs are multipotent like their mother population of the neural crest. SCPs are omnipresent in the body of vertebrate embryos accompanying the peripheral outgrowing innervation. Here we took advantage of single-cell transcriptomics to resolve SCP identity and to answer if SCPs represent the nerve-associated neural crest. To define the transcriptional states of the Schwann cell lineage, we relied on the concept of regulons, integrated transcriptional activation and trajectory analysis. Our results revealed that early SCPs and late migratory crest represent a multipotent “hub” state containing cells biased towards traditional neural crest fates. More advanced SCPs diverge from the crest after being primed towards the terminal Schwann cell fate. Furthermore, we revealed the subtypes of SCPs residing in distinct anatomical locations and identified new paths towards myelination and endoneurial fibroblasts.

Single-cell transcriptomics of human embryos identifies multiple sympathoblast lineages with potential implications for neuroblastoma origin.
Characterization of the progression of cellular states during human embryogenesis can provide insights into the origin of pediatric diseases. We examined the transcriptional states of neural crest- and mesoderm-derived lineages differentiating into adrenal glands, kidneys, endothelium and hematopoietic tissue between post-conception weeks 6 and 14 of human development. Our results reveal transitions connecting the intermediate mesoderm and progenitors of organ primordia, the hematopoietic system and endothelial subtypes. Unexpectedly, by using a combination of single-cell transcriptomics and lineage tracing, we found that intra-adrenal sympathoblasts at that stage are directly derived from nerve-associated Schwann cell precursors, similarly to local chromaffin cells, whereas the majority of extra-adrenal sympathoblasts arise from the migratory neural crest. In humans, this process persists during several weeks of development within the large intra-adrenal ganglia-like structures, which may also serve as reservoirs of originating cells in neuroblastoma.

Stem cell contributions to cementoblast differentiation in healthy periodontal ligament and periodontitis.
Loss of tissue attachment as a consequence of bacterial infection and inflammation represents the main therapeutic target for the treatment of periodontitis. Cementoblasts, the cells that produce the mineralized tissue, cementum, that is responsible for connecting the soft periodontal tissue to the tooth, are a key cell type for maintaining/restoring tissue attachment following disease. Here, we identify two distinct stem cell populations that contribute to cementoblast differentiation at different times. During postnatal development, cementoblasts are formed from perivascular-derived cells expressing CD90 and perivascular-associated cells that express Axin2. During adult homeostasis, only Wnt-responsive Axin2+ cells form cementoblasts but following experimental induction of periodontal disease, CD90+ cells become the main source of cementoblasts. We thus show that different populations of resident stem cells are mobilized at different times and during disease to generate precursors for cementoblast differentiation and thus provide an insight into the targeting cells resident cells for novel therapeutic approaches. The differentiation of these stem cells into cementoblasts is however inhibited by bacterial products such as lipopolysaccharides, emphasizing that regeneration of periodontal ligament soft tissue and restoration of attachment will require a multipronged approach.

Prototypical pacemaker neurons interact with the resident microbiota.
Pacemaker neurons exert control over neuronal circuit function by their intrinsic ability to generate rhythmic bursts of action potential. Recent work has identified rhythmic gut contractions in human, mice, and hydra to be dependent on both neurons and the resident microbiota. However, little is known about the evolutionary origin of these neurons and their interaction with microbes. In this study, we identified and functionally characterized prototypical ANO/SCN/TRPM ion channel-expressing pacemaker cells in the basal metazoan by using a combination of single-cell transcriptomics, immunochemistry, and functional experiments. Unexpectedly, these prototypical pacemaker neurons express a rich set of immune-related genes mediating their interaction with the microbial environment. Furthermore, functional experiments gave a strong support to a model of the evolutionary emergence of pacemaker cells as neurons using components of innate immunity to interact with the microbial environment and ion channels to generate rhythmic contractions.

Single cell RNA sequencing identifies early diversity of sensory neurons forming via bi-potential intermediates.
Somatic sensation is defined by the existence of a diversity of primary sensory neurons with unique biological features and response profiles to external and internal stimuli. However, there is no coherent picture about how this diversity of cell states is transcriptionally generated. Here, we use deep single cell analysis to resolve fate splits and molecular biasing processes during sensory neurogenesis in mice. Our results identify a complex series of successive and specific transcriptional changes in post-mitotic neurons that delineate hierarchical regulatory states leading to the generation of the main sensory neuron classes. In addition, our analysis identifies previously undetected early gene modules expressed long before fate determination although being clearly associated with defined sensory subtypes. Overall, the early diversity of sensory neurons is generated through successive bi-potential intermediates in which synchronization of relevant gene modules and concurrent repression of competing fate programs precede cell fate stabilization and final commitment.

Two different cell-cycle processes determine the timing of cell division in .
Cells must control the cell cycle to ensure that key processes are brought to completion. In , it is controversial whether cell division is tied to chromosome replication or to a replication-independent inter-division process. A recent model suggests instead that processes may limit cell division with comparable odds in single cells. Here, we tested this possibility experimentally by monitoring single-cell division and replication over multiple generations at slow growth. We then perturbed cell width, causing an increase of the time between replication termination and division. As a consequence, replication became decreasingly limiting for cell division, while correlations between birth and division and between subsequent replication-initiation events were maintained. Our experiments support the hypothesis that both chromosome replication and a replication-independent inter-division process can limit cell division: the two processes have balanced contributions in non-perturbed cells, while our width perturbations increase the odds of the replication-independent process being limiting.

Robust and Scalable Learning of Complex Intrinsic Dataset Geometry via ElPiGraph.
Multidimensional datapoint clouds representing large datasets are frequently characterized by non-trivial low-dimensional geometry and topology which can be recovered by unsupervised machine learning approaches, in particular, by principal graphs. Principal graphs approximate the multivariate data by a graph injected into the data space with some constraints imposed on the node mapping. Here we present ElPiGraph, a scalable and robust method for constructing principal graphs. ElPiGraph exploits and further develops the concept of elastic energy, the topological graph grammar approach, and a gradient descent-like optimization of the graph topology. The method is able to withstand high levels of noise and is capable of approximating data point clouds via principal graph ensembles. This strategy can be used to estimate the statistical significance of complex data features and to summarize them into a single consensus principal graph. ElPiGraph deals efficiently with large datasets in various fields such as biology, where it can be used for example with single-cell transcriptomic or epigenomic datasets to infer gene expression dynamics and recover differentiation landscapes.

Heterogeneity of spontaneous DNA replication errors in single isogenic cells.
Despite extensive knowledge of the molecular mechanisms that control mutagenesis, it is not known how spontaneous

mutations are produced in cells with fully operative mutation-prevention systems. By using a mutation assay that allows visualization of DNA replication errors and stress response transcriptional reporters, we examined populations of isogenic cells growing under optimal conditions without exogenous stress. We found that spontaneous DNA replication errors in proliferating cells arose more frequently in subpopulations experiencing endogenous stresses, such as problems with proteostasis, genome maintenance, and reactive oxidative species production. The presence of these subpopulations of phenotypic mutators is not expected to affect the average mutation frequency or to reduce the mean population fitness in a stable environment. However, these subpopulations can contribute to overall population adaptability in fluctuating environments by serving as a reservoir of increased genetic variability.

SPATIO-TEMPORAL DYNAMICS OF STOCHASTIC AXON TARGETING DURING CNS DEVELOPMENT

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Maheva Andriatsilavo[1,2,3], Alexandre Dumoulin[4], Esther Stoeckli[4], Robin Hiesinger[1], Bassem Hassan[1,2,5]
[1]Free University, Division Of Neurobiology Of The Institute For Biology, Berlin, Germany, [2]Charité Universitätsmedizin, Einstein-bih, Berlin, Germany, [3]Paris Brain Institute (ICM), Brain Development Team, Paris, France, [4]University of Zurich, Department Of Molecular Life Sciences, Zurich, Switzerland, [5]Paris Brain Institute, Brain Development, Paris, France

While adult brains present stereotypical wiring diagrams, developmental variation in axonal connectivity contributes to non-heritable behavioral individuality (Linneweber et al. 2020). The question of how and when these individualized wiring patterns emerge and become stable during development remains unexplored. Using long-term intravital live imaging of axonal growth and targeting of Dorsal Clustered Neurons/LC_{14} in the developing central nervous system of intact fruit flies, we show that axon selection is a multi-step process with variable outcomes. First, Notch-mediated lateral inhibition defines a subset of neurons with a potential to innervate distal targets. Live imaging and temporal optogenetic activation of Notch signaling reveal that while $Notch^{ON}$ axons stay near proximal targets, $Notch^{OFF}$ axons alter their growth cone morphology to create single-cell bundles of dynamic parallel fibers extending towards distal targets. Live tracking of microtubule dynamics identifies a second selection step, where a subset of $Notch^{OFF}$ axons randomly stabilize one fiber within their bundle structures. In contrast, $Notch^{OFF}$ axons that do not have microtubule stabilization in their bundles retract before reaching distal targets. We observed a similar axonal splitting/selection process in the developing chick spinal cord suggesting a conserved mechanism. Finally, microtubule developmental pattern predicts the adult wiring pattern of an individual and remain stable during adult life, supporting the idea that a temporal succession of stochastic processes explains the emergence of individual variation in robust wiring patterns.

ADHESION MOLECULE AMIGO2 IS INVOLVED IN THE FASCICULATION PROCESS OF THE FASCICULUS RETROFLEXUS.

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Verónica Company Devesa[1], Raquel Murcia-Ramón[2], Abraham Andreu-Cervera[1], Paula Aracil-Pastor[1], Francisca Almagro-García[1], Salvador Martínez[1], Diego Echevarría[1], Eduardo Puelles[1]

In the habenular complex, the fasciculus retroflexus is the main efference. It is composed by a core, where the medial habenular axons are located, and a shell composed by lateral habenular axons. Both group of fibers share the same initial way and differ in the final segment of the fascicle. The different behavior of the axonal fascicles is regulated by surface molecules. Amigo2, adhesion molecule with immunoglobulin like domain 2, codify for a membrane protein selectively expressed in the medial habenula. We selected this molecule as a candidate to control the medial Habenula axons fasciculation behavior. First, we studied in an Amigo2 lack of function mouse model the development of the habenular efference. The fasciculus retroflexus appeared defasciculated with a variable phenotype. Then, gain of function experiments allowed us to generate not only a more condensed tract but to recover the Amigo2 knock-out phenotype. Amigo2 alterations did not produce any modification in the habenular fibers guidance process. We have demonstrated that Amigo2 plays a role in the fasciculation process of the fasciculus retroflexus. Role in the Development of the Habenula and the Fasciculus Retroflexus.
is one of the morphogenes that controls the specification and differentiation of neuronal populations in the developing central nervous system. The habenula is a diencephalic neuronal complex located in the most dorsal aspect of the thalamic prosomere. This diencephalic neuronal population is involved in the limbic system and its malfunction is related with several psychiatric disorders. Our aim is to elucidate the role in the habenula and its main efferent tract, the fasciculus retroflexus, development. In order to achieve these objectives, we analyzed these structures development in a lack of function mouse model. The habenula was generated in our model, but it presented an enlarged volume. This alteration was due to an increment in habenular neuroblasts proliferation rate. The fasciculus retroflexus also presented a wider and disorganized distribution and a disturbed final trajectory toward its target. The mid-hindbrain territories that the tract must cross were miss-differentiated in our model. The specification of the habenula is independent. Nevertheless, it controls its precursors proliferation rate. expressed in the isthmic organizer is vital to induce the midbrain and rostral hindbrain territories. The alteration of these areas is responsible for the fasciculus retroflexus axons misroute.

Netrin 1-Mediated Role of the Substantia Nigra Pars Compacta and Ventral Tegmental Area in the Guidance of the Medial Habenular Axons.
The fasciculus retroflexus is an important fascicle that mediates reward-related behaviors and is associated with different psychiatric diseases. It is the main habenular efference and constitutes a link between forebrain regions, the midbrain, and the rostral hindbrain. The proper functional organization of habenular circuitry requires complex molecular programs to control the wiring of the habenula during development. However, the mechanisms guiding the habenular axons toward their targets remain mostly unknown. Here, we demonstrate the role of the mesodiencephalic dopaminergic neurons (substantia nigra pars compacta and ventral tegmental area) as an intermediate target for the correct medial habenular axons navigation along

the anteroposterior axis. These neuronal populations are distributed along the anteroposterior trajectory of these axons in the mesodiencephalic basal plate. Using and experiments, we determined that this navigation is the result of attraction generated by the mesodiencephalic dopaminergic neurons. This attraction is mediated by the receptor deleted in colorectal cancer (DCC), which is strongly expressed in the medial habenular axons. The increment in our knowledge on the fasciculus retroflexus trajectory guidance mechanisms opens the possibility of analyzing if its alteration in mental health patients could account for some of their symptoms.

Neuronal tangential migration from Nkx2.1-positive hypothalamus.
During the development of the central nervous system, the immature neurons suffer different migration processes. It is well known that Nkx2.1-positive ventricular layer give rise to critical tangential migrations into different regions of the developing forebrain. Our aim was to study this phenomenon in the hypothalamic region. With this purpose, we used a transgenic mouse line that expresses the tdTomato reporter driven by the promotor of Nkx2.1. Analysing the Nkx2.1-positive derivatives at E18.5, we found neural contributions to the prethalamic region, mainly in the zona incerta and in the mes-diencephalic tegmental region. We studied the developing hypothalamus along the embryonic period. From E10.5 we detected that the Nkx2.1 expression domain was narrower than the reporter distribution. Therefore, the Nkx2.1 expression fades in a great number of the early-born neurons from the Nkx2.1-positive territory. At the most caudal positive part, we detected a thin stream of positive neurons migrating caudally into the mes-diencephalic tegmental region using time-lapse experiments on open neural tube explants. Late in development, we found a second migratory stream into the prethalamic territory. All these tangentially migrated neurons developed a gabaergic phenotype. In summary, we have described the contribution of interneurons from the Nkx2.1-positive hypothalamic territory into two different rostrocaudal territories: the mes-diencephalic reticular formation through a caudal tangential migration and the prethalamic zona incerta complex through a dorsocaudal tangential migration.

Gestational Exposure to Sodium Valproate Disrupts Fasciculation of the Mesotelencephalic Dopaminergic Tract, With a Selective Reduction of Dopaminergic Output From the Ventral Tegmental Area.
Gestational exposure to valproic acid (VPA) is known to cause behavioral deficits of sociability, matching similar alterations in human autism spectrum disorder (ASD). Available data are scarce on the neuromorphological changes in VPA-exposed animals. Here, we focused on alterations of the dopaminergic system, which is implicated in motivation and reward, with relevance to social cohesion. Whole brains from 7-day-old mice born to mothers given a single injection of VPA (400 mg/kg b.wt.) on E13.5 were immunostained against tyrosine hydroxylase (TH). They were scanned using the iDISCO method with a laser light-sheet microscope, and the reconstructed images were analyzed in 3D for quantitative morphometry. A marked reduction of mesotelencephalic (MT) axonal fascicles together with a widening of the MT tract were observed in VPA treated mice, while other major brain tracts appeared anatomically intact. We also found a reduction in the abundance of dopaminergic ventral tegmental (VTA) neurons, accompanied by diminished tissue level of DA in ventrobasal telencephalic regions (including the nucleus accumbens (NAc), olfactory tubercle, BST, substantia innominata). Such a reduction of DA was not observed in the non-limbic caudate-putamen. Conversely, the abundance of TH+ cells in the substantia nigra (SN) was increased, presumably due to a compensatory mechanism or to an altered distribution of TH+ neurons occupying the SN and the VTA. The findings suggest that defasciculation of the MT tract and neuronal loss in VTA, followed by diminished dopaminergic input to the ventrobasal telencephalon at a critical time point of embryonic development (E13-E14) may hinder the patterning of certain brain centers underlying decision making and sociability.

The Amniote Oculomotor Complex.
The oculomotor (OM) complex is a combination of somatic and parasympatethic neurons. The correct development and wiring of this cranial pair is essential to perform basic functions: eyeball and eyelid movements, pupillary constriction, and lens accommodation. The improper formation or function of this nucleus leads pathologies such as strabismus. We describe the OM organization and function in different vertebrate brains, including chick, mouse, and human. The morphological localization is detailed, as well as the spatial relation with the trochlear nucleus in order to adjust some misleading anatomical topographic descriptions. We detailed the signaling processes needed for the specification of the OM neurons. The transcriptional programs driven the specification and differentiation of these neurons are partially determined. We summarized recent genetic studies that have led to the identification of guidance mechanisms involved in the migration, axon

pathfinding, and targeting of the OM neurons. Finally, we overviewed the pathology associated to genetic malformations in the OM development and related clinical alterations. Anat Rec, 302:446-451, 2019.

INTERPLAY BETWEEN TRANSCRIPTIONAL REGULATION AND NEUROTROPHIC SIGNALING IN RETINAL GANGLION CELL TYPE SPECIFICATION

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Tudor Badea[1,2], Vladimir Muzyka[1,3]
[1]National Eye Institute, Retinal Circuits Development And Genetics Unit, Bethesda, United States of America, [2]Transilvania University of Brasov, Research And Development Institute, Faculty Of Medicine, Brasov, Romania, [3]Laboratory of Genomic Structure, Function and Organization, Novosibirsk State University, Novosibirsk, Russian Federation

The interplay between transcriptional regulation and neurotrophic signaling in neuronal arbor formation is still poorly understood. In mice the transcription factor Brn3a/Pou4f1 is expressed in most RGCs, and is required for the specification of RGCs with small dendritic arbors. The GDNF receptor Ret is expressed in several RGC types, including some expressing Brn3a, but its role in RGC development is not defined. We used combinatorial genetics involving conditional knock-in reporter alleles at the Brn3a and Ret loci, in combination with retina- or Ret specific Cre drivers, to generate complete or mosaic ablations of either Brn3a or Ret in RGCs and study Brn3a and Ret gene dosage effects on RGC dendritic arbor morphology. We find that mosaic gene dosage manipulation of Brn3a in neurotrophic receptor Ret heterozygote RGCs results in altered cell fate decisions and/or morphological dendritic defects. Specific RGC types are lost if Brn3a is ablated during embryogenesis and only mildly affected by postnatal Brn3a ablation. Sparse but not complete Brn3a heterozygosity combined with complete Ret heterozygosity has striking effects on RGC type distribution, in particular on dendritic arbor morphology. While complete retinal ablation of Ret does not significantly affect Brn3a or Brn3b expression, Brn3a loss of function modestly but significantly affects distribution of Ret co-receptors GFRa1-3, and neurotrophin receptors TrkA and TrkC in RGCs. Based on these observations, we propose that Brn3a and Ret converge onto developmental pathways that control RGC type specification, potentially through a competitive mechanism requiring signaling from the surrounding tissue.

CELL LINEAGES AND PROGENITOR HETEROGENEITY IN THE CEREBRAL CORTEX

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Jorge Garcia-Marques
Cajal Institute, Molecular, Cellular And Developmental Neurobiology, Madrid, Spain

The brain contains an extensive catalog of distinct neuronal types. Such diversity emerges through cell specification processes in which progenitors proliferate while navigating a labyrinth of cell fate decisions. Cell lineage plays a pivotal role in neuronal specification, with sibling neurons exhibiting common traits. Decoding the relation between cell lineage and neuronal identity allows for the dissection of the exact progenitor cell and timing in which cell fate decisions occur. In the mouse cerebral cortex, the existence of fate-restricted progenitors remains a long-standing debate. Here, I will present evidence supporting these fate-restricted progenitors exist and may generate different neuronal classes.

SEMAPHORIN 3A REGULATES AXON GROWTH CONE ELONGATION DURING NEURONAL DIFFERENTIATION

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Gabriella Ferretti[1], Sara Serafini[1], Rossana Sirabella[1], Alessia Romano[2], Carmela Matrone[1]
[1]University of Naples Federico II, Dept. Of Neuroscience, Naples, Italy, [2]University of Naples "Federico II", Ceinge-advanced Biotechnologies S.c.ar.l.,, Naples, Italy

Introduction: During neuronal development axons navigate to their targets by sensing attractive and repulsive signals through receptors located on their growth cones. Semaphorins (Sema) are the largest family of repellent guidance cues considered essential in guiding axons during development. Class 3 Sema (Sema 3) are the only produced as secreted proteins in mammals, exerting both autocrine and paracrine functions. Interestingly, Sema 3A expression levels are increased in brains of patients with schizophrenia and polymorphisms in Sema 3A or in Sema 3A receptors, Neuropilin1 (Npn1) and Plexin As (PlxnA2), have been associated to neurodevelopmental disorders. **Aim:** We questioned how neural progenitors (NP) grow and differentiate when exposed to increased Sema 3A levels. **Methods:** To this aim, NP were transfected with Sema 3A or exposed to media from human Sema 3A overexpressing microglia. **Results:** Sema 3A overexpression causes axon growth cone retraction in NP. In addition, NP develop an aberrant proximal dendritic branching and die within a few hours after exposure. Axon retraction, disorganized dendritic arborization and neuronal death were prevented by the Sema 3A receptors silencing. Npn-1 or PlxnA2. **Conclusions** Sema3A regulates NP differentiation, as such any insult causing Sema 3A overexpression might affect axonal elongation and dendritic arborization. This will likely influence neuronal organization and connectivity and causes death. Future studies will be enquiring about how an increase in Sema3A signals might lead to neurodevelopmental disorders.

Fyn Tyrosine Kinase as Harmonizing Factor in Neuronal Functions and Dysfunctions.
Fyn is a non-receptor or cytoplasmatic tyrosine kinase (TK) belonging to the Src family kinases (SFKs) involved in multiple transduction pathways in the central nervous system (CNS) including synaptic transmission, myelination, axon guidance, and oligodendrocyte formation. Almost one hundred years after the original description of Fyn, this protein continues to attract extreme interest because of its multiplicity of actions in the molecular signaling pathways underlying neurodevelopmental as well as neuropathologic events. This review highlights and summarizes the most relevant recent findings pertinent to the role that Fyn exerts in the brain, emphasizing aspects related to neurodevelopment and synaptic plasticity. Fyn is a common factor in healthy and diseased brains that targets different proteins and shapes different transduction signals according to the neurological conditions. We will primarily focus on Fyn-mediated signaling pathways involved in neuronal differentiation and plasticity that have been subjected to considerable attention lately, opening the fascinating scenario to target Fyn TK for the development of potential therapeutic interventions for the treatment of CNS injuries and certain neurodegenerative disorders like Alzheimer's disease.

Putting Cells in Motion: Advantages of Endogenous Boosting of BDNF Production.
Motor exercise, such as sport or musical activities, helps with a plethora of diseases by modulating brain functions in neocortical and subcortical regions, resulting in behavioural changes related to mood regulation, well-being, memory, and even cognitive preservation in aging and neurodegenerative diseases. Although evidence is accumulating on the systemic neural mechanisms mediating these brain effects, the specific mechanisms by which exercise acts upon the cellular level are still under investigation. This is particularly the case for music training, a much less studied instance of motor exercise than sport. With regards to sport, consistent neurobiological research has focused on the brain-derived neurotrophic factor (BDNF), an essential player in the central nervous system. BDNF stimulates the growth and differentiation of neurons and synapses. It thrives in the hippocampus, the cortex, and the basal forebrain, which are the areas vital for memory, learning, and higher cognitive functions. Animal models and neurocognitive experiments on human athletes converge in demonstrating that physical exercise reliably boosts BDNF levels. In this review, we highlight comparable early findings obtained with animal

models and elderly humans exposed to musical stimulation, showing how perceptual exposure to music might affect BDNF release, similar to what has been observed for sport. We subsequently propose a novel hypothesis that relates the neuroplastic changes in the human brains after musical training to genetically- and exercise-driven BDNF levels.

Challenges in LC-MS-based metabolomics for Alzheimer's disease early detection: targeted approaches versus untargeted approaches.
Alzheimer's disease (AD) is one of the most common causes of dementia in old people. Neuronal deficits such as loss of memory, language and problem-solving are severely compromised in affected patients. The molecular features of AD are Aβ deposits in plaques or in oligomeric structures and neurofibrillary tau tangles in brain. However, the challenge is that Aβ is only one piece of the puzzle, and recent findings continue to support the hypothesis that their presence is not sufficient to predict decline along the AD outcome. In this regard, metabolomic-based techniques are acquiring a growing interest for either the early diagnosis of diseases or the therapy monitoring. Mass spectrometry is one the most common analytical platforms used for detection, quantification, and characterization of metabolic biomarkers. In the past years, both targeted and untargeted strategies have been applied to identify possible interesting compounds.

NON-CELL AUTONOMOUS REGULATION OF NEURONAL CIRCUITS FORMATION AT EARLY STAGES OF DEVELOPMENT IN THE VENTRAL SPINAL CORD

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Ana Dominguez Bajo, Andrea Angla-Navarro, Frederic Clotman
UCL, Louvain Institute Of Biomolecular Science And Technology, Louvain la Neuve, Belgium

So far, there are not so many studies that have explored non-cell autonomous mechanisms involved in the formation of neuronal circuits during the development of the spinal cord. Previous work of the lab demonstrated that the conditional inactivation of Onecut transcription factors in spinal motor neurons cause perturbations in the development of ventral interneuron populations in a non-cell autonomous manner. Moreover, some genes downstream of the Onecut factors that could be implicated in this process were identified by RNA-seq. In this work, we studied the potential role of two of the candidate genes, gfra3 (GDNF Family Receptor Alpha 3) and nt3 (neurotrophin-3), both related to neurotrophic factors, in ventral interneuron differentiation and distribution in the developing spinal cord. Possible cell-autonomous modulation of the motor neurons was also analyzed. For this purpose, their expression was first validated in the spinal cord by In-situ hybridization both in mice and chicken embryos. Then, vectors that allowed us to overexpress the genes of interest specifically in the ventral spinal motor neurons (pHb9-nt3/gfra3-IRES-GFP) were generated and electroporated in the spinal cord of chicken embryos. The possible effects of the induced perturbations on the different neuronal populations were studied at different stages by immunofluorescence techniques. Results showed that the overexpression of neurotrophin-3 in spinal motor neurons alters the differentiation of V2 interneurons in a non-cell autonomous manner. Further experiments in mice will be performed to assess that these genes regulated under the control of Onecut factors contribute to non-cell autonomous regulation of spinal interneuron development.

Graphene-Derived Materials Interfacing the Spinal Cord: Outstanding and Findings.
The attractiveness of graphene-derived materials (GDMs) for neural applications has fueled their exploration as components of biomaterial interfaces contacting the brain and the spinal cord. In the last years, an increasing body of work has been published on the ability of these materials to create biocompatible and biofunctional substrates able to promote the growth and activity of neural cells and positively interact with neural tissues when implanted . Encouraging results in the central nervous tissue might impulse the study of GDMs towards preclinical arena. In this mini-review article, we revise the most relevant literature on the interaction of GDMs with the spinal cord. Studies involving the implantation of these materials in the injured spinal cord are first discussed, followed by models with spinal cord slides and a final description of selected results with neural cells . A closing debate of the major conclusions of these results is presented to boost the investigation of GDMs in the field.

Nanostructured gold electrodes promote neural maturation and network connectivity.
Progress in the clinical application of recording and stimulation devices for neural diseases is still limited, mainly because of suboptimal material engineering and unfavorable interactions with biological entities. Nanotechnology is providing upgraded designs of materials to better mimic the native extracellular environment and attain more intimate contacts with individual neurons, besides allowing for the miniaturization of the electrodes. However, little progress has been done to date on the understanding of the biological impact that such neural interfaces have on neural network maturation and functionality. In this work, we elucidate the effect of a gold (Au) highly ordered nanostructure on the morphological and functional interactions with neural cells and tissues. Alumina-templated Au nanostructured electrodes composed of parallel nanowires of 160 nm in diameter and 1.2 μm in length (Au-NWs), with 320 nm of pitch, are designed and characterized. Equivalent non-structured Au electrodes (Au-Flat) are used for comparison. By using diverse techniques in in vitro cell cultures including live calcium imaging, we found that Au-NWs interfaced with primary neural cortical cells for up to 14 days allow neural networks growth

and increase spontaneous activity and ability of neuronal synchronization, thus indicating that nanostructured features favor neuronal network. The enhancement in the number of glial cells found is hypothesized to be behind these beneficial functional effects. The in vivo effect of the implantation of these nanostructured electrodes and its potential relevance for future clinical applicability has been explored in an experimental model of rat spinal cord injury. Subacute responses to implanted Au-NWs show no overt reactive or toxic biological reactions besides those triggered by the injury itself. These results highlight the translational potential of Au-NWs electrodes for in vivo applications as neural interfaces in contact with central nervous tissues including the injured spinal cord.

Interfacing Neurons with Nanostructured Electrodes Modulates Synaptic Circuit Features.
Understanding neural physiopathology requires advances in nanotechnology-based interfaces, engineered to monitor the functional state of mammalian nervous cells. Such interfaces typically contain nanometer-size features for stimulation and recording as in cell-non-invasive extracellular microelectrode arrays. In such devices, it turns crucial to understand specific interactions of neural cells with physicochemical features of electrodes, which could be designed to optimize performance. Herein, versatile flexible nanostructured electrodes covered by arrays of metallic nanowires are fabricated and used to investigate the role of chemical composition and nanotopography on rat brain cells in vitro. By using Au and Ni as exemplary materials, nanostructure and chemical composition are demonstrated to play major roles in the interaction of neural cells with electrodes. Nanostructured devices are interfaced to rat embryonic cortical cells and postnatal hippocampal neurons forming synaptic circuits. It is shown that Au-based electrodes behave similarly to controls. Contrarily, Ni-based nanostructured electrodes increase cell survival, boost neuronal differentiation, and reduce glial cells with respect to flat counterparts. Nonetheless, Au-based electrodes perform superiorly compared to Ni-based ones. Under electrical stimulation, Au-based nanostructured substrates evoke intracellular calcium dynamics compatible with neural networks activation. These studies highlight the opportunity for these electrodes to excite a silent neural network by direct neuronal membranes depolarization.

Myelinated axons and functional blood vessels populate mechanically compliant rGO foams in chronic cervical hemisected rats.
Neural diseases at the central nervous system including spinal cord injury (SCI) remain therapeutic challenges. Graphene materials are being delineated as alternative tools for neural repair. Herein, the regenerative ability of reduced graphene oxide (rGO) scaffolds to support pivotal features of neural repair at 4 months after SCI is assessed by an interdisciplinary approach. 3D randomly porous foams have been prepared in mechanical compliance with neural cells and tissues (Young's modulus of 1.3 ± 1.0 kPa) as demonstrated by atomic force microscopy techniques applied ex vivo. After implantation, the significant increase in Young's modulus caused by massive cell/protein infiltration does not alter the mechanical performance of the contralateral spinal cord but provides mechanical stability to the lesion. These aerogels appear fully vascularized and populated with neurites, some of them being myelinated excitatory axons. Clinically-inspired magnetic resonance imaging studies demonstrate that the scaffolds significantly reduce perilesional damage with respect to rats without implants and cause no compressive damage in the contralateral hemicord and rostral/caudal regions. The rGO implants do not either alter the rat spontaneous behaviour or induce toxicity in major organs. Finally, preliminary data suggest hints of rGO sheets dissociation and eventual degradation at the injured spinal cord for the first time. In summary, these 3D porous rGO scaffolds are able to induce, without any further biological functionalization, a compilation of positive effects that have been rarely described before, if ever, for any other material implanted in the injured spinal cord.

Graphene Oxide Microfibers Promote Regenerative Responses after Chronic Implantation in the Cervical Injured Spinal Cord.
Spinal cord injury (SCI) is characterized by the disruption of neuronal axons and the creation of an inhibitory environment for spinal tissue regeneration. For decades, researchers and clinicians have been devoting a great effort to develop novel therapeutic approaches which include the fabrication of biocompatible implants that could guide neural tissue repair in the lesion site in an attempt to recover the functionality of the nervous tissue. In this context, although fiberlike structures have been hypothesized to serve as a topographical guidance for axonal regrowth, work on the exploration of this type of materials is still limited for SCI. Aiming to develop such guidance platforms, we recently designed and explored reduced graphene oxide materials in the shape of microfibers (rGO-MFs). After preliminary studies to assess the feasibility of their implantation at the injured spinal cord , no evident signs of subacute local toxicity were noticed (10 days of implantation). In this work, we specifically examine for the first time the regenerative potential of these scaffolds, slightly modified in their fabrication for improved reproducibility, when chronically interfaced with a cervical spinal cord injury. After extensive characterization of their

physicochemical properties and experiments with neural progenitor cells, their neural regenerative capacity is investigated in a rat experimental model of SCI after 4 months of implantation (chronic state). Behavioral tests involving the use of forelimbs are performed. Immunofluorescence studies evidence that rGO-MFs scaffolds foster the presence of neuronal structures along with blood vessels both within the epicenter and in the surroundings of the lesion area. Moreover, the inflammatory response does not worsen by the presence of this material. These findings outline the potential of rGO-MF-based scaffolds to promote regenerative features at the injured spinal cord such as axonal and vascular growth. Further studies including biological functionalization might improve their therapeutic potential by a synergistic effect of topographical and chemical cues, thus boosting neural repair after SCI.

3D Reduced Graphene Oxide Scaffolds with a Combinatorial Fibrous-Porous Architecture for Neural Tissue Engineering.
Graphene oxide (GO) assists a diverse set of promising routes to build bioactive neural microenvironments by easily interacting with other biomaterials to enhance their bulk features or, alternatively, self-assembling toward the construction of biocompatible systems with specific three-dimensional (3D) geometries. Herein, we first modulate both size and available oxygen groups in GO nanosheets to adjust the physicochemical and biological properties of polycaprolactone-gelatin electrospun nanofibrous systems. The results show that the incorporation of customized GO nanosheets modulates the properties of the nanofibers and, subsequently, markedly influences the viability of neural progenitor cell cultures. Interestingly, the partially reduced GO (rGO) nanosheets with larger dimensions trigger the best cell response, while the rGO nanosheets with smaller size provoke an accentuated decrease in the cytocompatibility of the resulting electrospun meshes. Then, the most auspicious nanofibers are synergistically accommodated onto the surface of 3D-rGO heterogeneous porous networks, giving rise to fibrous-porous combinatorial architectures suitable for enhancing adhesion and differentiation of neural cells. By varying the chemical composition of the nanofibers, it is possible to adapt their performance as physical crosslinkers for the rGO sheets, leading to the modulation of both pore size and structural/mechanical integrity of the scaffold. Importantly, the biocompatibility of the resultant fibrous-porous systems is not compromised after 14 days of cell culture, including standard differentiation patterns of neural progenitor cells. Overall, in light of these results, the reported scaffolding approach presents not only an indisputable capacity to support highly viable and interconnected neural circuits but also the potential to unlock novel strategies for neural tissue engineering applications.

Combined Magnetoliposome Formation and Drug Loading in One Step for Efficient Alternating Current-Magnetic Field Remote-Controlled Drug Release.
We have developed a reproducible and facile one step strategy for the synthesis of doxorubicin loaded magnetoliposomes by using a thin-layer evaporation method. Liposomes of around 200 nm were made of 1,2-dipalmitoyl--glycero-3-phosphocholine (DPPC) and iron oxide nanoparticles (NPs) with negative, positive, and hydrophobic surfaces that were incorporated outside, inside, or between the lipid bilayers, respectively. To characterize how NPs are incorporated in liposomes, advanced cryoTEM and atomic force microscope (AFM) techniques have been used. It was observed that only when the NPs are attached outside the liposomes, the membrane integrity is preserved (lipid melt transition shifts to 38.7 °C with high enthalpy 34.8 J/g) avoiding the leakage of the encapsulated drug while having good colloidal properties and the best heating efficiency under an alternating magnetic field (AMF). These magnetoliposomes were tested with two cancer cell lines, MDA-MB-231 and HeLa cells. First, 100% of cellular uptake was achieved with a high cell survival (above 80%), which is preserved (83%) for doxorubicin-loaded magnetoliposomes. Then, we demonstrate that doxorubicin release can be triggered by remote control, using a noninvasive external AMF for 1 h, leading to a cell survival reduction of 20%. Magnetic field conditions of 202 kHz and 30 mT seem to be enough to produce an effective heating to avoid drug degradation. In conclusion, these drug-loaded magnetoliposomes prepared in one step could be used for drug release on demand at a specific time and place, efficiently using an external AMF to reduce or even eliminate side effects.

ONSET AND TIME COURSE OF EXPRESSION OF ODORANT RECEPTOR GENES DURING MOUSE EMBRYONIC DEVELOPMENT

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Maria Figueres Oñate[1,2], Mona Khan[1], Laura López-Mascaraque[2], Peter Mombaerts[1]
[1]Max Planck Institute, Research Unit Neurogenetics, Frankfurt am Main, Germany, [2]Instituto Cajal - CSIC, Molecular, Cellular And Developmental Neurobiology, Madrid, Spain

Olfactory perception is initiated by the interaction of odorants with odorant receptors (ORs) expressed by olfactory sensory neurons (OSN), which are located within the nasal cavity and are in direct contact with the external environment. A mature OSN is thought to express a single intact OR gene in a monogenic and monoallelic manner. The onset and time course expression of the OR repertoire – the largest gene family in the mouse genome – has not been studied extensively. Here we performed a NanoString transcriptomic study of 1047 OR genes in the whole olfactory mucosa (WOM), from the formation of the olfactory placode at embryonic day (E) 8.5 until postnatal day (PD) 0.5. Expression of some OR genes could be detected by NanoString technology as early as E9.5, and expression by in situ hybridization was detected from E11.5. Coexpression of OR genes occurred in some cells located in the mesenchyme and the prospective olfactory epithelium. Lineage tracing of olfactory progenitor cells was performed at E11.5 by using the UbC-StarTrack clonal method. Altogether, our data reveal transcriptomic and lineage features of how the OR gene family initiates its expression in the putative olfactory epithelium and how it is modulated throughout embryonic development.

Astrocytes and neurons share region-specific transcriptional signatures that confer regional identity to neuronal reprogramming.
Neural cell diversity is essential to endow distinct brain regions with specific functions. During development, progenitors within these regions are characterized by specific gene expression programs, contributing to the generation of diversity in postmitotic neurons and astrocytes. While the region-specific molecular diversity of neurons and astrocytes is increasingly understood, whether these cells share region-specific programs remains unknown. Here, we show that in the neocortex and thalamus, neurons and astrocytes express shared region-specific transcriptional and epigenetic signatures. These signatures not only distinguish cells across these two brain regions but are also detected across substructures within regions, such as distinct thalamic nuclei, where clonal analysis reveals the existence of common nucleus-specific progenitors for neurons and astrocytes. Consistent with their shared molecular signature, regional specificity is maintained following astrocyte-to-neuron reprogramming. A detailed understanding of these regional-specific signatures may thus inform strategies for future cell-based brain repair.

Deciphering neural heterogeneity through cell lineage tracing.
Understanding how an adult brain reaches an appropriate size and cell composition from a pool of progenitors that proliferates and differentiates is a key question in Developmental Neurobiology. Not only the control of final size but also, the proper arrangement of cells of different embryonic origins is fundamental in this process. Each neural progenitor has to produce a precise number of sibling cells that establish clones, and all these clones will come together to form the functional adult nervous system. Lineage cell tracing is a complex and challenging process that aims to reconstruct the offspring that arise from a single progenitor cell. This tracing can be achieved through strategies based on genetically modified organisms, using either genetic tracers, transfected viral vectors or DNA constructs, and even single-cell sequencing. Combining different reporter proteins and the use of transgenic mice revolutionized clonal analysis more than a decade ago and now, the availability of novel genome editing tools and single-cell sequencing techniques has vastly improved the capacity of lineage tracing to decipher progenitor potential. This review brings together the strategies used to study cell lineages in the brain and the role they have played in our understanding of the functional clonal relationships among neural cells. In addition, future

perspectives regarding the study of cell heterogeneity and the ontogeny of different cell lineages will also be addressed.

Lineage Tracing and Cell Potential of Postnatal Single Progenitor Cells In Vivo.
Understanding the contribution of adult neural progenitor cells (NPCs) and their lineage potential is a great challenge in neuroscience. To reveal progenitor diversity and cell-lineage relationships of postnatal NPCs in the subventricular zone (SVZ), we performed in vivo lineage-tracing genetic analysis using the UbC-StarTrack. We determined the progeny of single SVZ-NPCs, the number of cells per clone, the dispersion of sibling cells, and the cell types within clones. Long-term analysis revealed that both the cell-dispersion pattern and number of cells comprising clones varied depending on the glial/neuronal nature of sibling cells. Sibling-olfactory interneurons were primarily located within the same layer, while sibling-glial cells populated SVZ-adjacent areas. Sibling astrocytes and interneurons did not form big clones, whereas oligodendroglial-lineage clones comprised the largest clones originated in adult brains. These results demonstrate the existence of SVZ postnatal bipotential progenitors that give rise to clones widely dispersed across the olfactory bulb and SVZ-adjacent areas.

Development of Ependymal and Postnatal Neural Stem Cells and Their Origin from a Common Embryonic Progenitor.
The adult mouse brain contains an extensive neurogenic niche in the lateral walls of the lateral ventricles. This epithelium, which has a unique pinwheel organization, contains multiciliated ependymal (E1) cells and neural stem cells (B1). This postnatal germinal epithelium develops from the embryonic ventricular zone, but the lineage relationship between E1 and B1 cells remains unknown. Distinct subpopulations of radial glia (RG) cells in late embryonic and early postnatal development either expand their apical domain >11-fold to form E1 cells or retain small apical domains that coalesce into the centers of pinwheels to form B1 cells. Using independent methods of lineage tracing, we show that individual RG cells can give rise to clones containing E1 and B1 cells. This study reveals key developmental steps in the formation of the postnatal germinal niche and the shared cellular origin of E1 and B1 cells.

Stage-Specific Transcription Factors Drive Astrogliogenesis by Remodeling Gene Regulatory Landscapes.
A broad molecular framework of how neural stem cells are specified toward astrocyte fate during brain development has proven elusive. Here we perform comprehensive and integrated transcriptomic and epigenomic analyses to delineate gene regulatory programs that drive the developmental trajectory from mouse embryonic stem cells to astrocytes. We report molecularly distinct phases of astrogliogenesis that exhibit stage- and lineage-specific transcriptomic and epigenetic signatures with unique primed and active chromatin regions, thereby revealing regulatory elements and transcriptional programs underlying astrocyte generation and maturation. By searching for transcription factors that function at these elements, we identified NFIA and ATF3 as drivers of astrocyte differentiation from neural precursor cells while RUNX2 promotes astrocyte maturation. These transcription factors facilitate stage-specific gene expression programs by switching the chromatin state of their target regulatory elements from primed to active. Altogether, these findings provide integrated insights into the genetic and epigenetic mechanisms steering the trajectory of astrogliogenesis.

Multiple origins and modularity in the spatiotemporal emergence of cerebellar astrocyte heterogeneity.
The morphological, molecular, and functional heterogeneity of astrocytes is under intense scrutiny, but how this diversity is ontogenetically achieved remains largely unknown. Here, by quantitative in vivo clonal analyses and proliferation studies, we demonstrate that the major cerebellar astrocyte types emerge according to an unprecedented and remarkably orderly developmental program comprising (i) a time-dependent decline in both clone size and progenitor multipotency, associated with clone allocation first to the hemispheres and then to the vermis(ii) distinctive clonal relationships among astrocyte types, revealing diverse lineage potentials of embryonic and postnatal progenitors; and (iii) stereotyped clone architectures and recurrent modularities that correlate to layer-specific dynamics of postnatal proliferation/differentiation. In silico simulations indicate that the sole presence of a unique multipotent progenitor at the source of the whole astrogliogenic program is unlikely and rather suggest the involvement of additional committed components.

UbC-StarTrack, a clonal method to target the entire progeny of individual progenitors.

Clonal cell analysis defines the potential of single cells and the diversity they can produce. To achieve this, we have developed a novel adaptation of the genetic tracing strategy, UbC-StarTrack, which attributes a specific and unique color-code to single neural precursors, allowing all their progeny to be tracked. We used integrable fluorescent reporters driven by a ubiquitous promoter in PiggyBac-based vectors to achieve inheritable and stable clonal cell labeling. In addition, coupling this to an inducible Cre-LoxP system avoids the expression of non-integrated reporters. To assess the utility of this system, we first analyzed images of combinatorial expression of fluorescent reporters in transfected cells and their progeny. We also validated the efficiency of the UbC-StarTrack to trace cell lineages through in vivo, in vitro and ex vivo strategies. Finally, progenitors located in the lateral ventricles were targeted at embryonic or postnatal stages to determine the diversity of neurons and glia they produce, and their clonal relationships. In this way we demonstrate that UbC-StarTrack can be used to identify all the progeny of a single cell and that it can be employed in a wide range of contexts.

27242400: Figueres-Oñate M, López-Mascaraque L
Adult Olfactory Bulb Interneuron Phenotypes Identified by Targeting Embryonic and Postnatal Neural Progenitors.
Neurons are generated during embryonic development and in adulthood, although adult neurogenesis is restricted to two main brain regions, the hippocampus and olfactory bulb. The subventricular zone (SVZ) of the lateral ventricles generates neural stem/progenitor cells that continually provide the olfactory bulb (OB) with new granule or periglomerular neurons, cells that arrive from the SVZ via the rostral migratory stream. The continued neurogenesis and the adequate integration of these newly generated interneurons is essential to maintain homeostasis in the olfactory bulb, where the differentiation of these cells into specific neural cell types is strongly influenced by temporal cues. Therefore, identifying the critical features that control the generation of adult OB interneurons at either pre- or post-natal stages is important to understand the dynamic contribution of neural stem cells. Here, we used in utero and neonatal SVZ electroporation along with a transposase-mediated stable integration plasmid, in order to track interneurons and glial lineages in the OB. These plasmids are valuable tools to study the development of OB interneurons from embryonic and post-natal SVZ progenitors. Accordingly, we examined the location and identity of the adult progeny of embryonic and post-natally transfected progenitors by examining neurochemical markers in the adult OB. These data reveal the different cell types in the olfactory bulb that are generated in function of age and different electroporation conditions.

Spatiotemporal analyses of neural lineages after embryonic and postnatal progenitor targeting combining different reporters.
Genetic lineage tracing with electroporation is one of the most powerful techniques to target neural progenitor cells and their progeny. However, the spatiotemporal relationship between neural progenitors and their final phenotype remain poorly understood. One critical factor to analyze the cell fate of progeny is reporter integration into the genome of transfected cells. To address this issue, we performed postnatal and in utero co-electroporations of different fluorescent reporters to label, in both cerebral cortex and olfactory bulb, the progeny of subventricular zone neural progenitors. By comparing fluorescent reporter expression in the adult cell progeny, we show a differential expression pattern within the same cell lineage, depending on electroporation stage and cell identity. Further, while neuronal lineages arise from many progenitors in proliferative zones after few divisions, glial lineages come from fewer progenitors that accomplish many cell divisions. Together, these data provide a useful guide to select a strategy to track the cell fate of a specific cell population and to address whether a different proliferative origin might be correlated with functional heterogeneity.

Unraveling Cajal's view of the olfactory system.
The olfactory system has a highly regular organization of interconnected synaptic circuits from the periphery. It is therefore an excellent model for understanding general principles about how the brain processes information. Cajal revealed the basic cell types and their interconnections at the end of the XIX century. Since his original descriptions, the observation and analysis of the olfactory system and its components represents a major topic in neuroscience studies, providing important insights into the neural mechanisms. In this review, we will highlight the importance of Cajal contributions and his legacy to the actual knowledge of the olfactory system.

PERTURBING PUTATIVE NEURONAL FATE DETERMINANTS IN VIVO

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

May Ho, Elena Dvoretskova, Christian Mayer
Max Planck Institute for Biological Intelligence, Neurogenomics, Martinsried/Planegg, Germany

A number of transcription factors (TFs) are expressed during the neurogenesis and migration of inhibitory neurons from the ganglionic eminences. Diversity is first apparent in the regional expression of a limited number of transcription factors within the ganglionic eminences. However, their functional role in the specification of inhibitory neuron cell state remains unclear. To investigate which transcription factors in the ganglionic eminence facilitate inhibitory neuron fate commitment, we developed a single-cell RNA sequencing compatible CRISPR technique to introduce frameshift mutations to genes in vivo. The CRISPR constructs are first introduced to the embryonic progenitors via in utero electroporation and the perturbed cells are collected postnatally. Differential gene expression analysis allowed us to identify transcription factors that coordinate the gene programs between projection and interneurons. Moreover, we find that these factors coordinate a number of developmental processes such as neuronal differentiation and migration. Furthermore, we developed a novel lineage tracing technique to tag perturbed and non-perturbed progenitors with DNA lineage barcodes. Lineage tracing allowed us to follow clonally related progenitor cells through development and to investigate whether CRISPR perturbations triggered a change in fate.

Single-cell delineation of lineage and genetic identity in the mouse brain.
During neurogenesis, mitotic progenitor cells lining the ventricles of the embryonic mouse brain undergo their final rounds of cell division, giving rise to a wide spectrum of postmitotic neurons and glia. The link between developmental lineage and cell-type diversity remains an open question. Here we used massively parallel tagging of progenitors to track clonal relationships and transcriptomic signatures during mouse forebrain development. We quantified clonal divergence and convergence across all major cell classes postnatally, and found diverse types of GABAergic neuron that share a common lineage. Divergence of GABAergic clones occurred during embryogenesis upon cell-cycle exit, suggesting that differentiation into subtypes is initiated as a lineage-dependent process at the progenitor cell level.

Gene-edited murine cell lines for propagation of chronic wasting disease prions.
Prions cause fatal infectious neurodegenerative diseases in humans and animals. Cell culture models are essential for studying the molecular biology of prion propagation. Defining such culture models is mostly a random process, includes extensive subcloning, and for many prion diseases few or no models exist. One example is chronic wasting disease (CWD), a highly contagious prion disease of cervids. To extend the range of cell models propagating CWD prions, we gene-edited mouse cell lines known to efficiently propagate murine prions. Endogenous prion protein (PrP) was ablated in CAD5 and MEF cells, using CRISPR-Cas9 editing. PrP knock-out cells were reconstituted with mouse, bank vole and cervid PrP genes by lentiviral transduction. Reconstituted cells expressing mouse PrP provided proof-of-concept for re-established prion infection. Bank voles are considered universal receptors for prions from a variety of species. Bank vole PrP reconstituted cells propagated mouse prions and cervid prions, even without subcloning for highly susceptible cells. Cells reconstituted with cervid PrP and infected with CWD prions tested positive in prion conversion assay, whereas non-reconstituted cells were negative. This novel cell culture platform which is easily adjustable and allows testing of polymorphic alleles will provide important new insights into the biology of CWD prions.

LRRN2 AND LRRN3A SPECIFY PRECISE RETINO-TECTAL CONNECTIONS IN THE VERTEBRATE VISUAL SYSTEM

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Elena Putti, Fanny Eggeler, Filippo Del Bene, Shahad Albadri
Institut de la Vision, Department Of Development, Paris, France

Leucin-rich repeat proteins (LRR) have shown to be key players in several aspects of neuronal circuit development, from axon guidance to synapse formation. Among the LRR proteins, the leucin-rich repeat neuronal (LRRN) family comprises different adhesion molecules, such as Lrrn2 and Lrrn3a (orthologues of Capricious in *Drosophila*), whose expression pattern are conserved across species, from *Drosophila* to human. However, nothing is known about their function in the context of the visual system formation and axonal targeting. Their ortholog Capricious in *Drosophila* governs the synaptic targeting of specific photoreceptors to precise laminae of the fly brain. In vertebrates, we show that *lrrn2 and lrrn3a* are sparsely expressed in retinal ganglion cells (RGCs) and our preliminary data in the zebrafish larva demonstrate that their absence leads to mistargeting defects of a subset of RGCs. Indeed, the axons of this population of RGCs, normally projecting to deep layers of the fish brain retino-recipient optic tectum, are unable to reach these laminae in both *lrrn2* and *3a* mutants. Furthermore, the behavioral analysis of these mutants shows reduced hunting abilities. Together our results indicate that Lrrn2/3a are required for the specification and function of precise retino-tectal circuits, revealing their role for the first time in the vertebrate visual system.

A key event in brain development is cell migration and distribution, whose are modulated by molecular factors. At early stages of neocortical development, semaphorins, angiogenic factors and chemokines as CXCL12, assume crucial roles in orchestrating neuronal migration and distribution. There is increasing evidence that molecular and mechanical factors are associated to coordinate neuronal migration and axon elongation in brain development. Cajal-Retzius cells are generated in specific proliferative regions in the developing brain and migrate tangentially in the marginal zone covering the neocortical surface. These pioneer neurons play a crucial role in neocortical layered organization by secreting molecules such as Reelin. In this project we explore the intrinsic mechanical properties of the marginal zone of the developing brain in the migratory pathways and brain distribution of Cajal-Retzius cells. We observe a clear relation between mechanical cues and Cajal-Retzius cells migration in the developing brain. These mechanical factors act as a regulatory cue for their migration and distribution between differential stiffness regions on the neocortical surface. Also, Cajal-Retzius cells activity and migration can be modulated by inhibiting mechanotransduction receptors, indicating that can response to mechanical factors. Indeed, Cajal-Retzius cells from the migratory origins display different migratory capacities which may be involved in their differential distribution in the dorsal-lateral axis along the developing marginal zone. In resume, our results indicate that Cajal-Retzius cells migration and distribution are modulated by molecular and mechanical factors, as observed by the by the differential stiffness in their migratory routes and their specific cellular properties of Cajal-Retzius cells.

TANYCYTE NUCLEOLUS DURING EARLY POSTNATAL DEVELOPMENT AND AGING.

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Dina Sufieva, Dmitrii Korzhevskii
Institute of Experimental Medicine, Morphology, Saint Petersburg, Russian Federation

Tanycytes are highly specialized glial cells lining the infundibular recess. These cells are bipolar and have long basal process penetrating the adjacent nervous tissue of mediabasal hypothalamus. There are 4 types of tanycytes: α1-, α2-, β1- and β2-tanycytes. The nucleolus is one of the important markers reflecting the functional state of a cell. Despite the keen interest of researchers in tanycytes, this important nuclear structure hasn't yet been investigated in these cells. The aim of the research was to study nucleolus organization of tanycytes subpopulations in postnatal development and aging. Using immunohistochemical methods and confocal laser microscopy the brain of young (days 7, 14 and 30 of postnatal development), adult (4-6 months), and old (20 months) male Wistar rats was examined (n=3 for each term). It was established that tanycyte subpopulations are differ in nucleolus organization. Different tanycyte types vary in number, mean diameter and form of nucleolus. These data may indicate a different protein-synthetic activity and functional status of tanycyte subpopulations. For all tanycyte types it was shown that nucleoli diameter increases during postnatal development and aging. The number of nucleoli doesn't change during early postnatal development, but it decreases in aging. These results reflect differentiation processes in tanycytes and increase of synthetic activity in these cells during postnatal development and aging.

[Mast cells of the human pineal gland.]
The purpose of this study was to assess the possibilities of identifying mast cells using different histochemical and immunohistochemical methods and elucidating the features of their localization in the human pineal gland. The undertaken study showed that mast cells are an essential component of the human pineal gland, regardless of age. The data obtained indicate an increase in the number of mast cells in the pineal gland with age. Mast cells are mostly located in the pineal stroma and their preferred location has not been related to concrements, cysts or melanin accumulations. Mast cells in the pineal gland are predominantly non-degranulating, which indicates their inactive state. The detectability of mast cells in the pineal gland depended significantly on the applied method of staining of the preparations. The largest number of mast cells was revealed by tryptase immunohistochemistry, which should be used to accurately determine the population of mast cells of the pineal gland.

Apoptotic death in erythrocytes of lamprey Lampetra fluviatilis induced by ionomycin and tert-butyl hydroperoxide.
The work examined the effects of Ca overload and oxidative damage on erythrocytes of river lamprey Lampetra fluvialtilis. The cells were incubated for 3h with 0.1-5μM Ca ionophore ionomycin in combination with 2.5mM Ca and 10-100μM pro-oxidant agent tert-butyl hydroperoxide (tBHP). The sensitivity of lamprey RBCs to studied compounds was evaluated by the kinetics of their death. Both toxicants induced dose- and time dependent phosphatidylserine (PS) externalization (annexin V-FITC labeling) and loss of membrane integrity (propidium iodide uptake). Highest doses of ionomycin (1-2μM) increased the number of PS-exposed erythrocytes to 7-9% within 3h, while 100μM tBHP produced up to 50% of annexin V-FITC-positive cells. Caspase inhibitor Boc-D-FMK (50μM), calpain inhibitor PD150606 (10μM) and broad protease inhibitor leupeptin (200μM) did not prevent ionomycin-induced PS externalization, whereas tBHP-triggered apoptosis was blunted by Boc-D-FMK. tBHP-dependent death of lamprey erythrocytes was accompanied by the decrease in relative cell size, loss of cell viability, activation of caspases 9 and 3/7, and loss of mitochondrial membrane potential, but all these processes were partially attenuated by Boc-D-FMK. None of examined death-associated events were observed in ionomycin-treated erythrocytes except activation of caspase-9. Incubation with ionomycin did not alter intracellular K and Na content, while exposure to tBHP resulted in 80% loss of K and 2.8-fold accumulation of Na. Thus, lamprey erythrocytes appear to be more susceptible to oxidative damage. Ca overload does not activate the cytosolic death pathways in these cells.

[Three-dimensional visualization of the brain ependyma and tanycytes].
The aim of this investigation was to develop an integrated approach to spatial reconstruction of the cells lining the ventricles of the brain using confocal laser microscopy and immunocytochemical reaction to vimentin. The work was performed on paraffin sections of rat brain of different thickness (5 and 10 microm). To visualize the immunocytochemical reaction the fluorescent dyes in the visible range were selected: SYTOX Green selectively staining the nucleus and indocarbocyanin (Cy-3) conjugated with streptavidin. As a result of testing of various processing conditions, the protocol which allows to receive an intensive staining of the structures was developed. The set of fluorochromes proposed in confocal laser microscopy allows to separate easily the channels, to study the structures independently, if needed, and does not require the use of an expensive ultraviolet laser.

[STRUCTURAL ORGANIZATION OF THE PROCESSES OF EPENDYMO- CYTES LINING THE LATERAL VENTRICLES OF THE RAT BRAIN].
The aim of this study was to examine the structural organization of processes of ependymocytes lining the lateral ventricles of the rat brain using vimentin immunocytochemistry and confocal laser microscopy. The study was performed on adult male rats (n = 3). It was found that most typical ependymocytes had basal processes, while 1/3 of these cells had none. Some vimentin-immunopositive tanycyte-like cells with long processes appoaching blood vessels, were found inside the ependymal lining In some typical ependymocytes, cytroskeleton wa s formed by intermediate filaments of mixed type containing both vimentin and glial fibrillary acidic protein.

[CELL CONTACT PROTEIN BETA-CATENIN IN EPENDYMAL AND EPITHELIAL CELLS OF THE CHOROID PLEXUS OF THE CEREBRAL LATERAL VENTRICLES].
The purpose of this study was to examine the distribution pattern of cellular contacts protein beta-catenin in the choroid plexus and ependyma of lateral ventricles of the brain. The study was conducted on frontal sections of the brain of Wistar rats (n = 10) using polyclonal antibodies against beta-catenin. The obtained preparations were analyzed by microscopy in transmitted light and using confocal laser microscopy. To study the distribution of beta-catenin in different projections, three-dimensional reconstruction was performed. The study demonstrated different distribution patterns of this protein in ependyma and choroid plexus. Unlike ependyma, in the cells of the choroid plexus beta-catenin was distributed in the same way as in simple epithelial tissues (on the basal and lateral borders of the cells). This may indicate different tissue attribution of the ependyma and the choroid plexus epithelium, despite their common origin.

DEVELOPMENT AND REGENERATION OF CORNEA INNERVATION

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Bizzarri Elena[1], Quentin Rappeneau[2], Nacim Bouheraoua[1], Emiliano Ronzitti[3], Alain Chédotal[1]
[1]Institut De La Vision, Department Of Development, Paris, France, [2]Institut de la Vision, Eqs1 - Alain Chedotal, PARIS, France, [3]Institut De La Vision, Department Of Photonics, Paris, France

The cornea is a transparent and avascular structure in the anterior segment of the eye which allows a good visual acuity and acts as a protective barrier for the ocular surface. It is also the most innervated tissue of the human body and receives sensory inputs from the ophthalmic branch of the trigeminal nerve and autonomic axons from the ciliary and superior cervical ganglia. The features of corneal nerve patterning have been elucidated previously using standard immunostaining and electrophysiology approaches. Recently, the use of genetically modified mouse lines expressing fluorescent proteins or Cre recombinase made possible the direct visualization of corneal nerves. However, the understanding of corneal nerves morphology, distribution and plasticity is still elusive. Here we aimed at describing the development of corneal nerves using the *Phox2b*^{CRE} and *RosaTomato* transgenic lines in which a subset of axons are labelled in the cornea. We perform live imaging of fluorescent axons with confocal spinning disk microscopy and 2-photon. Corneal nerve density increases from early postnatal to adulthood, with axons becoming more centrally organized and with a higher branching complexity. In addition, immune cells (macrophages) have been identified in the corneal surface. We are also analyzing the cross-talk between neuronal and immune cells in the cornea. We follow the dynamics of axon-macrophage interaction over time in *Islet1*^{CRE}Rosa^{Tom}*;Cx3cr1*^{GFP} mice in normal and pathological conditions.

THE ATYPICAL CILIA OF CHOROID PLEXUS THROUGH DEVELOPMENTAL LENSES

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Kim Hoa Ho[1,2], Valentina Scarpetta[1,3], Chiara Salio[4], Elisa D'Este[5], Marco Sassoè-Pognetto[3], Annarita Patrizi[1]
[1]German Cancer Research Center DKFZ, Neuronal Signaling And Morphogenesis, Heidelberg, Germany, [2]Heidelberg University, Faculty Of Biosciences, Heidelberg, Germany, [3]University of Turin, Department Of Neurosciences, Turin, Italy, [4]University of Turin, Department Of Veterinary Sciences, Turin, Italy, [5]Max-Planck-Institute for Medical Research, Optical Nanoscopy, Heidelberg, Germany

Choroid plexus (CP) is located in all brain ventricles and is mainly comprised of epithelial cells. CP produces cerebrospinal fluid (CSF), forms the blood-CSF barrier and has been gaining increasingly significant roles in brain-body communication and neurological diseases. Differentiated CP epithelial cells harbor multiple cilia on the CSF-facing surface, which differ from cilia of the adjacent ependyma. While the latter is well characterized, little is known about CP cilia, hindering efforts to decipher CP-related disorders. **Aim**: Our goal is to shed light on CP ciliogenesis from embryogenesis to senescence, characterizing structural and molecular changes of cilia along the developmental trajectory. **Methods**: Mouse CP cilia from E11.5 to P720 were visualized using multiple microscopic techniques: confocal, STED and TEM. Transcriptomic changes relating to cilia formation and function were investigated by analyzing qPCR and snRNA data of CP in different age groups. **Results:** We discovered a novel mode of multi-ciliation that is spatio-temporally controlled and unique to CP. Our data show that CP cilia are unconventional as they bear characteristics of both primary and motile cilia. Moreover, we demonstrated that CP cilia are formed during early embryogenesis but gradually disappear starting from early postnatal ages, both in mice and humans, accompanied by selective transcriptional changes of related functional genes. **Conclusion:** CP cilia are of a structurally distinct type and represent an important differentiation marker of CP epithelium. Cilia presence and disappearance correlate with CP developmental stages, calling for more investigations on their functions and possible involvement in diseases, such as hydrocephalus.

Assessment of common housekeeping genes as reference for gene expression studies using RT-qPCR in mouse choroid plexus.
Choroid plexus (ChP), a vascularized secretory epithelium located in all brain ventricles, plays critical roles in development, homeostasis and brain repair. Reverse transcription quantitative real-time PCR (RT-qPCR) is a popular and useful technique for measuring gene expression changes and also widely used in ChP studies. However, the reliability of RT-qPCR data is strongly dependent on the choice of reference genes, which are supposed to be stable across all samples. In this study, we validated the expression of 12 well established housekeeping genes in ChP in 2 independent experimental paradigms by using popular stability testing algorithms: BestKeeper, DeltaCq, geNorm and NormFinder. Rer1 and Rpl13a were identified as the most stable genes throughout mouse ChP development, while Hprt1 and Rpl27 were the most stable genes across conditions in a mouse sensory deprivation experiment. In addition, Rpl13a, Rpl27 and Tbp were mutually among the top five most stable genes in both experiments. Normalisation of Ttr and Otx2 expression levels using different housekeeping gene combinations demonstrated the profound effect of reference gene choice on target gene expression. Our study emphasized the importance of validating and selecting stable housekeeping genes under specific experimental conditions.

VISUOMOTOR DEFECTS OF ACHIASMATIC MICE EXPRESSING A TRANSFER-DEFECTIVE VAX1 MUTANT

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Kwang Wook Min[1], Han-Woong Lee[2], Jin Woo Kim[1]
[1]Korea Advanced Institute of Science and Technology (KAIST), Department Of Biological Sciences, Daejeon, Korea, Republic of, [2]Yonsei University, Department Of Biochemistry, Seoul, Korea, Republic of

In binocular animals that exhibit stereoscopic visual responses, the axons of retinal ganglion cells (RGCs) connect to brain areas bilaterally by forming a commissure called the optic chiasm (OC). Ventral anterior homeobox 1 (Vax1) contributes to formation of the OC by acting endogenously in cells on RGC axon growth tracks, such as optic stalk and ventral hypothalamus, and exogenously in RGC axons. Here, we generated *Vax1*$^{AA/AA}$ mice expressing the Vax1^{AA} mutant, which is incapable of intercellular transfer. We found that RGC axons cannot take up Vax1^{AA} protein from the axon growth track cells and fail to access the midline. Consequently, RGC axons of *Vax1*$^{AA/AA}$ mice connect exclusively to ipsilateral brain areas, resulting in the losses of visual acuity and visuomotor responses. Together, our study provides physiological evidences for the necessity of intercellular transfer of Vax1 and the importance of the bilateral RGC axon projection in visuomotor responses.

The thalamus is a hub for the integration of sensory information and selection of behavioural responses. Anatomical and functional abnormalities in the thalamus and its axonal connections are often identified in neuropsychiatric disorders, such as schizophrenia and autism. Improper development of thalamic nuclei, aberrant growth of thalamocortical axons, or the emergence of atypical electrophysiological properties of thalamic neurons all could potentially contribute to the aetiology of said disorders. Unfortunately, our understanding of the thalamic development and its adult homeostasis was limited, as the molecular mechanisms which govern these processes were poorly characterized. Our studies shown that both depend on the transcription factor TCF7L2, which directly regulates the expression of many genes critical for thalamic development. Our goal was to determine the role of TCF7L2 in the embryonic development and postnatal maturation of the thalamus. To this end we examined mouse embryos with a total knockout of *Tcf7l2* and adolescent/adult mice with thalamus-specific, postnatal knockout of *Tcf7l2*. Anatomy, gene expression patterns, and axon fibres were visualised using Nissl staining, *in situ* hybridization, immunohistochemistry or DiI tracing. RNA-seq and ChIP-seq analyses were performed on thalami of both strains. Postnatal TCF7L2-deficent mice were used for behavioural tests and their brain slices were used for *in vitro* patch-clamp analysis. We show that the development of proper anatomy/cytoarchitecture of the thalamus, molecular identity of its neurons and growth of thalamocortical connections are all regulated by TCF7L2. TCF7L2 is further required for the functional maturation of thalamic neurons, and TCF7L2-deficent mice exhibit abnormal social behaviour.

ENDOCYTIC RECEPTOR LRP2: A NEW ROLE IN THE NEURAL CREST CELL DYNAMICS

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Sher Min Mak[1], Izabela Kowalczyk[1], Kerstin Feistel[2], Annette Hammes-Lewin[1]
[1]Max Delbrück Center for Molecular Medicine, Department Of Neuroscience, Berlin, Germany, [2]Universität Hohenheim, Department Of Zoology, Stuttgart, Germany

Morphogenesis during embryonic development involves dynamic changes in the tissue shape and organisation which requires multifaceted molecular events. Specifically, formation of embryonic brain begins when the highly polarized pseudostratified epithelium bends into neural folds which then form a closed neural tube. Endocytic receptor LRP2 (LDL receptor related protein 2) is localised on the apical surface of neuroepithelium and crucial for maintaining the neuroepithelial and neural crest cell (NCC) integrity during embryonic development. NCCs are migrating cells derived from the neuroepithelium through an epithelial-to-mesenchymal transition process and capable of transforming into multiple cell lineages when migrating to distinct locations. Dysregulated neuroepithelial and NCC integrity can lead to congenital anomalies in new-borns, such as neural tube defects and tissue malformation, respectively. We have previously ascertained that the loss of LRP2 is associated with impaired neuroepithelial cell polarity and neural tube closure failure due to disrupted subapical protein interactions harbouring NHERF1 and GIPC1. In addition, we have found that LRP2 is expressed in the NCC population and could contributes to the proper NCC dynamic. Our present study therefore would like to address whether LRP2 indeed plays a role in regulating the early NCC behaviour and understand the associated molecular mechanisms. Phenotypic comparison revealed that *Lrp2*$^{-/-}$ mouse embryos displayed craniofacial abnormalities at E18.5, implying an aberrant NCC dynamic. Spatiotemporal defect in the NCC localisation pattern was observed in *Lrp2*$^{-/-}$ embryos much earlier during embryonic development, starting from E8.5 onwards. Altogether, we conclude that LRP2 function is critical for governing both neuroepithelial and NCC dynamics.

ROLE OF LAMININ γ1 IN OLFACTORY PLACODE MORPHOGENESIS AND OLFACTORY AXON DEVELOPMENT IN ZEBRAFISH

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Pénélope Tignard[1], Marie Breau[1], Alain Trembleau[2], Karen Pottin[1], Audrey Geeverding[3]
[1]IBPS, Laboratoire De Biologie Du Développement, Paris, France, [2]IBPS, Neurosciences Paris Seine, Paris, France, [3]Institut de Biologie Paris Seine, Electron Microscopy Facility, PARIS, France

Laminins are major components of the extracellular matrix and play a critical role in the formation of basement membranes (BM). Here, we took advantage of the zebrafish *sly* mutation affecting Laminin γ1, to investigate its role in the development of the zebrafish olfactory system, which involves morphogenetic movements shaping the olfactory sensory placode, and the growth of the olfactory axons from the placode to the olfactory bulb in the brain. Using electron microscopy and immmunofluorescence for BM markers, we showed that the integrity of the BM surrounding the olfactory placodes and the brain is strongly affected in the mutant. Using transgenic lines allowing the expression of fluorescent reporters in defined populations of cells at selected stages of development, we performed a quantitative analysis of placode shape, cell movements and dynamic axon behaviours during olfactory system development *in vivo*. We showed that the olfactory placode displays an abnormal morphogenesis in *sly* mutants, characterized by aberrant tissue scattering and elongation. Olfactory axonal projections also display major defects including abnormal exit point from the placode and subsequent perturbed growth and navigation within the brain. Our results point to original roles for Laminins and BMs in neuronal development and tissue morphogenesis, such as tissue encapsulation providing resistance to stretching forces, substrate for the growth of sensory axons and precise definition of their entry point into the brain.

RCOR2 LOCALIZES IN CENTROSOMES AND INTERACTS WITH TUBULIN

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Daniel Verbel-Vergara, Gianluca Merello, Marcela González, Karina Reichel, María Andrés
Pontificia Universidad Catolica de Chile, Cellular And Molecular Biology, Santiago, Chile

REST corepressor 2 (RCOR2) belongs to the RCOR family proteins, which are mainly characterized as repressors of neuronal gene expression in non-neuronal cells. RCOR2 is required for cell proliferation and division of embryonic and neural stem cells, and neural progenitor cells. Although RCOR2 is expressed mainly in neural tissues and has a relevant role in the regulation of cortex development, it is unknown how it is distributed at the cellular level. The present study aimed to characterize the distribution of RCOR2 in neuronal cell lines and tissues. We identified cytoplasmic and nuclear subpopulations of RCOR2 in N2A, PC-12, HT22, and HEK293T cells using high-resolution microscopy. Immune staining for RCOR2 showed large granules within the nucleus and a smaller punctuated pattern in the cytoplasm in neuronal cell lines, whereas kidney cells showed a homogeneous small-punctuated pattern. Like neuronal cell lines, striatum cells showed large granules inside the nucleus. Additionally, we found that RCOR2 interacts with tubulin in interphase and mitotic cells. In metaphase cells, RCOR2 tends to accumulate in centrosomes. In conclusion, RCOR2 shows different distribution patterns according to cell type, and its colocalization with tubulin and centrosomes suggests additional functional roles beyond transcriptional corepression.

Cross-talk between dopamine D1 and corticotropin releasing factor type 2 receptors leads to occlusion of their ERK1/2 signaling.
One manner in which G protein-coupled receptors potentiate, increase, and change their functionality is through the formation of heteromers in a specific cellular context. Previously, we have shown that dopamine D1 receptor (D1R) and the corticotropin releasing factor receptor type-2α (CRF2α) heteromerize in HEK293T cells, enabling D1R to mobilize intracellular calcium in response to D1R agonists. In this study, we further investigated the pharmacological properties of the CRF2α-D1R heteromer and the consequences of the heteromerization in their signaling and subcellular localization when both receptors are co-expressed in HEK293T cells. Using immunoprecipitation assays, we observed that the addition of 10 μM dopamine in the incubation medium significantly decreased the amount of CRF2α on the cell surface of cells expressing both receptors. The presence of agonists of both receptors increased the interaction between CRF2α and D1R as assessed by co-immunoprecipitation. However, the presence of agonists of both receptors resulted in a lesser efficient activation of the mitogen-activated protein kinase/extracellular signal-regulated kinase. Using a synaptosomal preparation of rat prefrontal cortex devoid of post-synaptic elements, we found that CRF2α and D1R co-localize in synaptic terminals of the rat medial prefrontal cortex and that the simultaneous activation of both receptors also occluded phosphorylation of extracellular signal-regulated kinase. These results strengthen the idea that the heteromer CRF2a-D1R is an entity functionally different from each receptor that composes it and suggests that its formation is enhanced by CRF and dopamine co-transmission, as occurs in stress and addiction.

Evidence for anthropophily in five species of phlebotomine sand flies (Diptera: Psychodidae) from northern Colombia, revealed by molecular identification of bloodmeals.
Identification of the bloodmeal sources of phlebotomine sand flies is fundamental to determining which species are anthropophilic and understanding the transmission of Leishmania parasites in natural epidemiological settings. The objective of this study was to identify sand fly bloodmeals in the mixed leishmaniasis focus of the department of Sucre, northern Colombia. In all 141 engorged female sand flies were analyzed, after being captured in intradomiciliary, peridomiciliary and extradomiciliary habitats with Shannon and CDC traps and by active searching in diurnal resting sites. Bloodmeals were identified by sequencing and analysis of a 358bp fragment of the mitochondrial gene Cytochrome b (CYB) and a 330bp fragment of the nuclear gene prepronociceptin (PNOC). Using both genes 105 vertebrate bloodmeals were identified, with an efficiency of 72% for CYB but only 7% for PNOC. Ten species of vertebrates were identified as providing bloodmeal sources for 8 sand fly species: Homo sapiens (Lutzomyia evansi, Lutzomyia panamensis, Lutzomyia micropyga, Lutzomyia shannoni and Lutzomyia atroclavata), Equus caballus (L. evansi, L. panamensis and Lutzomyia cayennensis cayennensis), Equus asinus (L. evansi and L. panamensis), Bos taurus (L. evansi, L. panamensis and L. c. cayennensis), Tamandua mexicana (L. shannoni and Lutzomyia trinidadensis), Proechimys guyanensis (L. evansi, L. panamensis and L. c. cayennensis), Mabuya sp. (Lutzomyia micropyga), Anolissp. (L. micropyga), Sus scrofa (L. evansi and Lutzomyia gomezi) and Gallus gallus (L. evansi). Cattle, donkeys, humans and pigs were significantly more important than other animals (P=0.0001) as hosts of L. evansi, this being the most abundant sand fly species. The five Lutzomyia species in which blood samples of human origin were detected included L. micropyga and L. atroclavata, constituting the first evidence of anthropophily in both species.

GENERATION OF BRAIN ORGANOIDS WITH IMPROVED NEURAL FATE SPECIFICITY AND BLOCKAGE OF ABERRANT DEVELOPMENT OF MESODERMAL-DERIVED TISSUE

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Brina Stancic, Silvia Garcia-Lopez, Alberto Martinez-Serrano, Marta P. Pereira
CBMSO, UAM-CSIC, Unit Of Specification, Reprograming And Regeneration, Madrid, Spain

AIM Human brain organoids provide a valuable model to interrogate human-specific aspects of neurodevelopmental processes and disease pathology. Despite the advances in generation and manipulation of human induced pluripotent stem cells (hiPSCs), these are known to possess an epigenetic memory, which influences their capacity to differentiate into ectoderm and downstream neural cell types. Here, we explore the potential of using biocompatible and biodegradable 3D-printed polycaprolactone (PCL) scaffolds to constrain hiPSCs into adopting a neural fate, rather than other lineage identities. **METHODS** We use standardized human brain organoid cell culture conditions to compare spherical brain organoids with scaffold-based engineered flat brain organoids (efBOs). Their identity is subsequently analyzed using histological analyses and western blot. **RESULTS** Spherical brain organoids self-organize into regionally distinct parts that correspond to neural tissue, characterized by neural markers (TUJ1, DCX); and cardiac tissue, visualized as a synchronously beating contracting region. The identity of the second is confirmed by the presence of cardiomyocytes (ACTN1) and vessel structures spreading from the heart region (CD31). On the contrary, structural support eliminates the presence of cardiac tissue, as well as it enhances neural differentiation (NES, TUJ1, DCX, MAP2) of efBOs. These develop thick, radially organized neuroectoderm that beings to fold, resembling the gyrification process during human brain development. **CONCLUSIONS** We conclude that structural cues can aid hiPSCs in overriding their intrinsic tendency to preferentially differentiate into one of the three germ layers. By favoring neuronal differentiation, this approach could become a valuable tool for hiPSC-derived brain organoids and modeling neurological disorders.

UNDERSTANDING ARRHINIA AND ITS MOLECULAR PATHWAYS: WHERE ARE WE NOW?

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Estephania Candelo, Pamela Minoso, Sebastian Bonilla, Eidith Pineda, Harry Pachajoa
Universidad Icesi, Health Science, Cali, Colombia

Introduction: Congenital arrhinia is a rare medical condition with unknown causes; it has been related to alterations in the eyes, ears, palate, and other midline defects. **Methods:** We conducted a systematic review on MEDLINE, OVID, COCHRANE, and google scholar for clinical and molecular reports of Arhinia. The literature search was restricted to articles in English and Spanish, all the clinical reports were considered and further molecular analysis was done with reports with molecular data analysis of the arhinia spectrum including (Bosman syndrome, isolated arhinia, and holoprosencephaly) were done. Gene assortment was developed through a systematic literature review. Chromosomal aberrations and genetic variants were filtered, classified, and summarized. The arhinia-related genotype was analyzed by developing a protein-protein network using Cytoscape software (String database). The protein-protein network analysis was broken down into two major categories: comprehensive gene co-expression analysis particular to arrhinia and precision gene co-expression analysis suitable to biological features. **Results:** A total of 43 manuscripts were included. A sample of 78 patients in the arhinia spectrum was identified. The most frequent chromosomal aberration was trisomy 9, 13, and 18. Different genes and proteins were found related to the arhinia spectrum such as; PAX6, CHD7, SOX2, OTX2, and SMCHD1. These genes also formed a significant protein-protein interaction with other proteins involved in the biological features, which compromise mainly head and neck development **Discussions:** The present study characterized the clinical and molecular spectrum and suggests the possible pathophysiological pathways, which might be derived from the development of the arhinia spectrum.

Molecular characterization of mucopolysaccharidosis type IVA patients in the Andean region of Colombia.
Colombia has a high prevalence of mucopolysaccharidosis (MPS) type IVA. Nevertheless, data regarding the mutation spectrum for MPS IVA in this population have not been completely characterized. Forty-seven families and 53 patients from seven different Colombian regions were tested for MPS IVA mutations. We compared the sequences with the N-acetylgalactosamine-6-sulfatase (GALNS) reference sequence NM_000512.4, and gene variants were reported. Bioinformatics analysis was performed using SWISS-MODEL. The mutant proteins were generated by homology from the wild-type GALNS 4FDJ template obtained from the PDB database, and visualization was performed using Swiss-PDBViewer and UCSF Chimera. The predictive analysis was run using different bioinformatic tools, and the deleterious annotation of genetic variants was performed using a neural network. We found that 79% and 21% of the cohort was homozygous and compound heterozygous, respectively. The most frequent mutation observed was p.Gly301Cys (78.3% of alleles), followed by p.Arg386Cys (10.4% of alleles). A novel mutation (p.Phe72Ile) was described and classified in silico as a pathogenic variant. This study reveals the mutation spectrum of MPS IVA in Colombia. The high prevalence of the p.Gly301Cys mutation suggests a founder effect of this variant in the Colombian population that causes diseases in the Andean region (via migration). These data can facilitate genetic counseling, prenatal diagnosis, and the design of therapeutic interventions.

A Possible Association Between Zika Virus Infection and CDK5RAP2 Mutation.
Flaviviridae family belongs to the Spondweni serocomplex, which is mainly transmitted by vectors from the genus. Zika virus (ZIKV) is part of this genus. It was initially reported in Brazil in December 2014 as an unknown acute generalized exanthematous disease and was subsequently identified as ZIKV infection. ZIKV became widespread all over Brazil and was linked with potential cases of microcephaly.

MONITORING THE COMPLEXIFICATION OF CEREBELLAR AND THALAMIC CELLS DURING EARLY DEVELOPMENT WITH DIFFUSION-WEIGHTED MR SPECTROSCOPY

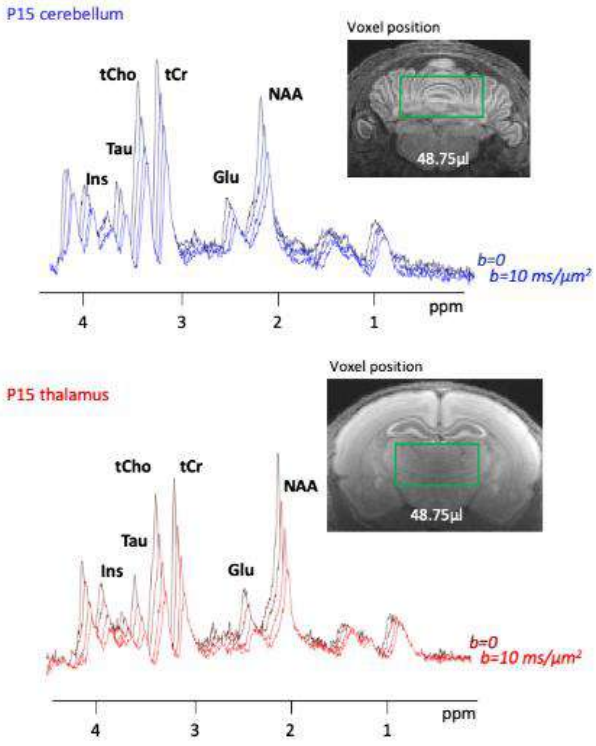
POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Clemence Ligneul[1], Marco Palombo[2], Lily Qiu[1], Jason Lerch[1]
[1]Wellcome Centre for Integrative Neuroimaging, FMRIB (University of Oxford), Nuffield Department Of Clinical Neurosciences, Oxford, United Kingdom, [2]Cardiff University, Cardiff University Brain Research Imaging Centre (cubric), HQ, United Kingdom

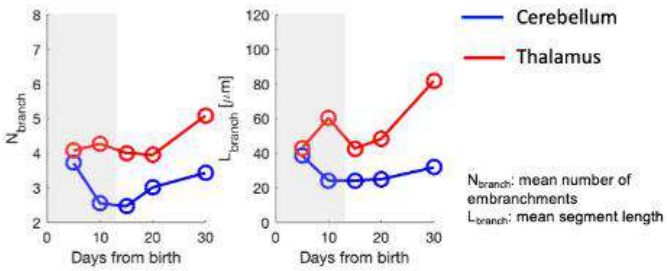
Aims This work aims to assess the potential of diffusion-weighted magnetic resonance spectroscopy (DWMRS) to follow cerebellar and thalamic cell development in the healthy rat brain from P5 to P30. Monitoring non-invasively the morphological development of brain cells in the neonate and infant brain could provide relevant biomarkers for tracking neurodevelopmental disorders. DWMRS is a MR-based method informing about the average morphology (i.e., cyto-architecture) of specific cell types (e.g. neurons, astrocytes) in a large region of interest. It is already implemented in some human scanners, providing the method with a high translational potential. **Methods** 18 Sprague-Dawley rats were scanned at 7T (at P5, P10, P15, P20 and P30), with a DWMRS sequence providing accurate voxel localisation and designed to measure the diffusion properties of metabolites at multiple diffusion times and diffusion-weightings (**FigA**), necessary for cyto-architecture modeling. **Results** Diffusion properties differ between both regions at each age, revealing different microenvironments. Diffusion of total creatine suggests it diffuses in smaller structures at P5/P10 than P20/30, as expected. Diffusion of taurine changes dramatically with age: its cellular compartmentation likely evolves during development. The cyto-architecture modeling relies on the assumption that metabolites primarily diffuse in long fibers. From P15 to P30, cell growth and complexification in both structures is well captured by the data and their modeling, but as expected, different modeling hypotheses may be needed at P5/P10, when the cell body/processes ratio is too high (**FigB/C**).

FENS Forum 2022
9-13 July 2022 | Paris, France

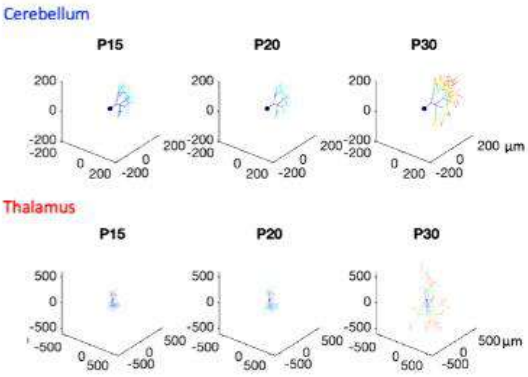
A. Representative high diffusion weightings DWMRS data



B. Cyto-architecture parameters calculated by the modeling of the total creatine long diffusion times data



C. Visualization of the cyto-architecture from P15 to P30 in both regions



Conclusion Overall results show that DWMRS is sensitive to microstructural changes in the developing brain.

ONTOGENY OF THE CAUDAL NEUROSECRETORY SYSTEM IN ZEBRAFISH REVEALED BY A TRANSGENIC (UTS2A:GFP) LINE.

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Faredin Alejevski[1], Bérénice Bichon[1], Anne-Laure Gaillard[1], Fabrice Girardot[1], Caroline Parmentier[2], Guillaume Pézeron[1], Hervé Tostivint[1]

The caudal neurosecretory system (CNSS) is a neuroendocrine complex whose existence is restricted to fishes. In teleosts, the neuroendocrine neurons of the CNSS, called Dahlgren cells, are located in the terminal segments of the spinal cord, and project to a neurohaemal organ, the urophysis, from which several neuropeptides, including urotensins, are released. Very little is currently known about the development of the CNSS. The aim of the present study was to study the ontogeny this system by using the zebrafish as a model. For this purpose a Tg(*uts2a : gfp*) fluorescent reporter line was constructed, in which GFP expression is driven by the uts2a gene promoter. The Tg(*uts2a : gfp*) line recapitulates faithfully the endogenous expression profile of the uts2a gene and allows to visualize Dahgren cells. With this line, the first GFP^+ cells could be detected as early as the hatching period in the caudal spinal cord. A few GFP^+ cell processes could be seen to project rostrally towards the brain, but most of them appeared to project towards the urophysis anlage. The morphogenesis of the urophysis could be indirectly followed thanks to the accumulation of GFP^+ fibers within it. In order to visualize the neurovascular interface within the urophysis, a Tg(uts2a : RFP) line was crossed with a vascular endothelial reporter expressing GFP in *kdr* -positive cells. The study of this new line is currently under investigation. In conclusion, the present work provides the basis for further studies on the mechanisms of development of the CNSS in zebrafish.

The cornea is the transparent surface of the eye that undergoes a life-long renewal. This tissue is composed of a stratified epithelium supported by a mesenchymal stroma. The cornea is also the most densely innervated tissue in the human body. It primarily receives sensory nerves originating from trigeminal ganglion neurons but also contains axons of the autonomic nervous system. The development of corneal nerves has been relatively well studied in chick embryos and to a lesser extent in mice. However, how the different types of axons invade the embryonic cornea and interact together and with corneal cells remains unknown. Importantly, what we know about the development of corneal innervation during human embryogenesis relies on a unique study performed more than 60 years ago. Our goal is to perform a comprehensive 3D analysis of the development of corneal nerves in mice and humans. We are combining whole-mount immunostaining and 3D imaging of solvent-cleared organs (iDISCO) with Light sheet fluorescence microscopy from embryonic day 12 (E12) to postnatal day 9 (P9) in mice and 6-12 post-conceptional weeks in human. We already validated a large panel of antibodies that allow visualizing embryonic sensory and autonomic nerves and neurons in mice and human embryos. Moreover, we used several transgenic mouse lines in which fluorescent proteins are expressed in all or a subset of corneal nerves. The pathway and developmental time-course of trigeminal, sympathetic and parasympathetic axons and is being analyzed in 3D.

Recent transcriptomic efforts to molecularly profile broad classes of neurons revealed considerable diversity among the major types of somatosensory neurons. In contrast, proprioceptive sensory neurons (PN) seem to represent a more homogenous population and so far, only molecular signatures for the three receptor types - Ia, Ib, II - have been described. In order to precisely adjust motor output according to the biomechanical requirements of different muscles, PN innervate central and peripheral targets with exquisite specificity, implying the existence of molecular programs defining PN muscle-type identities. However, the mechanisms controlling this critical aspect of PN identity are not clear yet. We devised a single cell transcriptomic approach that takes advantage of the topographic organization of the proprioceptive system to reveal features of cardinal proprioceptor muscle-types - epaxial and hypaxial - defined by their connectivity to limb, back, and abdominal muscles. First, we identified and validated molecular signatures for each of these subtypes. Second, we found that molecular programs defining their identities are acquired early in development and maintained until early postnatal stages. Finally, we discovered a role for ephrin-A5, a specific marker for limb-projecting PN, in the control of limb muscles connectivity. Altogether, this work reveals the molecular foundation of proprioceptor muscle-type identity, thus paving the way for studying the development and function of muscle specific sensory feedback circuits.

Non-thermal plasma activates human keratinocytes by stimulation of antioxidant and phase II pathways.
Non-thermal atmospheric pressure plasma provides a novel therapeutic opportunity to control redox-based processes, e.g. wound healing, cancer, and inflammatory diseases. By spatial and time-resolved delivery of reactive oxygen and nitrogen species, it allows stimulation or inhibition of cellular processes in biological systems. Our data show that both gene and protein expression is highly affected by non-thermal plasma. Nuclear factor erythroid-related factor 2 (NRF2) and phase II enzyme pathway components were found to act as key controllers orchestrating the cellular response in keratinocytes. Additionally, glutathione metabolism, which is a marker for NRF2-related signaling events, was affected. Among the most robustly increased genes and proteins, heme oxygenase 1, NADPH-quinone oxidoreductase 1, and growth factors were found. The roles of NRF2 targets, investigated by siRNA silencing, revealed that NRF2 acts as an important switch for sensing oxidative stress events. Moreover, the influence of non-thermal plasma on the NRF2 pathway prepares cells against exogenic noxae and increases their resilience against oxidative species. Via paracrine mechanisms, distant cells benefit from cell-cell communication. The finding that non-thermal plasma triggers hormesis-like processes in keratinocytes facilitates the understanding of plasma-tissue interaction and its clinical application.

Nontoxic, double-deletion-mutant rabies viral vectors for retrograde targeting of projection neurons.
Recombinant rabies viral vectors have proven useful for applications including retrograde targeting of projection neurons and monosynaptic tracing, but their cytotoxicity has limited their use to short-term experiments. Here we introduce a new class of double-deletion-mutant rabies viral vectors that left transduced cells alive and healthy indefinitely. Deletion of the viral polymerase gene abolished cytotoxicity and reduced transgene expression to trace levels but left vectors still able to retrogradely infect projection neurons and express recombinases, allowing downstream expression of other transgene

products such as fluorophores and calcium indicators. The morphology of retrogradely targeted cells appeared unperturbed at 1 year postinjection. Whole-cell patch-clamp recordings showed no physiological abnormalities at 8 weeks. Longitudinal two-photon structural and functional imaging in vivo, tracking thousands of individual neurons for up to 4 months, showed that transduced neurons did not die but retained stable visual response properties even at the longest time points imaged.

Adrenal gland medulla releases catecholamines mediating the bodily and behavioral responses to stress. The chromaffin cells of the adrenal medulla originate from nerve-associated Schwann Cell Precursors (SCP). SCPs lineage progression towards chromaffin cells includes a specific "bridge"-cell-state, with a key marker, the HTR3A gene which encodes a serotonin (5HT) receptor. Therefore, we hypothesized that 5HT plays a role in chromaffin cell development. Moreover, the adrenal gland is the typical location for neuroblastoma and the mechanism controlling differentiation may provide clues for neuroblastoma emergence. We investigated 5HT's role in adrenal gland development by combining single-cell transcriptomics, pharmacological treatments, immunohistochemistry, RNA in situ hybridization, behavioral studies, and evaluation of neuroblastoma cell lines. Following the increase of 5HT in pregnant mice and rats during the "bridge" stage, the number of chromaffin cells in embryos decreased due to a slowdown of "bridge" cells' cell-cycle progression. This mechanism appears to be responsible for preventing the overgrowth of chromaffin cells and may act in an autocrine fashion, as chromaffin cells are 5HT-positive. This results in a decreased number of chromaffin cells in adult life causing a drop in circulating levels of catecholamines and consequently, behavioral changes, rendering animals more cooperative and explorative. Importantly, HTR3Ahigh neuroblastoma cell lines result in tumor formation in contrast to HTR3Alow cells. Moreover, their proliferation is reduced in response to HTR3A receptor stimulation. Taking together, modulation of 5HT signaling during a specific period of chromaffin cell differentiation represents an important mechanism for the control of organ growth, neoplasia development, and animal behavior.

MULTIPLE REGIONALIZED GENES AND THEIR PUTATIVE NETWORKS IN THE INTERPEDUNCULAR NUCLEUS SUGGEST COMPLEX MECHANISMS OF NEURON DEVELOPMENT AND AXON GUIDANCE

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Isabel M García-Guillén, Antonia Alonso, Luis Puelles, Faustino Marín, Pilar Aroca
University of Murcia, Dpt. Human Anatomy And Psicobiology, Murcia, Spain

The interpeduncular nucleus (IPN) is a highly conserved limbic structure in the vertebrate brain, located in the isthmus and rhombomere 1. It is formed by various populations that migrate from different sites to the distinct domains within the IPN: the prodromal, rostral interpeduncular, and caudal interpeduncular nuclei. The aim here was to identify genes that are differentially expressed across these domains, characterizing their putative functional roles and interactions. To this end, we screened the 2,038 genes in the Allen Developing Mouse Brain Atlas database expressed at E18.5 and we identified 135 genes expressed within the IPN. The functional analysis of these genes highlighted an overrepresentation of gene families related to neuron development, cell morphogenesis and axon guidance. The interactome analysis within each IPN domain yielded specific networks that mainly involve members of the ephrin/Eph and Cadherin families, transcription factors and molecules related to synaptic neurotransmission. These results bring to light specific mechanisms that might participate in the formation, molecular regionalization, axon guidance and connectivity of the different IPN domains. This genoarchitectonic model of the IPN enables data on gene expression and interactions to be integrated and interpreted, providing a basis for the further study of the connectivity and function of this poorly understood nuclear complex under both normal and pathological conditions.

MICROFLUIDIC HIGH-THROUGHPUT SCREENING PLATFORM TO SCREEN PRE-CLINICAL STAGE COMPOUND EFFECTS ON NEURITE OUTGROWTH OF HUMAN MOTOR NEURONS POST INJURY

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Jessica Rontard, Aurélie Batut, Delphine Debis, Benoît Maisonneuve, Louise Dubuisson, Mélanie Gleyzes, Margot Libralato, Janaina Vieira, Marion Hochedel, Yannick Calderini, Thibault Honegger
NETRI, Auvergne Rhône Alpes, Lyon, France

There is a significant demand for physiologically relevant models of SCI. The major modeling challenge is to accurately perform the injury only on the neurites without affecting cell viability and to apply the pre-clinical stage compounds on cell soma only. Microfluidic chip designs applied to neuroscience research are based on connection between compartmentalized neuronal populations through guiding neurite outgrowth by using microchannels. The longitude of microchannels acts as a selective barrier for the exclusive passage of axons over dendrites and it promotes the unidirectional growth of the neurites from one compartment to the other. We will present the design of a compartmentalized microfluidic device with three compartments capable of both inducing a localized axotomy and a isolation of soma and axons. Human-induced pluripotent stem cell-derived motor neurons are maintained up to 7 weeks in vitro. We performed a chemically-induced axonal injury on isolated axons in the middle compartment only. We then follow the dynamics of the axonal regeneration using the triangular methodology with and without pharmacological compounds in soma channel. We show that this model can be sucessfully used for quantitative analysis of neurite outgrowth dynamics. To further strengthen the efficacy of those strategies, we will present a new technical feature with addition of a PDMS layer in which the microgrooves are hollowed out. Our data show an increase in the rate of axonal projections into triangular channel and an improvement in axon orientation and elongation.

EVALUATION OF THE ROLE OF EARLY NEURONAL ACTIVITY ON THE ZEBRAFISH DOPAMINERGIC CELLS DEVELOPMENT, A TRANSCRIPTOMIC STUDY.

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Michael Demarque
NeuroPSI, Neuroinfection And Immunity, saclay, France

Interneuronal communication starts before the establishment of the synapses with alternative forms of neuronal excitability, called here Embryonic Neuronal Excitability (ENE). We recently established the zebrafish as a model to study the developmental contribution of ENE to the differentiation of dopaminergic neurons. Based on previous work in Xenopus, we have validated pharmocological treatments to increase (Veratridine 10 µM) or decrease (TTX 2.5µM, Conotoxin 0.1µM, Nifedipin 0.5µM, Flunarizin 2.5µM) (TCNF) ENE in zebrafish embryos. To identify the genes whose expression was modified in monoaminergic precursors following alterations of ENE, we performed a comparative RNAseq analysis following these validated ENE-increasing or -decreasing treatments. vMAT2, encoded by slc18a2, is the key transporter of monamine neurotransmitters into synaptic vesicles. To restrict the analysis to monoaminergic cells, we FACS-sorted GFP-positive cells from dissociated Tg(VMAT2:GFP) embryos, 24 hours after pharmacological treatment. Bulk RNA-sequencing was conducted on these sorted cells, providing a list of activity-dependent factors in monoaminergic neurons. In this list we identified some transcription factors involved in the specification of the dopaminergic phenotype, including pax6a whose expression is decreased following TCNF exposure and dlx2a whose expression is decreased following veratridine exposure, and interestingly the expression of transcripts related to the innate immune response is also modified. The functional effects of the best candidate genes will be studied by gene inactivation using CRISPR technology. These results provide a convenient framework to study the molecular mechanisms linking ENE to neurotransmitter specification, with relevance to the pathogenesis of neurodevelopmental disorders. plutôt: synaptic networks?

DEVELOPMENTAL PROCESSES GOVERNING CELL TYPE IDENTITY IN THE CEREBRAL CORTEX

POSTER SESSION 05 - SECTION: EVO-DEVO - EVOLUTIONARY DEVELOPMENTAL NEUROSCIENCE

Katherine Matho[1], Xiaoyin Chen[2], Sweta Srivas[3], Erica Bulzomi[1], Dhananjay Huilgol[3], Z. Josh Huang[1,3]
[1]Cold Spring Harbor Laboratory, Neuroscience, Cold Spring Harbor, United States of America, [2]Allen Brain Institute for Brain Science, Neuroscience, Seattle, United States of America, [3]Duke University, Neuroscience, Durham, United States of America

Major efforts have aimed to classify the excitatory glutamatergic pyramidal neuron (PyN) cell types of cerebral cortex based on molecular, anatomic, and physiological features. Additionally, neurodevelopmental research has reconstructed developmental trajectories for PyNs based on fixed timepoints and pseudotime analyses. However, a significant knowledge gap remains in connecting the embryonic developmental history of PyNs with their ultimate cell fate in the mature, functional brain. PyNs arise from radial glial progenitors (RG) by direct or indirect neurogenesis (dNG or iNG) at specific embryonic timepoints. Advances in mouse genetics, based on decades of prior knowledge of cortical development and candidate marker genes of PyN subsets, have recently provided gene knock-in (KI) mouse lines to access and manipulate PyNs and progenitors. Here, we focus on a population of extratelencephalic PyNs which emerges during embryonic development from both dNG and iNG. We correlate the mode of neurogenesis, whether dNG or iNG, with molecular signatures using spatial transcriptomics in the adult cerebral cortex. This multi-modal approach reveals the effect of a transient developmental event occurring embryonically—dNG versus iNG—on PyN identity as we measure molecular signatures as a cell type readout. Assessing the relationship between developmental origin and cell-types allows us to achieve a finer granularity, required for understanding cortical function.

Autosomal Dominant Leukodystrophy (ADLD) is a rare genetic disease characterized by autonomic dysfunction and movement disorder and associated with white matter loss in the central nervous system. The genetic cause is the presence of three copies of the gene that contains the instructions to produce the lamin B1 (LMNB1) protein, which belongs to a group of structural proteins forming the nuclear membrane of the cell. Pathogenic mechanisms in ADLD have only initially been explored. Moreover, a therapy to treat this disease is not available at the moment. Based on the evidence showing glial pathology in ADLD patients, we generated human glial cells from both ADLD patient- and healthy donor (CTRL)- derived human-induced pluripotent stem cells (hiPSCs). We established a differentiation protocol based on three stages: the commitment to neural progenitors, the production of gliospheres and a further maturation step into authentic oligodendrocytes and astrocytes. Preliminary observations indicate a lower gliogenic potential in the hiPSC ADLD lineages, as revealed by gliosphere production. In ADLD astrocytes an altered expression of LMNB1 is confirmed by RT-qPCR and protein expression, together with morphological alterations affecting the nuclear shape that in turn impacts certain morphological features of the cell body (ramifications, area covered). Functional analyses will be devoted to investigate possible alterations correlated to the LMNB1 higher expression. Thus, the developed model appears as a promising "disease-in-a-dish" platform to further reveal so far unknown dysfunctions of the diseased cells and, prospectively, aid the development of effective therapeutic strategies for this rare genetic disease.

c-Jun N-terminal kinase 1 (JNK1) modulates oligodendrocyte progenitor cell architecture, proliferation and myelination.
During Central Nervous System ontogenesis, myelinating oligodendrocytes (OLs) arise from highly ramified and proliferative precursors called oligodendrocyte progenitor cells (OPCs). OPC architecture, proliferation and oligodendro-/myelino-genesis are finely regulated by the interplay of cell-intrinsic and extrinsic factors. A variety of extrinsic cues converge on the extracellular signal-regulated kinase/mitogen activated protein kinase (ERK/MAPK) pathway. Here we found that the germinal ablation of the MAPK c-Jun N-Terminal Kinase isoform 1 (JNK1) results in a significant reduction of myelin in the cerebral cortex and corpus callosum at both postnatal and adult stages. Myelin alterations are accompanied by higher OPC density and proliferation during the first weeks of life, consistent with a transient alteration of mechanisms regulating OPC self-renewal and differentiation. JNK1 KO OPCs also show smaller occupancy territories and a less complex branching architecture in vivo. Notably, these latter phenotypes are recapitulated in pure cultures of JNK1 KO OPCs and of WT OPCs treated with the JNK inhibitor D-JNKI-1. Moreover, JNK1 KO and WT D-JNKI-1 treated OLs, while not showing overt alterations of differentiation in vitro, display a reduced surface compared to controls. Our results unveil a novel player in the complex regulation of OPC biology, on the one hand showing that JNK1 ablation cell-autonomously determines alterations of OPC proliferation and branching architecture and, on the other hand, suggesting that JNK1 signaling in OLs participates in myelination in vivo.

A high-content drug screening strategy to identify protein level modulators for genetic diseases: A proof-of-principle in

autosomal dominant leukodystrophy.
In genetic diseases, the most prevalent mechanism of pathogenicity is an altered expression of dosage-sensitive genes. Drugs that restore physiological levels of these genes should be effective in treating the associated conditions. We developed a screening strategy, based on a bicistronic dual-reporter vector, for identifying compounds that modulate protein levels, and used it in a pharmacological screening approach. To provide a proof-of-principle, we chose autosomal dominant leukodystrophy (ADLD), an ultra-rare adult-onset neurodegenerative disorder caused by lamin B1 (LMNB1) overexpression. We used a stable Chinese hamster ovary (CHO) cell line that simultaneously expresses an AcGFP reporter fused to LMNB1 and a Ds-Red normalizer. Using high-content imaging analysis, we screened a library of 717 biologically active compounds and approved drugs, and identified alvespimycin, an HSP90 inhibitor, as a positive hit. We confirmed that alvespimycin can reduce LMNB1 levels by 30%-80% in five different cell lines (fibroblasts, NIH3T3, CHO, COS-7, and rat primary glial cells). In ADLD fibroblasts, alvespimycin reduced cytoplasmic LMNB1 by about 50%. We propose this approach for effectively identifying potential drugs for treating genetic diseases associated with deletions/duplications and paving the way toward Phase II clinical trials.

Allele-specific silencing as treatment for gene duplication disorders: proof-of-principle in autosomal dominant leukodystrophy.
Allele-specific silencing by RNA interference (ASP-siRNA) holds promise as a therapeutic strategy for downregulating a single mutant allele with minimal suppression of the corresponding wild-type allele. This approach has been effectively used to target autosomal dominant mutations and single nucleotide polymorphisms linked with aberrantly expanded trinucleotide repeats. Here, we propose ASP-siRNA as a preferable choice to target duplicated disease genes, avoiding potentially harmful excessive downregulation. As a proof-of-concept, we studied autosomal dominant adult-onset demyelinating leukodystrophy (ADLD) due to lamin B1 (LMNB1) duplication, a hereditary, progressive and fatal disorder affecting myelin in the CNS. Using a reporter system, we screened the most efficient ASP-siRNAs preferentially targeting one of the alleles at rs1051644 (average minor allele frequency: 0.45) located in the 3' untranslated region of the gene. We identified four siRNAs with a high efficacy and allele-specificity, which were tested in ADLD patient-derived fibroblasts. Three of the small interfering RNAs were highly selective for the target allele and restored both LMNB1 mRNA and protein levels close to control levels. Furthermore, small interfering RNA treatment abrogates the ADLD-specific phenotypes in fibroblasts and in two disease-relevant cellular models: murine oligodendrocytes overexpressing human LMNB1, and neurons directly reprogrammed from patients' fibroblasts. In conclusion, we demonstrated that ASP-silencing by RNA interference is a suitable and promising therapeutic option for ADLD. Moreover, our results have a broad translational value extending to several pathological conditions linked to gene-gain in copy number variations.

Aims: To understand how a ketogenic diet may influence brain development, we investigated how the primary ketone body Beta-hydroxybutyrate (β-OHB) affected the growth and differentiation of cortical neural stem cells (NSCs) in the presence or absence of potentially confounding culture metabolic substrates. **Methods:** NSCs were first grown in regular glucose (5 mM), low glucose (1 mM), glucose free (0 mM), glucose free without pyruvate, glucose free without glutamine and glucose free without pyruvate and glutamine containing media and supplemented with β-OHB for four days in vitro (DIV). To further investigate cellular development, NSCs were then differentiated using retinoic acid in the same media groups above for five, 10 and 15 DIV. The immunocytochemical markers βIII-tubulin, actin and DAPI were used to assess differentiation, neurite length and number, cell density and structure. MTT assays and microscopic analysis assessed cell viability. Statistical analysis was performed using GraphPad Prism 9. **Results:** Substrate deprivation reduced the growth, viability, and neuronal phenotype of cells. β-OHB induced a growth response in media without glucose and pyruvate at 4 DIV. β-OHB supplementation resulted in a growth response to cell growth, neurite length and neurite number in 1 mM glucose media and media without glucose and glutamine at 10 DIV and 15 DIV. **Conclusion:** These data indicate that β-OHB may rescue NSC growth in response to glucose deprivation. Furthermore, culture medium compositions play a key role in experimental paradigms where multiple fuel sources may offer alternative inputs to glycolytic and oxidative phosphorylation phases of NSC development.

The Growth Response to Beta-Hydroxybutyrate in SH-SY5Y Neuroblastoma Cells is Suppressed by Glucose and Pyruvate Supplementation.
Neuroblastoma (NB) is a childhood malignancy of the sympathetic nervous system and is commonly studied using the SH-SY5Y cell line. Its neoplastic and neurodevelopmental manifestations are characterised by a high glucose demand which maintains its high proliferative capacity. This metabolic phenotype may be utilised in dietary therapies such as the ketone diet which alter substrate availability and thus starve NB cells of their preferred biosynthetic requirements. However, the effects of ketone metabolism on cancer growth remain poorly understood due to the involvement of other metabolic substrates in experimental paradigms and complexities underlying the Warburg effect. We investigated how the primary ketone body beta-hydroxybutyrate (βOHB) affects the growth of SH-SY5Y NB cells in the presence or absence of culture metabolic substrates. We demonstrated that while glucose deprivation reduced the growth and viability of SH-SY5Y cells, they proliferated and were initially unaffected by the addition of βOHB. However, a growth response to βOHB was subsequently revealed in media containing low levels of glucose, as well as in glucose and pyruvate deprived conditions. These data shed light on the roles of metabolic substrate availability as key determinants of the responses of SH-SY5Y NB cells to ketone supplementation.

The ketogenic diet in disease and development.
The ketogenic diet, low in carbohydrates and high in fat, was initially designed to reduce seizure onset in epilepsy. More recent evidence has shown its effectiveness in the treatment of movement and psychological disorders, and in general health maintenance. The cellular significance of ketone body metabolism during development and in the adult central nervous system is being revealed; however, the effects of replacing glucose with ketone bodies as the brain's primary energy source especially in pregnancy are not fully understood. In this mini-review, we highlight key findings related to the functional consequences of ketone body metabolism and monocarboxylic transporter expression throughout development and adulthood. We outline the therapeutic relevance of ketone bodies, and place a spotlight on the known effects of a maternal

ketogenic diet on the developing brain.

Aim: The cerebral cortex is at the core of brain functions that are expanded in the human species. Human cortical pyramidal neurons display distinctive morphological and functional features, as well as prolonged neotenic development. Even tough gene regulatory networks of corticogenesis appear to be largely conserved among all mammals, the emergence of novel duplicated genes in hominid and human genomes (HS genes) may contribute to species specificities of neurodevelopment. Here we investigated the role of such duplicated genes in the maturation of human pyramidal neurons. Methods: Using a model of xenotransplantation of human cortical neurons in the mouse neonatal cortex, we explored the function of the HS gene SRGAP2C, previously implicated in synaptic development by gain of function in the mouse cortex. This model uniquely allows to assess the development and function of human neurons in vivo, from early development to neural circuit integration. We also extended our studies to other HS genes. Results: We found that the loss of function of SRGAP2C leads to a striking acceleration of dendritic spine and synaptic development of human cortical neurons in vivo, both morphologically and functionally. We also identified potential important functions for other HS genes in the control of human-specific neuronal features. Conclusion: Our data demonstrate the key role of SRGAP2C in the control of developmental timing of human neurons in vivo. They constitute the first evidence of the requirement of HS genes in human neurons, pointing to recent gene duplications as a key drive of human cortex evolution.

Cellular and Molecular Mechanisms Linking Human Cortical Development and Evolution.
The cerebral cortex is at the core of brain functions that are thought to be particularly developed in the human species. Human cortex specificities stem from divergent features of corticogenesis, leading to increased cortical size and complexity. Underlying cellular mechanisms include prolonged patterns of neuronal generation and maturation, as well as the amplification of specific types of stem/progenitor cells. While the gene regulatory networks of corticogenesis appear to be largely conserved among all mammals including humans, they have evolved in primates, particularly in the human species, through the emergence of rapidly divergent transcriptional regulatory elements, as well as recently duplicated novel genes. These human-specific molecular features together control key cellular milestones of human corticogenesis and are often affected in neurodevelopmental disorders, thus linking human neural development, evolution, and diseases.

Xenotransplanted Human Cortical Neurons Reveal Species-Specific Development and Functional Integration into Mouse Visual Circuits.
How neural circuits develop in the human brain has remained almost impossible to study at the neuronal level. Here, we investigate human cortical neuron development, plasticity, and function using a mouse/human chimera model in which xenotransplanted human cortical pyramidal neurons integrate as single cells into the mouse cortex. Combined neuronal tracing, electrophysiology, and in vivo structural and functional imaging of the transplanted cells reveal a coordinated developmental roadmap recapitulating key milestones of human cortical neuron development. The human neurons display a prolonged developmental timeline, indicating the neuron-intrinsic retention of juvenile properties as an important component of human brain neoteny. Following maturation, human neurons in the visual cortex display tuned, decorrelated responses to

visual stimuli, like mouse neurons, demonstrating their capacity for physiological synaptic integration in host cortical circuits. These findings provide new insights into human neuronal development and open novel avenues for the study of human neuronal function and disease. VIDEO ABSTRACT.

Auditory cortex interneuron development requires cadherins operating hair-cell mechanoelectrical transduction.
Many genetic forms of congenital deafness affect the sound reception antenna of cochlear sensory cells, the hair bundle. The resulting sensory deprivation jeopardizes auditory cortex (AC) maturation. Early prosthetic intervention should revive this process. Nevertheless, this view assumes that no intrinsic AC deficits coexist with the cochlear ones, a possibility as yet unexplored. We show here that many GABAergic interneurons, from their generation in the medial ganglionic eminence up to their settlement in the AC, express two cadherin-related (cdhr) proteins, cdhr23 and cdhr15, that form the hair bundle tip links gating the mechanoelectrical transduction channels. Mutant mice lacking either protein showed a major decrease in the number of parvalbumin interneurons specifically in the AC, and displayed audiogenic reflex seizures. - and -expressing interneuron precursors in and mouse embryos, respectively, failed to enter the embryonic cortex and were scattered throughout the subpallium, consistent with the cell polarity abnormalities we observed in vitro. In the absence of adhesion G protein-coupled receptor V1 (adgrv1), another hair bundle link protein, the entry of - and -expressing interneuron precursors into the embryonic cortex was also impaired. Our results demonstrate that a population of newborn interneurons is endowed with specific cdhr proteins necessary for these cells to reach the developing AC. We suggest that an "early adhesion code" targets populations of interneuron precursors to restricted neocortical regions belonging to the same functional area. These findings open up new perspectives for auditory rehabilitation and cortical therapies in patients.

DIFFERENTIATION AND TRANSPLANTATION OF DOPAMINERGIC NEURONS DERIVED FROM INDUCED PLURIPOTENT STEM CELLS IN PARKINSONIAN MARMOSETS

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Etienne Daadi, Elyas Daadi, Thomas Oh, Jeffrey Kim, Gourav Roy Choudhury, Marcel Daadi
Texas Biomedical Research Institute, Southwest National Primate Research Center, San Antonio, United States of America

Parkinson's disease (PD) is a chronic progressive neurodegenerative disorder caused by the death of dopaminergic neurons in the substantia nigra pars compacta (SNc). The loss of dopaminergic neurons in the SNc results in a range of debilitating movement disorders, such as bradykinesia, tremor, rigidity and postural instability in the affected patients. Induced pluripotent stem cells (iPSCs) are specialized cells that can be differentiated into the three germ layers and serve as a valuable source for cell-based replacement therapies. Evidence indicates that stem cell derived dopaminergic neurons are a promising avenue in the search for a viable long-term treatment of PD patients. Here, we report the isolation of self-renewable neural stem cells (NSCs) from human iPSCs derived from PD patients. The NSCs demonstrated the ability to proliferate in response to mitogenic growth factors. The isolated NSCs were further differentiated into neurons of dopaminergic lineage. The dopaminergic neurons co-expressed the tyrosine hydroxylase, β-tubulin and midbrain transcription factors. Quantitative analysis demonstrated that the number of dopaminergic neurons significantly increased on days 1, 2 and 7 in vitro compared to control-treated NSCs. Differentiated neurons were transplanted into the putamen of MPTP-lesioned marmoset model of PD. The animals were monitored for a period of 6 months. The object retrieval task with barrier detour, the PD rating scale (PDRS) and activity analysis were validated for evaluating motor and cognitive functions. The data suggests that grafted iPSC-derived dopaminergic neurons are efficacious in alleviating the behavioral deficits observed in the marmoset model of PD.

Dopamine D3 receptor ligand suppresses the expression of levodopa-induced dyskinesia in nonhuman primate model of parkinson's disease.
Parkinson's disease (PD) is a complex multisystem, chronic and so far incurable disease with significant unmet medical needs. The incidence of PD increases with aging and the expected burden will continue to escalate with our aging population. Since its discovery in the 1961 levodopa has remained the gold standard pharmacotherapy for PD. However, the progressive nature of the neurodegenerative process in and beyond the nigrostriatal system causes a multitude of side effects, including levodopa-induced dyskinesia within 5 years of therapy. Attenuating dyskinesia has been a significant challenge in the clinical management of PD. We report on a small molecule that eliminates the expression of levodopa-induced dyskinesia and significantly improves PD-like symptoms. The lead compound PD13R we discovered is a dopamine D3 receptor partial agonist with high affinity and selectivity, orally active and with desirable drug-like properties. Future studies are aimed at developing this lead compound for treating PD patients with dyskinesia.

Age-related cognitive decline in baboons: modeling the prodromal phase of Alzheimer's disease and related dementias.
The aging of brain cells and synaptic loss are the major underlying pathophysiological processes contributing to the progressive decline in cognitive functions and Alzheimer's disease. The difference in cognitive performances observed between adult and aged subjects across species highlights the decline of brain systems with age. The inflection point in age-related cognitive decline is important for our understanding of the pathophysiology of neurodegenerative diseases and for timing therapeutic interventions. Humans and nonhuman primates share many similarities including age-dependent changes in gene expression and decline in neural and immune functions. Given these evolutionary conserved organ systems, complex human-like behavioral and age-dependent changes may be modeled and monitored longitudinally in nonhuman primates. We integrated three clinically relevant outcome measures to investigate the effect of age on cognition, motor function and diurnal activity in aged baboons. We provide evidence of a naturally-occurring age-dependent precipitous decline in movement planning, in learning novel tasks, in simple discrimination and in motivation. These results suggest that baboons aged ~20

years (equivalent to ~60 year old humans) may offer a relevant model for the prodromal phase of Alzheimer's disease and related dementias to investigate mechanisms involved in the precipitous decline in cognitive functions and to develop early therapeutic interventions.

THE MORE, THE BETTER? NEUROPROTECTIVE EFFECTS OF DIFFERENT DRUG- AND STEM CELL-BASED THERAPIES AS NOVEL APPROACHES FOR NEURODEGENERATIVE DISEASES.

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Current therapeutic approaches based on “one gene, one drug, one disease” philosophy usually offer limited benefits for the treatment of neurodegenerative diseases. However, little is known about the synergy of combined therapies. In this study, the possible synergistic effect of the combination of the endocannabinoid oleoylethanolamide (OEA) and different stem cell (SC) therapies was assessed in a model of aggressive cerebellar degeneration, the PCD mouse. Three different therapies were evaluated: a) OEA (i.p., 10 mg/kg) at post-natal day 12 (P12), b) OEA + bone marrow ablation and $7.5x10^6$ bone marrow SC (BMSC) transplantation at P20, and c) OEA + $2.5x10^5$ mesenchymal SC (MSC) injection at P14-16-18-20-22-24-26-28. Both BMSC and MSC were harvested from healthy GFP-mice and administered through the retro-orbital plexus. *Rotarod* test was performed at P22 and P30, as PCD animals exhibit motor impairments. Finally, at P30, GFP-positive cells from peripheral blood were quantified by flow cytometry, animals were sacrificed, and their brain dissected. Both the neuroprotective effect on Purkinje cells density and morphology, and the analysis of the transplant-derived cells were carried out by immunofluorescence in cerebellar vermis sections. Our preliminary data showed that all the approaches evaluated exerted certain neuroprotection in PCD animals. Contrary to expectations, the most effective treatment was the single OEA treatment, followed by the combined OEA and quasi-continuous MSC transplantation, both at the cellular and behavioral level. Finally, GFP-positive cells were observed in all animals transplanted with BMSC or MSC, although a higher number was found in those treated with BMSC.

Oleoylethanolamide Delays the Dysfunction and Death of Purkinje Cells and Ameliorates Behavioral Defects in a Mouse Model of Cerebellar Neurodegeneration.
Oleoylethanolamide (OEA) is an endocannabinoid that has been proposed to prevent neuronal damage and neuroinflammation. In this study, we evaluated the effects of OEA on the disruption of both cerebellar structure and physiology and on the behavior of Purkinje cell degeneration (PCD) mutant mice. These mice exhibit cerebellar degeneration, displaying microtubule alterations that trigger the selective loss of Purkinje cells and consequent behavioral impairments. The effects of different doses (1, 5, and 10 mg/kg, i.p.) and administration schedules (chronic and acute) of OEA were assessed at the behavioral, histological, cellular, and molecular levels to determine the most effective OEA treatment regimen. Our in vivo results demonstrated that OEA treatment prior to the onset of the preneurodegenerative phase prevented morphological alterations in Purkinje neurons (the somata and dendritic arbors) and decreased Purkinje cell death. This effect followed an inverted U-shaped time-response curve, with acute administration on postnatal day 12 (10 mg/kg, i.p.) being the most effective treatment regimen tested. Indeed, PCD mice that received this specific OEA treatment regimen showed improvements in motor, cognitive and social functions, which were impaired in these mice. Moreover, these in vivo neuroprotective effects of OEA were mediated by the PPARα receptor, as pretreatment with the PPARα antagonist GW6471 (2.5 mg/kg, i.p.) abolished them. Finally, our in vitro results suggested that the molecular effect of OEA was related to microtubule stability and structure since OEA administration normalized some alterations in microtubule features in PCD-like cells. These findings provide strong evidence supporting the use of OEA as a pharmacological agent to limit severe cerebellar neurodegenerative processes.

The Selective Loss of Purkinje Cells Induces Specific Peripheral Immune Alterations.

The progression of neurodegenerative diseases is reciprocally associated with impairments in peripheral immune responses. We investigated different contexts of selective neurodegeneration to identify specific alterations of peripheral immune cells and, at the same time, discover potential biomarkers associated to this pathological condition. Consequently, a model of human cerebellar degeneration and ataxia -the Purkinje Cell Degeneration (PCD) mouse- has been employed, as it allows the study of different processes of selective neuronal death in the same animal, i.e., Purkinje cells in the cerebellum and mitral cells in the olfactory bulb. Infiltrated leukocytes were studied in both brain areas and compared with those from other standardized neuroinflammatory models obtained by administering either gamma radiation or lipopolysaccharide. Moreover, both myeloid and lymphoid splenic populations were analyzed by flow cytometry, focusing on markers of functional maturity and antigen presentation. The severity and type of neural damage and inflammation affected immune cell infiltration. Leukocytes were more numerous in the cerebellum of PCD mice, being located predominantly within those cerebellar layers mostly affected by neurodegeneration, in a completely different manner than the typical models of induced neuroinflammation. Furthermore, the milder degeneration of the olfactory bulb did not foster leukocyte attraction. Concerning the splenic analysis, in PCD mice we found: (1) a decreased percentage of several myeloid cell subsets, and (2) a reduced mean fluorescence intensity in those myeloid markers related to both antigen presentation and functional maturity. In conclusion, the selective degeneration of Purkinje cells triggers a specific effect on peripheral immune cells, fostering both attraction and functional changes. This fact endorses the employment of peripheral immune cell populations as concrete biomarkers for monitoring different neuronal death processes.

STUDYING NEURONAL PLASTICITY WITH HUMAN CORTICAL NEURONS XENOTRANSPLANTED INTO THE MOUSE VISUAL CORTEX

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Polona Jager[1], Ben Vermaercke[1], Ryohei Iwata[1], Vincent Bonin[2], Pierre Vanderhaeghen[1]

Aims Neural plasticity is greatest during development, but decreases into adulthood. Reversing this timeline would have major implications for treating brain diseases. A xenotransplantation method was previously developed in the lab, where human pyramidal neurons are derived from embryonic stem cells and transplanted into the neonatal mouse cortex. Transplanted human neurons retain their species-specific protracted development, displaying juvenile morphology and physiology even in an adult mouse host. Here, we explore whether transplanted human neurons also display prolonged functional plasticity, and investigate if developing human neurons impart their juvenile synaptic properties on the mature mouse circuits, thus increasing their plasticity. Methods We use longitudinal calcium imaging to track sensory responses of human neurons transplanted in the mouse visual cortex, and those of the surrounding adult mouse neurons. Monocular deprivation is performed to study functional plasticity of both neuronal populations. Finally, transsynaptic tracing is applied to selectively study plasticity of mouse neurons presynaptic to human cells. Results Human neurons in the mouse visual cortex respond to visual stimuli, and importantly, adapt their responses according to visual experience of the mouse host, thus displaying plasticity while embedded in the adult mouse circuits. For the adult mouse host neurons, our preliminary data show a plastic change selectively in those synaptically connected to transplanted human cells. Conclusions Xenotransplantation of developing human cortical neurons constitutes an attractive model for studying human neural plasticity *in vivo*, which could be applied to disease modeling, and for future studies on induction of plasticity in an adult brain.

Dual midbrain and forebrain origins of thalamic inhibitory interneurons.
The ubiquitous presence of inhibitory interneurons in the thalamus of primates contrasts with the sparsity of interneurons reported in mice. Here, we identify a larger than expected complexity and distribution of interneurons across the mouse thalamus, where all thalamic interneurons can be traced back to two developmental programmes: one specified in the midbrain and the other in the forebrain. Interneurons migrate to functionally distinct thalamocortical nuclei depending on their origin: the abundant, midbrain-derived class populates the first and higher order sensory thalamus while the rarer, forebrain-generated class is restricted to some higher order associative regions. We also observe that markers for the midbrain-born class are abundantly expressed throughout the thalamus of the New World monkey marmoset. These data therefore reveal that, despite the broad variability in interneuron density across mammalian species, the blueprint of the ontogenetic organisation of thalamic interneurons of larger-brained mammals exists and can be studied in mice.

Tectal-derived interneurons contribute to phasic and tonic inhibition in the visual thalamus.
The release of GABA from local interneurons in the dorsal lateral geniculate nucleus (dLGN-INs) provides inhibitory control during visual processing within the thalamus. It is commonly assumed that this important class of interneurons originates from within the thalamic complex, but we now show that during early postnatal development Sox14/Otx2-expressing precursor cells migrate from the dorsal midbrain to generate dLGN-INs. The unexpected extra-diencephalic origin of dLGN-INs sets them apart from GABAergic neurons of the reticular thalamic nucleus. Using optogenetics we show that at increased firing rates tectal-derived dLGN-INs generate a powerful form of tonic inhibition that regulates the gain of thalamic relay neurons through recruitment of extrasynaptic high-affinity GABA receptors. Therefore, by revising the conventional view of thalamic interneuron ontogeny we demonstrate how a previously unappreciated mesencephalic population controls thalamic relay neuron excitability.

Circadian factor BMAL1 in histaminergic neurons regulates sleep architecture.
Circadian clocks allow anticipation of daily environmental changes. The suprachiasmatic nucleus (SCN) houses the master clock, but clocks are also widely expressed elsewhere in the body. Although some peripheral clocks have established roles, it is unclear what local brain clocks do. We tested the contribution of one putative local clock in mouse histaminergic neurons in the tuberomamillary nucleus to the regulation of the sleep-wake cycle. Histaminergic neurons are silent during sleep, and start firing after wake onset; the released histamine, made by the enzyme histidine decarboxylase (HDC), enhances wakefulness. We found that hdc gene expression varies with time of day. Selectively deleting the Bmal1 (also known as Arntl or Mop3) clock gene from histaminergic cells removes this variation, producing higher HDC expression and brain histamine levels during the day. The consequences include more fragmented sleep, prolonged wake at night, shallower sleep depth (lower nonrapid eye movement [NREM] δ power), increased NREM-to-REM transitions, hindered recovery sleep after sleep deprivation, and impaired memory. Removing BMAL1 from histaminergic neurons does not, however, affect circadian rhythms. We propose that for mammals with polyphasic/nonwake consolidating sleep, the local BMAL1-dependent clock directs appropriately timed declines and increases in histamine biosynthesis to produce an appropriate balance of wake and sleep within the overall daily cycle of rest and activity specified by the SCN.

Background: Peripheral neuropathy is a common adverse effect observed during use of paclitaxel (PTX) as chemotherapy. Aim: The present investigation was directed to estimate the modulatory effect of bone marrow derived mesenchymal stem cells (BM-MSCs) on pregabalin (PGB) treatment in PTX-induced peripheral neuropathy. Methods: Neuropathic pain was induced in rats by injecting PTX (2 mg/kg, i.p) 4 times every other day. Rats were treated with PGB (30 mg/kg/day, p.o.) for 21 days with or without a single intravenous administration of BM-MSCs. At the end of experiment, behavioral and motor abnormalities were assessed. Animals were then sacrificed for measurement of total antioxidant capacity (TAC), nerve growth factor (NGF), nuclear factor kappa B p65 (NF-κB p65), tumor necrosis factor-alpha (TNF-α), interleukins 6 (IL-6), and active caspase-3 in the sciatic nerve. Moreover, protein expressions of Notch1 receptor, phosphorylated Janus kinase 2 (*p*-JAK2), phosphorylated signal transducer and activator of transcription 3 (*p*-STAT3), and phosphorylated p38 mitogen-activated protein kinase (*p*-p38-MAPK) were estimated. Finally, histological examinations were performed to assess severity of sciatic nerve damage and for estimation of BM-MSCs homing. Results: Combined PGB/BM-MSCs therapy provided an additional improvement toward reducing PTX-induced oxidative stress, neuro-inflammation, and apoptotic markers. Interestingly, BM-MSCs therapy effectively prevented motor impairment observed by PGB treatment. Combined therapy also induced a significant increase in cell homing and prevented PTX-induced sciatic nerve damage in histological examination. Conclusion: The present study highlights a significant role for BM-MSCs in enhancing treatment potential of PGB in peripheral neuropathy and reducing its motor side effects.

Neurodegenerative diseases represent a high economic and health burden for society, and efficient treatments are limited. One of the most promising therapeutic strategies is bone marrow-derived cells (BMDCs) transplantation. Indeed, our group has demonstrated that this strategy improves motor activity in a mouse model of cerebellar ataxia. Furthermore, we and others showed that BMDCs integrate into the central nervous system, either switching from one cell type to another (transdifferentiation) or by cell fusion (forming heterokaryons) as it happens with cerebellar Purkinje cells. Generally, the number of fused Purkinje cells after transplantation is small, which limits their analysis, and makes it difficult to verify the relationship between cell fusion and neuron survival suggested in literature. Nevertheless, few studies have reported a 20-fold increase of cell fusion in mice with experimental autoimmune encephalomyelitis (EAE), a model of induced multiple sclerosis. However, these studies differ in the methodologies used, mainly in experimental timings for transplant, EAE induction and sacrifice. Therefore, we aim to establish an optimal protocol to study cell fusion after BMDCs transplantation in EAE mice. We used different time windows between EAE induction and sacrifice and analysed the number of fused cells. Our data will allow us to estimate fusion rate variations over time, determining the dynamics of cell fusion. This will be crucial for future studies in which we will identify the molecular mechanisms involved in cell fusion by comparing the transcriptome of fused and non-fused Purkinje cells. Secretagogin expression in the mouse olfactory bulb under sensory impairments.
The interneurons of the olfactory bulb (OB) are characterized by the expression of different calcium-binding proteins, whose specific functions are not fully understood. This is the case of one of the most recently discovered, the secretagogin (SCGN), which is expressed in interneurons of the glomerular and the granule cell layers, but whose function in the olfactory pathway is still unknown. To address this question, we examined the distribution, generation and activity of SCGN-positive interneurons in the OB of two complementary models of olfactory impairments: Purkinje Cell Degeneration (PCD) and olfactory-deprived mice. Our results showed a significant increase in the density of SCGN-positive cells in the inframitral layers of olfactory-deprived mice as compared to control animals. Moreover, BrdU analyses revealed that these additional SCGN-positive cells are not newly formed. Finally, the neuronal activity, estimated by c-Fos expression, increased in preexisting SCGN-positive interneurons of both deprived and PCD mice -being higher in the later- in comparison with control animals. Altogether, our results suggest that the OB possesses different compensatory mechanisms depending on the type of alteration. Particularly, the SCGN expression is dependent of olfactory stimuli and its function may be related to a compensation against a reduction in sensory inputs.

TRANSPLANTATION OF SPINAL NEURON SUBTYPES GENERATED FROM HUMAN PLURIPOTENT STEM CELLS

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Stefano Frausin, Cameron Hunt, Clare Parish, Lachlan Thompson
The Florey Institute of Neuroscience and Mental Health, The Florey Institute Of Neuroscience And Mental Health, Parkville, Australia

The spinal cord is composed of heterogeneous neuronal populations organised in complex neural circuits that finely control many activities of our body. Traumatic injury or neurodegenerative diseases cause permanent damage and impairment in affected individuals. To date, the possibility to effectively treat these patients remains limited, and new approaches need to be investigated. The capacity of human pluripotent stem cells (hPSCs) to differentiate into a wide range of neuronal cell types makes these cells attractive for neural transplantation therapies aimed at repairing damaged spinal circuitry and/or supporting at risk host neurons. Current challenges for the development of stem cell-based therapies include low efficiency of differentiation protocols, limited capacity to derive specific spinal neural subtypes, and limited knowledge of cell behaviour after intraspinal transplantation. In this study, we developed 2D adherent differentiation protocols to derive progenitors for spinal motoneuron (spMN) and interneuron (spIN) subtypes. Transplantation studies showed the capacity of these progenitors to survive and retain neuronal phenotype *in vivo* after intra-spinal grafting in athymic rats. These results form a valuable platform for investigating the efficacy of cell transplantation for spinal cord injury on a cell type specific basis.

A combined cell and gene therapy approach for homotopic reconstruction of midbrain dopamine pathways using human pluripotent stem cells.
Midbrain dopamine (mDA) neurons can be replaced in patients with Parkinson's disease (PD) in order to provide long-term improvement in motor functions. The limited capacity for long-distance axonal growth in the adult brain means that cells are transplanted ectopically, into the striatal target. As a consequence, several mDA pathways are not re-instated, which may underlie the incomplete restoration of motor function in patients. Here, we show that viral delivery of GDNF to the striatum, in conjunction with homotopic transplantation of human pluripotent stem-cell-derived mDA neurons, recapitulates brain-wide mDA target innervation. The grafts provided re-instatement of striatal dopamine levels and correction of motor function and also connectivity with additional mDA target nuclei not well innervated by ectopic grafts. These results demonstrate the remarkable capacity for achieving functional and anatomically precise reconstruction of long-distance circuitry in the adult brain by matching appropriate growth-factor signaling to grafting of specific cell types.

Hemispheric cortical atrophy and chronic microglial activation following mild focal ischemic stroke in adult male rats.
Animal modeling has played an important role in our understanding of the pathobiology of stroke. The vast majority of this research has focused on the acute phase following severe forms of stroke that result in clear behavioral deficits. Human stroke, however, can vary widely in severity and clinical outcome. There is a rapidly building body of work suggesting that milder ischemic insults can precipitate functional impairment, including cognitive decline, that continues through the chronic phase after injury. Here we show that a small infarction localized to the frontal motor cortex of rats following injection of endothelin-1 results in an essentially asymptomatic state based on motor and cognitive testing, and yet produces significant histopathological change including remote atrophy and inflammation that persists up to 1 year. While there is understandably a major focus in stroke research on mitigating the acute consequences of primary infarction, these results point to progressive atrophy and chronic inflammation as additional targets for intervention in the chronic phase after injury. The present rodent model provides an important platform for further work in this area.

Focal Ischemic Injury to the Early Neonatal Rat Brain Models Cognitive and Motor Deficits with Associated Histopathological Outcomes Relevant to Human Neonatal Brain Injury.
Neonatal arterial ischemic stroke is one of the more severe birth complications. The injury can result in extensive neurological damage and is robustly associated with later diagnoses of cerebral palsy (CP). An important part of efforts to develop new therapies include the on-going refinement and understanding of animal models that capture relevant clinical features of neonatal brain injury leading to CP. The potent vasoconstrictor peptide, Endothelin-1 (ET-1), has previously been utilised in animal models to reduce local blood flow to levels that mimic ischemic stroke. Our previous work in this area has shown that it is an effective and technically simple approach for modelling ischemic injury at very early neonatal ages, resulting in stable deficits in motor function. Here, we aimed to extend this model to also examine the impact on cognitive function. We show that focal delivery of ET-1 to the cortex of Sprague Dawley rats on postnatal day 0 (P0) resulted in impaired learning in a touchscreen-based test of visual discrimination and correlated with important clinical features of CP including damage to large white matter structures.

In vivo survival and differentiation of Friedreich ataxia iPSC-derived sensory neurons transplanted in the adult dorsal root ganglia.
Friedreich ataxia (FRDA) is an autosomal recessive disease characterized by degeneration of dorsal root ganglia (DRG) sensory neurons, which is due to low levels of the mitochondrial protein Frataxin. To explore cell replacement therapies as a possible approach to treat FRDA, we examined transplantation of sensory neural progenitors derived from human embryonic stem cells (hESC) and FRDA induced pluripotent stem cells (iPSC) into adult rodent DRG regions. Our data showed survival and differentiation of hESC and FRDA iPSC-derived progenitors in the DRG 2 and 8 weeks post-transplantation, respectively. Donor cells expressed neuronal markers, including sensory and glial markers, demonstrating differentiation to these lineages. These results are novel and a highly significant first step in showing the possibility of using stem cells as a cell replacement therapy to treat DRG neurodegeneration in FRDA as well as other peripheral neuropathies.

Modelling the dopamine and noradrenergic cell loss that occurs in Parkinson's disease and the impact on hippocampal neurogenesis.
Key pathological features of Parkinson's Disease (PD) include the progressive degeneration of midbrain dopaminergic (DA) neurons and hindbrain noradrenergic (NA) neurons. The loss of DA neurons has been extensively studied and is the main cause of motor dysfunction. Importantly, however, there are a range of 'non-movement' related features of PD including cognitive dysfunction, sleep disturbances and mood disorders. The origins for these non-motor symptoms are less clear, but a possible substrate for cognitive decline may be reduced adult-hippocampal neurogenesis, which is reported to be impaired in PD. The mechanisms underlying reduced neurogenesis in PD are not well established. Here we tested the hypothesis that NA and DA depletion, as occurs in PD, impairs hippocampal neurogenesis. We used 6-hydroxydopamine or the immunotoxin dopamine-β-hydroxylase-saporin to selectively lesion DA or NA neurons, respectively, in adult Sprague Dawley rats and assessed hippocampal neurogenesis through phenotyping of cells birth-dated using 5-bromo-2'-deoxyuridine. The results showed no difference in proliferation or differentiation of newborn cells in the subgranular zone of the dentate gyrus after NA or DA lesions. This suggests that impairment of hippocampal neurogenesis in PD likely results from mechanisms independent of, or in addition to degeneration of DA and NA neurons.

Wharton's jelly derived mesenchymal stromal cells: Biological properties, induction of neuronal phenotype and current applications in neurodegeneration research.
Multipotent mesenchymal stromal cells, also known as mesenchymal stem cells (MSC), can be isolated from bone marrow or other tissues, including fat, muscle and umbilical cord. It has been shown that MSC behave in vitro as stem cells: they self-renew and are able to differentiate into mature cells typical of several mesenchymal tissues. Moreover, the differentiation toward non-mesenchymal cell lineages (e.g. neurons) has been reported as well. The clinical relevance of these cells is mainly related to their ability to spontaneously migrate to the site of inflammation/damage, to their safety profile thanks to their low immunogenicity and to their immunomodulation capacities. To date, MSCs isolated from the post-natal bone marrow have represented the most extensively studied population of adult MSCs, in view of their possible use in various therapeutical applications. However, the bone marrow-derived MSCs exhibit a series of limitations, mainly related to their problematic isolation, culturing and use. In recent years, umbilical cord (UC) matrix (i.e. Wharton's jelly, WJ) stromal cells have therefore emerged as a more suitable alternative source of MSCs, thanks to their primitive nature and the easy isolation without

relevant ethical concerns. This review seeks to provide an overview of the main biological properties of WJ-derived MSCs. Moreover, the potential application of these cells for the treatment of some known dysfunctions in the central and peripheral nervous system will also be discussed.

Aims: to propose an approach, using extracellular vesicles (EV) secreted from human mesenchymal stem cells isolated from adipose tissue (hAT-MSC), with a prolonged period for therapeutic intervention and a non-invasive route for administering the treatment of stroke. Methods: Wistar rats (90-120 days) were subjected to focal permanent ischemic stroke (IS), 24 hours after, were treated intranasally with EV (200 µg/kg) secreted by hAT-MSC. We analyzed front paws symmetry (Cylinder Task), short- and long-term memory (Open Field and Novel Object Recognition Task) and angiogenesis. Wistar Kyoto Spontaneously hypertensive rats (SHR) (90-120 days) were subjected to IS and we analyzed front paws symmetry (Cylinder Task). Results: In Wistar rats, EV treatment recovered front paws symmetry (Fig 1. A) and short- and long-term memory induced by ischemic stroke. Additionally, we observed stimulation of angiogenesis in the peri-infarction region in animals treated with EVs. For SHR rats, we have preliminary results, where we can observe that the outcome of ischemia induction is very different and with a chronic effect and without spontaneous recovery in the symmetry of the forepaws (Fig 1. B). Conclusions: In line with these findings, our work highlights hAT-MSC-derived EVs as a promising therapeutic strategy for stroke.

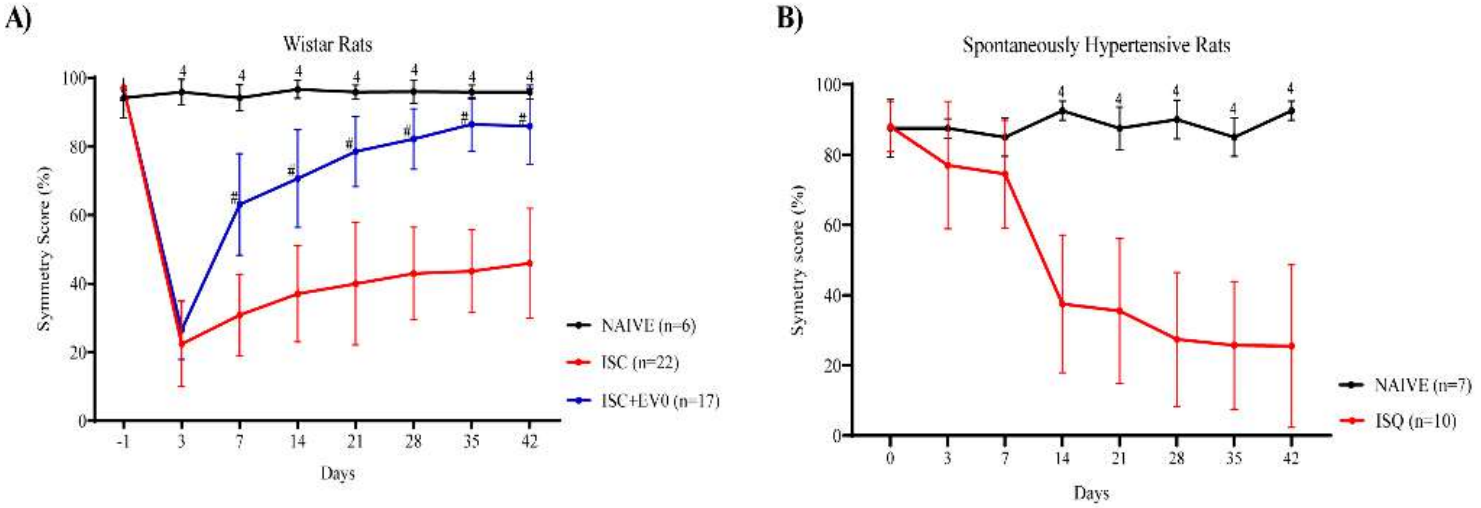

Fig 1. A) Effect of IS and EV treatment on front paws symmetry of Wistar rats. B) Effect of IS on front paws symmetry of SHR rats. Data: means ± SD, two-way ANOVA followed by Tukey's test; [4] $p < 0.0001$ compared ISC to naive; [#] $p < 0.0001$ compared ISC to ISC+EV0.

Ethylmalonic acid impairs bioenergetics by disturbing succinate and glutamate oxidation and induces mitochondrial permeability transition pore opening in rat cerebellum.
Tissue accumulation and high urinary excretion of ethylmalonic acid (EMA) are found in ethylmalonic encephalopathy (EE), an inherited disorder associated with cerebral and cerebellar atrophy whose pathogenesis is poorly established. The in vitro and in vivo effects of EMA on bioenergetics and redox homeostasis were investigated in rat cerebellum. For the in vitro studies, cerebellum preparations were exposed to EMA, whereas intracerebellar injection of EMA was used for the in vivo evaluation. EMA reduced state 3 and uncoupled respiration in vitro in succinate-, glutamate-, and malate-supported mitochondria, whereas decreased state 4 respiration was observed using glutamate and malate. Furthermore, mitochondria permeabilization and succinate supplementation diminished the decrease in state 3 with succinate. EMA also inhibited the activity of KGDH, an enzyme necessary for glutamate oxidation, in a mixed manner and augmented mitochondrial efflux of α-ketoglutarate. ATP levels were markedly reduced by EMA, reflecting a severe bioenergetic disruption. Docking simulations also indicated interactions between EMA and KGDH and a competition with glutamate and succinate for their mitochondrial transporters. In vitro findings also showed that EMA decreased mitochondrial membrane potential and Ca retention capacity, and induced swelling in the presence of Ca , which were prevented by cyclosporine A and ADP and ruthenium red, indicating mitochondrial permeability transition (MPT). Moreover, EMA, at high concentrations, mildly increased ROS levels and altered antioxidant defenses in vitro and in vivo. Our data indicate that EMA-induced impairment of glutamate and succinate oxidation and MPT may contribute to the pathogenesis of the cerebellum abnormalities in EE.

Guanosine Neuroprotection of Presynaptic Mitochondrial Calcium Homeostasis in a Mouse Study with Amyloid-β Oligomers.
Amyloid-β oligomers (AβOs) toxicity causes mitochondrial dysfunction, leading to synaptic failure in Alzheimer's disease (AD). Considering presynaptic high energy demand and tight Ca regulation, impairment of mitochondrial function can lead to deteriorated neural activity and cell death. In this study, an AD mouse model induced by ICV (intracerebroventricular) injection of AβOs was used to investigate the toxicity of AβOs on presynaptic function. As a therapeutic approach, GUO (guanosine) was given by oral route to evaluate the neuroprotective effects on this AD model. Following 24 h and 48 h from the model induction, behavioral tasks and biochemical analyses were performed, respectively. AβOs impaired object recognition (OR) short-term memory and reduced glutamate uptake and oxidation in the hippocampus. Moreover, AβOs decreased spare respiratory capacity, reduced ATP levels, impaired Ca handling, and caused mitochondrial swelling in hippocampal synaptosomes. Guanosine crossed the BBB, recovered OR short-term memory, reestablished glutamate uptake, recovered mitochondrial Ca homeostasis, and partially prevented mitochondrial swelling. Therefore, this endogenous purine presented a neuroprotective effect on presynaptic mitochondria and should be considered for further studies in AD models.

Characterization and antiproliferative activity of glioma-derived extracellular vesicles.
To characterize a method to isolate glioma-derived extracellular vesicles (GEVs) and understand their role in immune system modulation and glioma progression. GEVs were isolated by differential centrifugation from C6 cell supernatant and characterized by size and expression of CD9, HSP70, CD39 and CD73. The glioma model was performed by injecting C6 glioma cells into the right striatum of Wistar rats in the following groups: controls (C6 cells alone), coinjection (C6 cells + GEVs) and GEVs by intranasal administration followed by immune cells, tumor size and cells proliferation analyses. GEVs presented uniform size (175 nm), expressed CD9, HSP70, CD39, CD73 and produced adenosine. , we observed a reduction in tumor size, in cell proliferation (Ki-67) and in a regulatory cell marker (FoxP3). GEVs, administered before or at tumor challenge, have antiproliferative properties and reduce regulatory cells in the glioma microenvironment.

The neuroprotective role of melatonin in a gestational hypermethioninemia model.
Elevated levels of methionine in blood characterize the hypermethioninemia, which may have genetic or non-genetic origin, as for example from high protein diet. Born rats from hypermethioninemic mothers presented cerebral oxidative stress, inhibition of Na,K-ATPase, memory deficit and ultrastructure cerebral changes. Melatonin is a hormone involved in circadian rhythm and has antioxidant effects. The aim of this study was to verify the possible neuroprotective effects of melatonin administration in hypermethioninemic pregnant rats on damage to biomolecules (Na,K-ATPase, sulfhydryl content and DNA damage index) and behavior (open field, novel object recognition and water maze tasks), as well as its effect on cells

morphology by electron microscopy in offspring. Wistar female rats received methionine (2.68 µmol/g body weight) and/or melatonin (10 mg/kg body weight) by subcutaneous injections during entire pregnancy. Control rats received saline. Biochemical analyzes were performed at 21 and 30 days of life of offspring and behavioral analyzes were performed only at 30 days of age in male pups. Results showed that gestational hypermethioninemia diminished Na,K-ATPase activity and sulfhydryl content and increased DNA damage at 21 and 30 days of life. Melatonin was able to totally prevent Na,K-ATPase activity alteration at 21 days and partially prevent its alteration at 30 days of rats life. Melatonin was unable in to prevent sulfhydryl and DNA damage at two ages. It also improved DNA damage, but not at level of saline animals (controls). Regarding to behavioral tests, data showed that pups exposed to gestational hypermethioninemia decreased reference memory in water maze, spent more time to the center of the open field and did not differentiate the objects in the recognition test. Melatonin was able to prevent the deficit in novel object recognition task. Electron microscopy revealed ultrastructure alterations in neurons of hypermethioninemic at both ages of offspring, whose were prevented by melatonin. These findings suggest that melatonin may be a good neuroprotective to minimize the harmful effects of gestational hypermethioninemia on offspring.

Exogenous expression of caveolin-1 is sufficient for hepatic stellate cell activation.
Caveolin-1 (Cav-1) expression is increased in hepatic stellate cells (HSC) upon liver cirrhosis and it functions as an integral membrane protein of lipid rafts and caveolae that regulates and integrates multiple signals as a platform. This study aimed to evaluate the role of Cav-1 in HSC. Thus, the effects of exogenous expression of Cav-1 in GRX cells, a model of activated HSC, were determined. Here, we demonstrated through evaluating well-known HSC activation markers - such as α-smooth muscle actin, collagen I, and glial fibrillary acidic protein - that up regulation of Cav-1 induced GRX to a more activated phenotype. GRX presented an increased migration, an altered adhesion pattern, a reorganization f-actin cytoskeleton, an arrested cell cycle, a modified cellular ultrastructure, and a raised endocytic flux. Based on this, GRX represents a new cellular model that can be an important tool for understanding of events related to HSC activation. Furthermore, our results reinforce the role of Cav-1 as a molecular marker of HSC activation.

Dipyridamole impairs autophagic flux and exerts antiproliferative activity on prostate cancer cells.
Autophagy is a cellular bulk degradation process used as an alternative source of energy and metabolites and implicated in various diseases. Inefficient autophagy in nutrient-deprived cancer cells would be beneficial for cancer therapy making its modulation valuable as a therapeutic strategy for cancer treatment, especially in combination with chemotherapy. Dipyridamole (DIP) is a vasodilator and antithrombotic drug. Its major effects involve the block of nucleoside uptake and phosphodiestesase inhibition, leading to increased levels of intracellular cAMP. Here we report that DIP increases autophagic markers due to autophagic flux blockage, resembling autophagosome maturation and/or closure impairment. Treatment with DIP results in an increased number of autophagosomes and autolysosomes and impairs degradation of SQSTM1/p62. As blockage of autophagic flux decreases the recycling of cellular components, DIP reduced the intracellular ATP levels in cancer cells. Autophagic flux blockage was neither through inhibition of lysosome function nor blockage of nucleoside uptake, but could be prevented by treatment with a PKA inhibitor, suggesting that autophagic flux failure mediated by DIP results from increased intracellular levels of cAMP. Treatment with DIP presented antiproliferative effects in vitro alone and in combination with chemotherapy drugs. Collectively, these data demonstrate that DIP can impair autophagic degradation, by preventing the normal autophagosome maturation, and might be useful in combination anticancer therapy.

Neuroprotective Effects of Guanosine Administration on In Vivo Cortical Focal Ischemia in Female and Male Wistar Rats.
Guanosine (GUO) has neuroprotective effects in experimental models of brain diseases involving glutamatergic excitotoxicity in male animals; however, its effects in female animals are poorly understood. Thus, we investigated the influence of gender and GUO treatment in adult male and female Wistar rats submitted to focal permanent cerebral ischemia in the motor cortex brain. Female rats were subdivided into non-estrogenic and estrogenic phase groups by estrous cycle verification. Immediately after surgeries, the ischemic animals were treated with GUO or a saline solution. Open field and elevated plus maze tasks were conducted with ischemic and naïve animals. Cylinder task, immunohistochemistry and infarct volume analyses were conducted only with ischemic animals. Female GUO groups achieved a full recovery of the forelimb symmetry at 28-35 days after the insult, while male GUO groups only partially recovered at 42 days, in the final evaluation. The ischemic insult affected long-term memory habituation to novelty only in female groups. Anxiety-like behavior, astrocyte morphology and infarct volume were not affected. Regardless the estrous cycle, the ischemic injury affected differently female and male animals. Thus, this study points that GUO is a potential neuroprotective compound in experimental stroke and that

more studies, considering the estrous cycle, with both genders are recommended in future investigation concerning brain diseases.

Chronic Mild Hyperhomocysteinemia Alters Inflammatory and Oxidative/Nitrative Status and Causes Protein/DNA Damage, as well as Ultrastructural Changes in Cerebral Cortex: Is Acetylsalicylic Acid Neuroprotective?
Homocysteine is a sulfur-containing amino acid derived from methionine metabolism. When plasma homocysteine levels exceed 10-15 μM, there is a condition known as hyperhomocysteinemia, which occur as a result of an inborn error of methionine metabolism or by non-genetic causes. Mild hyperhomocysteinemia is considered a risk factor for development of neurodegenerative diseases. The objective of the present study was to evaluate whether acetylsalicylic acid has neuroprotective role on the effect of homocysteine on inflammatory, oxidative/nitrative stress, and morphological parameters in cerebral cortex of rats subjected to chronic mild hyperhomocysteinemia. Wistar male rats received homocysteine (0.03 μmol/g of body weight) by subcutaneous injections twice a day and acetylsalicylic acid (25 mg/Kg of body weight) by intraperitoneal injections once a day from the 30th to the 60th postpartum day. Control rats received vehicle solution in the same volume. Results showed that rats subjected to chronic mild hyperhomocysteinemia significantly increased IL-1β, IL-6, and acetylcholinesterase activity and reduced nitrite levels. Homocysteine decreased catalase activity and immunocontent and superoxide dismutase activity, caused protein and DNA damage, and altered neurons ultrastructure. Acetylsalicylic acid totally prevented the effect of homocysteine on acetylcholinesterase activity and catalase activity and immunocontent, as well as the ultrastructural changes, and partially prevented alterations on IL-1β levels, superoxide dismutase activity, sulfhydryl content, and comet assay. Acetylsalicylic acid per se increased DNA damage index. In summary, our findings showed that chronic chemically induced model of mild hyperhomocysteinemia altered some parameters and acetylsalicylic acid administration seemed to be neuroprotective, at least in part, on neurotoxicity of homocysteine.

Methionine Administration in Pregnant Rats Causes Memory Deficit in the Offspring and Alters Ultrastructure in Brain Tissue.
In the present work, we evaluated the effect of gestational hypermethioninemia on locomotor activity, anxiety, memory, and exploratory behavior of rat offspring through the following behavior tests: open field, object recognition, and inhibitory avoidance. Histological analysis was also done in the brain tissue of pups. Wistar female rats received methionine (2.68 μmol/g body weight) by subcutaneous injections during pregnancy. Control rats received saline. Histological analyses were made in brain tissue from 21 and 30 days of age pups. Another group was left to recover until the 30th day of life to perform behavior tests. Results from open field task showed that pups exposed to methionine during intrauterine development spent more time in the center of the arena. In the object recognition memory task, we observed that methionine administration during pregnancy reduced total exploration time of rat offspring during training session. The test session showed that methionine reduced the recognition index. Regarding to inhibitory avoidance task, the decrease in the step-down latency at 1 and 24 h after training demonstrated that maternal hypermethioninemia impaired short-term and long-term memories of rat offspring. Electron microscopy revealed alterations in the ultrastructure of neurons at 21 and 30 days of age. Our findings suggest that the cell morphological changes caused by maternal hypermethioninemia may be, at least partially, associated to the memory deficit of rat offspring.

Obesity associated with type 2 diabetes mellitus is linked to decreased PC1/3 mRNA expression in the Jejunum.
Bariatric surgery is the most effective therapeutic option for obesity and its complications, especially in type 2 diabetes. The aim of this study was to investigate the messenger RNA (mRNA) gene expression of proglucagon, glucose-dependent insulinotropic peptide (GIP), prohormone convertase 1/3 (PC1/3), and dipeptidyl peptidase-IV (DPP-IV) in jejunum cells of the morbidly obese (OB) non type 2 diabetes mellitus (NDM2) and type 2 diabetes mellitus (T2DM), to determine the molecular basis of incretin secretion after bariatric surgery.

Aims Huntington's disease (HD) is a currently incurable neurodegenerative disease primarily characterized by the loss of striatal medium spiny neurons (MSNs). Cell replacement therapy (CRT) is the only approach focused on structural and functional restoration of atrophied tissue in HD by replenishing the degenerating MSN population, but its clinical translation is limited by the heterogeneity of cell products. The aim of this work is to develop a novel therapeutic strategy to regenerate the brain tissue affected in HD by using cell sorting to generate safe, defined and reproducible cell products. **Methods** Here, we describe the identification of a marker for the selection of human pluripotent stem cell (hPSC)-derived striatal progenitors, and a method for the enrichment of these progenitors from heterogeneous cell populations. Furthermore, we characterize this subpopulation to assess its identity and potential to generate MSNs. Finally, we evaluate the survival of these progenitors following transplantation into the striatum of adult mice. **Results** We demonstrate that this approach reduces the heterogeneity of the final cell product and batch-to-batch variability using both control and HD hPSC lines. Moreover, we show that different neuroblast subtypes with the potential to generate MSNs can be enriched under different conditions. Finally, we provide evidence of the survival and integration into the striatum of the selected progenitors up to one-week post transplantation. **Conclusions** We conclude that the selection of striatal neuroblast populations prior to transplantation has the potential to generate safer and more defined cell products, which can be used to treat HD.

Stroke is the leading cause of acquired disability in adults and the second cause of non-degenerative dementia and death. To date, thrombolysis and thrombectomy are the only treatments that can be applied to a limited number of patients (15%) due to a short therapeutic window and there is no therapeutic alternative for the remaining 85% of patients. Stroke provokes a rapid neuronal death and the destruction of the extracellular matrix (ECM), associated to the degradation glycosaminoglycans which are mainly composed of heparan sulfates (HS). In addition, following stroke, numerous preclinical studies showed that mesenchymal stem cells (MSC) are able to protect the brain tissue and enhance recovery, however their actions are limited by the hostile environment in the damaged tissue. The present work showed that combining MSC treatment with the HS mimetic agent, OTR4132, after ischemic stroke conferred a long-lasting neuroprotection and reduced functional deficits in normotensive and hypertensive rats submitted to a 1-hour transient middle cerebral artery occlusion. Beside the beneficial effects of OTR4132 on ECM and as neuroprotectant, the compound favor MSC survival/migration into the ischemic brain. Neuroprotection and functional recovery may be also achieved through secretion of factors and/or extracellular vesicles (EV) by MSC as it has been suggested by many previous studies. Therefore, we also evaluated *in vitro* the effect of OTR4132 on the production of EV from rat MSC and their cargo through different approaches. Altogether, our data underlined that combining matrix and stem cell-based therapies is a promising approach to improve stroke recovery.

IN VIVO DIRECT REPROGRAMMING OF OPCS INTO GABAERGIC NEURONS IN ADOLESCENT AND ADULT MOUSE BRAIN

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Srisaiyini Kidnapillai
Lund University, Emv/regenerative Neurophysiology, Lund, Sweden

Aims GABAergic interneurons have been shown to be dysfunctional or lost in many neurological disorders, such as early-onset schizophrenia which affects adolescents, and epilepsy. Therefore, developing strategies for interneuron cell replacement is of great importance. An attractive alternative approach for neural restoration is through direct reprogramming where a somatic cell can be converted into a neuron through ectopic expression of neuronal genes. The technique allows for *in situ* brain repair, i.e., through reprogramming resident cells into neurons. Our group has previously shown that parvalbumin (PV) interneurons can be generated from resident glia (oligodendrocyte progenitor cells; OPCs) via *in vivo* reprogramming in adult mouse striatum. Methods In this study, we have compared *in vivo* reprogramming in adolescent and adult mice using a different combination of transcription factors in tamoxifen-regulated Cre mice. The purpose was to study morphology, functional integration, and diversification of reprogrammed interneurons. Results Preliminary data suggest an improved GABAergic interneuron reprogramming using fewer transcription factors in adolescent mice compared to adult mice. The reprogrammed neurons express some interneuron subtype markers such as PV and can also be seen in other structures apart from the striatum such as the cortex and hippocampus. Functional analysis of the reprogrammed neurons is underway. Conclusions In conclusion, we show that with only two factors we can successfully reprogram OPCs into GABAergic neurons in adolescent and adult mice. This has the potential for cell replacement therapy in schizophrenia and epilepsy.

Reprogramming Human Adult Fibroblasts into GABAergic Interneurons.
Direct reprogramming is an appealing strategy to generate neurons from a somatic cell by forced expression of transcription factors. The generated neurons can be used for both cell replacement strategies and disease modelling. Using this technique, previous studies have shown that γ-aminobutyric acid (GABA) expressing interneurons can be generated from different cell sources, such as glia cells or fetal fibroblasts. Nevertheless, the generation of neurons from adult human fibroblasts, an easily accessible cell source to obtain patient-derived neurons, has proved to be challenging due to the intrinsic blockade of neuronal commitment. In this paper, we used an optimized protocol for adult skin fibroblast reprogramming based on RE1 Silencing Transcription Factor (REST) inhibition together with a combination of GABAergic fate determinants to convert human adult skin fibroblasts into GABAergic neurons. Our results show a successful conversion in 25 days with upregulation of neuronal gene and protein expression levels. Moreover, we identified specific gene combinations that converted fibroblasts into neurons of a GABAergic interneuronal fate. Despite the well-known difficulty in converting adult fibroblasts into functional neurons in vitro, we could detect functional maturation in the induced neurons. GABAergic interneurons have relevance for cognitive impairments and brain disorders, such as Alzheimer's and Parkinson's diseases, epilepsy, schizophrenia and autism spectrum disorders.

Functional Assessment of Direct Reprogrammed Neurons In Vitro and In Vivo.
Direct reprogramming is an emerging research field where you can generate neurons from a somatic cell, such as a skin or glial cell by overexpressing neurogenic transcription factors. This technique allows fast generation of subtype-specific and functional neurons from both human and mouse cells. Despite the fact that neurons have been successfully generated both in vitro and in vivo, a more extensive analysis of the induced neurons including phenotypic functional identity or gradual maturity is still lacking. This is an important step for a further development of induced neurons towards cell therapy or disease modeling of neurological diseases. In this protocol, we describe a method for functional assessment of direct reprogrammed neuronal cells both in vitro and in vivo. Using a synapsin-driven reporter, our protocol allows for a direct identification of

the reprogrammed neurons that permits functional assessment using patch-clamp electrophysiology. For in vitro reprogramming we further provide an optimized coating condition that allows a long-term maturation of human induced neurons in vitro.

Dual modulation of neuron-specific microRNAs and the REST complex promotes functional maturation of human adult induced neurons.
Direct neuronal reprogramming can be achieved using different approaches: by expressing neuronal transcription factors or microRNAs; and by knocking down neuronal repressive elements. However, there still exists a high variability in terms of the quality and maturity of the induced neurons obtained, depending on the reprogramming strategy employed. Here, we evaluate different long-term culture conditions and study the effect of expressing the neuronal-specific microRNAs, miR124 and miR9/9*, while reprogramming with forced expression of the transcription factors Ascl1, Brn2, and knockdown of the neuronal repressor REST. We show that the addition of microRNAs supports neuronal maturation in terms of gene and protein expression, as well as in terms of electrophysiological properties.

Perinatal asphyxia (PA) is an obstetric complication occurring when the oxygen supply to the newborn is interrupted. This health problem is associated with high morbimortality in preterm and term neonates, and long-term deficits in the surviving neonates. It severely affects the structure and function of brain regions, including hippocampus, neostriatum and white matter. Using an animal model mimicking asphyxia occurring during labour, we investigated on the therapeutic potential of secretome (MSC-S) derived from human adipose mesenchymal stem cells, preconditioned with deferoxamine, intranasally administered. PA was generated by immersing foetus-containing uterine horns in a water bath at 37 °C for 21 min. Thereafter, 16 µL of MSC-S (containing 6 µg of protein derived from 2×10^5 preconditioned-MSC), or vehicle, were intranasally administered 2 h after birth to asphyxia-exposed and control rats, evaluated at postnatal day (P) 1 and P7. Alternatively, pups received a dose of either preconditioned MSC-S or vehicle, at 2 h and P7, evaluated at P14, P30, and P60. The preconditioned MSC-S treatment (i) reversed asphyxia-induced hippocampal oxidative stress; (ii) increased antioxidative Nrf2 translocation and Nrf2 target genes (*ho1, nqo1, gsr, prdx2);* (iii) reduced neuroinflammation; (iv) decreased cleaved-caspase-3 cell-death; (v) prevented hypomyelination, increasing the expression of ASCL and MBP; (vi) improved behavioural deficits, including righting reflex, negative geotaxis, cliff aversion, locomotor activity, motor coordination, anxiety, and recognition memory. Overall, it is proposed that intranasal administration of preconditioned MSC-S is a novel therapeutic strategy to prevent the long-term effects of PA. MODELLING SYNAPTIC FUNCTION USING HUMAN BRAIN ORGANOIDS WITH MICRO-ELECTRODE ARRAYS AND ELECTRON MICROSCOPY ANALYSIS

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Bronte Coorey[1], Scott Lee[2], Milan Fernando[2], Emma Kettle[3], Anai Gonzalez Cordero[4], Leszek Lisowski[5], Wendy Gold[1]
[1]The University of Sydney, Faculty Of Medicine And Health, Camperdown, Australia, [2]Children's Medical Research Institute, Stem Cell & Organoid Facility, Westmead, Australia, [3]Westmead Institute for Medical Research, Electron Microscope Facility, Westmead, Australia, [4]Children's Medical Research Institute, Stem Cell Medicine Group, Westmead, Australia, [5]Children's Medical Research Institute, Translational Vectorology Research Unit, Westmead, Australia

Aims: Human brain organoids derived from induced pluripotent stem cells (iPSCs) are an emerging model in which to better understand neurodevelopmental disorders and test therapeutic efficacy. This project aims to characterise patient-derived brain organoids as an appropriate model for the neurodevelopmental disorder Rett syndrome which is predominantly caused by mutations in the Methyl-CpG binding protein 2 (*MECP2*) gene. **Methods:** MeCP2-deficient and neurotypical control human brain organoids were grown in culture for 3-7 months and characterised morphologically and functionally. Electron microscopy was used to assess the differences in the size and number of synaptic vesicles present at synaptic junctions, as well the number and size of mitochondria. Organoids were also tested on micro-electrode arrays (MEAs) to determine the spike firing rates. Raw data was analysed using GraphPad Prism. **Results:** MeCP2-deficient organoids showed significantly less spike data (indicating lower neural activity) compared to neurotypical control organoids when measured on the MEAs. MeCP2-deficient organoids also showed significantly less vesicles present at synaptic junctions compared to neurotypical control organoids. In addition, despite the number of mitochondria being equal in the patient and control organoids, the average size of the mitochondria were observed to be significantly smaller in the MeCP2-deficient organoids than that of the neurotypical control, validating previously published reports in post-mortem brain and murine studies. **Conclusions:** These observed differences between patient and control brain organoids validates the existing literature as well as provides novel findings and supports the use of brain organoids as a model.

Breaking Boundaries in the Brain-Advances in Editing Tools for Neurogenetic Disorders.
Monogenic neurological disorders are devastating, affecting hundreds of millions of people globally and present a substantial burden to individuals, carers, and healthcare systems. These disorders are predominantly caused by inherited or variants that result in impairments to nervous system development, neurodegeneration, or impaired neuronal function. No cure exists for these disorders with many being refractory to medication. However, since monogenic neurological disorders have a single causal factor, they are also excellent targets for innovative, therapies such as gene therapy. Despite this promise, gene transfer therapies are limited in that they are only suitable for neurogenetic disorders that fit within the technological reach of these therapies. The limitations include the size of the coding region of the gene, the regulatory control of expression (dosage sensitivity), the mode of expression (e.g., dominant negative) and access to target cells. Gene editing therapies are an alternative strategy to gene transfer therapy as they have the potential of overcoming some of these hurdles, enabling the retention of physiological expression of the gene and offers precision medicine-based therapies where individual variants can be repaired. This review focusses on the existing gene editing technologies for neurogenetic disorders and how these propose to overcome the challenges common to neurogenetic disorders with gene transfer therapies as well as their own challenges.

Pre-clinical Investigation of Rett Syndrome Using Human Stem Cell-Based Disease Models.
Rett syndrome (RTT) is an X-linked neurodevelopmental disorder, mostly caused by mutations in . The disorder mainly affects girls and it is associated with severe cognitive and physical disabilities. Modeling RTT in neural and glial cell cultures and brain organoids derived from patient- or mutation-specific human induced pluripotent stem cells (iPSCs) has advanced our understanding of the pathogenesis of RTT, such as disease-causing mechanisms, disease progression, and cellular and

molecular pathology enabling the identification of actionable therapeutic targets. Brain organoid models that recapitulate much of the tissue architecture and the complexity of cell types in the developing brain, offer further unprecedented opportunity for elucidating human neural development, without resorting to conventional animal models and the limited resource of human neural tissues. This review focuses on the new knowledge of RTT that has been gleaned from the iPSC-based models as well as limitations of the models and strategies to refine organoid technology in the quest for clinically relevant disease models for RTT and the broader spectrum of neurodevelopmental disorders.

Genome-wide transcriptomic and proteomic studies of Rett syndrome mouse models identify common signaling pathways and cellular functions as potential therapeutic targets.
The discovery that Rett syndrome is caused by mutations in the MECP2 gene has provided a major breakthrough in our understanding of the disorder. However, despite this, there is still limited understanding of the underlying pathophysiology of the disorder hampering the development of curative treatments. Over the years, a number of animal models have been developed contributing to our knowledge of the role of MECP2 in development and improving our understanding of how subtle expression levels affect brain morphology and function. Transcriptomic and proteomic studies of animal models are useful in identifying perturbations in functional pathways and providing avenues for novel areas of research into disease. This review focuses on published transcriptomic and proteomic studies of mouse models of Rett syndrome with the aim of providing a summary of all the studies, the reported dysregulated genes and functional pathways that are found to be perturbed. The 36 articles identified highlighted a number of dysfunctional pathways as well as perturbed biological networks and cellular functions including synaptic dysfunction and neuronal transmission, inflammation, and mitochondrial dysfunction. These data reveal biological insights that contribute to the disease process which may be targeted to investigate curative treatments.

Human induced pluripotent stem cell (iPSC)-based technologies offer a unique resource for modeling disease and regenerating complex tissues such as the central nervous system (CNS). However, human iPSC models are still fraught with significant technical limitations including inefficient maturation, abnormal aggregation and reduced long-term viability of neurons. These problems are in part due to the absence of synergistic cues derived from the architecture, chemical composition and molecular dynamics of the native extracellular matrix (ECM). We reasoned that establishing a stable and bioactive ECM environment that mimics the adult CNS would facilitate the functional maturation of iPSC-derived neurons. To test this, we utilized peptide amphiphiles (PAs) that have the ability to self-assemble into supramolecular nanofibers capable of morphologically and chemically mimicking the adult CNS ECM. We designed a series of PA nanofibers containing a short bioactive peptide (IKVAV) found in Laminin-alpha-1, which is higher expressed over development in the CNS and plays a major role in neuronal behavior. The newly designed IKVAV-PAs have an almost identical chemical composition, except for a 4 amino acids modification in the non-bioactive domain that makes the IKVAV epitope be displayed in a more or less mobile fashion within the nanofiber. Interestingly, proteomic, biochemical and functional assays reveal that scaffolds with highly mobile molecules of IKVAV lead to enhanced beta-1-integrin pathway activation, reduced aggregation, increased arborization, and mature electrophysiological activity of human iPSC-derived neurons. Our work highlights the importance of designing bioactive ECMs to study the development, function and dysfunction of human neurons *in vitro*.

The human *HTT* gene encodes a large yet soluble protein named Huntingtin (HTT) ubiquitously expressed in all cells from the fertilized egg onward. This scaffold protein is involved in numerous cellular processes or machinery including intracellular transport, cell division, cell polarity, transcriptional regulation, autophagy, and apoptosis. Although it is best known for its life supporting activity in adult neurons, HTT is involved in several developmental processes such as gastrulation, epithelial morphogenesis, neural tube formation or neuroblast migration. Mutation of HTT cause the devastating neurodegenerative disorder, Huntington's disease (HD). HD is characterized by progressive degeneration in the basal ganglia and cerebral cortex. Neuronal loss is most marked among DARPP32-expressing medium-sized spiny projection neurons in the striatum. Most recent work in human fetuses carrying HD mutations evidenced as well neurodevelopmental defect at early embryonic stages. Here we describe the generation, by CRISPR-Cas9 technology, of HTT-gene edited isogenic clones of a human pluripotent stem cells (h-iPSC) line derived from an HD patient. We isolated and characterized, in particular, homozygous HTT knockout (-/-), wild-type-HTT hemizygote (wt/-) and mutant-HTT hemizygote (-/109Q) iPSC clones. Next, we used this genetic toolkit to explore the specific impact of mut-HTT isoform gain of function, wt-HTT loss of function and HTT gene complete inactivation on hPSC pluripotency, neural and striatal differentiation and neuronal function. Overall, we showed that wt and/or mut-HTT levels modulation do not disrupt h-iPSC pluripotency or neural induction but affect neural cell division, striatal maturation and BDNF axonal transport in neurons.

THE INTERPLAY BETWEEN CELL SHAPE/SIZE AND FUNCTION IN VITRO: INVESTIGATING THE EFFECT OF AXONAL LENGTH ON HUMAN SPINAL MOTOR NEURONS

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Cathleen Hagemann[1,2], Matthew Bailey[1,2], Carmen Moreno-Gonzalez[1,2], Andrea Serio[1,2]

The evolutionary link between cell shape and function is a tightly conserved paradigm, neurons for example present one of the architectural most complex shapes, and moreover neuronal subtypes show a broad variability of their cell sizes. Motorneurons (MNs) are one of the larges neurons and span in a human body up to one meter creating long-range connections between spinal cord and neuromuscular junction. As the axon of a MN spans across the periphery, this cell is confronted with even larger distances in other mammals, highlighting the outstanding variation of size and shape MNs experience. Such extreme cell shapes and sizes create biophysical constraints for the metabolism and homeostasis, which requires functional adaptations utilising basic engineering principles to maintain the integrity of the axon. Using the advantages of in vitro cultures and bioengineering techniques, we developed a platform which allows systematic analysis of axonal length as an isolated variable on biological processes, such as metabolism and homeostasis. This novel bioengineered platform combines iPSC-derived MNs, microfabrication and fluorescently encoded reporters, systematically obtaining arrays of axons up to several centimetres in length, while also allowing live imaging studies. Using the platform, we showed length dependent changes in cytoskeleton composition and changes to growth and dynamic homeostasis of the axoplasm. Moreover, we characterize mitochondrial dynamics and changes in the local protein translation an RNA binding protein concentration at different axonal lengths.

Modelling development and maturation of the human hippocampus in culture is crucial to elucidate the physiological and pathological mechanisms of its neurogenesis. We established human hippocampal cell cultures by means of controlled neuralization of human induced pluripotent stem cells (hiPSCs). The timely re-activation of WNT signalling in hiPSCs, which were previously driven toward a dorsal telencephalic identity by the combined inhibition of WNT, BMP and TGF-β signalling, produced neural progenitors with a gene expression signature typical of human embryonic dentate gyrus (DG) cells. Key markers of neurogenesis resulted downstream of the NOTCH and WNT pathway and were upregulated in these progenitors. Notably, we found that, in addition to continuous WNT signalling, a specific laminin isoform is crucial to prolonging DG stem state and to extend DG progenitor proliferation for over 200 days in vitro. In fact, transition from laminin 511 to mouse laminin inhibited cell proliferation and promoted the differentiation of DG cells. Interestingly, global gene expression profiles of early and late progenitor cells and neurons suggest that a niche of laminin 511 and WNT signalling is sufficient to maintain a cell population enriched in DG progenitor cells and neurons. Finally, the xenograft of human DG progenitors into the DG of adult immunosuppressed host mice produced efficient integration of neurons, which innervated CA3 layer cells with an area covered by synapses similar to the area covered by endogenous hippocampal neuron synapses. Our observations indicate that neurons produced in the established culture niche resemble bona-fide human DG neurons.

Human-induced pluripotent stem cell (hiPSC) technology enables us to obtain patient-specific cell type models relevant to the disease that could be otherwise unobtainable. This is the case for Congenital Central Hypoventilation Syndrome (CCHS), a rare neonatal disorder of the autonomic nervous system (ANS), characterized by a deficient control of autonomic ventilation and a global autonomic dysfunction. Indeed, the disease-defining gene, PHOX2B encodes a master transcription factor whose role is essential during development of the neural lineages of the ANS. *In vivo* and *in vitro* models of the disease provide a limited representation of human pathophysiology. To clarify the pathogenesis of CCHS, we have generated a hiPSC-derived autonomic neuronal model that fully recapitulates the patient's entire genetic profile. Using a non-integrating Sendai Virus (SeV), we reprogrammed fibroblasts from two CCHS patient's carrying the same genetic mutation but with different clinical manifestation of the disease. Here we show a complete characterization of both patient-derived iPSC lines by karyotyping, morphology study, immunocytochemistry, and qPCR analysis to confirm the presence of gene and protein expression of markers of pluripotency (e.g Nanog, Oct4 and SSEA4). Using a specific autonomic neural differentiation protocol, iPSC lines have been differentiated to neural crest stem cells (NCSCs), which bear the potential to develop into different lineages, among which peripheral autonomic PHOX2B positive neurons that carry the patient's specific mutation. This new personalized disease-in-a-dish model of CCHS opens numerous possibilities to identify molecular and cellular defects induced by the mutations as well as modelling for drug discovery/screening for therapeutic perspectives.

CULTURED BRAIN ORGANOID SLICES AS A MODEL SYSTEM TO STUDY HUMAN NEURONS AND GLIAL CELLS

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Laura Petersilie[1], Stephanie Le[2], Karl W. Kafitz[1], Alessandro Prigione[2,3], Christine R. Rose[1]
[1]Heinrich Heine University Duesseldorf, Institute Of Neurobiology, Duesseldorf, Germany, [2]University Children's Hospital, Heinrich Heine University Duesseldorf, Department Of General Pediatrics, Neonatology And Pediatric Cardiology, Duesseldorf, Germany, [3]Max Delbrueck Center for Molecular Medicine, (mdc), Berlin, Germany

Rodents are established as major model systems in brain research. Translation of findings to the human brain, however, is often difficult. Alternative strategies are therefore needed to overcome the resulting setbacks in the development of novel therapeutic approaches to treat human brain disease. A promising new model system are three-dimensional brain organoids derived from human induced pluripotent stem cells (Le et al., 2021). A limitation of this *in vitro* model is that differentiation and maturation of cells require a long-term cultivation. The latter is often accompanied by the development of a necrotic core which arises from insufficient delivery of oxygen and nutrients to deeper regions of the growing organoids. To overcome this drawback, air-liquid interface cerebral organoids were recently introduced (Giandomenico et al., 2019). Adapting this approach, we established slice cultures derived from 11 weeks-old human brain organoids. In brief, organoids were embedded in low-gelling-temperature agarose, cut into 300 µm slices, transferred on membranes and cultured in a humidified incubator. After another 5 weeks in culture, slices showed immunoreactivity for S100ß and MAP2, revealing the presence of (presumed) astrocytes and mature neurons. Ca^{2+} imaging demonstrated that cells exhibit spontaneous intracellular Ca^{2+} signals and respond to glutamate. Taken together, these results suggest that cultured brain organoid slices might serve as a new model system to study the development, cytoarchitecture and physiological properties of human neurons and glial cells under controlled conditions in culture. Supported by the DFG (RU 2795 "Synapses under stress", RO 2327/13-2).

FUNCTIONAL IMPACTS OF HUNTINGTIN LOWERING ON HUMAN ASTROCYTES DERIVED INDUCED PLURIPOTENT STEM CELLS

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Mathilde Louça[1], Donya El Akrouti[1], Morgane Louessard[1], Noelle Dufour[1], Nicole Déglon[2], Anselme Perrier[1]
[1]Université Paris-Saclay, CEA, CNRS, Mircen , Laboratoire Des Maladies Neurodégénératives: Mécanismes, Thérapies, Imagerie, Fontenay-aux-Roses, France, [2]Lausanne University Hospital (CHUV) and University of Lausanne (UNIL), Department Of Clinical Neuroscience, Lausanne, Switzerland

Aims: Huntingtin protein (HTT) is a multifunctional scaffold protein involved in numerous cellular processes including intracellular transport, cell division, cell polarity, ciliogenesis, transcriptional regulation, autophagy or apopotosis. Mutations in HTT are responsible for the devastating neurodegenerative disorder Huntington's disease (HD). Beyond neuronal dysfunctions and loss classically reported in HD, glial cells are as well impaired in the brain of HD patients. Lowering or inactivating the mutant or both, the wild-type and the mutant isoforms of HTT, are most likely the less disputed and direct paths to reduce HD symptoms and may be to cure HD patients. Multiple clinical trials are ongoing or in preparation to test this therapeutic approach despite the fact that the consequence of lowering or losing altogether wt-HTT isoforms in the human brain remains incompletely understood. HTT roles being mostly described in neurons, this issue is felt even more acutely regarding the understanding of HTT roles in astrocytes. Because human astrocytes feature specific morphology, diversity, functions and glia-to-neuron ratios, working on cells from humans is essential to model more precisely human astrocytes functions and interactions with neurons. **Methods**: Here we take advantage of human induced pluripotent stem cells (h-iPSC) technologies to explore the role of HTT protein in h-iPSC derived astrocytes. **Results**: We more specifically study astrocytic wt-HTT and mut-HTT functional alterations by HTT-lowering/editing treatments. **Conclusion**: We address these issues focusing on glutamate homeostasis and the signaling cascade mediated by primary cilia in h-iPSC derived astrocytes cultured alone or co-cultured with synaptically active human cortical neuronal network.

The maternal *in utero* environment can contribute to neurodevelopmental disorders in the offspring. There is evidence linking the gestational transfer of brain-reactive antibodies, such as anti-CASPR2, contributing to permanent anomalies in the developing brain. CASPR2 was originally described to be involved in the stabilization of voltage-gated potassium channels (Kv1.1 and Kv1.2) on the myelinated axons, and later to have a role in earlier phases of rodent brain development. Our aim is the development of brain organoids to study this process in a relevant human model during early developmental periods. **Methods:** Here, we evaluate gene expression, synaptic and neurophysiological consequences of exposing brain organoids, for 4 months, to human anti-CASPR2 antibodies, derived from an autoimmune encephalitis patient. **Results:** Our data show a decrease in protein levels of CASPR2, Contactin-2 and Kv1.2 in 6-month-old organoids exposed to anti-CASPR2 antibodies. Neuronal network dynamics was also evaluated and showed increased spontaneous calcium transients in CASPR2-exposed organoids. We also measured spontaneous excitatory postsynaptic currents (sEPSCs) and action potentials (APs) properties. We observed an increase in the frequency and amplitude of sEPSCs, and in the firing rate of APs. Additionally, we observed a decrease in the fast-afterhyperpolarization (fAHP) amplitude. **Conclusions:** These results point to potassium channels dysfunction and consequently to a hyperexcitability phenotype in organoids exposed to anti-CASPR2 antibodies. Moreover, our data highlights the value of using brain organoids exposed to external cues, as robust models to study neurodevelopment.

miRNAs: New Biomarkers and Therapeutic Targets in Dementia.
Dementia is a complex pathological state that affects millions of individuals worldwide and is responsible for a huge socioeconomic burden, making it a major health concern of current times. Given the impact of dementia in both patients and caregivers, it is crucial to fully clarify the molecular mechanisms underlying dementia-associated disorders, since without this knowledge our ability to correctly diagnose and treat these diseases is severely hampered.

The lack of efficient vascularization protocols is a major limitation for further development and implementation of iPSC-derived cerebral organoids for translational research. Although several attempts have been reported, so far, complete vascularization with a functional capillary network was achieved only via transplantation. In this study, we used a combination of an on-chip culture system and region-specific transcriptome analysis, to identify the molecular program of early angiogenesis in human iPSCs derived brain organoids. Brain organoids were cultured on a preformed 3D vasculature established from HUVEC cells for ten days. Outer cortical layer of cerebral organoids was microdissected using the UnipicK+ microdissection system at several time points (day 28, 31 and 35). Isolated total RNA was then subjected to a full transcriptome analysis using Agilent microarrays. Angiogenic-specific pathways and differentially regulated genes were identified. Several pro-angiogenic factors were tested for organoid vascularization and are discussed in this presentation. This study provides the first whole-genome analysis of cerebral organoid response to in vitro vasculature and highlights putative modifiers for efficient on-chip
vascularization.

BIOENGINEERED CORTICAL NEURONAL NETWORK (BIOCONNET): A STEM-CELL DERIVED NEURONAL ARRAY WITH DEFINED CIRCUITRY ARCHITECTURE IN VITRO

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Pacharaporn Suklai[1,2], Andrea Serio[1,2]
[1]King's College London, Craniofacial & Regenerative Biology, London, United Kingdom, [2]The Francis Crick Institute, The Francis Crick Institute, London, United Kingdom

The cortical neuronal network exhibits highly complex and organised network architecture to process functional neuronal communication. Induced pluripotent stem cell (IPSC) technology has provided the possibility to create simplified experimental models for systematic studies to understand the functional properties of the neuronal network. However, IPSC-based models still present the limitation in control of the network formation in a precise architecture, resulting in randomly arranged connections between neurons. This can particularly lead to the high variability of functional maturation because the maturation of neurons is highly dependent on the underlying network connectivity. Therefore, we are developing a controllable cortical network platform using the combination of IPSC-derived cortical neurons, bioengineering techniques that enable us to control the network architecture and its components, including the geometry of the network nodes and directionality of neurites, and applying optogenetic tools to be able to control neuronal activity of the network. Finally, we are using this platform to investigate the impact of different network architectures on cortical neuronal network functionality and maturation.

Aims: Current in vitro models of the Blood-Brain Barrier (BBB) include immortalized or primary brain microvascular endothelial cells (BMEC), pericytes, and astrocytes of human or animal origin. However, these systems do not recreate the physiological barrier function observed in vivo. Cell types derived from human induced pluripotent stem cells (iPSC) offer a promising alternative for BBB model development. **Methods:** Episomally-derived iPSC were differentiated to BMEC, pericytes, and astrocytes using defined protocols and then cryopreserved. Cells were thawed in optimized media and characterized for marker expression and function. Importantly, a Transwell® sandwich model was developed (BMEC on the apical, and astrocytes+pericytes on the basolateral side) to measure barrier function by TEER. **Results:** BMEC expressed high levels (>90%) of CD31, Glut-1, P-glycoprotein, MRP-1, Claudin-5, ZO-1 and transferrin receptor by flow cytometry, distinguishing them from other peripheral endothelial cells. Pericytes expressed high levels of PGDFR-β, NG2, CD13 cell type identity markers and co-expressed Desmin, DLK1, and α-SMA, which is associated with a contractile PC2 subtype for pericytes. Astrocytes not only expressed prototypical glial markers CD44, S100β, and GFAP, but also demonstrated robust glutamate uptake. Most notably, BMEC cultured with pericytes and astrocytes for at least 7 days in the sandwich model yielded TEER values >3000 ohm/cm^2, which is significantly enhanced over other model systems. **Conclusions:** The successful generation of cryopreserved and functional iPSC-derived BMEC, pericytes, and astrocytes has enabled the development of a BBB model that can be used to study barrier function, drug permeability/transport, and neurodegenerative disease.

DELINEATING THE IMMEDIATE MOLECULAR CONSEQUENCES OF THE GLIOBLASTOMA-ASSOCIATED H3.3K27M MUTATION

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Lea Cohen[1,2], Binyamin Kaffe[2], Eden Deri[1], Eran Meshorer[1]
[1]Hebrew University of Jerusalem, Edmond And Lily Safra Center For Neuroscience, Jerusalem, Israel, [2]Hebrew University of Jerusalem, Department Of Genetics, Jerusalem, Israel

The histone variant H3.3 is localized at specific regions in the genome, including telomeres as well as promoters of expressed genes and active enhancers. H3.3 has a role in development and its turnover plays a role in neuronal transcription and plasticity. A lysine to methionine substitution in lysine 27 (H3.3K27M) is one of the main causes of Diffuse intrinsic pontine glioma (DIPG) in children, a severe type of lethal cancer occurring in the brain stem. H3.3K27M was shown to have a dominant-negative effect by inhibiting the Polycomb Repressor 2 (PRC2) complex activity and causing a global reduction of H3K27me3. The mechanism by which H3.3K27M causes cancer is yet unknown, however current models refer to its effects on PRC2 activity. In this study, we aimed to identify the immediate, genome-wide, consequences of the H3.3K27M mutation on H3.3 binding, H3 modifications and gene expression dynamics. We managed to distinguish between the dominant-negative effects of H3.3K27M on PRC2 and effects due to the missing lysine and find that mutant cells differentiated to neural progenitors or oligodendrocyte progenitors, retain the expression of genes which are highly expressed in the pluripotent state, suggesting an immature gene expression signature independent on PRC2 activity. H3.3 binding capacity of genes was increased in H3.3K27M presence and was also PRC2 independent. Overall, our findings delineate the immediate consequences of H3.3K27 mutations on global gene expression and demonstrate that K27 is required for both proper H3.3 turnover as well as proper regulation of global gene expression during neural differentiation.

Human development relies on a balance between cellular and environmental clues that regulate fate decision and differentiation. Chromatin remodelers play an essential role in cell fate decisions. Thus, several chromatin remodelers are implicated in developmental diseases and cancer. Specifically, mutations in the ARID1A gene, a member of SWI/SNF complex, are associated with the Coffin-Siris syndrome, a developmental disorder with facial and central nervous system abnormalities. Intriguingly, ARID1A mutations are also observed in 20% of all cancers, which suggests a common mechanism involving cell growth regulation. In this study, we aim to investigate the effect of ARID1A mutation in hiPSC growth and survival. With CRISPR, we introduced 7bp frameshift mutation in the ARID1A gene and produced isogenic ARID1A +/+ and ARID1A+/- hiPSC lines. The mutant line had a lower growth rate compared to the wild type, so we conducted unbiased whole-genome CRISPRi screens to identify genes that modulate growth in an ARID1A-dependent way, and could potentially suppress the mutation effect. We observed that ARID1A$^{+/-}$ line is more sensitive to depletion of proteasome 20S subunit beta 2 (PSMB2), which can be targeted by proteasome inhibitors, thus providing a candidate therapeutic intervention. On the other hand, we showed that EZH2 silencing induces cell differentiation in ARID1A +/+ line but not in ARID1A +/- line, which might illuminate the ARID1A-dependent developmental disease mechanism. Overall, we established an efficient genome-scale method to identify genetic interactions with disease mutations, identified hits that are consistent with the target gene biology, and generated further hypotheses for the disease mechanisms.

In recent years, the rise of iPSC technology has created many opportunities for drug discovery and personalized medicine, this ability is most relevant in the research of orphan diseases. Familial Dysautonomia (FD), is an autosomal recessive, rare genetic disorder that affects the development and survival of neurons in the autonomic and sensory nervous system. FD is caused by a mutation in the Elongator like protein-1 (ELP1) gene. To this day available treatments for FD only alleviate the symptoms and there is no therapeutic cure available. In this work we differentiated patient's and paired control's iPSCs into sympathetic neurons, to assess their neuronal function to test efficacy of potential drugs for treatment using our functionality assessment pipeline. Several aspects of neuronal functionality are tested in this pipeline, including electrical activity using a multi electrode array (MEA), vesicular trafficking along neurites using live time-lapse imaging and mitochondrial activity using TMRE mitochondrial membrane potential imaging. The implementation of this pipeline and characterization of FD neuronal functionality will facilitate the process of drug discovery for this devastating disease.

[1]University of Verona, Diagnostics And Public Health, verona, Italy, [2]University of Modena and Reggio Emilia, Department Of Biomedical, Metabolic And Neural Sciences, Modena, Italy, [3]Istituto Italiano di Tecnologia, Department Of Neuroscience And Brain Technologies, Genova, Italy, [4]Tampere University, Biomeditech, Faculty Of Medicine And Health Technology, Tampere, Finland, [5]University of Verona, Department Of Surgery, Dentistry, Paediatrics And Gynaecology, verona, Italy, [6]University of Verona, Department Of Neurosciences, Biomedicine And Movement Sciences, verona, Italy, [7]University of Milan, Department Of Medical Biotechnology And Translational Medicine, Milan, Italy

Brain organoids are self-organized *in vitro* three-dimensional neural structures, which can be exploited in preclinical drug screening tests, neurodevelopmental studies, modeling neuronal diseases and regenerative medicine field. We isolated multipotent neural stem cells from the murine embryonic subgranular zone and developed a highly standardized, reproducible and fast (5 weeks) murine hippocampal brain organoid model. By adding a low concentration of the morphogen Wnt3a, we specifically induced the CA3-hippocampal phenotype. We showed that murine brain organoids progressively differentiate trough early, intermediate, and mature stages, defined by the expression of specific stemness (Vimentin, SOX2), neural progenitors (DCX) and mature neuronal (MAP2) markers. Additionally, functional properties measured by calcium imaging revealed that organoids increased their spontaneous calcium activity during maturation. Subsequently we investigated the specific hippocampal phenotype both via RT-PCR and immunofluorescence. RT-PCR analyses showed a high expression of hippocampal-related genes (e.g. Neurod1, Fzd9, Alk, Grik4) confirming the Wnt3a effectiveness in inducing the hippocampal patterning. We found the expression of the pan-hippocampal (ZBTB20) and CA3 (Ka1) markers in the mature organoids, hippocampal neurons ($ZBTB20^+/Map2^+$ and $Ka1^+/Map2^+$ cells) and a slight expression of the hippocampal CA1 (OCT6) and CA2 (FDZ9) markers. No expression of the DG (PROX1) marker was found. Overall, our results showed the establishment of murine three-dimensional *in vitro* hippocampal brain model that may be a useful tool for high-throughput drug screening and disease modelling. The possibility to generate functional mouse hippocampal organoids could be further exploited as an innovative tool for transplantation and regenerative purposes in pathological conditions, such as epilepsy.

BIOCOMPATIBLE SCAFFOLDS IMPROVE NEURALIZATION AND REPRODUCIBILITY OF STEM CELL-DERIVED BRAIN ORGANOIDS

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Brina Stancic[1], Silvia Garcia-Lopez[1], Alberto Martinez-Serrano[2], Marta P. Pereira[2]
[1]CBMSO, UAM-CSIC, Unit Of Specification, Reprograming And Regeneration, Madrid, Spain, [2]Centro de Biología Molecular Severo Ochoa (CBMSO), Department Of Molecular Biology, Madrid, Spain

Aim: Relying on minimal extrinsic interference, whole brain organoids generate multiple brain-like regions with diverse neuronal and glial cell types, as well as non-ectodermal lineage cells. As a result, they notoriously suffer from the “batch effect”, exhibiting highly variable efficiency and reproducibility in differentiation, morphology and size. To improve their homogeneity and anatomical features, hence increase their application in disease modeling and drug discovery, we present a novel highly reproducible protocol. **Methods:** Human induced pluripotent stem cell (hiPSC)-derived standard whole brain organoids (sBOs) and engineered flat brain organoids (efBOs) grown on a biocompatible 3D-printed polycaprolactone (PCL) scaffold are cultured using STEMdiff Cerebral Organoid Kit. Organoids are collected to evaluate the expression of the following makers: PAX6, NES, DCX, TUJ1, MAP2, AQP1, TTR and perform histological study of regional morphology by cresyl violet. **Results:** While sBOs display a loose tissue with large fluid-filled cysts positive for choroid plexus markers AQP1 and TTR, efBOs generate neural tissue with optically translucent neuroectoderm, neural stem cell-containing ventricular zones (PAX6+, NES+) surrounded by newly derived neurons (DCX+, TUJ1+) and mature neurons (MAP2+). **Conclusions:** Combining 3D cell culture with bioengineering, we have developed a protocol with simple tissue culture steps and consistent output with improved tissue architecture, enhanced neuronal differentiation and no fluid-filled cysts. As such, we address the existing shortcomings of human whole brain organoids, strongly increasing their reproducibility.

MODELLING DRAVET SYNDROME USING HUMAN IPSC-DERIVED NEURAL CIRCUITS

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Federica Riccio
King's College London, Centre For Gene Therapy & Regenerative Medicine, London, United Kingdom

BACKGROUND/AIMS: Dravet syndrome is a rare form of severe epilepsy with limited treatment options. The disease is primarily caused by mutations in the SCN1A gene, mainly affecting GABAergic inhibitory interneurons. Human induced Pluripotent Stem Cell (hiPSC) technologies have permitted initial studies on neuronal cells derived from Dravet patients. However, an *in vitro* disease model that accounts for the interaction between excitatory and inhibitory components of cortical circuits has yet to be established. With this project we aim to build a comprehensive human iPSC-based disease model for Dravet syndrome suitable for exploring disease phenotypes, performing mechanistic studies, and testing potential therapies. *METHODS*: Our *in vitro* disease model includes a co-culture of cortical excitatory neurons and GABAergic inhibitory interneurons derived from hiPSCs using forward-programming differentiation. Electrophysiological characterisation of individual neuronal populations was coupled with two-colour calcium imaging to evaluate network activity. *RESULTS*: We have generated wildtype and patient-derived hiPSCs suitable for differentiation into inhibitory interneurons and excitatory neurons. The differentiated populations express appropriate markers of mature identity and form functional synapses. Crucially, in mature cultures, single-neuron and network analysis show innate hyperactivity of excitatory neurons in the Dravet model compared to wildtype. *CONCLUSIONS*: Here we present evidence of a previously uncharacterised role for excitatory neurons in Dravet syndrome pathogenesis. This excitatory contribution was previously overlooked in animal and *in vitro* models and could explain the poor efficacy of current treatments. We believe this comprehensive co-culture system will prove an important tool in facilitating the discovery of novel therapeutic approaches.

Aims: Astrocytes are the most abundant glial cell type in the human brain. They control synapse formation, maturation, elimination and functions integrating in particular neuronal firing and synaptic transmission. In neurodegenerative or developmental disorders, astrocytes can play multiple roles, either neuroprotective or neurotoxic. Neuro-glial interactions have thus recently become novel targets for therapeutics development. Miniaturized in vitro models of such interactions, allowing high throughput approaches, is key from both fundamental and translational perspectives in drug discovery. Because human astrocytes feature specific morphology, diversity, functions and glia-to-neuron ratios compared to rodents, working on cells from humans is essential for accurate modeling of human neuro-glial interactions. Methods: Here we take advantage of human induced pluripotent stem cells (h-iPSC) technologies and the Neurolead platform, to model, in microplate format, non-cell-autonomous modulations by human astrocytes of the synaptic activity of human cortico-cortical neuronal networks. Results: We first confirmed such h-iPSC derived neuronal network self-organized and synchronized. We evidenced neuronal spontaneous synchronous calcium events measured with a kinetic microplate reader (FDSSµCell). We next showed that this synaptic activity is dependent on network maturation and can be modulated by pharmacological inhibitors of GABA and Glutamatergic synaptic activities. Finally, we explored how astrocyte co-culture changes human cortical neuronal network maturation, connectivity and synchronicity parameters. Conclusion: This in vitro model of “healthy” human neuro-glial interactions in synaptically active neuronal networks can be challenged with different types of neurodegenerative or neurodevelopmental disease determinants and is amenable to high throughput screening for lead discovery and drug optimization for such disorders.

THERAPEUTICAL APPROACH FOR A NOVEL IN VITRO MODEL OF X-LINKED ADRENOLEUKODYSTROPHY.

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Claudia Perez Garcia[1,2], Maria Luisa Molina-Gallego[2], Carlos Bueno[2], Emilio Geijo-Barrientos[2], Salvador Martínez[2]
[1]UCAM Catholic University of Murcia, Clinical Neuroscience, Murcia, Spain, [2]University of Miguel Hernandez de Elche, Institute Of Neuroscience, San Juan de Alicante, Spain

X-linked adrenoleukodystrophy (X-ALD) is an inborn error of metabolism caused by mutations in ABCD1 gene, which encodes a peroxisomal transmembrane protein called ALDP. This protein is involved in the transport of very-long chain fatty acid (VLCFA) for peroxisomal degradation. X-ALD patients show accumulation of VLCFA in tissue and blood. The outcome observed in patients with cerebral form of X-ALD is a devastating inflammatory demyelination. Unfortunately, there is not an effective therapy for all affected patients. A therapeutical option could be the use of bone marrow derived-mesenchymal stem cells (BMSCs). BMSCs have been proposed as a therapeutical approach in many neurological diseases as they have beneficial effect both in direct (cell-to cell contact) and indirect (paracrine signaling) mechanisms. The development of in vitro models of X-ALD is essential to increase knowledge about this complex disease. Here, we are developing a novel in vitro model to study X-ALD from dental pulp stem cells (DPSCs). We could analyse that DPSCs from a X-ALD patient showed specific phenotypical differences in comparison to healthy DPSCs. Also, X-ALD DPSCs could be differentiated into neural-like cells. Immunocytochemistry experiments revealed that X-ALD neural-like cells showed specific mature neural markers expression. Electrophysiological assays were carried out to further characterize X-ALD neural-like cells. These cells exhibited significant differences in amplitude and kinetics of sodium and potassium currents. Interestingly, when X-ALD neural-like cells were directly co-cultured with BMSCs, they rescued a healthy phenotype. Further investigation of the effect of BMSCs on X-ALD cells may provide relevant insights into X-ALD research.

[Mechanism of action of cell therapy in hereditary diseases].
Inherited metabolism disorders are serious childhood diseases that lead to significant cognitive impairment and regression of psychomotor development. The pathophysiology of the neural progressive deterioration is usually associated with severe neuroinflammation and demyelination, and as a consequence, neurodegeneration. At the moment they have no adequate treatment and require early and aggressive therapeutic approaches, which entail high mortality rates and, very frequently, low degrees of functional improvement and survival. Bone marrow transplantation and bone marrow mesenchymal cells grafts are therapeutic and experimental therapies that improve the course of these diseases through different mechanisms of action: enzyme replacement, membrane exchange and regulation of the inflammatory process.

SELF-ORGANIZING MODEL OF HUMAN CAUDAL EMBRYOGENESIS REVEALS SIGNALING PATHWAYS CONTROLLING NEURAL TUBE AND SOMITE MORPHOGENESIS

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Gribaudo Simona[1], Remi Robert[1], Bouhali Kamal[2], Xavier Morin[2], Anna Lyubimova[3], Alexander Van Oudenaarden[3], Stephane Nedelec[1]
[1]Inserm UMRS1270, Sorbonne Université, Institut Du Fer à Moulin, Paris, France, [2]Institut de Biologie de l'Ecole Normale Supérieure IBENS - INSERM U1024, Ens, Paris, France, [3]Hubrecht Institute, Van Oudenaarden Lab, The Netherlands, Netherlands

Understanding human nervous system development and its connectivity with peripheral targets is a major challenge for basic and translational research and requires experimental models of human embryology beyond neural organoids. Locomotor circuits, which control all executive functions of the nervous system, emerge during embryogenesis from the coordinated morphogenesis and patterning of the caudal neural tube and muscle-generating somites. Here, we show that aggregates of human induced pluripotent stem cells can undergo a WNT/TGF-B/BMP-dependent elongation mimicking the caudal extension of the developing embryo. Single-cell and spatial transcriptomics reveal the formation of a typical antero-posterior (AP) axis along which somitic and spinal cord differentiation trajectories self-organize giving rise to a folded functional neural tube surrounded by segmented somites. This organization is established in absence of endoderm, notochord or anterior neural fate. Strikingly, collinear *HOX* transcriptional profiles form along this AP axis and lead to the specification of an organized array of motor neuron subtypes belonging to different locomotor circuits in human embryos. Finally, a proof of principle chemical screen identifies signaling pathways and teratogens impact on human neural tube morphogenesis. Overall, we report the generation of a self-organizing, scalable, tractable model of human caudal embryogenesis amenable to drug screening for basic and translational research.

NEURODEVELOPMENTAL EFFECTS OF VALPROIC ACID EXPOSURE IN HUMAN BRAIN ORGANOIDS

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Giuseppe Cammarata, Ana Rafaela Oliveira, Catarina Seabra, Andre Cunha, Jorge Almeida, João Peça
Center for Neuroscience and Cell Biology, University Of Coimbra, Coimbra, Portugal

Valproic acid (VPA) is a widely prescribed anticonvulsant and mood stabilizer. Its antiepileptic properties have been attributed to inhibitory effects on the degradation of gamma-Aminobutyric acid and modulation of ion channel activity. VPA has also been shown to act as a Histone Deacetylase (HDAC) inhibitor, acting indirectly at the level of gene transcription and modulating the expression of transcription factors and growth factors. VPA usage is restricted during pregnancy due to the high risk of the unborn child later developing autism spectrum disorder (ASD) and mental disability. Experiments with VPA using animal models and cell cultures have suggested that the main features observed during development are an imbalance between the excitatory and inhibitory neuronal population, which leads to a hyperactive system. However, to date, little is known on the effects of VPA in the developing human brain, nor how the brain cellular architecture changes due to the effects of this drug. Our aim is to use human brain organoids as an in vitro model to study the effects of chronic exposure to VPA on human brain development and better understand its consequences at the molecular, cellular and circuitry level. Our preliminary data indicate that VPA induces network hyperactivity by lowering the intrinsic excitability of neurons. Even though VPA is now recognized as a major risk factor, our study will help shed light on the aetiology of neurodevelopmental disorders such as ASD and intellectual disability.

THE ROLE OF CALCIUM SIGNALING DURING NEURAL DEVELOPMENT IN BIPOLAR DISORDER (BPD)

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Mahnaz Nikpour, Mikael Landén, Erik Smedler
Institute of Neuroscience and Physiology, Department Of Psychiatry And Neurochemistry, Gothenburg, Sweden

Aims: In this project, we propose the use of induced pluripotent stem (IPS) cells from meticulously characterized patients and controls to study neural development in relation to genetic variants of the calcium (Ca^{2+}) channel gene (*CACNA1C*). **Methods:** To provide a study model for BPD, we generated IPS cell lines from human dermal fibroblasts by integration-free all synthetic RNA-based reprogramming system. These IPS lines then differentiated into neural progenitor cells (NPCs) and forebrain glutamatergic neurons by dual SMAD signaling inhibitors, Noggin and SB431542. Starting with NPC and upon neuronal differentiation cells will be used for multiple phenotypic analyses at several time points to determine the role of *CACNA1C* and Ca^{2+} signaling in neural development. **Results:** The study included six BPD patients and six controls genotyped for *CACNA1C* (12 total cell lines). Analyzing the expression of specific cell surface markers and intracellular transcription factors by fluorescence activated cell sorting (FACS) analyzer confirmed the quality of IPS lines which later on were differentiated to NPCs, and then further into forebrain-specific cortical neurons. Immunocytochemical staining using markers of pluripotency (SOX1, TRA-1), neural stem cells (NESTIN) and neurons (TUJ1 and MAP2), confirmed the stage of cells. These cells also express relevant markers on mRNA level and exhibit spontaneous Ca^{2+} activity. **Conclusions:** Cellular reprogramming of adult somatic cells into iPSCs and consequently into neurons which are genetically identical to the donor, enable us to study pathogenesis of mental disorders, including BPD, with disease-permissive genetic contexts.

A Glycoproteomic Approach to Identify Novel Proteoglycans.
In this chapter, we describe a glycoproteomic approach for the identification of novel chondroitin sulfate proteoglycans (CSPGs) using a combination of biochemical enrichments, enzymatic digestions, and nanoscale liquid chromatography tandem mass spectrometry (nLC-MS/MS) analysis. The identification is achieved by trypsin digestion of CSPG-containing samples, followed by enrichment of chondroitin sulfate (CS) glycopeptides by strong anion exchange chromatography (SAX). The enriched CS glycopeptides are then digested with chondroitinase ABC to depolymerize the CS polysaccharides, generating a residual hexasaccharide structure, composed of the linkage region tetrasaccharide extended with a terminal dehydrated disaccharide, still attached to the peptide. The obtained CS glycopeptides are analyzed by nLC-MS/MS, and the generated data sets are evaluated through proteomic software with adjustment in the settings to allow for glycopeptide identification. This approach has enabled the identification of several novel core proteins in human samples and in Caenorhabditis elegans. Here we specifically describe the procedure for the enrichment and characterization of CS glycopeptides from human cerebrospinal fluid (CSF).

Expanding the Chondroitin Sulfate Glycoproteome - But How Far?
Chondroitin sulfate proteoglycans (CSPGs) are found at cell surfaces and in connective tissues, where they interact with a multitude of proteins involved in various pathophysiological processes. From a methodological perspective, the identification of CSPGs is challenging, as the identification requires the combined sequencing of specific core proteins, together with the characterization of the CS polysaccharide modification(s). According to the current notion of CSPGs, they are often considered in relation to a functional role in which a given proteoglycan regulates a specific function in cellular physiology. Recent advances in glycoproteomic methods have, however, enabled the identification of numerous novel chondroitin sulfate core proteins, and their glycosaminoglycan attachment sites, in humans and in various animal models. In addition, these methods have revealed unexpected structural complexity even in the linkage regions. These findings indicate that the number and structural complexity of CSPGs are much greater than previously perceived. In light of these findings, the prospect of finding additional CSPGs, using improved methods for structural and functional characterizations, and studying novel sample

matrices in humans and in animal models is discussed. Further, as many of the novel CSPGs are found in low abundance and with not yet assigned functions, these findings may challenge the traditional notion of defining proteoglycans. Therefore, the concept of proteoglycans is considered, discussing whether "a proteoglycan" should be defined mainly on the basis of an assigned function or on the structural evidence of its existence.

Proteoglycan profiling of human, rat and mouse insulin-secreting cells.
Proteoglycans (PGs) are proteins with glycosaminoglycan (GAG) chains, such as chondroitin sulfate (CS) or heparan sulfate (HS), attached to serine residues. We have earlier shown that prohormones can carry CS, constituting a novel class of PGs. The mapping of GAG modifications of proteins in endocrine cells may thus assist us in delineating possible roles of PGs in endocrine cellular physiology. With this aim, we applied a glycoproteomic approach to identify PGs, their GAG chains and their attachment sites in insulin-secreting cells. Glycopeptides carrying GAG chains were enriched from human pancreatic islets, rat (INS-1 832/13) and mouse (MIN6, NIT-1) insulinoma cell lines by exchange chromatography, depolymerized with GAG lyases, and analyzed by nanoflow liquid chromatography tandem mass spectrometry. We identified CS modifications of chromogranin-A (CgA), islet amyloid polypeptide, secretogranin-1 and secretogranin-2, immunoglobulin superfamily member 10, and protein AMBP. Additionally, we identified two HS-modified prohormones (CgA and secretogranin-1), which was surprising, as prohormones are not typically regarded as HSPGs. For CgA, the glycosylation site carried either CS or HS, making it a so-called hybrid site. Additional HS sites were found on syndecan-1, syndecan-4, nerurexin-2, protein NDNF and testican-1. These results demonstrate that several prohormones, and other constituents of the insulin-secreting cells are PGs. Cell-targeted mapping of the GAG glycoproteome forms an important basis for better understanding of endocrine cellular physiology, and the novel CS and HS sites presented here provide important knowledge for future studies.

Domain Mapping of Chondroitin/Dermatan Sulfate Glycosaminoglycans Enables Structural Characterization of Proteoglycans.
Of all posttranslational modifications known, glycosaminoglycans (GAGs) remain one of the most challenging to study, and despite the recent years of advancement in MS technologies and bioinformatics, detailed knowledge about the complete structures of GAGs as part of proteoglycans (PGs) is limited. To address this issue, we have developed a protocol to study PG-derived GAGs. Chondroitin/dermatan sulfate conjugates from the rat insulinoma cell line, INS-1832/13, known to produce primarily the PG chromogranin-A, were enriched by anion-exchange chromatography after pronase digestion. Following benzonase and hyaluronidase digestions, included in the sample preparation due to the apparent interference from oligonucleotides and hyaluronic acid in the analysis, the GAGs were orthogonally depolymerized and analyzed using nano-flow reversed-phase LC-MS/MS in negative mode. To facilitate the data interpretation, we applied an automated LC-MS peak detection and intensity measurement via the Proteome Discoverer software. This approach effectively provided a detailed structural description of the nonreducing end, internal, and linkage region domains of the CS/DS of chromogranin-A. The copolymeric CS/DS GAGs constituted primarily consecutive glucuronic-acid-containing disaccharide units, or CS motifs, of which the N-acetylgalactosamine residues were 4-O-sulfated, interspersed by single iduronic-acid-containing disaccharide units. Our data suggest a certain heterogeneity of the GAGs due to the identification of not only CS/DS GAGs but also of GAGs entirely of CS character. The presented protocol allows for the detailed characterization of PG-derived GAGs, which may greatly increase the knowledge about GAG structures in general and eventually lead to better understanding of how GAG structures are related to biological functions.

MTDH/AEG-1 contributes to central features of the neoplastic phenotype in bladder cancer.
Carcinoma of the bladder is the fifth most common cancer whose incidence continues to rise. MTDH/AEG-1 is associated with the initiation and progression of many cancers including breast, hepatocellular, ovarian, and colorectal carcinomas. However, the expression and functional importance of MTDH/AEG-1 in bladder cancer remains unknown. The present study was aimed at exploring the functional role of MTDH/AEG-1 in selected bladder cancer cell lines.

Association of a common variant in TCF7L2 gene with type 2 diabetes mellitus in a Persian population.
Diabetes is one of the most common and challenging health problems. Studies in several nations show that polymorphisms within the transcription factor 7-like 2 genes could be associated with type 2 diabetes (T2D). Therefore, a case-control study was conducted to find the association between SNP rs7903146 and T2D in our population. The study consists of 110 patients referring to clinic and 80 healthy controls randomly selected based on WHO guideline. DNA was extracted from blood and

genotyped by PCR-RFLP with specific primers to amplify a fragment for restriction enzyme (RsaI). A chi-square test was calculated to compare the proportions of genotypes or alleles. Using a logistic regression model, the odds ratio for risk of developing T2D was calculated with and without adjustment for age, sex, and BMI. The frequency of the T allele of rs7903146 (C/T) polymorphism was significantly higher in diabetic subjects (47.3%) compared to that in normal subjects (34.4%). Logistic regression analysis of the rs7903146 polymorphism showed that the odds ratio was 3.71(95% CI: 1.43-9.56; P: 0.008) for the TT genotype and 1.26 (95% CI: 0.67-2.39; P: 0.516) for the CT genotype when compared with the CC genotype. Odds ratio adjusted for age, sex, and BMI have shown similar results. The results show that rs7903146 of TCF7L2 gene is an important susceptibility gene for T2D mellitus in the province of Isfahan, Iran. Our results support the recent findings that rs7903146 of TCF7L2 gene is an important genetic risk factor for the development of T2D in multiple ethnic groups.

MIDBRAIN ORGANOIDS WITH MICROGLIA REPRESENT A PROMISING TOOL FOR MODELLING AND STUDYING CELL AUTONOMOUS AND NON-CELL AUTONOMOUS MECHANISMS IN PD AT THE BRAIN TISSUE LEVEL

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Parkinson's disease (PD) is a common neurodegenerative disease affecting over 6 million people globally. Degeneration of the movement-controlling dopaminergic neurons in the midbrain results in the hallmark motor symptoms of PD. There are no curative or disease-modifying treatments for PD. **Aims**: To develop an hiPSC-derived in vitro 3D model system of PD using midbrain organoids (mORGs). The model is complemented with microglia-like cells to facilitate studying the non-cell autonomous mechanisms. Our focus is on optimizing the model for compatibility with functional readouts and for integration with microfluidic devices. **Methods**: Healthy control, patient-derived, and isogenic hiPSCs were seeded onto a silk scaffold to generate mORGs. Microglia progenitors were differentiated separately and co-cultured with the organoids on day 30. Correct patterning was assessed with RT-qPCR for midbrain markers. Immunohistochemical staining for Iba1 and TH were used to visualize microglia and dopaminergic neurons, respectively. Microdialysis was performed to measure extracellular dopamine and dopamine metabolites in the mORGs. **Results**: mORGs express appropriate midbrain-specific genes and contain neurons positive for FoxA2 and TH. Microglia progenitors migrate inside the organoid and give rise to Iba1+ cells with microglia-like morphology, and more ramified morphology after prolonged culture. Dopamine and its metabolites were detectable by HPLC in mORG dialysate. Microdialysis can be performed multiple times on the same mORG without significant damage, allowing for the monitoring of tissue dopamine at multiple time points. **Conclusions**: Our novel model is suitable for studying the effects of microglia on midbrain dopaminergic neurons in PD.

Utilising Induced Pluripotent Stem Cells in Neurodegenerative Disease Research: Focus on Glia.
Induced pluripotent stem cells (iPSCs) are a self-renewable pool of cells derived from an organism's somatic cells. These can then be programmed to other cell types, including neurons. Use of iPSCs in research has been two-fold as they have been used for human disease modelling as well as for the possibility to generate new therapies. Particularly in complex human diseases, such as neurodegenerative diseases, iPSCs can give advantages over traditional animal models in that they more accurately represent the human genome. Additionally, patient-derived cells can be modified using gene editing technology and further transplanted to the brain. Glial cells have recently become important avenues of research in the field of neurodegenerative diseases, for example, in Alzheimer's disease and Parkinson's disease. This review focuses on using glial cells (astrocytes, microglia, and oligodendrocytes) derived from human iPSCs in order to give a better understanding of how these cells contribute to neurodegenerative disease pathology. Using glia iPSCs in in vitro cell culture, cerebral organoids, and intracranial transplantation may give us future insight into both more accurate models and disease-modifying therapies.

High-Resolution Confocal Fluorescence Imaging of Serine Hydrolase Activity in Cryosections - Application to Glioma Brain Unveils Activity Hotspots Originating from Tumor-Associated Neutrophils.
Serine hydrolases (SHs) are a functionally diverse family of enzymes playing pivotal roles in health and disease and have emerged as important therapeutic targets in many clinical conditions. Activity-based protein profiling (ABPP) using fluorophosphonate (FP) probes has been a powerful chemoproteomic approach in studies unveiling roles of SHs in various biological systems. ABPP utilizes cell/tissue proteomes and features the FP-warhead, linked to a fluorescent reporter for in-gel fluorescence imaging or a biotin tag for streptavidin enrichment and LC-MS/MS-based target identification. Existing ABPP approaches characterize global SH activity based on mobility in gel or MS-based target identification and cannot reveal the

identity of the cell-type responsible for an individual SH activity originating from complex proteomes.

PTK2B REGULATES ELECTRICAL ACTIVITY IN HUMAN NEURONS AND PLAYS A ROLE IN THE Aβ1-42-MEDIATED NEURONAL HYPEREXCITABILITY

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Ana Raquel Melo De Farias[1,2,3], Johanna Gadaut[4], Orthis Saha[4], Jean-Charles Lambert[2,5], Marcos Costa[3,5]
[1]Institut Pasteur de Lille, Unit 1167, Lille, France, [2]Institut Pasteur de Lille, Inserm U1167 - Université De Lille – Chu De Lille – labex Distalz, Lille, France, [3]Federal University of Rio Grande do Norte, Brain Institute, Natal, France, [4]Institut Pasteur de Lille, U1167, Lille, France, [5]Institut Pasteur de Lille, Umr1167, Lille, France

PTK2B (Protein Tyrosine Kinase 2β) is a Ca^{2+}-activated non-receptor tyrosine kinase, identified as an important late-onset Alzheimer's disease (AD) risk gene and a major player in the mouse hippocampal synaptic plasticity. In this work, we aimed at studying the possible effects of PTK2B in neuronal electrical activity, taking advantage of human-induced pluripotent stem cell (hiPSC)-derived neurons (hiNs). We are using hiPSCs CRRSPR-cas9-edited to produce PTK2B homozygous, and heterozygous clones, spontaneously differentiated or lineage-reprogrammed (Neurog2) into hiNs. We evaluated the protein expression and cell composition using western blot and immunocytochemistry, and the neuronal electrical activity using calcium imaging and multi-electrode array (MEA) electrophysiology. Our data show that PTK2B under-expression leads to an increase in the frequency of calcium spikes, without significant changes in the percentage of active neurons. In KO cells, this is further enhanced, suggesting a dose-dependent effect of PTK2B in the regulation of neuronal activity. Interestingly, acute exposure to $Aβ_{1-42}$ increases the electrical activity in WT and HET but not in KOs, suggesting that PTK2B is necessary for Aβ-mediated neuronal hyperexcitability. MEA reveals changes in the electrical activity of PTK2B KO Neurog2-hiNs, suggesting a role of PTK2B in the regulation of electrical activity in glutamatergic neurons. Our preliminary data suggest that PTK2B regulates important biological processes involved in neuronal electrical activity under normal conditions, as well in an Alzheimer's model. Thus, altered expression of this risk gene in the AD brain could play a role in the neuronal hyperexcitability observed in patients at the early stages of the disease.

The human cerebral cortex is characterized by an extraordinary complexity of neuronal and non-neuronal cell types wired together for the execution of high-order cognitive functions. Alterations, during development as well as after birth, in the assembly of cortical circuits can lead to aberrant neuronal activity, shared sign of neurodevelopmental disorders. Developmental and Epileptic Encephalopathy (DEE), a heterogeneous group of epilepsy disorders with a strong genetic component, constitute the most precocious syndromes that can affect infants as early as in the womb. *De novo* mutations in the hyperpolarization-activated cyclic nucleotide gated channels (HCN1,HCN2) are associated with sever and untreatable DEE forms. Both genetic and non-genetic components have been linked to DEE, however the causative mechanisms remain elusive. Here, we aim at decoupling the effect of aberrant activity *per se* from the patient-specific genetic make-up to uncover novel DEE mechanisms. By exploiting a highly reproducible human cortical organoids (hCOs) system, on which acute seizure-like currents are induced, we model infantile/pediatric epilepsy in vitro. In parallel, we generated hCOs from HCN1-DEE patient specific iPSC lines to study HCN1 specific variants. We aim at mapping- at the single-cell level - the epigenetic and transcriptional landscapes of both hCOs models: this will allow to deciphering the epigenetic fingerprints produced by exacerbate activity in distinct cortical neuron types along their trajectory and dissect the specific HCN1 effects on cortical assembly. The integrated analysis will identify molecular fingerprints downstream of aberrant activity *per se* and HCN1-DEE, and provide an invaluable resource for new drug targets for infantile epilepsy.

N-GLYCOSYLATION OF INDUCED PLURIPOTENT STEM CELLS (IPSCS) AND NEURAL STEM CELLS (NSCS) DERIVED FROM A PERSON WITH DOWN SYNDROME (DS) CAUSED BY TRISOMY 21 (T21)

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Dražen Juraj Petrović[1,2], Ana Cindrić[1], Ivan Alić[3,4], Aoife Murray[4], Dinko Mitrečić[2], Jasminka Krištić[1], Tomislav Klarić[1], Gordan Lauc[1], Dean Nižetić[4]
[1]Genos d.o.o., Laboratory For Glycobiology, Zagreb, Croatia, [2]Croatian Institute for Brain Research, School of Medicine, University of Zagreb, Histology And Embriology, Zagreb, Croatia, [3]Faculty of Veterinary Medicine of University of Zagreb, Anatomy, Histology And Embriology, Zagreb, Croatia, [4]The Blizard Institute, Barts and The London School of Medicine, Queen Mary University of London, Genomics And Child Health, London, United Kingdom

Aim: To explore the difference in N-glycosylation between euploid disomic (D21) and trisomic (T21) isogenic human induced pluripotent stem cells (iPSCs) and neural stem cells (NSCs) derived from a person with mosaic Down syndrome (DS) trisomy of chromosome 21. Methods: Pellets of isogenic disomic and trisomic iPSCs are derived from a person with mosaic DS. Cells were lysed and (glyco)proteins were extracted. N-glycans were released from cell lysates and then fluorescently labeled. After a clean-up by hydrophilic interaction liquid chromatography (HILIC), labeled glycans were obtained and subsequently separated by HILIC-UHPLC (ultra-high performance liquid chromatography). Data was processed into chromatograms which were separated into 45 glycan peaks. Results: Comparison of iPSCs and NSCs revealed a clear difference in N-glycosylation. There was an increase in the relative abundance of five glycan peaks and a decrease in the abundance of nine glycan peaks in iPSCs when compared to NSCs. Comparison of disomic and trisomic iPSCs revealed no significant difference in the relative abundance of N-glycans. The same was true for disomic and trisomic NSCs. Conclusion: A significant difference was observed in N-glycosylation between isogenic iPSC and NSCs, which falls in line with recently published research that showed NSCs tend to have more N-glycosylation of NrCAM and Plexins compared to iPSCs. The lack of differences in N-glycosylation between disomic and trisomic cells might be explained by the small effect of increased gene expression of chromosome 21 during the pluripotent/stem cell stage, but also due to low levels of complex N-glycosylation in iPSCs (and NSCs).

VALIDATION OF THE ESSENTIAL ROLE OF THE 16P11.2 ASD CANDIDATE GENE QPRT IN HUMAN STEM CELL-DERIVED INEURONS

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Denise Haslinger[1,2], Christoph Dotter[2], Christine Freitag[1], Gaia Novarino[2], Andreas Chiocchetti[1]
[1]University Hospital Frankfurt, Department Of Child And Adolescent Psychiatry, Psychosomatics And Psychotherapy, Frankfurt am Main, Germany, [2]Institute of Science and Technology Austria, Life Sciences, Klosterneuburg, Austria

Altered neuronal development is discussed as the underlying pathogenic mechanism of autism spectrum disorders (ASD). We previously reported a gene of the ASD associated chromosomal region 16p11.2, *quinolinate phosphoribosyltransferase* (*QPRT*), to be essential for neuronal differentiation but not proliferation of the SH-SY5Y neuroblastoma model. QPRT is part of tryptophan metabolism and catabolizes quinolinic acid (QUIN). QUIN is an NMDA-R agonist and acts neurotoxic for glutamatergic cells. Our findings suggest QPRT to be involved in synaptic development and exlude a QUIN-driven neurotoxicity in the SH-SY5Y model. However, this needs to be replicated in a more mature human neuronal model allowing the investigation of functional glutamatergic and GABAergic neurons. Therefore, we further dissected the role of *QPRT* in human stem cell-derived iNeurons. Specifically, both glutamatergic and GABAergic iNeurons of QPRT-knockout cells were differentiated in co-cultures and compared to isogenic controls. Subsequent cell type-specific analysis was performed for each cell type labeled with a cell type-specific fluorophore. We will present the validity of our model as well as preliminary results of our analysis at morphological (Sholl analysis of e.g., neuritic complexity) and gene expression level of genes involved in tryptophan metabolism and of genes differentially regulated upon knockout of QPRT in the SH-SY5Y model. The analysis will be complemented by transcriptomic and network analysis during the time course of neuronal differentiation. Combining the readouts for morphological and transcriptomic assays will help to further dissect the etiology of ASD in 16p11.2 deletion carriers with the aim to identify new targets for potential pharmacological therapies.

GENERATION AND CHARACTERIZATION OF HUMAN VENTRAL MIDBRAIN ORGANOIDS DERIVED FROM PARKINSON'S DISEASE-DERIVED AND CONTROL INDUCED PLURIPOTENT STEM CELLS.

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Serena Viventi, Dad Abu-Bonsrah, Jennifer Jin, Leela Raonaq, Chiara Pavan, Clare Parish, Lachlan Thompson
The Florey Institute of Neuroscience and Mental Health, The Florey Institute Of Neuroscience And Mental Health, Parkville, Australia

Parkinson's disease (PD) is a neurodegenerative disorder characterized by the progressive degeneration of midbrain dopamine neurons. Current treatments mainly rely on pharmacotherapy, which seems to provide beneficial effects only in very early stages of the disease. Having an *in vitro* source of mature midbrain dopamine neurons from patients is paramount to initially reproduce disease phenotypes and subsequently identify disease-modifying drug candidates. In this context, three-dimensional (3D) induced pluripotent stem cell (iPSC)-derived brain organoids play an important role, as they mimic both cell-cell interactions and cytoarchitecture of the *in vivo* environment and also sustain longer term maturation than can be achieved with 2D adherent cultures. The aim of this study is to derive human midbrain organoids (hMOs) from control and PD patient-derived iPSC lines to identify distinctive hallmarks specifically related to the disease pathology. In addition, we perform 3D in vitro co-culture of hMOs with other neuronal and glial cell types to evaluate the impact on neural maturation, network complexity and also cell intrinsic and non-intrinsic disease mechanisms. Our results show successful derivation and long-term survival of hMOs both from control and PD-derived iPSCs and we are currently evaluating disease phenotype. In conclusion, hMOs represent an invaluable tool for developmental studies, disease modelling, and future high-throughput discovery.

A combined cell and gene therapy approach for homotopic reconstruction of midbrain dopamine pathways using human pluripotent stem cells.
Midbrain dopamine (mDA) neurons can be replaced in patients with Parkinson's disease (PD) in order to provide long-term improvement in motor functions. The limited capacity for long-distance axonal growth in the adult brain means that cells are transplanted ectopically, into the striatal target. As a consequence, several mDA pathways are not re-instated, which may underlie the incomplete restoration of motor function in patients. Here, we show that viral delivery of GDNF to the striatum, in conjunction with homotopic transplantation of human pluripotent stem-cell-derived mDA neurons, recapitulates brain-wide mDA target innervation. The grafts provided re-instatement of striatal dopamine levels and correction of motor function and also connectivity with additional mDA target nuclei not well innervated by ectopic grafts. These results demonstrate the remarkable capacity for achieving functional and anatomically precise reconstruction of long-distance circuitry in the adult brain by matching appropriate growth-factor signaling to grafting of specific cell types.

Neural differentiation medium for human pluripotent stem cells to model physiological glucose levels in human brain.
Cortical neurospheres (NSPs) derived from human pluripotent stem cells (hPSC), have proven to be a successful platform to investigate human brain development and neuro-related diseases. Currently, many of the standard hPSC neural differentiation media, use concentrations of glucose (approximately 17.5-25 mM) and insulin (approximately 3.2 μM) that are much greater than the physiological concentrations found in the human brain. These culture conditions make it difficult to analyse perturbations of glucose or insulin on neuronal development and differentiation. We established a new hPSC neural differentiation medium that incorporated physiological brain concentrations of glucose (2.5 mM) and significantly reduced insulin levels (0.86 μM). This medium supported hPSC neural induction and formation of cortical NSPs. The revised hPSC neural differentiation medium, may provide an improved platform to model brain development and to investigate neural differentiation signalling pathways impacted by abnormal glucose and insulin levels.

In vivo survival and differentiation of Friedreich ataxia iPSC-derived sensory neurons transplanted in the adult dorsal root ganglia.
Friedreich ataxia (FRDA) is an autosomal recessive disease characterized by degeneration of dorsal root ganglia (DRG) sensory neurons, which is due to low levels of the mitochondrial protein Frataxin. To explore cell replacement therapies as a possible approach to treat FRDA, we examined transplantation of sensory neural progenitors derived from human embryonic stem cells (hESC) and FRDA induced pluripotent stem cells (iPSC) into adult rodent DRG regions. Our data showed survival and differentiation of hESC and FRDA iPSC-derived progenitors in the DRG 2 and 8 weeks post-transplantation, respectively. Donor cells expressed neuronal markers, including sensory and glial markers, demonstrating differentiation to these lineages. These results are novel and a highly significant first step in showing the possibility of using stem cells as a cell replacement therapy to treat DRG neurodegeneration in FRDA as well as other peripheral neuropathies.

Distribution of Particles in Human Stem Cell-Derived 3D Neuronal Cell Models: Effect of Particle Size, Charge, and Density.
Neurodegenerative diseases are generally characterized by a progressive loss of neuronal subpopulations, with no available cure to date. One of the main reasons for the limited clinical outcomes of new drug formulations is the lack of appropriate in vitro human cell models for research and validation. Stem cell technologies provide an opportunity to address this challenge by using patient-derived cells as a platform to test various drug formulations, including particle-based drug carriers. The therapeutic efficacy of drug delivery systems relies on efficient cellular uptake of the carrier and can be dependent on its size, shape, and surface chemistry. Although considerable efforts have been made to understand the effects of the physiochemical properties of particles on two-dimensional cell culture models, little is known of their effect in three-dimensional (3D) cell models of neurodegenerative diseases. Herein, we investigated the role of particle size (235-1000 nm), charge (cationic and anionic), and density (1.05 and 1.8 g cm) on the interactions of particles with human embryonic stem cell-derived 3D cell cultures of sensory neurons, called sensory neurospheres (sNSP). Templated layer-by-layer particles, with silica or polystyrene cores, and self-assembled glycogen/DNA polyplexes were used. Particles with sizes <280 nm effectively penetrated sNSP. Additionally, effective plasmid DNA delivery was observed up to 6 days post-transfection with glycogen/DNA polyplexes. The findings provide guidance in nanoparticle design for therapies aimed at neurodegenerative diseases, in particular Friedreich's ataxia, whereby sensory neurons are predominantly affected. They also demonstrate the application of 3D models of human sensory neurons in preclinical drug development.

Particle-mediated delivery of frataxin plasmid to a human sensory neuronal model of Friedreich's ataxia.
Increasing frataxin protein levels through gene therapy is envisaged to improve therapeutic outcomes for patients with Friedreich's ataxia (FRDA). A non-viral strategy that uses submicrometer-sized multilayered particles to deliver frataxin-encoding plasmid DNA affords up to 27 000-fold increase in frataxin gene expression within 2 days in vitro in a stem cell-derived neuronal model of FRDA.

Generation of Neural Crest Progenitors from Human Pluripotent Stem Cells.
There are a vast range of diseases and disorders that are neurocristopathic in origin, including Hirschsprung's disease, pheochromocytoma, familial dysautonomia, craniofacial disorders, and melanomas. Having a source of human neural crest cells is highly valuable for investigating potential treatments for such diseases. This chapter describes a robust and well-characterized protocol for deriving neural crest from human pluripotent stem cells (hPSCs), which can then be differentiated to neuronal and non-neuronal lineages. The protocol is adapted to suit hPSC maintenance as a monolayer bulk culture or as manual-passaged colonies, which makes it widely applicable to researchers that may use different systems for hPSC maintenance.

Modelling the dorsal root ganglia using human pluripotent stem cells: A platform to study peripheral neuropathies.
Sensory neurons of the dorsal root ganglia (DRG) are the primary responders to stimuli inducing feelings of touch, pain, temperature, vibration, pressure and muscle tension. They consist of multiple subpopulations based on their morphology, molecular and functional properties. Our understanding of DRG sensory neurons has been predominantly driven by rodent studies and using transformed cell lines, whereas less is known about human sensory DRG neurons simply because of limited availability of human tissue. Although these previous studies have been fundamental for our understanding of the sensory system, it is imperative to profile human DRG subpopulations as it is becoming evident that human sensory neurons

do not share the identical molecular and functional properties found in other species. Furthermore, there are wide range of diseases and disorders that directly/indirectly cause sensory neuronal degeneration or dysfunctionality. Having an in vitro source of human DRG sensory neurons is paramount for studying their development, unique neuronal properties and for accelerating regenerative therapies to treat sensory neuropathies. Here we review the major studies describing generation of DRG sensory neurons from human pluripotent stem cells and fibroblasts and the gaps that need to be addressed for using in vitro-generated human DRG neurons to model human DRG tissue.

Phenotypic and Functional Characterization of Peripheral Sensory Neurons derived from Human Embryonic Stem Cells.
The dorsal root ganglia (DRG) consist of a multitude of sensory neuronal subtypes that function to relay sensory stimuli, including temperature, pressure, pain and position to the central nervous system. Our knowledge of DRG sensory neurons have been predominantly driven by animal studies and considerably less is known about the human DRG. Human embryonic stem cells (hESC) are valuable resource to help close this gap. Our previous studies reported an efficient system for deriving neural crest and DRG sensory neurons from hESC. Here we show that this differentiation system gives rise to heterogeneous populations of sensory neuronal subtypes as demonstrated by phenotypic and functional analyses. Furthermore, using microelectrode arrays the maturation rate of the hESC-derived sensory neuronal cultures was monitored over 8 weeks in culture, showing their spontaneous firing activities starting at about 12 days post-differentiation and reaching maximum firing at about 6 weeks. These studies are highly valuable for developing an in vitro platform to study the diversity of sensory neuronal subtypes found within the human DRG.

Wharton's jelly derived mesenchymal stromal cells: Biological properties, induction of neuronal phenotype and current applications in neurodegeneration research.
Multipotent mesenchymal stromal cells, also known as mesenchymal stem cells (MSC), can be isolated from bone marrow or other tissues, including fat, muscle and umbilical cord. It has been shown that MSC behave in vitro as stem cells: they self-renew and are able to differentiate into mature cells typical of several mesenchymal tissues. Moreover, the differentiation toward non-mesenchymal cell lineages (e.g. neurons) has been reported as well. The clinical relevance of these cells is mainly related to their ability to spontaneously migrate to the site of inflammation/damage, to their safety profile thanks to their low immunogenicity and to their immunomodulation capacities. To date, MSCs isolated from the post-natal bone marrow have represented the most extensively studied population of adult MSCs, in view of their possible use in various therapeutical applications. However, the bone marrow-derived MSCs exhibit a series of limitations, mainly related to their problematic isolation, culturing and use. In recent years, umbilical cord (UC) matrix (i.e. Wharton's jelly, WJ) stromal cells have therefore emerged as a more suitable alternative source of MSCs, thanks to their primitive nature and the easy isolation without relevant ethical concerns. This review seeks to provide an overview of the main biological properties of WJ-derived MSCs. Moreover, the potential application of these cells for the treatment of some known dysfunctions in the central and peripheral nervous system will also be discussed.

NEURONS, ASTROCYTES, AND OLIGODENDROCYTES ARE PRESENT IN SPINAL ORGANOIDS DERIVED FROM HUMAN INDUCED PLURIPOTENT STEM CELLS (HIPSC)

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Katarzyna Plesniar, Valerie Van Steenbergen, Florence Bareyre
University Hospital LMU Munich, Institute For Clinical Neuroimmunology, Munich, Germany

Aims
Human iPSCs can be used to generate 3D organoid cultures that can partially represent neuronal structures. To determine whether spinal organoids can be used to study interactions between distinct cell types, we examined mature spinal organoids for the presence of neuronal and non-neuronal cells. **Methods**
Spinal organoids were grown up to 82 days and fixed at distinct differentiation steps. Following paraformaldehyde fixation, the organoids were cut and immunostained for the presence of neurons (β3-Tubulin, ISL1), astrocytes (GFAP) and oligodendrocytes (MBP, CC1). **Results**
Cells positive for β3-Tubulin and ISL1 were present throughout the spinal organoid structure, marking the presence of distinct neuronal subtypes including motor neurons. Cells expressing GFAP, a marker for reactive astrocytes were present in mature spinal organoids. The presence of oligodendrocytes was determined with antibodies directed to CC1 and MBP. Co-localisation of CC1 in a subset of MBP positive cells indicates the presence of oligodendrocytes at different maturation stages. Apart from oligodendrocyte markers, the cells furthermore resembled the typically expected morphology. **Conclusion**
Here we show that neuronal and non-neuronal cell types are present in spinal organoids, offering a research model for cellular interactions within the spinal cord. Further research should focus on elucidating the functional interactions between the cells in healthy and diseases conditions.

DISSECTING THE LINK BETWEEN GLIAL CELL SHAPE AND FUNCTION IN VITRO USING HUMAN INDUCED PLURIPOTENT STEM CELL-DERIVED ASTROCYTES

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Kelly O'Toole[1,2], Ludovica Guetta[1,2], Andrea Serio[1,2]

Astrocytes are glial cells with a dynamic and complex morphology, characterised by their multiple primary branches which then ramify into thousands of peripheral processes. These processes function as contact points between adjacent astrocytes and synapses, allowing astrocytes to perform their key brain functions. Astrocyte shape and process organisation changes based on their subtype, region and in response to their microenvironment, including stress and injury. However, it is not fully understood how an astrocyte's unique and dynamic shape impacts its performance in vital homeostatic functions. To address this, we performed a systematic characterisation on astrocytes differentiated from human induced pluripotent stem cells (iPSC) to investigate how shape is linked to an astrocyte's performance in resting and reactive states. We have optimised the generation of iPSC-derived astrocytes with distinct morphologies using a combination of different defined media with developmentally-relevant cytokines. Quantitative single cell and population level analysis on astrocyte shape uncovered the timepoint of astrocyte shape divergence, plasticity and morphological changes which occur between different astrocytes across varying culture conditions, such as in neuronal co-culture and reactivity. Additionally, we found that the differences in shape between astrocytes translates into distinct functional profiles and characteristics *in vitro*. Our systematic characterisation has revealed a link between dynamic glial shapes and their underlying functional profile, to provide insight on the significance of astrocyte shape changes in both health and injury.

CANNABIDIVARIN AND NEURAL STEM CELLS, A NEW HOPE FOR RETT SYNDROME?

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Diogo Lourenço[1,2,3], Svitlana Zavalko[1,2,3], Rita Soares[1,2,3], Joana Mateus[1,2,3], Rui S. Rodrigues[1,2,3], Catarina Miranda-Lourenço[1,2,3], Ana M. Sebastião[1,2,3], Francisco Mouro[1,2,3], Maria J. Diógenes[1,2,3], Sara Xapelli[1,2,3]

Rett Syndrome (RTT) is a rare progressive neurodevelopmental X-linked disorder, caused mostly by mutations in *MECP2* gene. This transcriptional and epigenetic regulator has been proposed to modulate neurogenesis and neuronal maturation, processes known to be affected in both RTT patients and mouse models. Cannabidivarin (CBDV) a non-psychotomimetic cannabinoid, currently undergoing phase 2 clinical trials for medical use in humans, has been reported to bind to TRPV1, with unknown effects on adult neurogenesis. Using the neurosphere assay, *in vitro*, cells were subjected to pharmacological treatments for 2 or 7 days according to the experimental protocol. CBDV-treated cells for 2 days in vitro (DIV2) promoted an increase in cell survival and cell proliferation. While at DIV7, CBDV promoted an increase in neuronal differentiation and inhibited oligodendroglial maturation. Importantly, TRPV1 antagonist 5′-Iodoresiniferatoxin blocked the effects on cell death and cell proliferation mediated by CBDV, further suggesting TRPV1-dependency. *In vivo*, using a female mouse model of RTT, animals were subjected to a chronic treatment with CBDV on the pre-symptomatic stage, followed by a battery of behaviour tests, used to gauge the putative therapeutic effects of CBDV administration. Preliminary data from the Novel Object Recognition test suggested that CBDV ameliorates cognitive impairments in these animals. Additionally, RTT animals show an increased abnormal hippocampal neurogenesis that seems to be attenuated in CBDV treated animals. Taken together, this project explores the novel neurogenic potential of CBDV via TRPV1 which will provide new insights for future research aiming to repurpose CBDV as a viable drug to treat RTT.

Neural Stem Cells and Cannabinoids in the Spotlight as Potential Therapy for Epilepsy.
Epilepsy is one of the most common brain diseases worldwide, having a huge burden in society. The main hallmark of epilepsy is the occurrence of spontaneous recurrent seizures, having a tremendous impact on the lives of the patients and of their relatives. Currently, the therapeutic strategies are mostly based on the use of antiepileptic drugs, and because several types of epilepsies are of unknown origin, a high percentage of patients are resistant to the available pharmacotherapy, continuing to experience seizures overtime. Therefore, the search for new drugs and therapeutic targets is highly important. One key aspect to be targeted is the aberrant adult hippocampal neurogenesis (AHN) derived from Neural Stem Cells (NSCs). Indeed, targeting seizure-induced AHN may reduce recurrent seizures and shed some light on the mechanisms of disease. The endocannabinoid system is a known modulator of AHN, and due to the known endogenous antiepileptic properties, it is an interesting candidate for the generation of new antiepileptic drugs. However, further studies and clinical trials are required to investigate the putative mechanisms by which cannabinoids can be used to treat epilepsy. In this manuscript, we will review how cannabinoid-induced modulation of NSCs may promote neural plasticity and whether these drugs can be used as putative antiepileptic treatment.

Isolation and Expansion of Neurospheres from Postnatal (P1-3) Mouse Neurogenic Niches.
The neurosphere assay is an extremely useful in vitro technique for studying the inherent properties of neural stem/progenitor cells (NSPCs) including proliferation, self-renewal and multipotency. In the postnatal and adult brain, NSPCs are mainly present in two neurogenic niches: the subventricular zone (SVZ) lining the lateral ventricles and the subgranular zone of the

hippocampal dentate gyrus (DG). The isolation of the neurogenic niches from postnatal brain allows obtaining a higher amount of NSPCs in culture with a consequent advantage of higher yields. The close contact between cells within each neurosphere creates a microenvironment that may resemble neurogenic niches. Here, we describe, in detail, how to generate SVZ- and DG-derived neurosphere cultures from 1-3-day-old (P1-3) mice, as well as passaging, for neurosphere expansion. This is an advantageous approach since the neurosphere assay allows a fast generation of NSPC clones (6-12 days) and contributes to a significant reduction in the number of animal usage. By plating neurospheres in differentiative conditions, we can obtain a pseudomonolayer of cells composed of NSPCs and differentiated cells of different neural lineages (neurons, astrocytes and oligodendrocytes) allowing the study of the actions of intrinsic or extrinsic factors on NSPC proliferation, differentiation, cell survival and neuritogenesis.

Cannabinoid Actions on Neural Stem Cells: Implications for Pathophysiology.
With the increase of life expectancy, neurodegenerative disorders are becoming not only a health but also a social burden worldwide. However, due to the multitude of pathophysiological disease states, current treatments fail to meet the desired outcomes. Therefore, there is a need for new therapeutic strategies focusing on more integrated, personalized and effective approaches. The prospect of using neural stem cells (NSC) as regenerative therapies is very promising, however several issues still need to be addressed. In particular, the potential actions of pharmacological agents used to modulate NSC activity are highly relevant. With the ongoing discussion of cannabinoid usage for medical purposes and reports drawing attention to the effects of cannabinoids on NSC regulation, there is an enormous, and yet, uncovered potential for cannabinoids as treatment options for several neurological disorders, specifically when combined with stem cell therapy. In this manuscript, we review in detail how cannabinoids act as potent regulators of NSC biology and their potential to modulate several neurogenic features in the context of pathophysiology.

Succinic semialdehyde dehydrogenase (SSADH) deficiency is an autosomal-recessive neurometabolic disorder caused by bi-allelic mutations in the ALDH5A1 gene. It is the most prevalent inherited disorder of GABA metabolism and is characterized by accumulation of two neuromodulators, GABA and GHB (gamma-hydroxybutyric acid), in the CNS. Previous studies using rodent models have shown that disruption in GABA signaling can lead to dysregulation of mitochondria numbers, turnover, and function. Over the last 30 years, an expanded understanding of pathophysiology based on the corresponding animal model (*Aldh5a1*-/- mice) has emerged but effective pharmacotherapy remains elusive. Alternative models and therapies that address the accumulation of GABA and GHB, and their downstream effects, are needed. In collaboration with the HumanNeuronCore at the Boston Children's Hospital, five clinically-phenotyped patients and unaffected sex-matched parents have been consented and recruited from our SSADH deficiency registry. Fibroblasts have been collected for reprogramming. Three iPSC patient lines and sex-matched parental controls have been generated at the Harvard Stem Cell Institute. We have established the first *in vitro* model of SSADH Deficiency based on iPSC-derived neurons. We successfully generated GABAergic and excitatory neurons based on transcription factor programming (Yang et al., 2017; Zhang et al., 2013) and characterized these models in respect to SSADH deficiency phenotypes such as GABA levels and mitochondria function. Additionally, we performed functional assays to investigate neuronal excitability based on optogenetics and calcium imaging in co-cultures of GABAergic and excitatory neurons to evaluate epileptiform activity in SSADH deficient iPSC-derived neurons and create cell-based models suitable for drug screening.

Generation and characterization of six human induced pluripotent stem cell lines (iPSC) from three families with AP4M1-associated hereditary spastic paraplegia (SPG50).
Biallelic loss-of-function variants in the subunits of the adaptor protein complex 4 lead to childhood-onset hereditary spastic paraplegia (AP-4-HSP): SPG47 (AP4B1), SPG50 (AP4M1), SPG51 (AP4E1), and SPG52 (AP4S1). Here, we describe the generation of induced pluripotent stem cells (iPSCs) from three AP-4-HSP patients with biallelic, loss-of-function variants in AP4M1 and their sex-matched parents (asymptomatic, heterozygous carriers). Following reprogramming using non-integrating Sendai virus, iPSCs were characterized following standard protocols including karyotyping, embryoid body formation, pluripotency marker expression and STR profiling. These first iPSC lines for SPG50 provide a valuable resource for studying this rare disease and related forms of hereditary spastic paraplegia.

Balancing serendipity and reproducibility: Pluripotent stem cells as experimental systems for intellectual and developmental disorders.
Reprogramming of somatic cells into induced pluripotent stem cells (iPSCs) and their differentiation into neural lineages is a revolutionary experimental system for studying neurological disorders, including intellectual and developmental disabilities (IDDs). However, issues related to variability and reproducibility have hindered translating preclinical findings into drug discovery. Here, we identify areas for improvement by conducting a comprehensive review of 58 research articles that utilized iPSC-derived neural cells to investigate genetically defined IDDs. Based upon these findings, we propose recommendations for best practices that can be adopted by research scientists as well as journal editors.

Recent advances in human stem cell-based modeling of Tuberous Sclerosis Complex.
Tuberous sclerosis complex (TSC) is an autosomal dominant disorder characterized by epilepsy, intellectual disability, and benign tumors of the brain, heart, skin, and kidney. Animal models have contributed to our understanding of normal and abnormal human brain development, but the construction of models that accurately recapitulate a human pathology remains challenging. Recent advances in stem cell biology with the derivation of human-induced pluripotent stem cells (hiPSCs) from somatic cells from patients have opened new avenues to the study of TSC. This approach combined with gene-editing tools such as CRISPR/Cas9 offers the advantage of preserving patient-specific genetic background and the ability to generate isogenic controls by correcting a specific mutation. The patient cell line and the isogenic control can be differentiated into the cell type of interest to model various aspects of TSC. In this review, we discuss the remarkable capacity of these cells to be used as a model for TSC in two- and three-dimensional cultures, the potential variability in iPSC models, and highlight differences between findings reported to date.

All-Optical Assay to Study Biological Neural Networks.
We introduce a novel all-optical assay for functional studies of biological neural networks . We created a novel optogenetic construct named OptoCaMP which is a combination of a channelrhodopsin variant (CheRiff) and a red genetically encoded calcium indicator (GECI) (jRCaMP1b). It enables simultaneous optical stimulation and recording from large population of neurons with single-cell readout. Additionally, we have developed a spatio-temporal all-optical assay to simultaneously stimulate a sub-section of a neural network and record evoked calcium activity, in both stimulated and non-stimulated neurons, thus allowing the investigation of the spread of excitation through an interconnected network. Finally, we demonstrate the sensitivity of this assay to the change of neural network connectivity.

Wide-field multiphoton imaging through scattering media without correction.
Optical approaches to fluorescent, spectroscopic, and morphological imaging have made exceptional advances in the last decade. Super-resolution imaging and wide-field multiphoton imaging are now underpinning major advances across the biomedical sciences. While the advances have been startling, the key unmet challenge to date in all forms of optical imaging is to penetrate deeper. A number of schemes implement aberration correction or the use of complex photonics to address this need. In contrast, we approach this challenge by implementing a scheme that requires no a priori information about the medium nor its properties. Exploiting temporal focusing and single-pixel detection in our innovative scheme, we obtain wide-field two-photon images through various turbid media including a scattering phantom and tissue reaching a depth of up to seven scattering mean free path lengths. Our results show that it competes favorably with standard point-scanning two-photon imaging, with up to a fivefold improvement in signal-to-background ratio while showing significantly lower photobleaching.

Modeling pain in vitro using nociceptor neurons reprogrammed from fibroblasts.
Reprogramming somatic cells from one cell fate to another can generate specific neurons suitable for disease modeling. To maximize the utility of patient-derived neurons, they must model not only disease-relevant cell classes, but also the diversity of neuronal subtypes found in vivo and the pathophysiological changes that underlie specific clinical diseases. We identified five transcription factors that reprogram mouse and human fibroblasts into noxious stimulus-detecting (nociceptor) neurons. These recapitulated the expression of quintessential nociceptor-specific functional receptors and channels found in adult mouse nociceptor neurons, as well as native subtype diversity. Moreover, the derived nociceptor neurons exhibited TrpV1 sensitization to the inflammatory mediator prostaglandin E2 and the chemotherapeutic drug oxaliplatin, modeling the inherent mechanisms underlying inflammatory pain hypersensitivity and painful chemotherapy-induced neuropathy. Using fibroblasts from patients with familial dysautonomia (hereditary sensory and autonomic neuropathy type III), we found that the technique was able to reveal previously unknown aspects of human disease phenotypes in vitro.

HUMAN DORSAL FOREBRAIN ORGANOIDS HELP TO ELUCIDATE CELL TYPE-SPECIFIC EFFECTS OF MATERNAL IMMUNE ACTIVATION ON FETAL CORTICAL DEVELOPMENT

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Kseniia Sarieva[1,2], Shokoufeh Khakipoor[2], Theresa Kagermeier[1,2], Zeynep Yentuer[1,2], Simone Mayer[2]
[1]International Max Planck Research School, University of Tuebingen, Graduate Training Centre Of Neuroscience, Tuebingen, Germany, [2]Hertie Institute for Clinical Brain Research, Molecular Brain Development, Tuebingen, Germany

Prenatal exposure to maternal immune activation (MIA) during the first trimester of gestation is correlated with long-term deficits in brain development in the offspring, including increased risks for autism spectrum disorder (ASD) in humans. Rodent models show causal links between prenatal exposure to MIA and ASD-like behavioral deficits in pups that are mediated by deficits in protein translation in neurons. While the majority of studies on the effects of MIA focus on neuronal abnormalities, a growing body of evidence suggests that defects in proliferative and neurogenic capacity of neural stem cells may be important contributors to ASD. In order to determine changes in neurogenesis following MIA in human neural stem cells, we treat human iPSC-derived dorsal forebrain organoids with molecular mediators of MIA. We have validated our model by showing that both dorsal forebrain organoids and midgestational human neocortex express the molecular machinery necessary for the response to the mediators of MIA. We have investigated the consequences of signaling pathway activation by mediators of MIA using immunohistochemistry. Single-cell RNA sequencing of more than 10,000 cells showed that dorsal forebrain organoids represent the diversity of cell types in the developing human neocortex. Additionally, we found that mediators of MIA induce differential gene expression in organoids. Currently, we are further characterizing differentially expressed genes in distinct cell types. Taken together, we have established a human in vitro model system of MIA that allows us to untangle cellular and molecular changes at an unprecedented resolution.

The Effects of Environmental Adversities on Human Neocortical Neurogenesis Modeled in Brain Organoids.
Over the past decades, a growing body of evidence has demonstrated the impact of prenatal environmental adversity on the development of the human embryonic and fetal brain. Prenatal environmental adversity includes infectious agents, medication, and substances of use as well as inherently maternal factors, such as diabetes and stress. These adversities may cause long-lasting effects if occurring in sensitive time windows and, therefore, have high clinical relevance. However, our knowledge of their influence on specific cellular and molecular processes of brain development remains scarce. This gap of knowledge can be partially explained by the restricted experimental access to the human embryonic and fetal brain and limited recapitulation of human-specific neurodevelopmental events in model organisms. In the past years, novel 3D human stem cell-based modeling systems, so-called brain organoids, have proven their applicability for modeling early events of human brain development in health and disease. Since their emergence, brain organoids have been successfully employed to study molecular mechanisms of Zika and Herpes simplex virus-associated microcephaly, as well as more subtle events happening upon maternal alcohol and nicotine consumption. These studies converge on pathological mechanisms targeting neural stem cells. In this review, we discuss how brain organoids have recently revealed commonalities and differences in the effects of environmental adversities on human neurogenesis. We highlight both the breakthroughs in understanding the molecular consequences of environmental exposures achieved using organoids as well as the on-going challenges in the field related to variability in protocols and a lack of benchmarking, which make cross-study comparisons difficult.

Pharmacological HIF1 Inhibition Eliminates Downregulation of the Pentose Phosphate Pathway and Prevents Neuronal Apoptosis in Rat Hippocampus Caused by Severe Hypoxia.
The pentose phosphate pathway (PPP) of glucose metabolism in the brain serves as a primary source of NADPH which in turn plays a crucial role in multiple cellular processes, including maintenance of redox homeostasis and antioxidant defense. In our model of protective mild hypobaric hypoxia in rats (3MHH), an inverse correlation between hypoxia-inducible factor-1 (HIF1) activity and mRNA levels of glucose-6-phosphate dehydrogenase (G6PD), the key enzyme of PPP, was observed. In

the present study, it was demonstrated that severe hypobaric hypoxia (SH) induced short-term upregulation of HIF1 alpha-subunit (HIF1α) in the hippocampal CA1 subfield and decreased the activity of G6PD. The levels of NADPH were also reduced, promoting oxidative stress, triggering apoptosis, and neuronal loss. Injection of a HIF1 inhibitor (HIF1i), topotecan hydrochloride (5 mg/kg, i.p.), before SH prevented the upregulation of HIF1α and normalized G6PD activity. In addition, HIF1i injection caused an increase in NADPH levels, normalization of total glutathione levels and of the cellular redox status as well as suppression of free-radical and apoptotic processes. These results demonstrate a new molecular mechanism of post-hypoxic cerebral pathology development which involves HIF1-dependent PPP depletion and support a recently suggested injurious role of HIF1 activation in the acute phase of cerebral hypoxia/ischemia. Application of PPP stimulators in early post-hypoxic/ischemic period might represent a promising neuroprotective strategy. Graphical abstract HIF1-dependent down-regulation of the pentose phosphate pathway contributes to the hypoxia-induced oxidative stress and neuronal apoptosis in the rat hippocampus.

Neuroprotective effect of hypobaric hypoxic postconditioning is accompanied by dna protection and lipid peroxidation changes in rat hippocampus.
The present study was performed to explore the effect of severe hypobaric hypoxia (180Torr, 3h) and severe hypoxia followed by hypoxic postconditioning (360Torr, 2h, 3 episodes) on DNA fragmentation and dynamics of lipid peroxidation products in rat hippocampus. The severe hypoxia induced intense DNA fragmentation in the hippocampus. A persistent decrease of thiobarbituric acid reactive substances in the hippocampus was also detected in response to severe hypoxia while the levels of Schiff bases did not significantly change. The postconditioning prevented severe hypoxia-induced DNA fragmentation, returned the levels of thiobarbituric acid reactive substances to the baseline and decreased the levels of Schiff bases. These findings indicate that the neuroprotective effect of hypoxic postconditioning on hippocampal neurons detected as suppression of hypoxia-induced DNA fragmentation is accompanied by the changes in lipid peroxidation processes.

Neuroprotective Mechanism of Hypoxic Post-conditioning Involves HIF1-Associated Regulation of the Pentose Phosphate Pathway in Rat Brain.
Post-conditioning is exposure of an injured organism to the same harmful factors but of milder intensity which mobilizes endogenous protective mechanisms. Recently, we have developed a novel noninvasive post-conditioning (PostC) protocol involving three sequential episodes of mild hypobaric hypoxia which exerts pronounced neuroprotective action. In particular, it prevents development of pathological cascades caused by severe hypobaric hypoxia (SH) such as cellular loss, lipid peroxidation, abnormal neuroendocrine responses and behavioural deficit in experimental animals. Development of these post-hypoxic pathological effects has been associated with the delayed reduction of hypoxia-inducible factor 1 (HIF1) regulatory α-subunit levels in rat hippocampus, whereas PostC up-regulated it. The present study has been aimed at experimental examination of the hypothesis that intrinsic mechanisms underlying the neuroprotective and antioxidant effects of PostC involves HIF1-dependent stimulation of the pentose phosphate pathway (PPP). We have observed that SH leads to a decrease of glucose-6-phosphate dehydrogenase (G6PD) activity in the hippocampus and neocortex of rats as well as to a reduction in NADPH and total glutathione levels. This depletion of the antioxidant defense system together with excessive lipid peroxidation during the reoxygenation phase resulted in increased oxidative stress and massive cellular death observed after SH. In contrast, PostC led to normalization of G6PD activity, stabilization of the NADPH and total glutathione levels and thereby resulted in recovery of the cellular redox state and prevention of neuronal death. Our data suggest that stabilization of the antioxidant system via HIF1-associated PPP regulation represents an important neuroprotective mechanism enabled by PostC.

IDENTIFICATION OF CHANGES IN THE ELECTROPHYSIOLOGICAL ACTIVITIES IN MATURE HUMAN CEREBRAL ORGANOIDS

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Francesco Di Matteo[1,2], Hanna Schmidt[1], Ane_Ayo Martin[1], Rossella Di Giaimo[2], Veronica M Pravata[2], Giuseppina Maccarone[2], Stephen P Robertson[3], Matthias Eder[2], Silvia Cappello[2]
[1]Max Planck Institute of Psychiatry, Imprs-tp, Munich, Germany, [2]Max Planck Institute of Psychiatry, Developmental Neurobiology, Munich, Germany, [3]University of Otago, Department Of Women's And Children's Health, Dunedin, New Zealand

Human cerebral organoids recapitulate some unique features of human brain development and are increasingly being used as model systems to shed new light on the cellular mechanisms underlying the development of a variety of neurological diseases. However, the presence of functional neural network activities has only recently been demonstrated. Here, we investigate the spontaneous activity frequencies of mature human cerebral organoids using extracellular recordings that reveal the existence of a functional neuronal network. Moreover, we demonstrate an altered functional activity in cerebral organoids derived from individuals with neuronal heterotopia carrying mutations in two different genes, resulting in a higher number of spikes and a higher percentage of high-frequency spikes. We also performed single-cell characterization at functional and morphological levels by patch-clamp recordings and morphological reconstruction of human neurons in 2D, revealing the existence of distinctive and common phenotypes, depending on the specific mutations. Specifically, patients' neurons are hyperexcitable with altered morphology and complexity and an increased number of excitatory pre-synaptic vesicles, that could lead to the observed functional activity. In accordance, transcriptomic and proteomic analyses of mature cerebral organoids suggest alteration at the morphological and synaptic levels. Together, these findings provide an essential base for the use of cerebral organoids to investigate human brain development and disorders at the functional level and illustrate their potential role in therapeutic and personalized treatments.

TOWARD A BETTER UNDERSTANDING OF ITM2B PATHOGENICITY IN A SPECIFIC RETINAL DYSTROPHY, AND ITS POTENTIAL ROLE IN MITOCHONDRIA

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Tasnim Ben Yacoub
Institut de la vision, Genetics, PARIS, France

Our team identified a missense mutation in ITM2B underlying a novel autosomal dominant retinal dystrophy with ganglion cell loss, inner retinal dysfunction and progressive retinal degeneration but the function of ITM2B in the retina and physio-pathological mechanisms remains poorly understood. In a previous work, we obtained patient- and control-derived retinal organoids to model the disease recently showed that ITM2B may interact with mitochondrial proteins, implicated in oxidative stress in human retina. This project aims to investigate ITM2B in mitochondrial function and determined if it is altered in the disease. Two inducted pluripotent cell lines (iPSC) derived from an affected and unaffected sibling were used. ITM2B mitochondrial immunolocalization in 60 days aged organoids was studied using two mitochondrial markers COX5B and ATP-β. Furthermore, IPSC metabolism was analyzed in control and mutant cell lines using a mitostress seahorse assay. ITM2B immuno-localizes with both COX5B and ATB-β mitochondrial markers in retinal organoid sections. No difference was noticed between the mutant and the control organoids suggesting that mutant ITM2B does not modify the localization of the protein at this stage. Furthermore, no difference in oxygen consumption rate was observed in mutant IPSC compared to control cells, but further experiments will be performed in differentiated cells to which to try to highlight a mitochondrial defect in the mutant cell line, as well as a low capacity to respond to stress. Our findings suggest a central role of the mitochondria underlying ITM2B pathogenesis in the retina. Further studies using biochemical assays, respiratory function using sea-horse and

RAPID, HIGH-EFFICIENCY DIFFERENTIATION OF MOTOR NEURONS FROM HUMAN PLURIPOTENT STEM CELLS

POSTER SESSION 05 - SECTION: PLURIPOTENT STEM CELLS IN DISEASE MODELING

Jinyuan Wang[1], Jeanne Chan[1], Allen Eaves[2,3], Sharon Louis[1], Erin Knock[1,4]
[1]STEMCELL Technologies Inc., Research And Development, Vancouver, Canada, [2]STEMCELL Technologies Inc., President And Ceo, Vancouver, Canada, [3]BC Cancer, Terry Fox Laboratory, Vancouver, Canada, [4]Simon Fraser University, Department Of Biological Sciences, Burnaby, Canada

Human motor neuron (MN) diseases include devastating disorders such as amyotrophic lateral sclerosis (ALS) and spinal muscular atrophy (SMA). A reliable human MN model is critical to uncover disease mechanisms. Here we present the STEMdiff™ Motor Neuron Culture System which generates MNs from human pluripotent stem cells (hPSCs) at high efficiency. The hPSCs were aggregated to embryoid bodies (EBs) with STEMdiff™ Motor Neuron Differentiation Kit in an ultra-low attachment or an AggreWell™400 plate. On day 9, EBs were dissociated into single cells and replated for adherent culture. On day 14, the cells were either matured using the STEMdiff™ Motor Neuron Maturation Kit or assessed by immunocytochemistry and qPCR for motor neuron markers BIIITUB, ISL1, and HB9. The MNs were co-cultured with either myotubes generated using MyoCult™ Differentiation Kit (Human) or with microglia generated using STEMdiff™ Microglia Kits for one week, and then analyzed via immunocytochemistry. A highly pure population of MNs was observed at day 14 (BIIITUB: 92.6 ± 3.7%; ISL1: 56.0 ± 13.9%; HB9: 65.2 ± 13.2%; mean ± standard deviation, n = 6) with cervical identity by the expression of HOXA5 through qPCR. After two weeks in the maturation medium, the MNs showed high expression of mature markers including CHAT, MAP2 and SYP. Finally, MNs were successfully co-cultured with hPSC-derived myotubes or microglia for one week. Taken together, STEMdiff™ Motor Neuron Culture System provides a powerful tool to generate hPSC-derived MNs and co-culture systems for in vitro studies of human MN diseases.

MORPHOLOGICAL AND PHYSIOLOGICAL CHARACTERIZATION OF SUBICULAR PRINCIPAL CELLS

POSTER SESSION 05 - SECTION: CELLULAR ARCHITECTURE OF THE BRAIN

Alix Guinet, Sabine Grosser, Yoshihisa Ishihara, Imre Vida
Charité, Institute Of Integrative Neuroanatomy, Berlin, Germany

The subiculum is an output region of the hippocampal formation relaying information between the hippocampus proper and entorhinal cortex. While a divergence along its proximo-distal axis has been recognized by early studies, there is increasing evidence for further spatial subdivisions (Ishihara et al., 2020) and a high molecular heterogeneity of its principal cells (Cembrowski et al., 2018). Indeed, a neuroanatomical characterization of the subiculum indicates that the distal part of this area (subiculum-1) diverges in its cytoarchitecture, neuronal density and immunocytochemical staining pattern from the proximal parts (subiculum-2): it has a dense homogenous cell population, with consistent expression of fibronectin-1 (FN1) in contrast to the sparse, layered cytostructure largely lacking FN1 immunoreactivity. In contrast, parvalbumin positive axonal arborization of putative basket cells was found to be high in subiculum-2 but low in the subiculum-1, suggesting a differential organization of the inhibitory system in these two subregions. Therefore, in this study we investigated the electrophysiological and morphological characteristics as well as the inhibitory input of its principal neurons of these two regions in a comparative manner by using whole-cell recordings in combination with intracellular filling in acute mouse slices. To analyze the inhibitory input from PV-positive basket cell, photostimulation was performed in slices from transgenic mice expressing channel rhodopsin-2 under the parvalbumin promoter. Preliminary results indicate that neurons of the subiculum-1 and subiculum-2 diverge in specific morphological characteristics: cell body size, dendritic length and spatial spreading of the apical dendrite, but their intrinsic physiological properties are largely comparable.

THE ULTRASTRUCTURAL CHARACTERIZATION OF THE CELL POPULATION OF THE MOUSE PARALAMINAR NUCLEUS OF THE AMYGDALA REVEALS THREE STATES OF NEURONAL ACTIVE MATURATION AT POSTNATAL STAGES

POSTER SESSION 05 - SECTION: CELLULAR ARCHITECTURE OF THE BRAIN

Lucía Inés Torrijos Saiz[1], Vicente Herranz Pérez[1], Jose Manuel García Verdugo[1], Shawn Sorrells[2]
[1]University of Valencia, Cavanilles Institute Of Biodiversity And Evolutive Biology, Valencia, Spain, [2]University of Pittsburgh, Department Of Neuroscience, Pittsburgh, United States of America

The paralaminar nucleus (PL) is a region located in the ventral amygdala whose cells show a late maturation profile. Despite its heterogeneous cellular composition, a large population present, at postnatal stages, simple morphology, dense clustering, and expression of doublecortin (DCX) and PSA-NCAM, both markers of immature neurons. Our aim is to characterize the ultrastructure of each cell type in the mouse PL at postnatal stages P7, P14, P21, P28, P60, 7 months and 1 year. Regarding the methodology, we first characterized the PL cell typology by fluorescence immunohistochemistry in paraffin sagittal sections. Subsequently, the ultrastructural characteristics were studied by transmission electron microscopy and *pre-embedding* immuno-gold for a range of molecular markers. Our results indicate that, in the mice PL, there is presence of mature excitatory and inhibitory neurons, immature neurons, oligodendrocytes, OPCs, astrocytes and microglia cells. Focusing on neurons, ultrastructurally, most of DCX^+ neurons presented immature morphology, compacted heterochromatin and reduced cytoplasmatic volume, while DCX^- neurons corresponded to completely mature and developed neurons. However, we found an intermediate neuron population with low expression of DCX but quite developed cytoplasm, suggesting progressive maturation of the PL neurons. Remarkably, we observed some neurons with migratory morphology, directing outside de PL region towards the piriform cortex. In conclusion, the presence of immature DCX^+ cells in the PL of mice which mature at juvenile postnatal stages and may even migrate to other brain areas supports the idea that protracted maturation could provide neuronal plasticity at an important time in the development of the amygdala.

DEVELOPMENT OF ACD NEURONS IN THE MURINE HIPPOCAMPUS AND PRIMARY SOMATOSENSORY CORTEX

POSTER SESSION 05 - SECTION: CELLULAR ARCHITECTURE OF THE BRAIN

Nadja Lehmann[1], Stefan Markovic[2], Maren Engelhardt[2]
[1]Heidelberg University, Institute Of Neuroanatomy, Mannheim Centre For Translational Neuroscience (mctn), Medical Faculty Mannheim, Mannheim, Germany, [2]Johannes Kepler University, Institute Of Anatomy And Cell Biology, Medical Faculty, Linz, Austria

Cortical principal neurons receive synaptic input at their dendrites and convey them to the soma. After integration, the axon initial segment (AIS) initiates action potentials. Classically, the axon emerges from the soma. However, in axon-carrying dendrite (AcD) neurons, the axon originates from a basal dendrite resulting in potentially distinct functional implications. Although AcD neurons have been described in numerous cortical regions and across species, their developmental profile remains largely unknown. Therefore, this project focuses on the early maturation profile of AcD neurons in comparison to nonAcD neurons in the murine ventral hippocampus (vHC) and primary somatosensory (S1) cortex. Parameters include the occurrance of both subtypes across numerous ages, as well as the maturation of AIS-specific features (e.g. expression of voltage-gated sodium channels and the emergence of GABAergic axo-axonic synapses (AAS)). Data show that in vHC, the number of AcD neurons steadily increases until P28, while in S1, AcD neurons peak at P16. AcD neurons show shorter $Na_V1.6$ channel distribution than nonAcD neurons in both brain regions. Live-cell imaging in cortical slice cultures reveals a striking morphological dynamic in pyramidal neurons, which transform from one type to the other during development. Preliminary data also indicate that the development of AcD neurons has an activity-dependent component. In summary, our data imply that entire cells exhibit morphological plasticity, the regulating mechanisms of which remain to be studied in vivo.

Neurovascular coupling (NVC), the tight coupling between neural activity and cerebral blood flow, is essential for brain function and integrity. Prostaglandin E2 (PGE2) produced by cyclooxygenase-2 (COX-2) activity of pyramidal cells plays a key role in NVC accounting for about half of the blood perfusion increase induced by sensory stimulation. **Aims:** We sought to determine the regime of pyramidal neurons activity triggering an optimal NVC response. **Methods**: Pyramidal cells were optogenetically stimulated in cortical brain slices of 3-week-old Emx1-Cre::Ai32 mice. Vascular responses were visualized by infrared videomicroscopy and the underlying mechanisms dissected-out by pharmacological approaches. The expression profile of prostaglandin synthesizing enzymes in pyramidal cells was determined by single-cell RT-PCR after patch-clamp. **Results**: Photostimulation of pyramidal cells at low (2 Hz) and high (20 Hz) frequencies elicited, respectively, vasodilation and vasoconstriction requiring COX-2 activity. Molecular profiling revealed that one-third of pyramidal cells expressed COX-2 and terminal synthesizing enzymes for both PGE2 and the vasoconstrictor PGF2a. Optogenetically-induced vasoconstrictions were mediated by the PGE2 receptors EP1 and EP3, but not by the PGF2α receptor. Furthermore, exogenous PGE2 induced vasodilation and vasoconstriction when applied at low (<100nM) and high (>1 µM) concentrations, respectively. Moreover, vasoconstriction was mimicked by an EP1/EP3 agonist. Action potentials and neuropeptide Y, but not constrictive astrocytic pathways, were also required for optogenetically-induced vasoconstrictions. **Conclusions**: These results indicate that pyramidal neurons and PGE2 bidirectionally control NVC. This finding will help to understand the physiopathological adaptations of NVC in neurological disorders.

Amygdala refers to a cluster of structurally distinct nuclei in the brain. Its core unit is the basolateral amygdala complex (BLA) and the central amygdala (CeA). The former region includes the lateral (LA), basal (BA) and basomedial (BMA) nuclei. The BLA is involved in numerous cognitive operations, such as fear memory processes. To understand how the amygdala fulfils its various functions, we need to reveal the organization principles of intra-amygdalar connections. Therefore, our aim was to examine the connectivity within the amygdala at single cell and population levels. To this end, we used different tracing techniques corroborated by the *post hoc* reconstruction of 21 principal neurons (PNs) labelled *in vivo* using juxtacellular technique in the mouse brain. The latter provided an opportunity to morphollogically characterize the PNs of the BLA. In accord with previous results, we confirmed the reciprocal connectivity between the LA and BMA and the directionality within the amygdala networks. Considering the anatomical characteristics of the reconstructed cells, we defined groups of BA and LA PNs with different morhological patterns. Additionally, two distinct units were distinguished within the BA: a lateral-posterior one that typically projects to the lateral part of the CeA, and a medial-anterior one that does not. Based on these observations, the lateral part of the BA conveys information towards the CeA, while the medial part forms a separate functional unit with other brain areas, including the prefrontal cortex, suggesting the presence of discrete information flow pathways within the BLA.

SVCT2 OVEREXPRESSION AND ASCORBIC ACID UPTAKE INCREASE CORTICAL NEURON DIFFERENTIATION, WHICH IS DEPENDENT ON VITAMIN C RECYCLING BETWEEN NEURONS AND ASTROCYTES

POSTER SESSION 05 - SECTION: CELLULAR ARCHITECTURE OF THE BRAIN

Francisco Nualart, Katterine Salazar, Francisca Espinoza, Luciano Ferrada, Rocio Magdalena, Eder Ramírez, Natalia Saldivia, Ninoschka Troncoso, Fernando Martínez
Concepción University, Cellular Biology, Concepción, Chile

During brain development, sodium–vitamin C transporter (SVCT2) has been detected primarily in radial glial cells in situ, with low-to-absent expression in cerebral cortex neuroblasts. However, strong SVCT2 expression is observed during the first postnatal days, resulting in increased intracellular concentration of vitamin C. Hippocampal neurons isolated from SVCT2 knockout mice showed shorter neurites and low clustering of glutamate receptors, suggesting that ascorbic acid (AA) and SVCT2 have important roles in postnatal neuronal differentiation and neurite formation. In this study, SVCT2 lentiviral overexpression induced branching and increased synaptic proteins expression in primary cultures of cortical neurons. Analysis in neuroblastoma 2a (Neuro2a) and human subventricular tumor C3 (HSVT-C3) cells showed similar branching results. SVCT2 was mainly observed in the cell membrane and endoplasmic reticulum; however, it was not detected in the mitochondria. Cellular branching in neuronal cells and in a previously standardized neurosphere assay is dependent on the recycling of vitamin C or reduction in dehydroascorbic acid (DHA, produced by neurons) by glial cells. The effect of WZB117, a selective glucose/DHA transporter 1 (GLUT1) inhibitor expressed in glial cells, was also studied. By inhibiting GLUT1 glial cells, a loss of branching is observed in vitro, which is reproduced in the cerebral cortex in situ. We concluded that vitamin C recycling between neurons and astrocyte-like cells is fundamental to maintain neuronal differentiation in vitro and in vivo. The recycling activity begins at the cerebral postnatal cortex when neurons increase SVCT2 expression and concomitantly, GLUT1 is expressed in glial cells.

How have complex brain regions, circuits, and cell types evolved from simple origins? We are investigating brain region evolution at cell-type resolution in the cerebellar nuclei, the output structures of the cerebellum. In recent work, we applied single-nucleus RNA sequencing in chickens, mice, and humans, STARmap spatial transcriptomic analysis in chicken and mice, and whole-CNS projection mapping in mice. Our work revealed a conserved cell type set containing three classes of region-invariant inhibitory neurons and two classes of region-specific excitatory neurons. This cell type set forms an archetypal cerebellar nucleus that was repeatedly duplicated to create new regions, and thus cerebellar output channels. In excitatory neurons, duplication was accompanied by divergence in gene expression and shifts in projection patterns. By contrast, inhibitory neurons maintained their gene expression signatures. Interestingly, the excitatory cell class that preferentially funnels information to lateral frontal cortices in mice becomes predominant in the massively expanded human Lateral CN. This data provide the first characterization of CN transcriptomic cell types in three species and suggest a model of brain region evolution by duplication and divergence of entire cell type sets. We are now working to extend these findings to tetrapods and to query the evolution of new connectomic cell types using cellular barcoding techniques MAPseq and BARseq in different species.

TOWARDS TRANSLATING SINGLE-NEURON AXONAL RECONSTRUCTIONS INTO MESO-SCALE STRUCTURAL CONNECTIVITY STATISTICS

POSTER SESSION 05 - SECTION: CELLULAR ARCHITECTURE OF THE BRAIN

Nestor Timonidis[1], Rembrandt Bakker[1], Maria Carla Piastra[2], Maria Garcia-Amado[3], Mario Rubio-Teves[4], Francisco Clascá[5], Paul Tiesinga[1]
[1]Radboud University Nijmegen, Neuroinformatics, Donders Institute, Nijmegen, Netherlands, [2]University of Twente, Institute For Technical Medicine, Enschede, Netherlands, [3]School of Medicine, Department Of Anatomy And Neuroscience, Madrid, Spain, [4]School of Medicine. Autonomous University of Madrid, Department Of Anatomy And Neuroscience, Madrid, Spain, [5]Autonoma de Madrid University, Department Of Anatomy, Histology And Neuroscience, Madrid, Spain

Aims The past decade has seen a tremendous development of connectomics approaches, with single-neuron reconstructions bridging the gap between cellularly resolved micro-circuits and whole-brain bulk axonal projections. However, characterizing brain-wide projection motifs in thousands of neurons is still challenging. We have thus developed a tool for translating ~3000 axonal morphologies into projection statistics across different brain areas, using reconstructed neurons from high throughput repositories and from our recently developed pipeline. **Methods** We first identify neurons with similar axonal morphology and registration coordinates using an in-house neuron as template. Particularly, we apply the Coherent Point Drift method to compute similarity by first finding correspondences between points in target and template neuron followed by determining the mean squared distance between corresponding points. Given the group of most similar neurons, we use the Allen Reference Atlas to measure the distribution of axonal length across cortical layers and subcortical nuclei. **Results** We obtained projection statistics for a group of similar thalamic neurons showing high axonal overlap in layers 2-5 of the lateral visual area and in various thalamic nuclei. In addition, we repeated the procedure with the more densely sampled intra-cortical projection neurons, however results are still preliminary. **Conclusions** Our approach represents a significant extension to existing tools, since it accounts for full axonal trees instead of only regions of interest. Moreover, it is applicable to neurons reconstructed in smaller laboratories and allows for integration with other similarly registered datasets. We further intend to extend our approach to uncover complex projection motifs.

FOXP1 AND NNOS NEURONAL POPULATIONS IN THE ADULT HUMAN, MOUSE AND RAT SUBTHALAMIC NUCLEUS

POSTER SESSION 05 - SECTION: CELLULAR ARCHITECTURE OF THE BRAIN

Tila Medenica[1,2], Ema Bokulić[1,2], Goran Sedmak[1,2]
[1]University of Zagreb, School of Medicine, Croatian Institute for Brain Research, Section For Developmental Neuroscience, Zagreb, Croatia, [2]University of Zagreb School of Medicine, Scientific Centre Of Excellence For Basic, Clinical, And Translational Neuroscience, Zagreb, Croatia

Introduction: The subthalamic nucleus (STN) is a subcortical structure which is an important part of the basal ganglia circuitry. nNOS is an enzyme which produces nitric oxide, a neurotransmitter implicated in learning, memory, and brain plasticity. FOXP1 is a transcription factor whose deficiency causes FOXP1 syndrome – a neurodevelopmental disorder associated with intellectual disability, language deficits and autism. **Aims:** Besides its role in motor control, STN is significantly involved in cognitive and limbic processes in the brain. Because of the importance of NO and FOXP1 in these processes, the aim of our study was to determine the quantity and spatial distribution of FOXP1 and nNOS-IR neurons in the adult human, mouse and rat STN. **Methods:** We performed immunofluorescent double-labelling with antibodies for FOXP1 and nNOS proteins, with HuC/HuD antibody (a pan-neuronal marker) on STN sections of FFPE adult human, mouse, and rat brains. Immunofluorescent slides were imaged using confocal microscopy and used to quantify the colocalization. **Results:** We show that in mouse, the FOXP1 and nNOS populations are clearly separated and almost non-overlapping. FOXP1 neurons group on the antero-ventral portion of STN, while nNOS neurons group on the postero-dorsal portion. In rat, the populations are mostly separated but overlapping and colocalizing in the center. In human, the populations are partially colocalizing and they are not spatially separated but rather intermixed and dispersed evenly throughout the STN. **Conclusions:** This study shows FOXP1 and nNOS expression in the mammalian subthalamic nucleus and may explain the STN involvement in cognitive and limbic processes.

Zebrafish is extensively used for investigating fundamental principles underlying the assembly and the function of the vertebrate brain, most commonly for the study of sensory-motor computations in larval zebrafish midbrain and hindbrain. Recent studies have shown that juvenile and adult zebrafish can perform cognitively demanding tasks, which is partly attributed to the maturation of forebrain networks, ancestral to mammalian cortico-limbic structures. Nonetheless, the molecular cytoarchitecture and cell types of adult zebrafish forebrain and its homologies to terrestrial vertebrates are yet to be discovered. In order to identify distinct regions and cell types of the adult zebrafish forebrain, we generated a serial-section transcriptomic atlas for 99 genes at subcellular resolution, and by aligning sections we created a high resolution three-dimensional atlas. For validation and to predict homologies, we integrated our molecular atlas with single-cell RNA sequencing data from zebrafish and several terrestrial vertebrates. Our results revealed multiple excitatory and inhibitory neuron types and non-neuronal cells across the forebrain. We observed that some of these cell types are dispersed widely while others are spatially organized. We also identified novel and anatomically distinct forebrain regions with predicted homologies to mammalian cortical and sub-cortical structures. Finally, we match several of these molecularly identified zebrafish forebrain regions with functional maps based on calcium imaging of ongoing brain activity. Our results highlight the evolutionary conservation and divergence of the anatomy and the cytoarchitecture of zebrafish forebrain with the rest of terrestrial vertebrates.

Pubmed:

MOCCA: a flexible suite for modelling DNA sequence motif occurrence combinatorics.
Cis-regulatory elements (CREs) are DNA sequence segments that regulate gene expression. Among CREs are promoters, enhancers, Boundary Elements (BEs) and Polycomb Response Elements (PREs), all of which are enriched in specific sequence motifs that form particular occurrence landscapes. We have recently introduced a hierarchical machine learning approach (SVM-MOCCA) in which Support Vector Machines (SVMs) are applied on the level of individual motif occurrences, modelling local sequence composition, and then combined for the prediction of whole regulatory elements. We used SVM-MOCCA to predict PREs in Drosophila and found that it was superior to other methods. However, we did not publish a polished implementation of SVM-MOCCA, which can be useful for other researchers, and we only tested SVM-MOCCA with IUPAC motifs and PREs.
BMC Bioinformatics, 2021; 22
31340029: Bredesen BA, Rehmsmeier M
DNA sequence models of genome-wide Drosophila melanogaster Polycomb binding sites improve generalization to independent Polycomb Response Elements.
Polycomb Response Elements (PREs) are cis-regulatory DNA elements that maintain gene transcription states through DNA replication and mitosis. PREs have little sequence similarity, but are enriched in a number of sequence motifs. Previous methods for modelling Drosophila melanogaster PRE sequences (PREdictor and EpiPredictor) have used a set of 7 motifs and a training set of 12 PREs and 16-23 non-PREs. Advances in experimental methods for mapping chromatin binding factors and modifications has led to the publication of several genome-wide sets of Polycomb targets. In addition to the seven motifs previously used, PREs are enriched in the GTGT motif, recently associated with the sequence-specific DNA binding protein Combgap. We investigated whether models trained on genome-wide Polycomb sites generalize to independent PREs when trained with control sequences generated by naive PRE models and including the GTGT motif. We also developed a

new PRE predictor: SVM-MOCCA. Training PRE predictors with genome-wide experimental data improves generalization to independent data, and SVM-MOCCA predicts the majority of PREs in three independent experimental sets. We present 2908 candidate PREs enriched in sequence and chromatin signatures. 2412 of these are also enriched in H3K4me1, a mark of Trithorax activated chromatin, suggesting that PREs/TREs have a common sequence code.

The brain is an exceptionally sophisticated organ consisting of billions of cells and trillions of connections that orchestrate our cognition and behavior. To decode its complex connectivity, it is pivotal to disentangle its intricate architecture spanning from cm-sized circuits down to tens of nm-small synapses. To achieve this goal, we have developed CATS - Comprehensive Analysis of nervous Tissue across Scales, a toolbox for obtaining a holistic view of nervous tissue context with fluorescence microscopy. CATS provides rich ultrastructural context by creating contrast between the intra- and extracellular space in a variety of samples types, including slice cultures, perfused brain tissue and clinical samples. It is compatible with common (super-resolution) fluorescence imaging techniques, such as STED and expansion microscopy, as well as labeling of molecular markers. We interface this toolbox with a state-of-a-art machine-learning based analysis pipeline for segmentation and annotation. CATS enables the analysis of key features of nervous tissue connectivity across scales, ranging from whole tissue organization down to synapse architecture. We present the potential of this novel toolbox by reconstructing neuronal in- and output fields in the mouse hippocampus, a feat that so far has only been achieved by electron microscopy. Further, we combine CATS with electrophysiological recordings to investigate structure-function relationships in the brain, apply it to human clinical samples to study tissue context and fully annotate a piece of cerebral organoid, thereby paving the way towards light microscopy-based saturated reconstruction of nervous tissue.

ROLES OF EARLY MICROGLIA IN THE WIRING OF PERISOMATIC INHIBITION AND CRITICAL PERIODS

POSTER SESSION 05 - SECTION: CELLULAR ARCHITECTURE OF THE BRAIN

Alice Canzi[1], Jérôme Ribot[2], Morgane Thion[1], Nathalie Rouach[2], Sonia Garel[1,3]
[1]Institut de Biologie de l'ENS (IBENS), Ecole Normale Supérieure, CNRS, Inserm, Université Psl, Paris, France, [2]Center for Interdisciplinary Research in Biology, Collège de France, Cnrs Umr 7241, Inserm U1050, Labex Memolife, Psl Research University, Paris, France, [3]Collège de France, Université Psl, Paris, France

Parvalbumin (PV)-expressing interneurons play important roles at different steps of sensory cortex development and their dysfunction is a hallmark of neurodevelopmental disorders(NDD) as shown by genetic mouse models analyses. PV neurons act as gain modulators via perisomatic inhibition of pyramidal neurons and display, in association with the closure of critical periods(CP), a progressive enwrapping by perineuronal nets(PNNs). We previously found that PV neurons development is altered by embryonic depletion of immune brain resident cells, microglia, as well as by prenatal inflammation mediated by maternal immune activation(MIA). While these results highlighted potential convergence of genetic and immune risks for NND onto PV neuron wiring, they raised questions about both the mechanisms involved as well as the long-term consequences. To address these issues, we are taking advantage of transient embryonic macrophage depletions, MIA and genetic models to explore the development of perisomatic inhibition and how these processes may be perturbed by early alteration in microglia functioning. In parallel, we are investigating the long-term consequences of these early wiring deficits on PV neurons circuit integration and the features of the CP in a well-characterized model of ocular dominance plasticity in the primary visual cortex. To this aims, we are combining morphological studies of PNNs with ocular dominance experiments after monocular deprivation at different developmental stages to assess the kinetics and characteristics of plasticity in these distinct experimental paradigms. Our ongoing results support a novel role for early neuroimmune interactions in the development of PV neurons wiring, with long-lasting impact on cortical circuit properties.

CORTICAL INTERNEURONS PRESENT MARKED DIFFERENCES IN THEIR PH AND INTRACELLULAR CHLORIDE LEVELS

POSTER SESSION 05 - SECTION: CELLULAR ARCHITECTURE OF THE BRAIN

Laura Alberio[1], Robert Graham[1], Connie Mackenzie-Gray Scott[1], Luciano Saieva[1], Claudia Racca[1], Gian-Michele Ratto[2], Andrew Trevelyan[1]

Background: Chloride and pH levels inside neurons play an important role in determining neuronal excitability. In particular, the intracellular chloride concentration, $[Cl^-]_i$, dictates the efficacy of fast GABAergic synaptic inhibition; and the activity of most neuronal receptors is highly sensitive to deviations even within the physiological pH range (7.0-7.4). Thus changes in pH and $[Cl^-]_i$ have a very powerful effect on network excitability. However, little is known about how chloride and pH levels differ between cell classes *in vivo*. These measures are now possible thanks to the development of ClopHensor (Arosio et al., 2010), a genetically encoded sensor, and its optimisation for 2-photon microscopy (Sulis Sato et al., 2017). Using ClopHensor, we have demonstrated that diurnal changes in $[Cl^-]_i$ of cortical pyramidal cells have deep effects on the network excitability (Pracucci et al., 2021, biorxiv). Aims: We investigate pH and $[Cl^-]_i$ levels *in vivo* in two major classes of cortical interneurons: Parvalbumin- (PV), and Somatostatin-positive (SST). Methods: We modified ClopHensor by changing the linker sequence, to improve the sensor stability, and we calibrated the new construct. We packaged the sensor into an AAV vector for cell-specific gene delivery (cre/lox system), and used this to target PV and SST interneurons. Results: We present population statistics of pH and $[Cl^-]_i$ in PV and SST interneurons *in vivo*, obtained using 2-photon microscopy. Our measures show marked differences between the two populations in both their pH and $[Cl^-]_i$ values, suggesting the presence of independent regulation mechanisms in these cell classes.

Gating movements and ion permeation in HCN4 pacemaker channels.
The HCN1-4 channel family is responsible for the hyperpolarization-activated cation current I/I that controls automaticity in cardiac and neuronal pacemaker cells. We present cryoelectron microscopy (cryo-EM) structures of HCN4 in the presence or absence of bound cAMP, displaying the pore domain in closed and open conformations. Analysis of cAMP-bound and -unbound structures sheds light on how ligand-induced transitions in the channel cytosolic portion mediate the effect of cAMP on channel gating and highlights the regulatory role of a Mg coordination site formed between the C-linker and the S4-S5 linker. Comparison of open/closed pore states shows that the cytosolic gate opens through concerted movements of the S5 and S6 transmembrane helices. Furthermore, in combination with molecular dynamics analyses, the open pore structures provide insights into the mechanisms of K/Na permeation. Our results contribute mechanistic understanding on HCN channel gating, cyclic nucleotide-dependent modulation, and ion permeation.

A light-gated potassium channel for sustained neuronal inhibition.
Currently available inhibitory optogenetic tools provide short and transient silencing of neurons, but they cannot provide long-lasting inhibition because of the requirement for high light intensities. Here we present an optimized blue-light-sensitive synthetic potassium channel, BLINK2, which showed good expression in neurons in three species. The channel is activated by illumination with low doses of blue light, and in our experiments it remained active over (tens of) minutes in the dark after the illumination was stopped. This activation caused long periods of inhibition of neuronal firing in ex vivo recordings of mouse neurons and impaired motor neuron response in zebrafish in vivo. As a proof-of-concept application, we demonstrated

that in a freely moving rat model of neuropathic pain, the activation of a small number of BLINK2 channels caused a long-lasting (>30 min) reduction in pain sensation.

Yeast-Based Screening System for the Selection of Functional Light-Driven K Channels.
Ion channels control the electrical properties of cells by opening and closing (gating) in response to a wide palette of environmental and physiological stimuli. Endowing ion channels with the possibility to be gated by remotely applied stimuli, such as light, provides a tool for in vivo control of cellular functions in behaving animals. We have engineered a synthetic light-gated potassium (K) channel by connecting an exogenous plant photoreceptor LOV2 domain to the K channel pore Kcv. Here, we describe the experimental strategy that we have used to evolve the properties of the channel toward full control of light on pore gating. Our method combines rational and random mutagenesis of the channel followed by a yeast-based screening system for light-activated K conductance.

Optogenetics. Engineering of a light-gated potassium channel.
The present palette of opsin-based optogenetic tools lacks a light-gated potassium (K(+)) channel desirable for silencing of excitable cells. Here, we describe the construction of a blue-light-induced K(+) channel 1 (BLINK1) engineered by fusing the plant LOV2-Jα photosensory module to the small viral K(+) channel Kcv. BLINK1 exhibits biophysical features of Kcv, including K(+) selectivity and high single-channel conductance but reversibly photoactivates in blue light. Opening of BLINK1 channels hyperpolarizes the cell to the K(+) equilibrium potential. Ectopic expression of BLINK1 reversibly inhibits the escape response in light-exposed zebrafish larvae. BLINK1 therefore provides a single-component optogenetic tool that can establish prolonged, physiological hyperpolarization of cells at low light intensities.

DOWNREGULATION OF EXTRA-SYNAPTIC DELTA GABAA RECEPTORS IS CORRELATED WITH DISRUPTED TONIC INHIBITION IN AN APP KNOCK-IN MOUSE MODEL OF ALZHEIMER'S DISEASE

POSTER SESSION 05 - SECTION: CELLULAR ARCHITECTURE OF THE BRAIN

Alaa Alhamdi, Anam Islam, Weicong Zhang, Afia Ali
University college London, School Of Pharmacy, London, United Kingdom

Aim: We recently reported that Alzheimer's disease (AD) is associated with synaptic hyperexcitability, and is correlated with disrupted tonic inhibition, which is thought to be regulated by extra-synaptic delta-subunit containing gamma-aminobutyric acid receptor (δ-GABAAR). Therefore, this study investigated whether δ-GABAARs altered during AD pathogenesis, and whether pharmacological modulation of this receptor could "normalise" the disrupted tonic inhibition observed in AD. Method: Using the APPNL-F/NL-F knock-in mouse model of AD, age-matched to wild-type mice, we performed immunohistochemistry combined with in vitro electrophysiological whole-cell recordings in the hippocampal CA1 and dentate gyrus (DG) regions. Furthermore, neuroanatomy experiments were performed using post-mortem brain of human AD patients, age-matched to healthy controls. Results: Immunohistochemistry and confocal microscope analysis revealed a downregulation of δ-GABAARs in the presence of the classical hallmarks of AD including amyloid beta plaques and increased astrocytosis in CA1 and DG of 12- 14-months old APPNL-F/NL-F mice compared to age-matched wild-type mice. This observation was consistent in post-mortem brain tissue of AD patients compared to the age-matched controls. Furthermore, there was a cell-type specific co-localisation of the δ-subunit with interneurons containing parvalbumin, and neuropeptide Y, but not in calretinin-expressing cells. Using whole-cell recordings, positive allosteric modulation of the δ-GABAARs using a δ-subunit selective compound 2 "normalised" tonic inhibition and hyperexcitability in the AD model. Conclusions: Our data suggest that δ-GABAARs located in discreet neuronal circuitry of the hippocampus, are downregulated during AD, and modulation of this subunit using a δ-subunit selective agonist, has therapeutic potential.

FUNCTIONAL AND STRUCTURAL DIVERSITY OF PARVALBUMIN-EXPRESSING INTERNEURONS IN THE MOUSE DENTATE GYRUS

POSTER SESSION 05 - SECTION: CELLULAR ARCHITECTURE OF THE BRAIN

Maria Del Angel Ocaña Fernandez[1,2], Rita Loureiro[3], Johanna Tamm[1], Claudio Elgueta[1], Imre Vida[3], Marlene Bartos[1]

Fast spiking parvalbumin positive interneurons (PVIs) contribute largely to the unique sparse coding by granule cell (GC) ensembles of the dentate gyrus (DG). Here we provide morphological, neurochemical and electrophysiological evidence for two subtypes of DG PVIs using whole-cell patch clamp recordings of tdTomato-expressing PVIs in acute hippocampal slices. PVIs with soma location in the inner versus outer granule cell layer (PVIis, PVIos, respectively) correlate with distinct structural-functional properties. (1) Reconstructions of the somato-dendritic domain revealed a higher number of basal dendritic arbors and a larger vertical extension of apical dendrites in PVIis than PVIos, pointing to higher dendritic complexity and integration of larger numbers of inputs. (2) PVIis had a more positive resting potential, exhibited a lower spike-threshold and discharged at higher maximal frequency compared to PVIos. (3) Antibody labeling revealed more PVIis expressing mGluR5, a receptor involved in long-term plasticity (LTP) induction at their GC inputs. (4) PVIis show stronger GC-mediated LTP. (5) Paired GC-PVI recordings revealed higher connection probability at PVIis, indicating stronger feedback excitation of PVIis. Perforant path-mediated EPSCs were elicited after shorter latencies, with larger amplitude and faster decay at PVIos, indicating a stronger recruitment by feedforward excitation. Finally, PVI-GC paired recordings revealed similar functional properties of unitary IPSCs, however, failure rate and the CV of individual IPSCs were lower at PVIi-GC synapses with pronounced multiple-pulse depression. In contrast, PVIo-GC synapses lacked dynamic changes. Thus, our data suggest that PVIis provide reliable phasic feedback, whereas PVIos unreliable and fluctuating feedforward inhibition to the DG network.

Somatostatin-containing (Sst) neurons are a well-known subtype of the inhibitory interneurons in the mammalian brain. At the same time, a major part of known GABAergic long-range projections express Sst neuropeptide and are involved in the synchronization of oscillatory activity of distant brain regions. Such neurons were found in the cortex, amygdala, and hippocampus (Viollet et al., 2008; *Mol Cell Endocrinol*). In our recent work (Nagaeva et al., 2020; *eLife*) we described the Sst population in mouse VTA, showing that these neurons are very heterogeneous: there are three different electrophysiological subtypes, which express GABAergic inhibitory and/or glutamatergic excitatory markers, and some of them even dopaminergic markers. Physiologically, VTA Sst neurons acted as interneurons and inhibited neighboring dopamine cells. Here we report that the mouse VTA Sst neurons also send projections far outside the midbrain. We injected anterograde Cre-dependent viral tracer into the VTA of Sst-CRE mice and found fluorescent Sst axons in the lateral hypothalamus, the medial part of the central amygdala, bilaterally in the paraventricular thalamic nucleus, and in the lateral division of bed nucleus of stria terminalis. Next, we injected a retrograde Cre-dependent viral tracer into each of these target regions and confirmed that VTA Sst axons ended up in the above regions and were not only passing by. Our results demonstrate that Sst neurons in the VTA, as in several other brain regions, can be both interneurons and projection neurons, suggesting that the VTA Sst neurons are a part of the brain's somatostatinergic system.

NEURENSIN-2: A NOVEL CELL-TYPE-SPECIFIC MEDIATOR OF DEPRESSION

POSTER SESSION 05 - SECTION: CELLULAR ARCHITECTURE OF THE BRAIN

Gali Umschweif Nevo[1], Lucian Medrihan[2], Yotam Sagi[2], Paul Greengard[2]
[1]The Hebrew University of Jerusalem, School Of Pharmacy, Jerusalem, Israel, [2]The Rockefeller University, Cellular And Molecular Neuroscience, New York, United States of America

Major depressive disorder (MDD) is a common psychiatric condition with insufficient available therapies. While the molecular and cellular mechanisms that underlie MDD remain elusive, the hippocampal inhibitory interneurons that dictate local excitation/inhibition balance emerge as key players in MDD and its treatments. Thus, identifying the cellular and molecular pathways that drive functional alterations in these cells may pave the path to the development of improved antidepressants. In this study, we applied the Ribosome Affinity Purification (TRAP) technique in a subtype of hippocampal interneurons, the CCK cells. By this, we were able to analyze the molecular changes in these interneurons in depression. Using this approach, we discovered a new cell-type-specific mediator of depression and anxiety, Neurensin-2. This endosome-associated protein expression is markedly enhanced in the depressed state and is reduced after treatment with traditional antidepressants. Moreover, overexpression and deletion of Neurensin-2 result in depression and stress resilience, respectively. While the molecular mechanism is still unknown, we showed that Neurensin-2 is a robust mediator of the excitatory transmission in the inhibitory neurons. Therefore, we suggest that Neurensin-2 mediates behavior by modifying the function of the inhibitory tone in the hippocampus. The identification of a novel protein that dramatically and adaptively regulates inhibition in the hippocampus provides new insights into how the local E/I balance responds to stress and modulates behavior. Furthermore, these findings implicate Neurensin-2 in the pathophysiology and future treatments of neuropsychiatric disorders, including MDD and anxiety.

Axo-axonic cells (AACs) are GABAergic interneurons targeting with an exquisite specificity the axon initial segment of pyramidal neurons, where axon potentials are generated. This particularity indicates that they may provide an ultimate effect on pyramidal neuron output. Whether this effect is inhibitory or excitatory is still debated, which probably depends on the activity state of pyramidal cells and on their innervation pattern by AACs. Testing these hypothesis has long been challenging due to the absence of genetic tools allowing the selective targeting of AACs. The implementation of the Nkx2.1-CreER mouse line, in which late embryonic tamoxifen induction results in the expression of a chosen reporter in postmitotic AACs, offered a tool to unveil the functions of AACs. However the Nkx2.1Cre-ER model has not been fully characterized, and conflicting data have been reported on the selectivity of ChCs targeting. In this project, we investigated the specificity and efficiency of this novel mouse line for AAC targeting and manipulation in the prefrontal cortex (PFC). To address this question, we used immunohistochemistry and electrophysiological recordings. We found a 70% specificity for AACs in the PFC of Nkx2.1-CreER mice, along with ex-vivo firing properties reminiscent of fast spiking neurons. Our immunohistochemistry study also showed moderate efficiency of this mouse line in targeting AACs. Those results provide a stronger basis for the use of this model for studies using *in vivo* manipulation of AACs activity.

MORPHOLOGICAL AND PHYSIOLOGICAL FEATURES OF CHANDELIER CELLS IN THE PREFRONTAL CORTEX RECORDED IN TWO TRANSGENIC MOUSE LINES

POSTER SESSION 05 - SECTION: CELLULAR ARCHITECTURE OF THE BRAIN

Petra Nagy-Pál[1,2], Zsuzsanna Fekete[1,2], Judit Veres[2], Norbert Hájos[2]
[1]Semmelweis University, János Szentágothai Doctoral School Of Neurosciences, Budapest, Hungary, [2]ELRN Institute of Experimental Medicine, 'lendület' Laboratory Of Network Neurophysiology, Budapest, Hungary

Chandelier cells (ChCs) that are present only in cortical structures selectively form synapses on the axon initial segments (AISs) of principal cells (PCs) – the site of action potential generation. Thus, these GABAergic cells are in the position to control the spiking of their postsynaptic partners in the most powerful way. Here, we examined and compared anatomical and electrophysiological features of ChCs sampled in the mouse medial prefrontal cortex (mPFC) of Nkx2.1-Cre and PVeGFP lines. We performed whole-cell recordings in ChCs in acute prefrontal cortical slices that were prepared from the two different transgenic mouse lines. Using paired recordings we found no major differences in the properties of unitary inhibitory postsynaptic currents (uIPSCs) detected in postsynaptic PCs. Recordings were accompanied by intracellular biocytin filling that allowed us *post hoc* morphological analysis of the recorded ChCs. The distribution of axons and dendrites of ChCs sampled in two distinct transgenic mouse lines showed some differences between layers, indicating potentially distinct input and output features. Additionally, we examined the number and the distribution of single ChC boutons along the individual AISs. We observed that the number and the position of boutons, but not the area of innervated segments, were different for ChCs recorded in the two mouse lines. These results show that ChCs in the mPFC are morphologically distinct and show anatomical, but not electrophysiological, differences in their inhibitory connections. The variability of ChCs in prefrontal cortical microcircuits might be an important factor in control of local network operation.

Vasoactive Intestinal Polypeptide-Immunoreactive Interneurons within Circuits of the Mouse Basolateral Amygdala.
In cortical structures, principal cell activity is tightly regulated by different GABAergic interneurons (INs). Among these INs are vasoactive intestinal polypeptide-expressing (VIP+) INs, which innervate preferentially other INs, providing a structural basis for temporal disinhibition of principal cells. However, relatively little is known about VIP+ INs in the amygdaloid basolateral complex (BLA). In this study, we report that VIP+ INs have a variable density in the distinct subdivisions of the mouse BLA. Based on different anatomical, neurochemical, and electrophysiological criteria, VIP+ INs could be identified as IN-selective INs (IS-INs) and basket cells expressing CB1 cannabinoid receptors. Whole-cell recordings of VIP+ IS-INs revealed three different spiking patterns, none of which was associated with the expression of calretinin. Genetic targeting combined with optogenetics and recordings enabled us to identify several types of BLA INs innervated by VIP+ INs, including other IS-INs, basket and neurogliaform cells. Moreover, light stimulation of VIP+ basket cell axon terminals, characterized by CB1 sensitivity, evoked IPSPs in ~20% of principal neurons. Finally, we show that VIP+ INs receive a dense innervation from both GABAergic inputs (although only 10% from other VIP+ INs) and distinct glutamatergic inputs, identified by their expression of different vesicular glutamate transporters.In conclusion, our study provides a wide-range analysis of single-cell properties of VIP+ INs in the mouse BLA and of their intrinsic and extrinsic connectivity. Our results reinforce the evidence that VIP+ INs are structurally and functionally heterogeneous and that this heterogeneity could mediate different roles in amygdala-dependent functions. We provide the first comprehensive analysis of the distribution of vasoactive intestinal polypeptide-expressing (VIP+) interneurons (INs) across the entire mouse amygdaloid basolateral complex (BLA), as well as of their morphological and physiological properties. VIP+ INs in the neocortex preferentially target other INs to form a disinhibitory network that facilitates principal cell firing. Our study is the first to demonstrate the presence of such a disinhibitory circuitry in the BLA. We observed structural and functional heterogeneity of these INs and characterized their input/output connectivity. We also identified several types of BLA INs that, when inhibited, may provide a temporal window for principal cell firing and facilitate associative plasticity, e.g., in fear learning.

GABAergic interneurons are key inhibitory regulators of neocortical circuit function. Although several dozens of transcriptionally distinct types of interneurons have been identified in the adult mouse neocortex, the developmental molecular mechanisms underlying this diversity remain largely unknown. Here, focusing on neurogliaform cells (NGCs), we combine single-cell transcriptomics, genetic fate-mapping and electrophysiological assessment to show that discrete subtypes of NGCs emerge from a common progenitor domain in the embryonic preoptic area (POA). Using loss-of-function genetic approaches, we confirm that the transcription factor *Tox2* is critical for the proper development of NGCs. Together, these results reveal that NGC diversity emerges from a spatially restricted pool of progenitors and is gradually acquired post-mitotically through diverging molecular programs.

The Striatum is the main input structure of the basal ganglia system, which is implicated in motor control, emotions, and procedure learning. It is predominantly inhibitory, containing 95% spiny projections neurons and 5% interneurons, most of which are GABAergic. A recent study from Muñoz-Manchado et *al* (Cell Reports, 2018) revealed a striatal population of *Pthlh*-expressing interneurons, containing *Pvalb*-expressing cells in a gradient manner. The level of *Pvalb* expression in this population correlates with electrophysiological and morphological properties (Bengtsson et *al* 2020). It has also been described that *Pvalb*-expressing cells are responsible for strong somatic inhibition onto their target cells, making them crucial for the modulation of basal ganglia circuit output. However, it is not clear how they could influence behaviour and disease. Understanding the *Pthlh* population during development and degenerative processes is crucial to reveal its role and underlying mechanisms in a regular and altered state. With that purpose we designed the Pthlh^{cre}::R26R-tdTomato line, based on a *Pthlh* constitutive knockin mouse crossed with a Rosa26-tdTomato strain, leading to fluorescence labelled *Pthlh* neurons, that will allow us to thoroughly characterize this population. Therefore, we will conduct molecular and histological profiling including connectivity and distribution analysis. Next, we will compare our findings to the situation in *Pthlh* neurons from the 6-hydroxydopamine hemiparkinsonian mouse model, to identify disease-related differences. This study will allow us to have a more complete and deeper understanding of the molecular changes, *Pthlh* cell localization and their contribution in the regulation of the basal ganglia circuits and neurodegenerative disorders.

Phorbol Diesters and 12-Deoxy-16-hydroxyphorbol 13,16-Diesters Induce TGFα Release and Adult Mouse Neurogenesis.
A small library of phorbol 12,13-diesters bearing low lipophilicity ester chains was prepared as potential neurogenic agents in the adult brain. They were also used in a targeted UHPLC-HRMS screening of the latex of . Two new 12-deoxy-16-hydroxyphorbol 13,16-diesters were isolated, and their structures were deduced using two-dimensional NMR spectroscopy and NOE experiments. The ability of natural and synthetic compounds to stimulate transforming growth factor alpha (TFGα) release, to increase neural progenitor cell proliferation, and to stimulate neurogenesis was evaluated. All compounds that facilitated TGFα release promoted neural progenitor cell proliferation. The presence of two acyloxy moieties on the tigliane skeleton led to higher levels of activity, which decreased when a free hydroxyl group was at C-12. Remarkably, the compound bearing isobutyryloxy groups was the most potent on the TGFα assay and at inducing neural progenitor cell proliferation , also leading to enhanced neurogenesis when administered intranasally to mice.

Protein Kinase C Inhibition Mediates Neuroblast Enrichment in Mechanical Brain Injuries.
Brain injuries of different etiologies lead to irreversible neuronal loss and persisting neuronal deficits. New therapeutic strategies are emerging to compensate neuronal damage upon brain injury. Some of these strategies focus on enhancing endogenous generation of neurons from neural stem cells (NSCs) to substitute the dying neurons. However, the capacity of the injured brain to produce new neurons is limited, especially in cases of extensive injury. This reduced neurogenesis is a consequence of the effect of signaling molecules released in response to inflammation, which act on intracellular pathways, favoring gliogenesis and preventing recruitment of neuroblasts from neurogenic regions. Protein kinase C (PKC) is a family of intracellular kinases involved in several of these gliogenic signaling pathways. The aim of this study was to analyze the role of

PKC isozymes in the generation of neurons from neural progenitor cells (NPCs) and in brain injuries. PKC inhibition , in cultures of NPC isolated from the subventricular zone (SVZ) of postnatal mice, leads differentiation towards a neuronal fate. This effect is not mediated by classical or atypical PKC. On the contrary, this effect is mediated by novel PKCε, which is abundantly expressed in NPC cultures under differentiation conditions. PKCε inhibition by siRNA promotes neuronal differentiation and reduces glial cell differentiation. On the contrary, inhibition of PKCθ exerts a small anti-gliogenic effect and reverts the effect of PKCε inhibition on neuronal differentiation when both siRNAs are used in combination. Interestingly, in cortical brain injuries we have found expression of almost all PKC isozymes found . Inhibition of PKC activity in this type of injuries leads to neuronal production. In conclusion, these findings show an effect of PKCε in the generation of neurons from NPC , and they highlight the role of PKC isozymes as targets to produce neurons in brain lesions.

MORPHOLOGICAL AND FUNCTIONAL CHARACTERISTICS OF DENTATE GYRUS NDNF-EXPRESSING INTERNEURONS

POSTER SESSION 05 - SECTION: CELLULAR ARCHITECTURE OF THE BRAIN

Federico Torelli[1,2], Claudio Elgueta[1], Marlene Bartos[1]
[1]Albert-Ludwigs-University Freiburg, Medical Faculty, Institute Of Physiology I, Freiburg, Germany, [2]Albert-Ludwigs-University of Freiburg, Faculty Of Biology, Freiburg, Germany

The Dentate Gyrus (DG) receives rich multimodal inputs from the entorhinal cortex and translates them into a sparse code for CA3. During the exploration of new environments, groups of coactive DG principal cells (granule cells) emerge, representing the architectural elements of new memories. The activity of granule cells is strongly modulated by a large and heterogeneous inhibitory network. Besides regulating the granule cells assembly dynamics, DG GABAergic interneurons (INs) are also involved in the generation of hippocampal oscillations and pattern separation. However, a clear understanding of how different INs types participate in these mechanisms is still missing. Recently, a novel population of GABAergic INs expressing the neuron-derived neutrophic factor (NDNFIs) has been identified as a key component of cortical network computations. We found that NDNFIs are also present in the DG where they provide dendritic inhibition to granule cells. We investigated their distribution, morphology, electrical properties, and functional connectivity. Based on morphological reconstructions, we distinguished 2 subpopulations of NDNFIs: the neurogliaform-like (NG-L) cells located in the medial and outer molecular layer, and a second class of NDNFIs located between the granular cell layer and the hilus. Despite the morphological differences and the distinct firing pattern properties, they express the same molecular markers, including Reelin and NPY. In accordance with their dendrites distribution, NDNFIs receive synaptic inputs prevalently from the perforant path or the hilus, depending on their soma-location. Combining in-vitro and in-vivo approaches, we provide the first characterization of NDNF-expressing GABAergic interneurons in the DG.

FUNCTIONAL ANALYSIS OF CHOLINERGIC NEUROMODULATION OF CHANDELIER CELLS FROM SINGLE-CELL TO CIRCUIT

POSTER SESSION 05 - SECTION: CELLULAR ARCHITECTURE OF THE BRAIN

Emilio Martínez-Márquez, Santiago Reyes-León, Guadalupe Asensio-Gómez, José Luis Nieto-González, Pablo García-Junco-Clemente
Instituto de Biomedicina de Sevilla (IBiS/HUVR/CSIC/Universidad de Sevilla), Departamento De Fisiología Médica Y Biofísica / Ciberned, Sevilla, Spain

Chandelier cells (ChCs) are GABAergic cortical interneurons that innervate the axon initial segment of pyramidal neurons, controlling the cell firing output. They are abundant in the association cortical areas, where acetylcholine inputs are essential for normal cognitive performance. Located at the layer1/layer2 boundary, they extend their dendrites towards layer1, suggesting that may receive inputs from other cortical areas and deep nuclei, such as basal forebrain, which projects the strongest cholinergic innervation to layer1, implying a plausible role for ChCs as circuit switches. Our interest lies in studying the role of ChCs in the control of cortical networks, with a special focus on its presumable cholinergic modulation. We have identified cortical ChCs using a mouse model expressing td-Tomato under control of precise Cre- and Flp- dependent promoters. Using immunohistochemical and electrophysiological techniques, we have described the existence of cholinergic neuromodulation of ChCs through specific nicotinic receptors. To clarify its role in the regulation of the prefrontal cortical circuitry, we performed *in vivo* 2-photon imaging experiments in awake animals using GECIs, showing that ChCs present a collective behaviour during arousal. We used DREADDs to modulate their activity to uncover its influence in the control of the excitatory network. Our results demonstrate that prefrontal ChCs are a subpopulation of fast-spiking interneurons modulated by cholinergic inputs activated during arousal states in awake mice, with a prominent role in the control of the pyramidal neurons. We are grateful to C. Cabrera-Romero for excellent technical assistance. Supported by: RyC-2016-19906, PRE2019-087729 (MCI/AEI/FSE,UE), VI PPIT-US and PGC2018-095656-B-I00 (MCI/AEI/FEDER,UE).

Computation within cortical microcircuits is based on functional properties of neurons and their synaptic connections. Heterogeneity of these basic building blocks is suggested to be computationally relevant. While diversity of cortical inhibitory interneurons has been studied extensively, the anatomical, physiological, and molecular differentiation of excitatory neurons is less understood. To address functional heterogeneity of excitatory neurons and their synaptic connections, we focused on human layer 2-3 cortex, which expanded remarkably during evolution. We conducted multi-neuron patch-clamp recordings in brain slices from temporal cortex of 22 patients with pharmacoresistant epilepsy. We recorded up to 80 neurons per patient and characterized the electrophysiological properties of more than 1.000 excitatory neurons. Hierarchical clustering of intrinsic electrophysiological properties yielded functionally distinct excitatory neuron clusters, which were present across individuals. Additionally, we probed more than 9.000 and found over 1.300 monosynaptic connections. We observed that excitatory neurons display non-uniform connectivity patterns and differences in synaptic properties depending on cluster identity. Overall, there is a large diversity in intrinsic electrophysiological and synaptic properties with intra-individual variability being severalfold greater than inter-individual variability. We argue that heterogeneity of excitatory neurons and synapses is a common principle present in all individuals. We conclude that the diversity of cell properties and linked differences in synaptic connectivity point towards excitatory neuron specialization within the temporal cortical microcircuit of the human brain.

Of Veterinary Sciences, Neuroscience Institute Cavalieri Ottolenghi, Orbassano (Turin), Italy, [4]University of Michigan, Department Of Human Genetics, Ann Harbor, United States of America

In the developing mouse forebrain, temporally distinct waves of oligodendrocyte progenitor cells (OPCs) arise from different germinal zones and eventually populate either dorsal or ventral regions, where they present as transcriptionally and functionally equivalent cells. Despite that, developmental heterogeneity influences adult OPC responses upon demyelination. Here we show that accumulation of DNA damage due to ablation of citron-kinase or cisplatin treatment cell-autonomously disrupts OPC fate, resulting in cell death and senescence in the dorsal and ventral subsets, respectively. Such alternative fates are associated with distinct developmental origins of OPCs, and with a different activation of NRF2-mediated anti-oxidant responses. These data indicate that, upon injury, dorsal and ventral OPC subsets show functional and molecular diversity that can make them differentially vulnerable to pathological conditions associated with DNA damage.

TRACING GLIA-INTO-NEURON CONVERSION IN THE AGED MOUSE BRAIN USING SINGLE CELL SPATIAL TRANSCRIPTOMICS

POSTER SESSION 05 - SECTION: CELLULAR ARCHITECTURE OF THE BRAIN

Roy Maimon, Carlos Chilion Marinas, Don Cleveland
University of California at San Diego, Cellular And Molecular, La Jolla, United States of America

Reports of methods to reprogram glial cells into neurons have open the door to producing new neurons in the adult mammalian brain, including for the replacment of neurons lost in neurodegenerative diseases. Not yet established are the molecular events underlying glia to neuron identity conversion, including identification of the initiating glial cell, the events driving its conversion and subsequent maturation into functional neuron, and the final neuronal subtype produced. We recently demostrated a therapeutically viable approach to generate neurons in the dentate gyrus of aged adult mouse brain by transiently suppressing the RNA binding protein Polypyrimidine Tract Binding Protein-1 using antisense oligonucleotide (ASO) delivered by single injection into the cerebral spinal fluid (CSF). Radial glial-like cells convert into new neurons over a two-month period, aquire mature neuronal character, and functionally integrate into endogenous circuits that modify mouse behavior, thereby opening peospects for production of neurons tto replace those lost during disease or aging. We now utilize a transformative single cell spatial transcriptomics thechnology,
termed Multiplexed Error Robust Fluoresence In Situ Hybridization (MERFISH), to systematically identify the funcionality, localization and specification of the cell origin(s), lineage pathway(s) and newly generated neuron(s) in glia-into-neuron cell conversion. These approaches uncover new mechanistic insights in cell reprograming and might lead to new concept for treating neurodegeneration.

DLX5/6 LEVELS IN MOUSE GABAERGIC NEURONS AFFECT ADULT PARVALBUMIN-POSITIVE NEURONAL DENSITY AND CONTROL ANXIETY/COMPULSIVE BEHAVIOURS.

POSTER SESSION 05 - SECTION: CELLULAR ARCHITECTURE OF THE BRAIN

Rym Aouci, Giovanni Levi, Nicolas Narboux-Nême
CNRS/MNHN, Aviv, Paris, France

Introduction: *Dlx5/6* genes encode for two homeobox transcription factors which, during development, are involved in differentiation of Parvalbumin-positive GABAergic inhibitory interneurons (PV). In the adult, these genes continue to be expressed in most forebrain GABAergic neurons where their role is only partially elucidated. PV interneurons are essential for normal brain function and their activity and distribution is altered in psychiatric conditions such as schizophrenia. Brains from autistic and schizophrenic patients and from mouse models of these diseases present regional defects in PV interneurons. Furthermore, large epidemiological studies suggest a link of the *Dlx5/6* locus with schizophrenia, autism spectrum disorder and Rett syndrome. **Results:** Here we evaluate the neuroanatomical and behavioural consequences of targeted *Dlx5/6* gene dosage alterations in adult mouse GABAergic neurons. We compare the effects of homozygous and heterozygous *Dlx5/6* deletions to those of *Dlx5* targeted overexpression. We find a linear correlation between *Dlx5/6* allelic dosage and the density of PV-positive neurons in the adult prelimbic cortex and in the hippocampus.In parallel, we observe that *Dlx5/6* expression levels in GABAergic neurons are also linearly associated with the intensity of anxiety and compulsivity-like behaviours. Higher levels of *Dlx5/6* expression in GABAergic neurons are associated with increased anxiety and compulsivity while deletion of *Dlx5/6* results in reduced anxiety and compulsivity with hyper-vocalization and socialization phenotype. **Conclusion:** Our findings reinforce the notion that regulation of *Dlx5/6* expression is involved in individual cognitive variability and, possibly, in the genesis of certain neuropsychiatric conditions.

GENETIC ARCHITECTURE OF THE WHITE MATTER CONNECTOME OF THE HUMAN BRAIN

POSTER SESSION 05 - SECTION: CELLULAR ARCHITECTURE OF THE BRAIN

Zhiqiang Sha[1], Dick Schijven[1], Simon Fisher[2], Clyde Francks[3]
[1]Max Planck Institute for Psycholinguistics, Department Of Language & Genetics, Nijmegen, Netherlands, [2]Max Planck & Donders Institutes, Department Of Language & Genetics, Nijmegen, Netherlands, [3]Max Planck Institute & Donders Institute & Radboud University Medical Center, Imaging Genomics Research Group, Nijmegen, Netherlands

White matter tracts form the structural basis of large-scale functional networks in the human brain. We applied brain-wide tractography to diffusion images from 30,810 adult participants (UK Biobank), and found significant heritability for 90 regional connectivity measures and 851 tract-wise connectivity measures. Multivariate genome-wide association analyses identified 355 independently associated lead SNPs across the genome, of which 77% had not been previously associated with human brain metrics. Enrichment analyses implicated neurodevelopmental processes including neurogenesis, neural differentiation, neural migration, neural projection guidance, and axon development, as well as prenatal brain expression especially in stem cells, astrocytes, microglia and neurons. We used the multivariate association profiles of lead SNPs to identify 26 genomic loci implicated in structural connectivity between core regions of the left-hemisphere language network, and also identified 6 loci associated with hemispheric left-right asymmetry of structural connectivity. Polygenic scores for schizophrenia, bipolar disorder, autism spectrum disorder, attention-deficit hyperactivity disorder, left-handedness, Alzheimer's disease, amyotrophic lateral sclerosis, and epilepsy showed significant multivariate associations with structural connectivity, each implicating distinct sets of brain regions with trait-relevant functional profiles. This large-scale mapping study revealed common genetic contributions to the structural connectome of the human brain in the general adult population, highlighting links with polygenic disposition to brain disorders and behavioural traits.

A NOVEL LAYER4 CORTICOFUGAL CELL TYPE/PROJECTION INVOLVED IN THALAMO-CORTICO-STRIATAL SENSORY PROCESSING

POSTER SESSION 05 - SECTION: CELLULAR ARCHITECTURE OF THE BRAIN

Alice Bertero, Alfonso Junior Apicella
University of Texas at San Antonio, Neuroscience, Developmental And Regenerative Biology, San Antonio, United States of America

In sensory cortices, the information flow has been thought to be processed vertically across cortical layers, with layer 4 being the major thalamo-recipient one which relays thalamic signals to layer 2/3, which in turn transmit thalamic information to layer 5 and 6 to then leave the cortex to reach subcortical and cortical long-range structures. Although several exceptions to this model have been described, neurons in layer 4 are still considered to establish only local (i.e., interlaminar and short-range) connections. Here, taking advantage of anatomical, electrophysiological, optogenetic techniques, we describe for the first time a long-range corticostriatal class of pyramidal neurons in layer 4 (CS-L4) of the mouse auditory cortex that receive direct thalamic inputs. The CS-L4 neurons are embedded in a feedforward inhibitory circuit involving local parvalbumin neurons and establish connections in the posterior striatum in yet another feedforward inhibitory **thalamo→cortico(L4)→striatal circuit** to potentially contribute to control the output of striatal spiny projection neurons.Here we propose a new wiring diagram that implemented the old one, in which layer 4 is not only involved in the transfer of thalamic input to the upper layer 2/3 but can exert a direct top-down control, bypassing intracortical processing, of subcortical structure such as the posterior part of the dorsal striatum posing a new conceptual cell element (CS-L4 neurons) for experimental and theoretical work of the cortical function.

BRIEF SYNAPTIC INHIBITION PERSISTENTLY INTERRUPTS FIRING OF FAST-SPIKING INTERNEURONS

POSTER SESSION 05 - SECTION: INTERNEURONS AND DENDRITES

Simon Chamberland, Monica Hanani, Robert Egger, Erica Nebet, Samantha Larsen, Katherine Eyring, Richard Tsien
New York University School of Medicine, Neuroscience Institute, New York City, United States of America

Input-output operations performed by neurons rely on their ability to integrate synaptic activity with their intrinsic electrical properties, a process thought to be constrained by the duration of synaptic events. At variance with this classical view, we find that the sustained firing of CA1 hippocampal fast-spiking (FS) parvalbumin-expressing interneurons (PV-INs) is persistently interrupted for several hundred milliseconds following brief GABAAR-mediated inhibition. A single presynaptic neuron could interrupt PV-INs, occasionally with a single action potential (AP), and reliably with brief bursts of APs. Experiments and a computational model revealed that the persistent interruption of firing maintains neurons in a depolarized, quiescent state through a cell-autonomous mechanism dependent on an inactivating Kv1.1-mediated current and largely inactivated Na+ channels. Strikingly, interrupted PV-INs are highly responsive to Schaffer collateral inputs, with subthreshold stimuli at rest becoming suprathreshold during the interruption. We show that the persistent interruption of firing represents a powerful disinhibitory mechanism that favors spike generation in CA1 pyramidal cells. Overall, our results demonstrate that neuronal silencing can far outlast brief synaptic inhibition owing to a well-tuned interplay between neurotransmitter release and postsynaptic membrane dynamics, thus impacting circuit function.

Slow-decaying presynaptic calcium dynamics gate long-lasting asynchronous release at the hippocampal mossy fiber to CA3 pyramidal cell synapse.
Action potentials trigger two modes of neurotransmitter release, with a fast synchronous component and a temporally delayed asynchronous release. Asynchronous release contributes to information transfer at synapses, including at the hippocampal mossy fiber (MF) to CA3 pyramidal cell synapse where it controls the timing of postsynaptic CA3 pyramidal neuron firing. Here, we identified and characterized the main determinants of asynchronous release at the MF-CA3 synapse. We found that asynchronous release at MF-CA3 synapses can last on the order of seconds following repetitive MF stimulation. Elevating the stimulation frequency or the external Ca concentration increased the rate of asynchronous release, thus, arguing that presynaptic Ca dynamics is the major determinant of asynchronous release rate. Direct MF bouton Ca imaging revealed slow Ca decay kinetics of action potential (AP) burst-evoked Ca transients. Finally, we observed that asynchronous release was preferentially mediated by Ca influx through P/Q-type voltage-gated Ca channels, while the contribution of N-type VGCCs was limited. Overall, our results uncover the determinants of long-lasting asynchronous release from MF terminals and suggest that asynchronous release could influence CA3 pyramidal cell firing up to seconds following termination of granule cell bursting.

Calcium extrusion mechanisms in dendrites of mouse hippocampal CA1 inhibitory interneurons.
Local circuit GABAergic inhibitory interneurons control the integration and transfer of information in many brain regions. Several different forms of plasticity reported at interneuron excitatory synapses are triggered by cell- and synapse-specific postsynaptic calcium (Ca) mechanisms. To support this function, the spatiotemporal dynamics of dendritic Ca elevations must be tightly regulated. While the dynamics of postsynaptic Ca signaling through activation of different Ca sources has been explored, the Ca extrusion mechanisms that operate in interneuron dendrites during different patterns of activity remain largely unknown. Using a combination of whole-cell patch-clamp recordings and two-photon Ca imaging in acute mouse hippocampal slices, we characterized the Ca extrusion mechanisms activated by Ca transients (CaTs) associated with backpropagating action potentials (bAPs) in dendrites of hippocampal CA1 stratum radiatum interneurons. Our data showed that Ca clearance increased as a function of activity, pointing to an activity-dependent recruitment of specific Ca extrusion mechanisms. bAP-CaTs were significantly prolonged in the presence of the plasma membrane Ca ATPase (PMCA) and Na/Ca exchanger (NCX) inhibitors as well as the sarco/endoplasmic reticulum Ca ATPase (SERCA) and the mitochondria Ca

uniporter (MCU) blockers. While PMCA, NCX and SERCA pumps cooperated in the cytosolic Ca removal at a wide range of concentrations, the MCU was only activated at higher Ca loads produced by repetitive interneuron firing. These results identify a division of labor between distinct Ca extrusion mechanisms shaping dendritic Ca dynamics and possibly contributing to activity-dependent regulation of synaptic inputs in interneurons. In addition, the MCU activated by larger Ca levels may be involved in the activity-dependent ATP production or interneuron-selective vulnerability associated with cytosolic Ca overloads under pathological conditions.

Action potential counting at giant mossy fiber terminals gates information transfer in the hippocampus.
Neuronal communication relies on action potential discharge, with the frequency and the temporal precision of action potentials encoding information. Hippocampal mossy fibers have long been recognized as conditional detonators owing to prominent short-term facilitation of glutamate release displayed during granule cell burst firing. However, the spiking patterns required to trigger action potential firing in CA3 pyramidal neurons remain poorly understood. Here, we show that glutamate release from mossy fiber terminals triggers action potential firing of the target CA3 pyramidal neurons independently of the average granule cell burst frequency, a phenomenon we term action potential counting. We find that action potential counting in mossy fibers gates glutamate release over a broad physiological range of frequencies and action potential numbers. Using rapid Ca imaging we also show that the magnitude of evoked Ca influx stays constant during action potential trains and that accumulated residual Ca is gradually extruded on a time scale of several hundred milliseconds. Using experimentally constrained 3D model of presynaptic Ca influx, buffering, and diffusion, and a Monte Carlo model of Ca-activated vesicle fusion, we argue that action potential counting at mossy fiber boutons can be explained by a unique interplay between Ca dynamics and buffering at release sites. This is largely determined by the differential contribution of major endogenous Ca buffers calbindin-D and calmodulin and by the loose coupling between presynaptic voltage-gated Ca channels and release sensors and the relatively slow Ca extrusion rate. Taken together, our results identify a previously unexplored information-coding mechanism in the brain.

Sex-Specific Consequences of Neonatal Stress on Cardio-Respiratory Inhibition Following Laryngeal Stimulation in Rat Pups.
The presence of liquid near the larynx of immature mammals triggers prolonged apneas with significant O desaturations and bradycardias. When excessive, this reflex (the laryngeal chemoreflex; LCR) can be fatal. Our understanding of the origins of abnormal LCR are limited; however, perinatal stress and male sex are risk factors for cardio-respiratory failure in infants. Because exposure to stress during early life has deleterious and sex-specific consequences on brain development it is plausible that respiratory reflexes are vulnerable to neuroendocrine dysfunction. To address this issue, we tested the hypothesis that neonatal maternal separation (NMS) is sufficient to exacerbate LCR-induced cardio-respiratory inhibition in anesthetized rat pups. Stressed pups were separated from their mother 3 h/d from postnatal days 3 to 12. At P14-P15, pups were instrumented to monitor breathing, O saturation (So), and heart rate. The LCR was activated by water injections near the larynx (10 µl). LCR-induced apneas were longer in stressed pups than controls; O desaturations and bradycardias were more profound, especially in males. NMS increased the frequency and amplitude of spontaneous EPSCs (sEPSCs) in the dorsal motor nucleus of the vagus (DMNV) of males but not females. The positive relationship between corticosterone and testosterone observed in stressed pups (males only) suggests that disruption of neuroendocrine function by stress is key to sex-based differences in abnormal LCR. Because testosterone application onto medullary slices augments EPSC amplitude only in males, we propose that testosterone-mediated enhancement of synaptic connectivity within the DMNV contributes to the male bias in cardio-respiratory inhibition following LCR activation in stressed pups.

Fast two-photon imaging of subcellular voltage dynamics in neuronal tissue with genetically encoded indicators.
Monitoring voltage dynamics in defined neurons deep in the brain is critical for unraveling the function of neuronal circuits but is challenging due to the limited performance of existing tools. In particular, while genetically encoded voltage indicators have shown promise for optical detection of voltage transients, many indicators exhibit low sensitivity when imaged under two-photon illumination. Previous studies thus fell short of visualizing voltage dynamics in individual neurons in single trials. Here, we report ASAP2s, a novel voltage indicator with improved sensitivity. By imaging ASAP2s using random-access multi-photon microscopy, we demonstrate robust single-trial detection of action potentials in organotypic slice cultures. We also show that ASAP2s enables two-photon imaging of graded potentials in organotypic slice cultures and in . These results demonstrate that the combination of ASAP2s and fast two-photon imaging methods enables detection of neural electrical activity with subcellular spatial resolution and millisecond-timescale precision.

Short-Term Facilitation at a Detonator Synapse Requires the Distinct Contribution of Multiple Types of Voltage-Gated Calcium Channels.
Neuronal calcium elevations are shaped by several key parameters, including the properties, density, and the spatial location of voltage-gated calcium channels (VGCCs). These features allow presynaptic terminals to translate complex firing frequencies and tune the amount of neurotransmitter released. Although synchronous neurotransmitter release relies on both P/Q- and N-type VGCCs at hippocampal mossy fiber-CA3 synapses, the specific contribution of VGCCs to calcium dynamics, neurotransmitter release, and short-term facilitation remains unknown. Here, we used random-access two-photon calcium imaging together with electrophysiology in acute mouse hippocampal slices to dissect the roles of P/Q- and N-type VGCCs. Our results show that N-type VGCCs control glutamate release at a limited number of release sites through highly localized Ca elevations and support short-term facilitation by enhancing multivesicular release. In contrast, Ca entry via P/Q-type VGCCs promotes the recruitment of additional release sites through spatially homogeneous Ca elevations. Altogether, our results highlight the specialized contribution of P/Q- and N-types VGCCs to neurotransmitter release. In presynaptic terminals, neurotransmitter release is dynamically regulated by the transient opening of different types of voltage-gated calcium channels. Hippocampal giant mossy fiber terminals display extensive short-term facilitation during repetitive activity, with a large several fold postsynaptic response increase. Though, how giant mossy fiber terminals leverage distinct types of voltage-gated calcium channels to mediate short-term facilitation remains unexplored. Here, we find that P/Q- and N-type VGCCs generate different spatial patterns of calcium elevations in giant mossy fiber terminals and support short-term facilitation through specific participation in two mechanisms. Whereas N-type VGCCs contribute only to the synchronization of multivesicular release, P/Q-type VGCCs act through microdomain signaling to recruit additional release sites.

Functionally heterogeneous synaptic vesicle pools support diverse synaptic signalling.
Synaptic communication between neurons is a highly dynamic process involving specialized structures. At the level of the presynaptic terminal, neurotransmission is ensured by fusion of vesicles to the membrane, which releases neurotransmitter in the synaptic cleft. Depending on the level of activity experienced by the terminal, the spatiotemporal properties of calcium invasion will dictate the timing and the number of vesicles that need to be released. Diverse presynaptic firing patterns are translated to neurotransmitter release with a distinct temporal feature. Complex patterns of neurotransmitter release can be achieved when different vesicles respond to distinct calcium dynamics in the presynaptic terminal. Specific vesicles from different pools are recruited during various modes of release as the particular molecular composition of their membrane proteins define their functional properties. Such diversity endows the presynaptic terminal with the ability to respond to distinct physiological signals via the mobilization of specific subpopulation of vesicles. There are several mechanisms by which a diverse vesicle population could be generated in single presynaptic terminals, including distinct recycling pathways that utilize various adaptor proteins. Several additional factors could potentially contribute to the development of a heterogeneous vesicle pool such as specialized release sites, spatial segregation within the terminal and specialized delivery pathways. Among these factors molecular heterogeneity plays a central role in defining the functional properties of different subpopulations of vesicles.

Interplay between synchronization of multivesicular release and recruitment of additional release sites support short-term facilitation at hippocampal mossy fiber to CA3 pyramidal cells synapses.
Synaptic short-term plasticity is a key regulator of neuronal communication and is controlled via various mechanisms. A well established property of mossy fiber to CA3 pyramidal cell synapses is the extensive short-term facilitation during high-frequency bursts. We investigated the mechanisms governing facilitation using a combination of whole-cell electrophysiological recordings, electrical minimal stimulation, and random-access two-photon microscopy in acute mouse hippocampal slices. Two distinct presynaptic mechanisms were involved in short-term facilitation, with their relative contribution dependent on extracellular calcium concentration. The synchronization of multivesicular release was observed during trains of facilitating EPSCs recorded in 1.2 mM external Ca(2+) ([Ca(2+)]e). Indeed, covariance analysis revealed a gradual augmentation in quantal size during trains of EPSCs, and application of the low-affinity glutamate receptor antagonist γ-D-glutamylglycine showed an increase in cleft glutamate concentration during paired-pulse stimulation. Whereas synchronization of multivesicular release contributed to the facilitation in 1.2 mM [Ca(2+)]e, variance-mean analysis showed that recruitment of more release sites (N) was likely to account for the larger facilitation observed in 2.5 mM [Ca(2+)]e. Furthermore, this increase in N could be promoted by calcium microdomains of heterogeneous amplitudes observed in single mossy fiber boutons. Our findings suggest that the combination of multivesicular release and the recruitment of additional

release sites act together to increase glutamate release during burst activity. This is supported by the compartmentalized spatial profile of calcium elevations in boutons and helps to expand the dynamic range of mossy fibers information transfer.

Dendritic inhibition provided by interneuron-specific cells controls the firing rate and timing of the hippocampal feedback inhibitory circuitry.
In cortical networks, different types of inhibitory interneurons control the activity of glutamatergic principal cells and GABAergic interneurons. Principal neurons represent the major postsynaptic target of most interneurons; however, a population of interneurons that is dedicated to the selective innervation of GABAergic cells exists in the CA1 area of the hippocampus. The physiological properties of these cells and their functional relevance for network computations remain unknown. Here, we used a combination of dual simultaneous patch-clamp recordings and targeted optogenetic stimulation in acute mouse hippocampal slices to examine how one class of interneuron-specific (IS) cells controls the activity of its GABAergic targets. We found that type 3 IS (IS3) cells that coexpress the vasoactive intestinal polypeptide (VIP) and calretinin contact several distinct types of interneurons within the hippocampal CA1 stratum oriens/alveus (O/A), with preferential innervation of oriens-lacunosum moleculare cells (OLMs) through dendritic synapses. In contrast, VIP-positive basket cells provided perisomatic inhibition to CA1 pyramidal neurons with the asynchronous GABA release and were not connected with O/A interneurons. Furthermore, unitary IPSCs recorded at IS3-OLM synapses had a small amplitude and low release probability but summated efficiently during high-frequency firing of IS3 interneurons. Moreover, the synchronous generation of a single spike in several IS cells that converged onto a single OLM controlled the firing rate and timing of OLM interneurons. Therefore, dendritic inhibition originating from IS cells is needed for the flexible activity-dependent recruitment of OLM interneurons for feedback inhibition.

Inhibitory control of hippocampal inhibitory neurons.
Information processing within neuronal networks is determined by a dynamic partnership between principal neurons and local circuit inhibitory interneurons. The population of GABAergic interneurons is extremely heterogeneous and comprises, in many brain regions, cells with divergent morphological and physiological properties, distinct molecular expression profiles, and highly specialized functions. GABAergic interneurons have been studied extensively during the past two decades, especially in the hippocampus, which is a relatively simple cortical structure. Different types of hippocampal inhibitory interneurons control spike initiation [e.g., axo-axonic and basket cells (BCs)] and synaptic integration (e.g., bistratified and oriens-lacunosum moleculare interneurons) within pyramidal neurons and synchronize local network activity, providing a means for functional segregation of neuronal ensembles and proper routing of hippocampal information. Thus, it is thought that, at least in the hippocampus, GABAergic inhibitory interneurons represent critical regulating elements at all stages of information processing, from synaptic integration and spike generation to large-scale network activity. However, this raises an important question: if inhibitory interneurons are fundamental for network computations, what are the mechanisms that control the activity of the interneurons themselves? Given the essential role of synaptic inhibition in the regulation of neuronal activity, it would be logical to expect that specific inhibitory mechanisms have evolved to control the operation of interneurons. Here, we review the mechanisms of synaptic inhibition of interneurons and discuss their role in the operation of hippocampal inhibitory circuits.

DENDRITIC AXON ORIGIN ENABLES SELECTIVE INFORMATION GATING BY PERISOMATIC INHIBITION IN PYRAMIDAL NEURONS

POSTER SESSION 05 - SECTION: INTERNEURONS AND DENDRITES

Alexander Hodapp[1], Martin Kaiser[1], Lingjun Ding[2], Christian Thome[1], Andrei Rozov[1], Nikolas Stevens[1], Matthias Klumpp[1], Nadja Lehmann[3], Andreas Draguhn[1], Andrea Burgalossi[2], Maren Engelhardt[4], Martin Both[1]

Information processing in cortical pyramidal neurons involves the specific activation into functional ensembles. In this process, only a minority of neurons is recruited while the majority remains silent. This sparse activation is believed to result from widespread perisomatic inhibition in conjunction with specific synaptic excitation. We have previously shown that in ~50% of hippocampal pyramidal cells the axon emerges from a basal dendrite. Here, we propose that this particular morphology provides a mechanism for selective activation of participating neurons through these morphologically unique axo-dendritic compartments. In awake, head-fixed mice, we found that CA1 pyramidal neurons with a dendritic axon origin displayed a ~4-fold higher firing frequency during network activation compared to neurons with somatic axon origin. This difference was absent outside ripples. Extra- and intracellular recordings in mouse brain slices and computer simulations led us to hypothesize that the axon is forming a functional unit together with the axon-carrying dendrite. We show that excitatory input to axon-carrying dendrites remains efficient even during strong perisomatic inhibition. Other dendrites become uncoupled from this compartment, preventing their input to trigger action potentials. This may likewise apply to all neurons with somatic axon origin. Therefore, cells with axon-carrying dendrites may be privileged members of neuronal ensembles during states of strong perisomatic inhibition, such as fast network oscillations. By this mechanism, activation of inhibitory interneurons and targeted excitation of the respective dendrite may dynamically change the functional network topology, resulting in the activation of defined neuronal ensembles.

HYPERPOLARIZATION-ACTIVATED CYCLIC NUCLEOTIDE-GATED CHANNELS REGULATE RESPONSE PROBABILITY IN THE TERMINALS OF PARVALBUMIN POSITIVE BASKET CELLS

POSTER SESSION 05 - SECTION: INTERNEURONS AND DENDRITES

Tobias Bock, Eric Buss, Olivia Lofaro, Bina Santoro, Steven Siegelbaum
Columbia University, Department Of Neuroscience, New York, United States of America

Hyperpolarization-activated, cyclic nucleotide-gated (HCN) channels generate the cationic current I_h, which has been found to regulate the excitability of neuronal networks. The function of HCN channels depends, in part, on their subcellular localization. HCN channels are abundantly expressed in the dendrites of pyramidal neurons in hippocampal area CA1 where they act as an inhibitory constraint on dendritic integration and synaptic plasticity. HCN1 is also strongly expressed in presynaptic terminals of parvalbumin-positive inhibitory neuron basket cells (PVBCs). We found that application of HCN channel blockers strongly inhibit IPSCs in CA1 pyramidal neurons evoked by electrical stimulation or PVBC-specific optogenetic stimulation. To investigate the impact of HCN channels in presynaptic terminals, we performed 2-photon imaging in acute brain slices, expressing GCaMP6s specifically in the terminals of CA1 PVBCs. Bath application of the HCN blocker ZD7288 reduced the amplitude of dF/F transients in PVBC terminals elicited by a 5-pulse train of electrical stimulation (30 Hz) delivered to stratum pyramidale. When examining responses to single electrical stimuli, we found that the response of individual terminals to single stimuli was probabilistic; some stimuli elicited a measurable response and some stimuli failed to elicit a response. ZD7288 did not reduce the amplitude of the successful responses to single electrical stimuli, but rather decreased the probability with which single stimuli evoked a successful response. Thus we conclude that HCN channels in the axonal terminals of PVBCs upregulate the probability of terminal activation (and thus vesicle release) rather than the amplitude of the Ca^{2+} response to such activation.

Dendritic encoding of sensory stimuli controlled by deep cortical interneurons.
The computational power of single neurons is greatly enhanced by active dendritic conductances that have a large influence on their spike activity. In cortical output neurons such as the large pyramidal cells of layer 5 (L5), activation of apical dendritic calcium channels leads to plateau potentials that increase the gain of the input/output function and switch the cell to burst-firing mode. The apical dendrites are innervated by local excitatory and inhibitory inputs as well as thalamic and corticocortical projections, which makes it a formidable task to predict how these inputs influence active dendritic properties in vivo. Here we investigate activity in populations of L5 pyramidal dendrites of the somatosensory cortex in awake and anaesthetized rats following sensory stimulation using a new fibre-optic method for recording dendritic calcium changes. We show that the strength of sensory stimulation is encoded in the combined dendritic calcium response of a local population of L5 pyramidal cells in a graded manner. The slope of the stimulus-response function was under the control of a particular subset of inhibitory neurons activated by synaptic inputs predominantly in L5. Recordings from single apical tuft dendrites in vitro showed that activity in L5 pyramidal neurons disynaptically coupled via interneurons directly blocks the initiation of dendritic calcium spikes in neighbouring pyramidal neurons. The results constitute a functional description of a cortical microcircuit in awake animals that relies on the active properties of L5 pyramidal dendrites and their very high sensitivity to inhibition. The microcircuit is organized so that local populations of apical dendrites can adaptively encode bottom-up sensory stimuli linearly across their full dynamic range.

Impact of calcium-activated potassium channels on NMDA spikes in cortical layer 5 pyramidal neurons.
Active electrical events play an important role in shaping signal processing in dendrites. As these events are usually associated with an increase in intracellular calcium, they are likely to be under the control of calcium-activated potassium channels. Here, we investigate the impact of calcium-activated potassium channels onN-methyl-d-aspartate (NMDA) receptor-dependent spikes, or NMDA spikes, evoked by glutamate iontophoresis onto basal dendrites of cortical layer 5 pyramidal neurons. We found that small-conductance calcium-activated potassium channels (SK channels) act to reduce

NMDA spike amplitude but at the same time, also decrease the iontophoretic current required for their generation. This SK-mediated decrease in NMDA spike threshold was dependent on R-type voltage-gated calcium channels and indicates a counterintuitive, excitatory effect of SK channels on NMDA spike generation, whereas the capacity of SK channels to suppress NMDA spike amplitude is in line with the expected inhibitory action of potassium channels on dendritic excitability. Large-conductance calcium-activated potassium channels had no significant impact on NMDA spikes, indicating that these channels are either absent from basal dendrites or not activated by NMDA spikes. These experiments reveal complex and opposing interactions among NMDA receptors, SK channels, and voltage-gated calcium channels in basal dendrites of cortical layer 5 pyramidal neurons during NMDA spike generation, which are likely to play an important role in regulating the way these neurons integrate the thousands of synaptic inputs they receive.

The Impact of BK Channels on Cellular Excitability Depends on their Subcellular Location.
Large conductance calcium-activated potassium channels (or BK channels) fulfil a multitude of roles in the central nervous system. At the soma of many neuronal cell types they control the speed of action potential (AP) repolarization and therefore they can have an impact on neuronal excitability. Due to their presence in nerve terminals they also regulate transmitter release. BK channels have also been shown to be present in the dendrites of some neurons where they can regulate the magnitude and duration of dendritic spikes. Here, we investigate the impact of modulating the activation of BK channels at different locations on the cellular excitability of cortical layer 5 pyramidal neurons. We find that while somatic BK channels help to repolarize APs at the soma and mediate the fast after-hyperpolarization, dendritic BK channels are responsible for repolarization of dendritic calcium spikes and thereby regulate somatic AP burst firing. We found no evidence for a role of dendritic BK channels in the regulation of backpropagating AP amplitude or duration. These experiments highlight the diverse roles of BK channels in regulating neuronal excitability and indicate that their functional impact depends on their subcellular location.

Paradoxical Excitatory Impact of SK Channels on Dendritic Excitability.
Dendritic excitability regulates how neurons integrate synaptic inputs and thereby influences neuronal output. As active dendritic events are associated with significant calcium influx they are likely to be modulated by calcium-dependent processes, such as calcium-activated potassium channels. Here we investigate the impact of small conductance calcium-activated potassium channels (SK channels) on dendritic excitability in male and female rat cortical pyramidal neurons and Using local applications of the SK channel antagonist apamin , we show that blocking somatic SK channels enhances action potential output, whereas blocking dendritic SK channels paradoxically reduces the generation of dendritic calcium spikes and associated somatic burst firing. Opposite effects were observed using the SK channel enhancer NS309. The effect of apamin on dendritic SK channels was occluded when R-type calcium channels were blocked, indicating that the inhibitory impact of apamin on dendritic calcium spikes involved R-type calcium channels. Comparable effects were observed Intracellular application of apamin via the somatic whole-cell recording pipette reduced the medium afterhyperpolarization and increased action potential output during UP states. In contrast, extracellular application of apamin to the cortical surface to block dendritic SK channels shifted the distribution of action potentials within UP states from an initial burst to a more distributed firing pattern, while having no impact on overall action potential firing frequency or UP and DOWN states. These data indicate that somatic and dendritic SK channels have opposite effects on neuronal excitability, with dendritic SK channels counter-intuitively promoting rather than suppressing neuronal output. Neurons typically receive input from other neurons onto processes called dendrites, and use electrical events such as action potentials for signaling. As electrical events in neurons are usually associated with calcium influx they can be regulated by calcium-dependent processes. One such process is through the activation of calcium-dependent potassium channels, which usually act to reduce action potential signaling. Although this is the case for calcium-dependent potassium channels found at the cell body, we show here that calcium-dependent potassium channels in dendrites of cortical pyramidal neurons counter-intuitively promote rather than suppress action potential output.

Enkephalin release from VIP interneurons in the hippocampal CA2/3a region mediates heterosynaptic plasticity and social memory.
The hippocampus contains a diverse array of inhibitory interneurons that gate information flow through local cortico-hippocampal circuits to regulate memory storage. Although most studies of interneurons have focused on their role in fast synaptic inhibition mediated by GABA release, different classes of interneurons express unique sets of neuropeptides, many of which have been shown to exert powerful effects on neuronal function and memory when applied pharmacologically.

However, relatively little is known about whether and how release of endogenous neuropeptides from inhibitory cells contributes to their behavioral role in regulating memory formation. Here we report that vasoactive intestinal peptide (VIP)-expressing interneurons participate in social memory storage by enhancing information transfer from hippocampal CA3 pyramidal neurons to CA2 pyramidal neurons. Notably, this action depends on release of the neuropeptide enkephalin from VIP neurons, causing long-term depression of feedforward inhibition onto CA2 pyramidal cells. Moreover, VIP neuron activity in the CA2 region is increased selectively during exploration of a novel conspecific. Our findings, thus, enhance our appreciation of how GABAergic neurons can regulate synaptic plasticity and mnemonic behavior by demonstrating that such actions can be mediated by release of a specific neuropeptide, rather than through classic fast inhibitory transmission.

PNN-DEPENDENT REGULATION OF THALAMO-CORTICAL INPUTS ONTO PARVALBUMIN INTERNEURONS IN ADULT MOUSE PRIMARY VISUAL CORTEX

POSTER SESSION 05 - SECTION: INTERNEURONS AND DENDRITES

Lucie Gallet, Alberto Bacci, Laurence Cathala
Sorbonne University, Paris Brain Institute, Paris, France

Sensory, motor and cognitive development of the neocortex requires a critical period (CP) of plasticity, during which neuronal circuits are strongly regulated by experience. Its closure is associated with the accumulation of perineuronal nets (PNNs) around layer 4 parvalbumin (PV)- interneurons. Previous work from the lab has shown that *in vivo* acute PNN removal leads to increased recruitment of PV cells by thalamocortical (TC) inputs, which convey sensory information into the cortex. First, by combining optogenetic and electrical stimulations with patch-clamp recordings in acute V1 slices of adult mice, we have set up protocols for single TC axon activation onto patched layer 4 PV-interneurons. This allowed establishing the properties of thalamic recruitment of PV interneurons in V1 that are poorly known, compared to somatosensory cortex. We found that unitary TC synaptic transmission had high release probability ensuring a reliable transmission. Second, we compared the properties of TC synaptic transmission onto PV cells in control and after acute PNN degradation following *in vivo* ChABC injections, known to reactivate adult cortical plasticity. We found that PNN removal did not affect synaptic strength, short-term plasticity nor the contribution of AMPA and NMDA receptors of unitary TC synaptic transmission. These results suggest that acute disruption of PNNs does not directly affect synaptic transmission and provide compelling evidence that PNNs regulate the structural connectivity between the thalamus and PV interneurons.

DENDRITIC VOLTAGE SIGNALING IN CEREBELLAR PURKINJE NEURONS DURING ASSOCIATIVE MOTOR LEARNING

POSTER SESSION 05 - SECTION: INTERNEURONS AND DENDRITES

Lina Koronfel, Christopher Roome, Bernd Kuhn
Okinawa institute of science and technology, Optical Neuroimaging Unit, Okinawa, Japan

The cerebellar cortex is critical for many forms of associative learning, such as the timing of delay eyeblink conditioning. Here, we use two-photon voltage imaging of Purkinje neuron (PN) dendrites to study changes in dendritic activity during associative motor learning in habituated mice. PNs expressing a genetically encoded Ca^{2+} sensor (GCaMP6f) were selected if they reliably responded to an air puff stimulus directed towards the eye. Using a chronic cranial window with access port, the responsive PNs were loaded with the voltage-sensitive dye ANNINE-6plus via electroporation, allowing dendritic voltage imaging *in vivo*. Excitatory and inhibitory postsynaptic voltage signals were recorded with sub-millisecond temporal precision, repeatedly over several weeks, from up to two PNs per mouse. First, we recorded dendritic voltage signals during the presentation of a novel stimulus (blue LED light). Next, we examined dendritic voltage signaling during associative motor learning. In this case, the novel stimulus was associated with an unconditioned stimulus (an aversive air puff directed to the eye). Finally, we examined dendritic voltage signaling while the association between the two stimuli was unlearned. Behavioral recording, at 200Hz, tracked learning and was compared with voltage imaging data on a trial-to-trial basis, to investigate short- and long-term changes in dendritic signaling during the eyeblink conditioning training sessions.

Elimination of glutamatergic transmission from Hb9 interneurons does not impact treadmill locomotion.
The spinal cord contains neural circuits that can produce the rhythm and pattern of locomotor activity. It has previously been postulated that a population of glutamatergic neurons, termed Hb9 interneurons, contributes to locomotor rhythmogenesis. These neurons were identified by their expression of the homeobox gene, Hb9, which is also expressed in motor neurons. We developed a mouse line in which Cre recombinase activity is inducible in neurons expressing Hb9. We then used this line to eliminate vesicular glutamate transporter 2 from Hb9 interneurons, and found that there were no deficits in treadmill locomotion. We conclude that glutamatergic neurotransmission by Hb9 interneurons is not required for locomotor behaviour. The role of these neurons in neural circuits remains elusive.

Dendrites of hippocampal CA1 pyramidal cells amplify clustered glutamatergic input by activation of voltage-gated sodium channels and N-methyl-D-aspartate receptors (NMDARs). NMDAR activity depends on the presence of NMDAR co-agonists such as D-serine, but how co-agonists influence dendritic integration is not well understood. Using combinations of whole-cell patch clamp, iontophoretic glutamate application, two-photon excitation fluorescence microscopy and glutamate uncaging we found that exogenous D-serine reduces the threshold of dendritic spikes and increases their amplitude. Triggering an astrocytic mechanism controlling endogenous D-serine supply via endocannabinoid receptors (CBRs) also increased dendritic spiking. Unexpectedly, this pathway was activated by pyramidal cell activity primarily in the theta range, which required HCN channels and astrocytic CB1Rs. Therefore, astrocytes close a positive and frequency-dependent feedback loop between pyramidal cell activity and their integration of dendritic input. Its disruption led to an impairment of spatial memory, which demonstrates its behavioral relevance.

Local Efficacy of Glutamate Uptake Decreases with Synapse Size.
Synaptically released glutamate is largely cleared by glutamate transporters localized on perisynaptic astrocyte processes. Therefore, the substantial variability of astrocyte coverage of individual hippocampal synapses implies that the efficacy of local glutamate uptake and thus the spatial fidelity of synaptic transmission is synapse dependent. By visualization of sub-diffraction-limit perisynaptic astrocytic processes and adjacent postsynaptic spines, we show that, relative to their size, small spines display a stronger coverage by astroglial transporters than bigger neighboring spines. Similarly, glutamate transients evoked by synaptic stimulation are more sensitive to pharmacological inhibition of glutamate uptake at smaller spines, whose high-affinity N-methyl-D-aspartate receptors (NMDARs) are better shielded from remotely released glutamate. At small spines, glutamate-induced and NMDAR-dependent Ca entry is also more strongly increased by uptake inhibition. These findings indicate that spine size inversely correlates with the efficacy of local glutamate uptake and thereby likely determines the probability of synaptic crosstalk.

Local Resting Ca Controls the Scale of Astroglial Ca Signals.
Astroglia regulate neurovascular coupling while engaging in signal exchange with neurons. The underlying cellular machinery is thought to rely on astrocytic Ca signals, but what controls their amplitude and waveform is poorly understood. Here, we employ time-resolved two-photon excitation fluorescence imaging in acute hippocampal slices and in cortex in vivo to find that resting [Ca] predicts the scale (amplitude) and the maximum (peak) of astroglial Ca elevations. We bidirectionally manipulate resting [Ca] by uncaging intracellular Ca or Ca buffers and use ratiometric imaging of a genetically encoded Ca indicator to establish that alterations in resting [Ca] change co-directionally the peak level and anti-directionally the amplitude of local Ca transients. This relationship holds for spontaneous and for induced (for instance by locomotion) Ca signals. Our findings uncover a basic generic rule of Ca signal formation in astrocytes, thus also associating the resting Ca level with the physiological "excitability" state of astroglia.

Stress and Corticosteroids Aggravate Morphological Changes in the Dentate Gyrus after Early-Life Experimental Febrile Seizures in Mice.
Stress is the most frequently self-reported seizure precipitant in patients with epilepsy. Moreover, a relation between ear stress and epilepsy has been suggested. Although ear stress and stress hormones are known to influence seizure threshold in rodents, effects on the development of epilepsy (epileptogenesis) are still unclear. Therefore, we studied the consequences of ear corticosteroid exposure for epileptogenesis, under highly controlled conditions in an animal model. Experimental febrile seizures (eFS) were elicited in 10-day-old mice by warm-air induced hyperthermia, while a control group was exposed to a normothermic condition. In the following 2 weeks, mice received either seven corticosterone or vehicle injections or were left undisturbed. Specific measures indicative for epileptogenesis were examined at 25 days of age and compared with vehicle injected or untreated mice. We examined structural [neurogenesis, dendritic morphology, and mossy fiber sprouting (MFS)] and functional (glutamatergic postsynaptic currents and long-term potentiation) plasticity in the dentate gyrus (DG). We found that differences in DG morphology induced by eFS were aggravated by repetitive (mildly stressful) vehicle injections and corticosterone exposure. In the injected groups, eFS were associated with decreases in neurogenesis, and increases in cell proliferation, dendritic length, and spine density. No group differences were found in MFS. Despite these changes in DG morphology, no effects of eFS were found on functional plasticity. We conclude that corticosterone exposure during early epileptogenesis elicited by eFS aggravates morphological, but not functional, changes in the DG, which partly supports the hypothesis that ear stress stimulates epileptogenesis.

The structural and functional evidence for vesicular release from astrocytes in situ.
The concept of the tripartite synapse states that bi-directional signalling between perisynaptic astrocyte processes, presynaptic axonal boutons and postsynaptic neuronal structures defines the properties of synaptic information processing. Ca-dependent vesicular release from astrocytes, as one of the mechanisms of astrocyte-neuron communication, has attracted particular attention but has also been the subject of intense debate. In neurons, regulated vesicular release is a strongly coordinated process. It requires a complex release machinery comprised of many individual components ranging from vesicular neurotransmitter transporters and soluble NSF attachment protein receptors (SNARE) proteins to Ca-sensors and the proteins that spatially and temporally control exocytosis of synaptic vesicles. If astrocytes employ similar mechanisms to release neurotransmitters is less well understood. The aim of this review is therefore to discuss recent experimental evidence that sheds light on the central structural components responsible for vesicular release from astrocytes in situ.

INTERNEURON-SPECIFIC DENDRITIC COMPUTATIONS IN THE NEOCORTEX

POSTER SESSION 05 - SECTION: INTERNEURONS AND DENDRITES

Annunziato Morabito[1], Joana Lourenco[1], David Digregorio[2], Alberto Bacci[1], Nelson Rebola[1]
[1]ICM - Institut du Cerveau | Paris Brain Institute, Sorbonne Université - Cnrs - Inserm, Paris, France, [2]Institut Pasteur, Department Of Neuroscience, Paris, France

Neurons receive the majority of their excitatory synaptic inputs on dendrites, which can differ in shape, size, and density of active conductances. This variability can differentially affect dendritic integration and hence neuronal computations. While the role of dendrites in computations performed by excitatory neurons has been substantially investigated, much less is known about the influence of dendritic integration in GABAergic interneurons (INs). Here we compared the dendritic integration properties of soma-targeting parvalbumin (PV^+)-positive and dendritic-targeting somatostatin (SST^+)-positive INs in the primary somatosensory cortex of the mouse. Using two-photon glutamate uncaging we observed that PV^+-INs display mostly sublinear subthreshold input-output relationships, in agreement with local synaptic saturation, as reported for this interneuron subtype in other brain areas. However, SST^+-INs dendrites integrate quasi-synchronous inputs supralinearly in a NMDA-dependent manner, similar to observations from excitatory neurons. While both interneurons have relatively similar dendrite diameters, unitary NMDA/AMPA-EPSCs amplitude ratio was nearly doubled in SST^+-INs. Furthermore, monitoring neurotransmitter release using a glutamate sensor (iGluSnFR) at single unitary contacts in both PV^+-INs and SST^+-INs revealed that short trains of stimuli are associated with multivesicular release with imaging trials detecting zero, one or two quantal release events. Surprisingly, we observed that dendrites of SST^+-INs integrated double-quanta linearly all along the dendritic tree while PV^+-IN dendrites exhibited a progressive somato-dendritic attenuation of the single/double-quanta amplitude ratio as expected for a passive cable. In conclusion, our data demonstrate that IN-specific dendritic integration properties further contribute to the already diverse functional differences between PV^+-INs and SST^+-INs in neocortical microcircuits.

A large fraction of hippocampal pyramidal cells have axons emerging from a basal or, in rare cases, from the apical dendrite rather than from the soma. We have previously shown that such axon-carrying dendrites (AcD) constitute a privileged pathway for action-potential generation. Here, we studied the distribution of morphological features and the input connectivity of pyramidal cells in the adult mouse hippocampus. We found considerable variability between hippocampal sub-regions ranging from 70% AcD-morphology in the central area CA1 of medial portions of the hippocampus to 5% in dorsal CA1. Comparison of dendritic trees showed that AcD branches are longer than nonAcD branches of both, AcD and non AcD cells, while there is no difference in overall basal dendrite length between the two cell types. To assess the functionalrole of AcD-cells we investigated differences of innervation of AcD and nonAcD cells, using optogenetic stimulation of virus-targeted presynaptic fibres combined with patch-clamp recordings. We found that contralateral inputs from CA3 on the basal dendrite were stronger in AcD-cells compared to nonAcD-neurons. Also, axons from CA3 contra have more putative synapses with AcD-cells focused on the AcD. In contrast to basal dendrites, stimulation of inputs to apical dendrites showed no differences between the two cell types. Similarly, inputs from ipsilateral CA3 and CA2 were not different. These data show a functional asymmetry of synaptic connectivity between cells with and without a privileged dendritic input branch. In summary, our findings may be relevant for understanding cell-specific activation of principal cells in the hippocampal network.

Regenerative voltage responses produced by dendrites fundamentally influence input-output transformation of cortical pyramidal neurons. Dendritic Ca^{2+} spikes are generally thought to produce slow afterdepolarization (ADP) following action potentials (APs) that evokes complex spike burst (CSB) at the soma. Pyramidal cells (PCs) of the hippocampal CA3 area - a region essential for associative memory - have highly heterogeneous propensity to produce CSBs, but the underlying putative dendritic Ca^{2+} spikes remained incompletely characterized. We combined patch-clamp recordings with two-photon microscopy in acute rat brain slices to elucidate the biophysical properties of dendritic Ca^{2+} spikes in CA3PCs. Somatic depolarization effectively triggered dendritic Ca^{2+} spikes in the presence of tetrodotoxin. We found large cell-to-cell variability in the kinetic properties of somatically recorded Ca^{2+} spikes, depending on the topographic position of neurons. All Ca^{2+} spike forms were eliminated by an L-type Ca^{2+} channel antagonist, while blockers of other Ca^{2+} channel types (T, R, N, P/Q) had no effect. We assessed the roles of several K^+ channels types (Kv1, Kv2, Kv4, Kv7, BK and SK) applying selective inhibitors. Using dendritic recordings in higher-order apical trunks, we identified distinct types of dendritic Ca^{2+} spikes: 1) ADP-type global Ca^{2+} spikes promoting CSBs, and 2) a novel fast Ca^{2+} spike form generated locally in dendritic subtrees that promotes strictly single APs at the soma. Our results point to unique properties of Ca^{2+} spikes in CA3PCs compared to other PC types and suggest an important role for these spikes in input-output transformation of CA3PCs associative memory functions.

Diverse synaptic and dendritic mechanisms of complex spike burst generation in hippocampal CA3 pyramidal cells.
Complex spike bursts (CSBs) represent a characteristic firing pattern of hippocampal pyramidal cells (PCs). In CA1PCs, CSBs are driven by regenerative dendritic plateau potentials, produced by correlated entorhinal cortical and CA3 inputs that simultaneously depolarize distal and proximal dendritic domains. However, in CA3PCs neither the generation mechanisms nor the computational role of CSBs are well elucidated. We show that CSBs are induced by dendritic Ca spikes in CA3PCs. Surprisingly, the ability of CA3PCs to produce CSBs is heterogeneous, with non-uniform synaptic input-output transformation rules triggering CSBs. The heterogeneity is partly related to the topographic position of CA3PCs; we identify two ion channel types, HCN and Kv2 channels, whose proximodistal activity gradients contribute to subregion-specific modulation of CSB propensity. Our results suggest that heterogeneous dendritic integrative properties, along with previously reported synaptic connectivity gradients, define functional subpopulations of CA3PCs that may support CA3 network computations underlying associative memory processes.

Distinct dendritic Ca spike forms produce opposing input-output transformations in rat CA3 pyramidal cells.
Proper integration of different inputs targeting the dendritic tree of CA3 pyramidal cells (CA3PCs) is critical for associative learning and recall. Dendritic Ca spikes have been proposed to perform associative computations in other PC types by detecting conjunctive activation of different afferent input pathways, initiating afterdepolarization (ADP), and triggering burst firing. Implementation of such operations fundamentally depends on the actual biophysical properties of dendritic Ca spikes; yet little is known about these properties in dendrites of CA3PCs. Using dendritic patch-clamp recordings and two-photon Ca imaging in acute slices from male rats, we report that, unlike CA1PCs, distal apical trunk dendrites of CA3PCs exhibit distinct forms of dendritic Ca spikes. Besides ADP-type global Ca spikes, a majority of dendrites expresses a novel, fast Ca spike type that is initiated locally without bAPs, can recruit additional Na currents, and is compartmentalized to the activated dendritic subtree. Occurrence of the different Ca spike types correlates with dendritic structure, indicating morpho-functional heterogeneity among CA3PCs. Importantly, ADPs and dendritically initiated spikes produce opposing somatic output: bursts

versus strictly single-action potentials, respectively. The uncovered variability of dendritic Ca spikes may underlie heterogeneous input-output transformation and bursting properties of CA3PCs, and might specifically contribute to key associative and non-associative computations performed by the CA3 network.

DIFFERENT INVOLVEMENT OF AXON-CARRYING DENDRITE VERSUS CANONICAL NEURONS DURING LEARNING PROCESSES

POSTER SESSION 05 - SECTION: INTERNEURONS AND DENDRITES

Nadja Sharkov[1], Matthias Klumpp[1], Nikolas Stevens[1], Christian Thome[1], Janina Kupke[2], Andreas Draguhn[1], Ana Oliveira[2], Martin Both[1]

The hippocampus is important for the formation of declarative memories. It generates distinct network oscillations, during which functional ensembles are specifically activated. The formation of coherently active ensembles requires integration of multiple synaptic inputs within single neurons. According to current understanding, dendritic excitatory synaptic potentials are integrated at the soma which is directly connected with the axon. Signal flow to the axon can be blocked by perisomatic inhibition which is particularly active during network oscillations. Recently, we have shown that in about 50% of hippocampal CA1 pyramidal neurons the axon emerges from a basal dendrite (AcD, ‘axon-carrying dendrite’). This particular dendrite is largely independent from somatic signal integration and can efficiently convert excitatory inputs into APs, even under conditions of strong perisomatic inhibition. We therefore hypothesize that AcD cells are more active during states of strong perisomatic inhibition. Based on this mechanism, AcD and canonical cells might be differently involved in the formation and consolidation of episodic memory. To test this hypothesis, we trained mice on a spatial memory task (m-maze). Active neurons are expected to express immediate early genes (e.g. cFos), and can be identified by ex vivo staining. Additional, staining of the axon initial segment enabled us to sort task-activated neurons into AcD and canonical cells. Interestingly, nonAcD cells have a two times stronger expression of cFos than AcD after 7 days of training. While the underlying mechanisms are presently unclear it does, however indicate distinct roles of AcD and non-AcD cells during formation and consolidation of memory.

DENDRITIC PROCESSING IMPLEMENTS SPIKE-TIMING DEPENDENT PLASTICITY (STDP) IN CEREBELLAR GOLGI CELLS

POSTER SESSION 05 - SECTION: INTERNEURONS AND DENDRITES

Eleonora Pali[1], Teresa Sorbo[1], Francesca Prestori[1], Egidio D'Angelo[1,2]
[1]University of Pavia, Dept. Of Brain And Behavioral Sciences, Pavia, Italy, [2]IRCCS Mondino Foundation, Brain Connectivity Center, Pavia, Italy

The existence of a precisely organized neuronal circuitry in the cerebellum is crucial for information processing and induction of long-term synaptic plasticity. This latter determines persistent modifications in neuronal activity and synaptic transmission, providing the basis for timing and adaptation in the cerebellum. At the cerebellar input stage, timing is tightly controlled by Golgi cells (GoCs), inhibitory interneurons that process inputs conveyed by parallel fibers (pfs) and mossy fibers (mfs) on their apical and basal dendrites. Although many works highlighted the complexity of GoCs dendritic organization and synaptic inputs, the mechanisms through which GoCs integrate complex input patterns are still unclear. Based on recent computational model predictions, GoCs dendritic processing might depend on spike time intervals between mfs and pfs inputs, implying spike-timing dependent plasticity (STDP) at the mf-GoC synapse as a key plasticity mechanism of GoCs. To verify the validity of model predictions, GoC STDP was experimentally investigated performing whole-cell patch-clamp recordings in acute coronal slices of mouse cerebellar vermis. STDP showed a peculiar temporal order-dependence, with long-term potentiation and long-term depression elicited when mfs spikes anticipated or followed those on pfs, respectively, within a ms-accurate timing interval. In the presence of NMDA receptor inhibitors, STDP is abolished, corroborating the computational suggestions that NMDA channel unblock at mf-GoC synapses is the coincidence detectors of mfs and pfs activity. Overall, this work shows that dendritic processing is instrumental to STDP and opens new perspectives on the role of GoCs in determining learning and plasticity in the cerebellar circuit.

HUMAN FAST-SPIKING INHIBITORY NEURONS IN THE NEOCORTEX ACCELERATE THEIR INPUT-OUTPUT FUNCTION WITH SOMATIC HCN CHANNELS

POSTER SESSION 05 - SECTION: INTERNEURONS AND DENDRITES

Viktor Szegedi[1], Emoke Bakos[1], Szabina Furdan[1], Daniel Varga[2], Miklos Erdelyi[2], Pal Barzo[3], Attila Szucs[4], Gábor Tamás[1], Karri Lamsa[1]

There is increasing evidence showing species-related differences in neurons of the mammalian brain. Yet, our knowledge of neocortical neuron physiology is heavily based on experiments with rodents and other experimental animals. Human-specific neuronal phenotypes are poorly understood, particularly in the neocortex, where the most complex neuronal operations take place. We studied here a common and abundant type of inhibitory neurons, the fast-spiking basket cell in the neocortex. We found that the inhibitory neurons in human characteristically exhibit hyperpolarization-activated cyclic nucleotide-gated cation (HCN) channels in their somatic cell membrane, whereas somatic HCN channels are virtually absent in their rodent neuronal counterparts. With the HCN channels in soma, human fast-spiking inhibitory neurons facilitate their input-output fidelity, accelerate their somatic membrane potential kinetics, and shorten the action potential initiation lag for excitation in soma. With help of computational modeling we demonstrate that somatic HCN channels are well-fitted to facilitate these functions in human fast-spiking neurons. The facilitatory somatic mechanism may have evolved in human inhibitory neurons to accelerate their relatively slow passive membrane potential kinetics which apparently arises from low persistent membrane leakiness compared to their rodent counterparts. With help of somatic HCN channels human fast-spiking cells reach somatic input-output rate similar to their cell type equivalent in rodent.

PARADOXICAL SOMATO-DENDRITIC DECOUPLING SUPPORTS CORTICAL PLASTICITY DURING REM SLEEP

POSTER SESSION 05 - SECTION: INTERNEURONS AND DENDRITES

Mattia Aime[1], Niccolo Calcini[1], Micaela Borsa[1], Tiago Campelo[1], Thomas Rusterholz[1], Andrea Sattin[2], Tommaso Fellin[3], Antoine Adamantidis[1]

REM sleep is associated with the consolidation of emotional memories encoded by neuronal circuits from the limbic system and prefrontal cortex in mammals. Yet, the underlying neocortical circuits and synaptic mechanisms remain unclear. Here, we found that REM sleep is associated with a somato-dendritic decoupling in pyramidal neurons of the prefrontal cortex, using simultaneous 2-photon calcium imaging and electrophysiological recordings in sleeping mice. This decoupling reflects a shift of inhibitory balance between PV neurons-mediated somatic inhibition and VIP-mediated dendritic disinhibition, mostly driven by neurons from the central medial thalamus. We further showed that REM-specific optogenetic suppression of dendritic activity led to a loss of danger versus safety discrimination during associative learning and a lack of synaptic plasticity, whereas optogenetic release of somatic inhibition resulted in enhanced discrimination and synaptic potentiation. Collectively, our results demonstrated that somato-dendritic decoupling during REM sleep promotes opposite synaptic plasticity mechanisms that optimize emotional response to future behavioral stressors.

The integration of Gaussian noise by long-range amygdala inputs in frontal circuit promotes fear learning in mice.
Survival depends on the ability of animals to select the appropriate behavior in response to threat and safety sensory cues. However, the synaptic and circuit mechanisms by which the brain learns to encode accurate predictors of threat and safety remain largely unexplored. Here, we show that frontal association cortex (FrA) pyramidal neurons of mice integrate auditory cues and basolateral amygdala (BLA) inputs non-linearly in a NMDAR-dependent manner. We found that the response of FrA pyramidal neurons was more pronounced to Gaussian noise than to pure frequency tones, and that the activation of BLA-to-FrA axons was the strongest in between conditioning pairings. Blocking BLA-to-FrA signaling specifically at the time of presentation of Gaussian noise (but not 8 kHz tone) between conditioning trials impaired the formation of auditory fear memories. Taken together, our data reveal a circuit mechanism that facilitates the formation of fear traces in the FrA, thus providing a new framework for probing discriminative learning and related disorders.

Protein Kinase A Deregulation in the Medial Prefrontal Cortex Impairs Working Memory in Murine Oligophrenin-1 Deficiency.
Classical and systems genetics have identified wide networks of genes associated with cognitive and neurodevelopmental diseases. In parallel to deciphering the role of each of these genes in neuronal or synaptic function, evaluating the response of neuronal and molecular networks to gene loss of function could reveal some pathophysiological mechanisms potentially accessible to nongenetic therapies. Loss of function of the Rho-GAP oligophrenin-1 is associated with cognitive impairments in both human and mouse. Upregulation of both PKA and ROCK has been reported in mice, but it remains unclear whether kinase hyperactivity contributes to the behavioral phenotypes. In this study, we thoroughly characterized a prominent perseveration phenotype displayed by -deficient mice using a Y-maze spatial working memory (SWM) test. We report that deficiency in the mouse generated severe cognitive impairments, characterized by both a high occurrence of perseverative behaviors and a lack of deliberation during the SWM test. and pharmacological experiments suggest that PKA dysregulation in the mPFC underlies cognitive dysfunction in -deficient mice, as assessed using a delayed spatial alternation task results. Functionally, mPFC neuronal networks appeared to be affected in a PKA-dependent manner, whereas hippocampal-PFC projections involved in SWM were not affected in mice. Thus, we propose that discrete gene mutations in intellectual disability might generate "secondary" pathophysiological mechanisms, which are prone to become pharmacological targets for curative strategies in adult patients. Here we report that deficiency generates severe impairments in performance at spatial working

memory tests, characterized by a high occurrence of perseverative behaviors and a lack of decision making. This cognitive deficit is consecutive to PKA deregulation in the mPFC that prevents KO mice to exploit a correctly acquired rule. Functionally, mPFC neuronal networks appear to be affected in a PKA-dependent manner, whereas behaviorally important hippocampal projections were preserved by the mutation. Thus, we propose that discrete gene mutations in intellectual disability can generate "secondary" pathophysiological mechanisms prone to become pharmacological targets for curative strategies in adults.

UNDERSTANDING HOW INTERNEURONS IN THE MEDIAL PREFRONTAL CORTEX MODULATE ASSOCIATIVE RECOGNITION MEMORY

POSTER SESSION 05 - SECTION: INTERNEURONS AND DENDRITES

Genevieve Yvon-Durocher, Zafar Bashir, Clea Warburton
University of Bristol, Faculty Of Life Science, School Of Physiology, Pharmacology And Neuroscience, Bristol, United Kingdom

Associative recognition memory, such as recognising your misplaced house key or finding your car in a carpark, requires the integration of familiarity, spatial location and temporal information that is vital for everyday learning and episodic experience. The medial prefrontal cortex (mPFC) is the central processing unit within the associative recognition memory circuit as it receives long range excitatory inputs from the nucleus reuniens (NRe) and intermediate hippocampus (iHPC), both pathways being critical for learning. It is well known that inhibitory interneurons play essential roles in memory function by balancing excitation and modulating mPFC microcircuits. However, the roles mPFC interneurons have in associative recognition memory and its networks are unknown. Combining AAV1 mediated anterograde tracing, slice electrophysiology and *in vivo* wireless optogenetics, this project investigates; if different interneurons, pavalbumin (PV), somatostatin (SOM), neuron derived neurotrophic factor (NDNF) in mPFC are involved in different phases of recognition memory, the anatomical distribution and possible convergence of afferent excitatory projections from the iHPC and NRe and if these projections differentially engage interneuron subtypes, modulating mPFC network activity. Here we show iHPC and NRe projections have distinct laminar distribution within the prelimbic cortex aswell as layer 1 (L1) targeting of NRe inputs that receive specific iHPC monosynaptic projections. iHPC and NRe inputs differentially recruit PV interneurons and have opposing short term plasticity at L1 NDNF interneurons. SOM electrophysiology and *in vivo* work are ongoing. This work provides an important foundation for understanding the complex role of mPFC interneurons in the circuit function of associative recognition memory.

Obsessive Compulsive Disorder (OCD) is a severe, chronic, and ubiquitous neuropsychiatric disorder that affects 2-3% of worldwide population. Corticostriatal dysfunction is considered a major factor in the pathogenesis of OCD.
In *Sapap3* knockout (KO) mouse, a well-validated model of compulsive behavior, it has been reported that the striatal region receives increased levels of synaptic input from the secondary motor area (M2). M2 is thought to be homologous to the Supplementary Motor Area in humans, an area showing hyperactivity in OCD patients. Cortical disinhibition in OCD patients due to GABAergic deficits has been proposed to be related to its pathogenesis. Therefore, we study, using a combination of *in vitro* and *in vivo* 2-photon experiments, the cortical GABAergic circuitry involving PV^+ interneurons in layer 2/3 of the premotor area (M2). We have developed a *Sapap3* null mouse line that expresses td-Tomato under the control of the PV promoter. The preliminary results show a decrease in the number of PV^+ interneurons in M2. Furthermore, using electrophysiological recording in brain slice preparation, PV+ interneurons show increased input resistance, decreased rheobase and increased firing frequency gain. All together indicate that PV^+ interneurons are hyperexcitable. *In vivo* calcium imaging experiments in awake animals are in progress to confirm the hyperexcitability of PV^+ neurons, and how the excitatory network is affected. We are grateful to C. Cabrera Romero for excellent technical assistance. Supported by: RyC-2016-19906, PRE2019-087729 (MCI/AEI/FSE, UE), VI PPIT-US and US-1264432 (US/JUNTA/FEDER, UE).

Monoaminergic systems are phylogenetically old hub networks which receive a diverse constellation of long-range synaptic inputs, yet the local processing rules that govern computations over these inputs are poorly understood. Here, we used optogenetic, electrophysiological, computational and behavioral strategies to analyze information transmission from the habenula (LHb) to 5-HT neurons in the dorsal raphe nucleus (DRN). Habenulo-raphe afferents to 5-HT neurons triggered both short-timescale monosynaptic excitation, and inhibition over hundreds of milliseconds which reflected activation of 5-HT1A receptors. Optogenetic and pharmacological manipulations in DRN revealed that 5-HT neurons are organized in a recurrent inhibitory network, refuting the classical model of autocrine activation of 5-HT1ARs. We quantified short-term dynamics at serotonin-serotonin connections with electrical stimulation approaches, revealing dramatic short-term facilitation which was formalized with a linear-nonlinear plasticity model. Next, we outline general principles of information transmission through this circuit with network modeling and targeted slice experiments, including an inversion of response sign at high input intensities, and winner-take-all competition between submodules in DRN. We tested key predictions of our model by combining a classical conditioning paradigm with optogenetic strategies, uncovering a nonlinear transformation whereby stimulating the habenulo-raphe pathway at high frequencies, but not at low frequencies, depressed goal-directed anticipatory licking behavior. We suggest that the computation sustained by this circuit motif in the DRN categorizes synaptic inputs to implement optimal adaption of behavioural policies in dynamic environments.

Accurate Silent Synapse Estimation from Simulator-Corrected Electrophysiological Data Using the SilentMLE Python Package.
The proportion of silent (AMPAR-lacking) synapses is thought to be related to the plasticity potential of neural networks. We created a maximum-likelihood estimator of silent synapse fraction based on simulations of the underlying experimental methodology. Here, we provide a set of guidelines for running a Python package on compatible experimental synaptic data. Compared with traditional failure-rate approaches, this synthetic likelihood estimator improves the validity and accuracy of the estimates of the silent synapse fraction. For complete details on the use and execution of this protocol, please refer to Lynn et al. (2020).

A Synthetic Likelihood Solution to the Silent Synapse Estimation Problem.
Functional features of synaptic populations are typically inferred from random electrophysiological sampling of small subsets of synapses. Are these samples unbiased? Here, we develop a biophysically constrained statistical framework to address this question and apply it to assess the performance of a widely used method based on a failure-rate analysis to quantify the occurrence of silent (AMPAR-lacking) synapses. We simulate this method in silico and find that it is characterized by strong and systematic biases, poor reliability, and weak statistical power. Key conclusions are validated by whole-cell recordings from hippocampal neurons. To address these shortcomings, we develop a simulator of the experimental protocol and use it to compute a synthetic likelihood. By maximizing the likelihood, we infer silent synapse fraction with no bias, low variance, and superior statistical power over alternatives. Together, this generalizable approach highlights how a simulator of experimental methodologies can substantially improve the estimation of physiological properties.

The Eloquent Silent Synapse.
The ability of central synapses to undergo long-term potentiation (LTP) still captures the imagination of scientists and has become one of the most fascinating and deeply studied questions in modern neuroscience. By the mid-1990s, however, the field was deeply ensnarled in trying to answer a passionately dichotomous question: is LTP expressed by a pre- or a postsynaptic mechanism? Experimental results that could only be seen by many as being incontrovertibly contradictory presented a perplexing conundrum. However, two papers published in 1995 fundamentally redefined critical assumptions and provided a cunningly simple and elegant solution to an otherwise inextricable impasse.

The ability of brain regions to regulate information processing stems from an intricate and precisely organized network architecture. In the prefrontal cortex (PFC), a meticulously coordinated mosaic of cell types contributes to the regulation of a broad array of executive functions. **Aim:** Here, we detailed how the interaction of excitatory (E) and inhibitory (I) neurons contribute to the activity of broader cortical circuits, allowing for an elaborate repertoire of computations to arise. **Methods:** To examine the contribution of different neuronal subtypes to cortical dynamics, we combined electrophysiology, viral strategies, optogenetics, and pharmacology while recording spiking activity in acute slices of PFC on high-density multi-electrode arrays containing 4096 closely spaced electrodes. **Results:** To parse out the contribution of distinct cell types, we first developed spike sorting techniques that combined spline interpolation and principal component analysis to distinguish regular-spiking excitatory neurons from fast-spiking inhibitory interneurons. We validated this cell-type classification using a targeted combination of viral and optogenetic strategies to selectively activate parvalbumin (PV) interneurons. Next, using a sequential pharmacological approach, we systematically tested the contribution of each connection type to the activity patterns of each cell type. In intact networks, activating parvalbumin (PV) neurons had no effect on their firing rate, indicating complex compensatory mechanisms in the network. However, with GABAergic and glutamatergic transmission blocked, activating PV neurons reliably increased their firing rate. **Conclusion:** Together, these results provide insights on how complex connectivity motifs can affect respective E and I cell population activity.

Neuronal pattern separation of motion-relevant input in LIP activity.
In various regions of the brain, neurons discriminate sensory stimuli by decreasing the similarity between ambiguous input patterns. Here, we examine whether this process of pattern separation may drive the rapid discrimination of visual motion stimuli in the lateral intraparietal area (LIP). Starting with a simple mean-rate population model that captures neuronal activity in LIP, we show that overlapping input patterns can be reformatted dynamically to give rise to separated patterns of neuronal activity. The population model predicts that a key ingredient of pattern separation is the presence of heterogeneity in the response of individual units. Furthermore, the model proposes that pattern separation relies on heterogeneity in the temporal dynamics of neural activity and not merely in the mean firing rates of individual neurons over time. We confirm these predictions in recordings of macaque LIP neurons and show that the accuracy of pattern separation is a strong predictor of behavioral performance. Overall, results propose that LIP relies on neuronal pattern separation to facilitate decision-relevant discrimination of sensory stimuli. A new hypothesis is proposed on the role of the lateral intraparietal (LIP) region of cortex during rapid decision making. This hypothesis suggests that LIP alters the representation of ambiguous inputs to reduce their overlap, thus improving sensory discrimination. A combination of computational modeling, theoretical analysis, and electrophysiological data shows that the pattern separation hypothesis links neural activity to behavior and offers novel predictions on the role of LIP during sensory discrimination.

INTEGRATION OF MEDIAL AND LATERAL ENTORHINAL CORTEX IN HIPPOCAMPAL AREA CA3

POSTER SESSION 05 - SECTION: INTERNEURONS AND DENDRITES

Keelin O'Neil, Jayeeta Basu
New York University, Neuroscience Institute, New York, United States of America

Distinct brain areas encode different sensory features of the environment and route this information to the hippocampus (HC) where integration can lead to complex representations. However, what are the cellular and circuit mechanisms underlying the association of multisensory information within the brain to permit memory formation and recall remains an open question. To answer this, I am examining how different cortical inputs from medial (MEC) and lateral entorhinal cortex (LEC), carrying spatial and non-spatial sensory information respectively, integrate in single neurons in area CA3 of the hippocampus. CA3 plays a pivotal role in encoding and recall of episodic memory, likely due to its ability to form and reactivate ensembles of neurons. Identifying the circuit interactions driving input-output transformations and network dynamics within CA3 is crucial for understanding the neural computations underlying memory formation and recall. The longstanding dogma in field assumes that the association of information about place and context provided by MEC and LEC is key to forming accurate, complete and long-lasting hippocampal representations. However, this still remains mostly theoretical due to technical limitations. Using slice electrophysiology, dual-color optogenetic stimulation, and pharmacology we have shown that LEC and MEC do converge on to a single CA3 pyramidal neuron. Findings from our study will reveal how this underlying connectivity between these two sensory cortical inputs and their integration of and CA3 PNs drive the input/output transformations and associational plasticity.

Corticostriatal Flow of Action Selection Bias.
The posterior parietal cortex (PPC) performs many functions, including decision making and movement control. It remains unknown which input and output pathways of PPC support different functions. We addressed this issue in mice, focusing on PPC neurons projecting to the dorsal striatum (PPC-STR) and the posterior secondary motor cortex (PPC-pM2). Projection-specific, retrograde labeling showed that PPC-STR and PPC-pM2 represent largely distinct subpopulations, with PPC-STR receiving stronger inputs from association areas and PPC-pM2 receiving stronger sensorimotor inputs. Two-photon calcium imaging during decision making revealed that the PPC-STR population encodes history-dependent choice bias more strongly than PPC-pM2 or general PPC populations. Furthermore, optogenetic inactivation of PPC-STR neurons or their terminals in STR decreased history-dependent bias, while inactivation of PPC-pM2 neurons altered movement kinematics. Therefore, PPC biases action selection through its STR projection while controlling movements through PPC-pM2 neurons. PPC may support multiple functions through parallel subpopulations, each with distinct input-output connectivity.

Reorganization of corticospinal output during motor learning.
Motor learning is accompanied by widespread changes within the motor cortex, but it is unknown whether these changes are ultimately funneled through a stable corticospinal output channel or whether the corticospinal output itself is plastic. We investigated the consistency of the relationship between corticospinal neuron activity and movement through in vivo two-photon calcium imaging in mice learning a lever-press task. Corticospinal neurons exhibited heterogeneous correlations with movement, with the majority of movement-modulated neurons decreasing activity during movement. Individual cells changed

their activity across days, which led to changed associations between corticospinal activity and movement. Unlike previous observations in layer 2/3, activity accompanying learned movements did not become more consistent with learning; instead, the activity of dissimilar movements became more decorrelated. These results indicate that the relationship between corticospinal activity and movement is dynamic and that the types of activity and plasticity are different from and possibly complementary to those in layer 2/3.

PARVALBUMIN-EXPRESSING INHIBITORY NEURONS AT THE MEDIODORSAL NUCLEUS OF THE THALAMUS INHIBIT THE PROLONGED FRONTO-THALAMOCORTICAL ACTIVITY LOOP.

POSTER SESSION 05 - SECTION: INTERNEURONS AND DENDRITES

Yena Kim[1,2], Jong-Cheol Rah[2]
[1]DGIST, Brain Science, Daegu, Korea, Republic of, [2]Korea Brain Research Institute, 5-1 Office, Daegu, Korea, Republic of

The mediodorsal nucleus of the thalamus (MD) forms reciprocal connectivity with the medial prefrontal cortex (mPFC), which has been demonstrated to support the persistent activity in the mPFC observed in short-term memory maintenance. The thalamic reticular nucleus (TRN) neurons have been suggested to be the primary inhibitory input on the MD. Although there are inhibitory interneurons at the MD (MD_{IN}), it hasn't been studied thoroughly. Here, we examined the local inhibition in MD and the possible function of MD_{IN}, with a focus on the regulation of the frontothalamic activity loop using histological, electrophysiological, and behavioral analysis. The MD_{IN}, the majority of which expressed parvalbumin (PV), were found throughout the MD with a slight bias toward the lateral part of the MD. Their dendrites were aspiny and beaded similarly with the dendro-dendritic connections in the inhibitory neurons in sensory thalamic nuclei. MD_{IN} formed inhibitory, ionotropic GABAergic synapses on the local excitatory neurons (MD_{EX}). MD_{IN} received direct excitatory inputs from the mPFC with strong short-term synaptic facilitation. The high-frequency stimulation of mPFC axons, imitating the persistent neural activity during short-term memory, enhanced the chance of action potential evoked in MD_{IN}. In corroboration, inhibitory synaptic inputs were significantly increased by the trains of mPFC activity in MD_{EX}, without TRN inputs. Furthermore, we found that the increased firing of MD_{IN} significantly disturbed the maintenance of short-term memory, suggesting that local inhibition through MD_{IN} may play a regulatory role in the MD-mPFC activity loop by inhibiting prolonged high-frequency frontothalamic excitation transfer during the short-term memory.

HOMEOSTATIC REGULATION OF CA1 FIRING RATE SET POINTS IN RESPONSE TO CHRONIC HYPERACTIVATION OF INTERNEURONS

POSTER SESSION 05 - SECTION: INTERNEURONS AND DENDRITES

Homeostatic mechanisms stabilize activity of neural circuits by keeping firing rates in a given circuitry within a set-point range. Accumulated evidence suggests that mean firing rate (MFR) represents a physiological variable regulated by homeostatic systems. While all the studies *in vivo* have been conducted in primary visual cortex, whether MFRs in the hippocampus are homeostatically regulated and whether this regulation is gated by specific brain states remain unknown. To address this, we applied long-term single-unit recordings in freely behaving mice, along with chronic chemogenetic perturbations of specific neuronal populations – by expressing designer drug (Gq-DREADD) in all inhibitory interneuron types of the CA1 region of the hippocampus. After applying constant dosage of clozapine N-oxide (CNO) via osmotic pump for five days led to an immediate suppression of CA1 pyramidal cells activity that gradually recover after 3 days, returning MFR to its original set point, indicating that MFR and network patterns properties of pyramidal cells in the CA1 area is found under homeostatic regulation. In addition, we analyzed whether the pattern of spikes is also homeostatically regulated and whether homeostatic plasticity is gated by a specific vigilance state. This research may provide new insights on how hippocampal activity set points are regulated in behaving mice and whether homeostatic system is capable to compensate chronic hyperexcitability of interneurons.

The presubiculum is part of the parahippocampal cortex and plays a fundamental role for orientation in space. Many principal neurons of the presubiculum signal head direction, and show persistent firing when the head of an animal is oriented in a specific preferred direction. GABAergic neurons of the presubiculum seem likely to control the timing, sensitivity and selectivity of head directional signals. Head direction signals reach the presubiculum via the anterior thalamic nuclei (ATN). Their axons directly excite pyramidal cells in layer III, and also Parvalbumin expressing interneurons, which mediate feedforward inhibition. Presubicular Somatostatin interneurons are indirectly excited and mediate a delayed feed-back inhibition. The role of Vasoactive intestinal peptide (VIP) expressing interneurons in the presubicular microcircuit has not yet been addressed. Here, we examined the intrinsic properties of VIP interneurons as well as their input connectivity following photostimulation of ATN axons. Interneurons were recorded from VIPcre::tdTomato brain slices using the patch-clamp technique. Our results show that presubicular VIP interneurons were mostly distributed in superficial layers. Two distinct physiological groups of presubicular VIP interneurons emerged from the unsupervised cluster analysis performed on the electrophysiological parameters. The expression of AAV5-Chronos viral vectors in the ATN of VIP::tdTomato mice let us examine thalamic input connectivity onto VIP interneurons. They were recruited in an activity dependent manner and with facilitating dynamics. Our data provide initial insight into the contribution of VIP interneurons for the integration of thalamic head direction information in the presubiculum.

PREFRONTAL DISINHIBITION DISRUPTS REVERSAL PERFORMANCE

POSTER SESSION 05 - SECTION: INTERNEURONS AND DENDRITES

Jacco Renstrom[1], Charlotte Taylor[1], Joanna Loayza[1], Paula Moran[1], Silvia Maggi[1], Carl Stevenson[1], Moritz Von Heimendahl[2], Serena Deiana[2], Tobias Bast[1]
[1]University of Nottingham, School Of Psychology, Nottingham, United Kingdom, [2]Boehringer Ingelheim Pharma GmbH & Co. KG, Cns Diseases, ngelheim am Rhein, Germany

A reduction in prefrontal GABAergic inhibition, so-called neural disinhibition, is a key feature of schizophrenia. Additionally, schizophrenia is characterised by marked reversal learning deficits (Leeson et al.,2009,*BiolPsychiatry*). Reversal learning has mainly been found to require the orbitofrontal, but not prefrontal, cortex (Boulougouris et al.,2007,*BehavBrainRes).* However, we hypothesised that prefrontal disinhibition may impair reversal performance, because such disinhibition causes aberrant prefrontal neuron firing and may, thus, also disrupt processing in projections sites (Bast et al.,2017,*BrJPharmacol*), including the orbitofrontal cortex (Sesack et al.,1989,*JCompNeurol*). We manipulated prefrontal GABAergic activity in rats using local microinfusions of a GABA-A receptor agonist (muscimol), resulting in functional inhibition, and antagonist (picrotoxin), resulting in disinhibition (Pezze et al.,2014,*JNeurosci*). Reversal learning performance was assessed using an operant two-lever repeated reversal paradigm adapted from Brady & Floresco (2015,*JVisExp*). Beyond classical performance measures, including trials-to-criterion and %-correct, we used a Bayesian approach to assess trial-by-trial strategy probabilities to assess how prefrontal GABA manipulations affect the implementation of successful strategies underlying reversal performance. Prefrontal disinhibition, but not inhibition, markedly impaired repeated reversal performance. Although prefrontal disinhibition reduced expression of the old rule, rats with prefrontal disinhibition failed to reduce their adherence to the old rule and to shift to the new rule following reversal. Trial-by-trial strategy analysis suggested that prefrontal disinhibition disrupted the pursuit of strategies supporting reversal performance, including a lose-shift strategy. Overall, although reversal performance does not require prefrontal neural activity (i.e., is unaffected by muscimol inhibition), aberrant prefrontal activity due to disinhibition disrupts reversal performance.

EXCITATORY ACTION OF GABA/GLYCINE SYNAPTIC ACTIVITY IS FAVORED IN PRENATAL SOD1G93A MOTONEURONS

POSTER SESSION 05 - SECTION: INTERNEURONS AND DENDRITES

Hongmei Zhu, Urvashi Dalvi, William Cazenave, Daniel Cattaert, Pascal Branchereau
University of Bordeaux, Institut De Neurosciences Cognitives Et Intégratives D'aquitaine Cnrs Umr5287, Bordeaux, France

We have previously shown that prenatal spinal motoneurons (MNs) of the SOD1^{G93A} mouse model of amyotrophic lateral sclerosis are hyperexcitable and exhibit an altered chloride homeostasis with a more depolarized chloride equilibrium (E_{Cl}). Here, we aimed to verify whether low frequency depolarizing GABAergic/glycinergic postsynaptic potentials (dGPSPs) exert excitation in SOD1^{G93A} MNs before switching to inhibition at high frequency. Such dual effect was evidenced using simulation from SOD-like MNs (Branchereau et al. eLife 2019). E_{Cl} was set below spike threshold and electrical stimulations of the ventro-lateral funiculus were performed at different frequency in order to test the ability of dGPSPs to excite or inhibit the firing activity of E17.5 lumbar spinal MNs from the lateral motor column. Dual effect was more often, but not only, detected in SOD1^{G93A} MNs. WT MNs were classified into two clusters (dual effect or pure inhibition) according to Rm, dual responses being specific to high Rm and pure inhibition to low Rm. This was not the case in SOD1^{G93A} MNs that could express dual, pure inhibition but also pure excitation, whatever Rm value. Simulation showed that pure excitation could be obtained in SOD-like MNs by moving away the inhibitory input from the cell body to dendrites. MNs reconstructions highlighted a distinct morphology between the two WT clusters and VIAAT terminals density / size were smaller in SOD1^{G93A} MNs compared to WT. In conclusion, low density and location of GABA/glycine synaptic inputs, in addition to morphological changes, favor excitatory effects of dGPSP trains in E17.5 SOD1^{G93A} MNs.

SILENT SYNAPSES IN THE ADULT MOUSE NEOCORTEX

POSTER SESSION 05 - SECTION: INTERNEURONS AND DENDRITES

Dimitra Vardalaki[1,2], Mark Harnett[1,2]
[1]MIT, Department Of Brain & Cognitive Sciences, Cambridge, United States of America, [2]MIT, Mcgovern Institute For Brain Research, Cambridge, United States of America

Newly generated excitatory synapses in the mammalian cortex lack sufficient AMPA-type glutamate receptors to mediate neurotransmission, resulting in functionally silent synapses that require activity-dependent plasticity to mature. Silent synapses are abundant in early development, where they mediate circuit formation and refinement, but they are thought to be scarce in adulthood. However, adults retain a capacity for neural plasticity and flexible learning that suggests that the formation of new connections is still prevalent. Here, we used super-resolution proteomic imaging to visualize synaptic proteins at 2,234 synapses from layer 5 pyramidal neurons in the primary visual cortex of adult mice. Surprisingly, ~25% of these synapses lack AMPA receptors. These putative silent synapses were located at the tips of thin dendritic protrusions, known as filopodia, which were more abundant by an order of magnitude than previously believed (compromising ~30% of all dendritic protrusions). Physiological experiments revealed that filopodia do indeed lack AMPAR-mediated transmission, but they exhibit NMDAR mediated transmission. We further show that functionally silent synapses on filopodia can be unsilenced via Hebbian plasticity, recruiting new active connections into
a neuron’s input matrix. These results challenge the model that functional connectivity is largely fixed in the adult cortex and demonstrate a new mechanism for flexible control of synaptic wiring that expands the learning capabilities of the mature brain.

EXCITATORY DRIVE OF CORTICAL FAST-SPIKING GABAERGIC INTERNEURONS IS SET BY D-SERINE ACTING ON NMDA RECEPTORS

POSTER SESSION 05 - SECTION: INTERNEURONS AND DENDRITES

Isis Souza[1], Pierre Lecouflet[1], Steeve Maldera[1], Brigitte Potier[1], Loredano Pollegioni[2], Jean-Pierre Mothet[1]
[1]CNRS - ENS Paris-Saclay, Laboratoire Lumin Umr9024, Gif-sur-Yvette, France, [2]University of Insubria, Department Of Biotechnology And Life Sciences, Varese, Italy

N-methyl-D-aspartate receptors (NMDARs) populate GABAergic interneurons, where they play a critical role in shaping circuit motifs and memory. However, we are largely ignoring whether and how NMDARs at GABAergic interneurons are gated by signals released in their surrounding microenvironment. Here we explore the dynamics of the co-agonist site occupancy by D-serine and glycine at glutamatergic synapses onto parvalbumin positive GABAergic interneurons in the adolescent prefrontal cortex, an area central to complex cognitive operation. By combining cellular electrophysiology with the use of unique pharmacological interventions and genetic manipulations, we report that the firing activity of layer 5 fast-spiking-PV$^+$ interneurons and their excitatory synaptic coupling with principal neurons is under the control of NMDA receptors which are gated by D-serine but not glycine and that the identity of the co-agonist is not determined by the synaptic regime of the excitatory input. We further show that D-serine-deficient mice, a model of NMDAR hypofunction that exhibits schizophrenia-like phenotypes display attenuated firing pattern of the interneurons and no long-term potentiation. Our study extends the physiological implications of D-serine in brain physiopathology by uncovering its control of inhibitory synaptic networks through NMDARs.

REGION SELECTIVE INPUT FROM THE FRONTAL CORTEX MEDIATES INSTANTANEOUS CORRELATION BETWEEN CORTICAL ACTIVITY AND INTRATHALAMIC INHIBITION

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Nora Hadinger, Andor Domokos, László Acsády
Institute of Experimental Medicine, Laboratory Of Thalamus Research, BUDAPEST, Hungary

It has long been known that the neocortex is organized into areas with different cognitive functions. Although emerging data shows that the thalamus is involved in basically all cortical functions, including higher order cognitive processes, we only start to address if and how corticothalamic interactions are regionally specialized. Here we report a qualitative, region-specific difference in the organization of corticothalamic pathways. Using conditional viral tracing and *in vivo* electrophysiological experiments in the layer 5 (L5)-specific Rbp4-Cre and Thy1-Chr2-EYFP mouse lines we show that L5 pyramidal cells of the frontal, but not other cortical regions establish monosynaptic connection with the anterior part of the inhibitory thalamic reticular nucleus (TRN). Optogenetic activation of L5 cells elicited bursts in anterior TRN cells with short latency and high fidelity. Gradually increasing the number of the optogenetically activated L5 cells resulted in gradual change of TRN burst properties including increase in the intraburst frequencies and the number of spikes per burst. Similarly, spontaneous firing pattern of L5-innervated TRN neurons showed tight and gradual correlation with the ongoing frontal cortical activity. While single spike events showed low correlation burst firing was tightly coupled to the frontal population activity. Higher frequency burst with more spikes were correlated with faster, high amplitude cortical LFP events. This correlation disappeared upon optogenetic perturbation of the L5-TRN connection. The data suggest a powerful, region-specific and temporally precise cortical control in frontal cortico-thalamic circuits via the strong coupling of intrathalamic inhibition to the ongoing cortical oscillations.

DEVELOPMENTAL INCREASE OF INHIBITION DRIVES DECORRELATION OF NEURAL ACTIVITY

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Mattia Chini[1], Thomas Pfeffer[2], Ileana Hanganu-Opatz[1]
[1]University Medical Center Hamburg-Eppendorf, Institute Of Developmental Neurophysiology, Hamburg, Germany, [2]Universitat Pompeu Fabra, Center For Brain And Cognition, Barcelona, Spain

Throughout development, the brain transits from early highly synchronous activity patterns to a mature state with sparse and decorrelated neural activity, yet the mechanisms underlying this process are unknown. The developmental transition has important functional consequences, as the latter state allows for more efficient storage, retrieval and processing of information. Here, we show that, in the mouse medial prefrontal cortex (mPFC), neural activity during the first two postnatal weeks decorrelates following specific spatial patterns. This process is accompanied by a concomitant tilting of excitation/inhibition (E-I) ratio towards inhibition. Using optogenetic manipulations and neural network modeling, we show that the two phenomena are mechanistically linked, and that a relative increase of inhibition drives the decorrelation of neural activity. Accordingly, in two mouse models of neurodevelopmental disorders, subtle alterations in E-I ratio are associated with specific impairments in the correlational structure of spike trains. Finally, capitalizing on EEG data from newborn babies, we show that an analogous developmental transition takes place also in the human brain. Thus, changes in E-I ratio control the (de)correlation of neural activity and, by these means, its developmental imbalance might contribute to the pathogenesis of neurodevelopmental disorders.

A transient developmental increase in prefrontal activity alters network maturation and causes cognitive dysfunction in adult mice.
Disturbed neuronal activity in neuropsychiatric pathologies emerges during development and might cause multifold neuronal dysfunction by interfering with apoptosis, dendritic growth, and synapse formation. However, how altered electrical activity early in life affects neuronal function and behavior in adults is unknown. Here, we address this question by transiently increasing the coordinated activity of layer 2/3 pyramidal neurons in the medial prefrontal cortex of neonatal mice and monitoring long-term functional and behavioral consequences. We show that increased activity during early development causes premature maturation of pyramidal neurons and affects interneuronal density. Consequently, altered inhibitory feedback by fast-spiking interneurons and excitation/inhibition imbalance in prefrontal circuits of young adults result in weaker evoked synchronization of gamma frequency. These structural and functional changes ultimately lead to poorer mnemonic and social abilities. Thus, prefrontal activity during early development actively controls the cognitive performance of adults and might be critical for cognitive symptoms in neuropsychiatric diseases.

Anesthetics fragment hippocampal network activity, alter spine dynamics, and affect memory consolidation.
General anesthesia is characterized by reversible loss of consciousness accompanied by transient amnesia. Yet, long-term memory impairment is an undesirable side effect. How different types of general anesthetics (GAs) affect the hippocampus, a brain region central to memory formation and consolidation, is poorly understood. Using extracellular recordings, chronic 2-photon imaging, and behavioral analysis, we monitor the effects of isoflurane (Iso), medetomidine/midazolam/fentanyl (MMF), and ketamine/xylazine (Keta/Xyl) on network activity and structural spine dynamics in the hippocampal CA1 area of adult mice. GAs robustly reduced spiking activity, decorrelated cellular ensembles, albeit with distinct activity signatures, and altered spine dynamics. CA1 network activity under all 3 anesthetics was different to natural sleep. Iso anesthesia most closely resembled unperturbed activity during wakefulness and sleep, and network alterations recovered more readily than with Keta/Xyl and MMF. Correspondingly, memory consolidation was impaired after exposure to Keta/Xyl and MMF, but not Iso. Thus, different anesthetics distinctly alter hippocampal network dynamics, synaptic connectivity, and memory consolidation, with implications for GA strategy appraisal in animal research and clinical settings.

Prefrontal Cortex Development in Health and Disease: Lessons from Rodents and Humans.
The role of the prefrontal cortex (PFC) takes center stage among unanswered questions in modern neuroscience. The PFC has a Janus-faced nature: it enables sophisticated cognitive and social abilities that reach their maximum expression in humans, yet it underlies some of the devastating symptoms of psychiatric disorders. Accordingly, appropriate prefrontal development is crucial for many high-order cognitive abilities and dysregulation of this process has been linked to various neuropsychiatric diseases. Reviewing recent advances in the field, with a primary focus on rodents and humans, we highlight why, despite differences across species, a cross-species approach is a fruitful strategy for understanding prefrontal development. We briefly review the developmental contribution of molecules and extensively discuss how electrical activity controls the early maturation and wiring of prefrontal areas, as well as the emergence and refinement of input-output circuitry involved in cognitive processing. Finally, we highlight the mechanisms of developmental dysfunction and their relevance for psychiatric disorders.

Resolving and Rescuing Developmental Miswiring in a Mouse Model of Cognitive Impairment.
Cognitive deficits, core features of mental illness, largely result from dysfunction of prefrontal networks. This dysfunction emerges during early development, before a detectable behavioral readout, yet the cellular elements controlling the abnormal maturation are still unknown. Here, we address this open question by combining in vivo electrophysiology, optogenetics, neuroanatomy, and behavioral assays during development in mice mimicking the dual genetic-environmental etiology of psychiatric disorders. We report that pyramidal neurons in superficial layers of the prefrontal cortex are key elements causing disorganized oscillatory entrainment of local circuits in beta-gamma frequencies. Their abnormal firing rate and timing relate to sparser dendritic arborization and lower spine density. Administration of minocycline during the first postnatal week, potentially acting via microglial cells, rescues the neuronal deficits and restores pre-juvenile cognitive abilities. Elucidation of the cellular substrate of developmental miswiring causing later cognitive deficits opens new perspectives for identification of neurobiological targets amenable to therapies.
Neuron, 2020; 105
31087437: Oberlander VC, Xu X, Chini M, Hanganu-Opatz IL
Developmental dysfunction of prefrontal-hippocampal networks in mouse models of mental illness.
Despite inherent difficulties to translate human cognitive phenotype into animals, a large number of animal models for psychiatric disorders, such as schizophrenia, have been developed over the last decades. To which extent they reproduce common patterns of dysfunction related to mental illness and abnormal processes of maturation is still largely unknown. While the devastating symptoms of disease are firstly detectable in adulthood, they are considered to reflect profound miswiring of brain circuitry as result of abnormal development. To reveal whether different disease models share common dysfunction early in life, we investigate the prefrontal-hippocampal communication at neonatal age in (a) mice mimicking the abnormal genetic background (22q11.2 microdeletion, DISC1 knockdown), (b) mice mimicking the challenge by environmental stressors (maternal immune activation during pregnancy), (c) mice mimicking the combination of both aetiologies (dual-hit models) and pharmacological mouse models. Simultaneous extracellular recordings in vivo from all layers of prelimbic subdivision (PL) of prefrontal cortex (PFC) and CA1 area of intermediate/ventral hippocampus (i/vHP) show that network oscillations have a more fragmented structure and decreased power mainly in neonatal mice that mimic both genetic and environmental aetiology of disease. These mice also show layer-specific firing deficits in PL. Similar early network dysfunction was present in mice with 22q11.2 microdeletion. The abnormal activity patterns are accompanied by weaker synchrony and directed interactions within prefrontal-hippocampal networks. Thus, only severe genetic defects or combined genetic environmental stressors are disruptive enough for reproducing the early network miswiring in mental disorders.

Transient Knock-Down of Prefrontal DISC1 in Immune-Challenged Mice Causes Abnormal Long-Range Coupling and Cognitive Dysfunction throughout Development.
Compromised brain development has been hypothesized to account for mental illness. This concept was underpinned by the function of the molecule disrupted-in-schizophrenia 1 (DISC1), which represents an intracellular hub of developmental processes and has been related to cognitive dysfunction in psychiatric disorders. Mice with whole-brain DISC1 knock-down show impaired prefrontal-hippocampal function and cognitive abilities throughout development and at adulthood, especially when combined with early environmental stressors, such as maternal immune activation (MIA). However, the contribution of

abnormal DISC1-driven maturation of either prefrontal cortex (PFC) or hippocampus (HP) to these deficits is still unknown. Here, we use electroporation to restrict the DISC1 knock-down to prefrontal layer II/III pyramidal neurons during perinatal development and expose these mice to MIA as an environmental stressor (dual-hit GE mice, both sexes). Combining electrophysiology and neuroanatomy with behavioral testing, we show that GE mice at neonatal age have abnormal patterns of oscillatory activity and firing in PFC, but not HP. Abnormal firing rates in PFC of GE mice relate to sparser dendritic arborization and lower spine density. Moreover, the long-range coupling within prefrontal-hippocampal networks is decreased at this age. The transient prefrontal DISC1 knock-down was sufficient to permanently perturb the prefrontal-hippocampal communication and caused poorer recognition memory performance at pre-juvenile age. Thus, developmental dysfunction of prefrontal circuitry causes long-lasting disturbances related to mental illness. Hypofrontality is considered a main cause of cognitive deficits in mental disorders, yet the underlying mechanisms are still largely unknown. During development, long before the emergence of disease symptoms, the functional coupling within the prefrontal-hippocampal network, which is the core brain circuit involved in cognitive processing, is reduced. To assess to which extent impaired prefrontal development contributes to the early dysfunction, immune-challenged mice with transient DISC1 knock-down confined to PFC were investigated in their prefrontal-hippocampal communication throughout development by electrophysiology and behavioral testing. We show that perturbing developmental processes of prefrontal layer II/III pyramidal neurons is sufficient to diminish prefrontal-hippocampal coupling and decrease the cognitive performance throughout development.

Neural Correlates of Anesthesia in Newborn Mice and Humans.
Monitoring the hypnotic component of anesthesia during surgeries is critical to prevent intraoperative awareness and reduce adverse side effects. For this purpose, electroencephalographic (EEG) methods complementing measures of autonomic functions and behavioral responses are in use in clinical practice. However, in human neonates and infants existing methods may be unreliable and the correlation between brain activity and anesthetic depth is still poorly understood. Here, we characterized the effects of different anesthetics on brain activity in neonatal mice and developed machine learning approaches to identify electrophysiological features predicting inspired or end-tidal anesthetic concentration as a proxy for anesthetic depth. We show that similar features from EEG recordings can be applied to predict anesthetic concentration in neonatal mice and humans. These results might support a novel strategy to monitor anesthetic depth in human newborns.

Glutamatergic drive along the septo-temporal axis of hippocampus boosts prelimbic oscillations in the neonatal mouse.
The long-range coupling within prefrontal-hippocampal networks that account for cognitive performance emerges early in life. The discontinuous hippocampal theta bursts have been proposed to drive the generation of neonatal prefrontal oscillations, yet the cellular substrate of these early interactions is still unresolved. Here, we selectively target optogenetic manipulation of glutamatergic projection neurons in the CA1 area of either dorsal or intermediate/ventral hippocampus at neonatal age to elucidate their contribution to the emergence of prefrontal oscillatory entrainment. We show that despite stronger theta and ripples power in dorsal hippocampus, the prefrontal cortex is mainly coupled with intermediate/ventral hippocampus by phase-locking of neuronal firing via dense direct axonal projections. Theta band-confined activation by light of pyramidal neurons in intermediate/ventral but not dorsal CA1 that were transfected by electroporation with high-efficiency channelrhodopsin boosts prefrontal oscillations. Our data causally elucidate the cellular origin of the long-range coupling in the developing brain.

Sleep Loss Promotes Astrocytic Phagocytosis and Microglial Activation in Mouse Cerebral Cortex.
We previously found that and its ligand , astrocytic genes involved in phagocytosis, are upregulated after acute sleep deprivation. These results suggested that astrocytes may engage in phagocytic activity during extended wake, but direct evidence was lacking. Studies in humans and rodents also found that sleep loss increases peripheral markers of inflammation, but whether these changes are associated with neuroinflammation and/or activation of microglia, the brain's resident innate immune cells, was unknown. Here we used serial block-face scanning electron microscopy to obtain 3D volume measurements of synapses and surrounding astrocytic processes in mouse frontal cortex after 6-8 h of sleep, spontaneous wake, or sleep deprivation (SD) and after chronic (~5 d) sleep restriction (CSR). Astrocytic phagocytosis, mainly of presynaptic components of large synapses, increased after both acute and chronic sleep loss relative to sleep and wake. MERTK expression and lipid peroxidation in synaptoneurosomes also increased to a similar extent after short and long sleep loss, suggesting that astrocytic phagocytosis may represent the brain's response to the increase in synaptic activity associated with prolonged wake, clearing worn components of heavily used synapses. Using confocal microscopy, we then found that CSR but not SD mice show morphological signs of microglial activation and enhanced microglial phagocytosis of

synaptic elements, without obvious signs of neuroinflammation in the CSF. Because low-level sustained microglia activation can lead to abnormal responses to a secondary insult, these results suggest that chronic sleep loss, through microglia priming, may predispose the brain to further damage. We find that astrocytic phagocytosis of synaptic elements, mostly of presynaptic origin and in large synapses, is upregulated already after a few hours of sleep deprivation and shows a further significant increase after prolonged and severe sleep loss, suggesting that it may promote the housekeeping of heavily used and strong synapses in response to the increased neuronal activity of extended wake. By contrast, chronic sleep restriction but not acute sleep loss activates microglia, promotes their phagocytic activity, and does so in the absence of overt signs of neuroinflammation, suggesting that like many other stressors, extended sleep disruption may lead to a state of sustained microglia activation, perhaps increasing the brain's susceptibility to other forms of damage.

Contribution of sleep to the repair of neuronal DNA double-strand breaks: evidence from flies and mice.
Exploration of a novel environment leads to neuronal DNA double-strand breaks (DSBs). These DSBs are generated by type 2 topoisomerase to relieve topological constrains that limit transcription of plasticity-related immediate early genes. If not promptly repaired, however, DSBs may lead to cell death. Since the induction of plasticity-related genes is higher in wake than in sleep, we asked whether it is specifically wake associated with synaptic plasticity that leads to DSBs, and whether sleep provides any selective advantage over wake in their repair. In flies and mice, we find that enriched wake, more than simply time spent awake, induces DSBs, and their repair in mice is delayed or prevented by subsequent wake. In both species the repair of irradiation-induced neuronal DSBs is also quicker during sleep, and mouse genes mediating the response to DNA damage are upregulated in sleep. Thus, sleep facilitates the repair of neuronal DSBs.

LOCAL INTEGRATION OF LONG-RANGE INPUTS FROM THE LATERAL ENTORHINAL CORTEX IN HIPPOCAMPAL AREA CA3 DRIVES DENDRITIC NON-LINEARITIES AND SOMATIC OUTPUT

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Vincent Robert, Rodrigo De La Torre, Keelin O'Neil, Jayeeta Basu
New York University, Neuroscience Institute, New York, United States of America

Functional interactions between the entorhinal cortex and the hippocampus are crucial learning and memory. By integrating context-laden direct inputs from the lateral entorhinal cortex (LEC) with local feedforward dentate gyrus (DG) and feedback CA3 inputs, area CA3 is poised to gate hippocampal information flow and mnemonic function. However, the mechanisms of dendritic integration of LEC inputs in CA3 pyramidal cells and how they contribute to the flexibility of spatial representations displayed by CA3 ensembles remain unknown. Here we use dual color optogenetic circuit mapping *ex vivo* and 2-photon imaging with chemogenetic manipulations *in vivo* to dissect the functional role of LEC excitatory and inhibitory inputs to CA3. We found that LEC direct glutamatergic inputs drove spiking in CA3 interneurons, whereas LEC inhibitory inputs shunted interneuron excitability. In CA3 pyramidal cells, LEC excitatory inputs evoked monosynaptic excitation and disynaptic inhibition which acted to prevent CA3 output. Combined stimulation of LEC excitatory projections with local DG and CA3 recurrent inputs could drive CA3 output, and recruitment of LEC inhibitory projections further boosted CA3 output. Dendritic recordings from CA3 pyramidal cells suggest that this disinhibitory effect may facilitate the generation of dendritic spikes, which ultimately impact somatic excitability. These results demonstrate that LEC inputs can drive CA3 output when coordinated with local inputs, highlighting the role of dendritic integration of LEC signals in CA3 dendrites. To assess the role of this circuit on CA3 spatial coding, we are currently silencing LEC excitatory and inhibitory inputs while imaging CA3 place cell activity *in vivo*.

Fear conditioning potentiates synaptic transmission onto long-range projection neurons in the lateral subdivision of central amygdala.
Recent studies indicate that the lateral subdivision of the central amygdala (CeL) is essential for fear learning. Specifically, fear conditioning induces cell-type-specific synaptic plasticity in CeL neurons that is required for the storage of fear memories. The CeL also controls fear expression by gating the activity of the medial subdivision of the central amygdala (CeM), the canonical amygdala output to areas that mediate defensive responses. In addition to the connection with CeM, the CeL sends long-range projections to innervate extra-amygdala areas. However, the long-range projection CeL neurons have not been well characterized, and their role in fear regulation is unknown. Here we show in mice that a subset of CeL neurons directly project to the midbrain periaqueductal gray (PAG) and the paraventricular nucleus of the thalamus, two brain areas implicated in defensive behavior. These long-range projection CeL neurons are predominantly somatostatin-positive (SOM(+)) neurons, which can directly inhibit PAG neurons, and some of which innervate both the PAG and paraventricular nucleus of the thalamus. Notably, fear conditioning potentiates excitatory synaptic transmission onto these long-range projection CeL neurons. Thus, our study identifies a subpopulation of SOM(+) CeL neurons that may contribute to fear learning and regulate fear expression independent of CeM.

The paraventricular thalamus controls a central amygdala fear circuit.
Appropriate responses to an imminent threat brace us for adversities. The ability to sense and predict threatening or stressful events is essential for such adaptive behaviour. In the mammalian brain, one putative stress sensor is the paraventricular nucleus of the thalamus (PVT), an area that is readily activated by both physical and psychological stressors. However, the role of the PVT in the establishment of adaptive behavioural responses remains unclear. Here we show in mice that the PVT regulates fear processing in the lateral division of the central amygdala (CeL), a structure that orchestrates fear learning and expression. Selective inactivation of CeL-projecting PVT neurons prevented fear conditioning, an effect that can be

accounted for by an impairment in fear-conditioning-induced synaptic potentiation onto somatostatin-expressing (SOM(+)) CeL neurons, which has previously been shown to store fear memory. Consistently, we found that PVT neurons preferentially innervate SOM(+) neurons in the CeL, and stimulation of PVT afferents facilitated SOM(+) neuron activity and promoted intra-CeL inhibition, two processes that are critical for fear learning and expression. Notably, PVT modulation of SOM(+) CeL neurons was mediated by activation of the brain-derived neurotrophic factor (BDNF) receptor tropomysin-related kinase B (TrkB). As a result, selective deletion of either Bdnf in the PVT or Trkb in SOM(+) CeL neurons impaired fear conditioning, while infusion of BDNF into the CeL enhanced fear learning and elicited unconditioned fear responses. Our results demonstrate that the PVT-CeL pathway constitutes a novel circuit essential for both the establishment of fear memory and the expression of fear responses, and uncover mechanisms linking stress detection in PVT with the emergence of adaptive behaviour.

Chronic Loss of CA2 Transmission Leads to Hippocampal Hyperexcitability.
Hippocampal CA2 pyramidal cells project into both the neighboring CA1 and CA3 subfields, leaving them well positioned to influence network physiology and information processing for memory and space. While recent work has suggested unique roles for CA2, including encoding position during immobility and generating ripple oscillations, an interventional examination of the integrative functions of these connections has yet to be reported. Here we demonstrate that CA2 recruits feedforward inhibition in CA3 and that chronic genetically engineered shutdown of CA2-pyramidal-cell synaptic transmission consequently results in increased excitability of the recurrent CA3 network. In behaving mice, this led to spatially triggered episodes of network-wide hyperexcitability during exploration accompanied by the emergence of high-frequency discharges during rest. These findings reveal CA2 as a regulator of network processing in hippocampus and suggest that CA2-mediated inhibition in CA3 plays a key role in establishing the dynamic excitatory and inhibitory balance required for proper network function.

Hippocampal area CA2: properties and contribution to hippocampal function.
This review focuses on area CA2 of the hippocampus, as recent results have revealed the unique properties and surprising role of this region in encoding social, temporal and contextual aspects of memory. Originally identified and described by Lorente de No, in 1934, this region of the hippocampus has unique intra-and extra-hippocampal connectivity, sending and receiving input to septal and hypothalamic regions. Recent in vivo studies have indicated that CA2 pyramidal neurons encode spatial information during immobility and play an important role in the generation of sharp-wave ripples. Furthermore, CA2 neurons act to control overall excitability in the hippocampal network and have been found to be consistently altered in psychiatric diseases, indicating that normal function of this region is necessary for normal cognition. With its unique role, area CA2 has a unique molecular profile, interneuron density and composition. Furthermore, this region has an unusual manifestation of synaptic plasticity that does not occur post-synaptically at pyramidal neuron dendrities but through the local network of inhibitory neurons. While much progress has recently been made in understanding the large contribution of area CA2 to social memory formation, much still needs to be learned.

Routing Hippocampal Information Flow through Parvalbumin Interneuron Plasticity in Area CA2.
The hippocampus is critical for the formation of episodic memory. It is, therefore, important to understand intra-hippocampal circuitry, especially in the often overlooked area CA2. Using specific transgenic mouse lines combined with opto- and chemogenetics, we show that local plasticity of parvalbumin-expressing interneurons in area CA2 allows CA3 input to recruit CA2 pyramidal neurons (PNs), thereby increasing the excitatory drive between CA3 and CA1. CA2 PNs provide both stronger excitation and larger feed-forward inhibition onto deep, compared with superficial, CA1 PNs. This feed-forward inhibition, largely mediated by parvalbumin-expressing interneurons, normalizes the excitatory drive onto deep and superficial CA1 PNs. Finally, we identify a target of CA2 in area CA1, i.e., CA1 PNs, whose soma are located in stratum radiatum. These data provide insight into local hippocampal circuitry and reveal how localized plasticity can potentially control information flow in the larger hippocampal network.

The mechanisms shaping CA2 pyramidal neuron action potential bursting induced by muscarinic acetylcholine receptor activation.
Recent studies have revealed that hippocampal area CA2 plays an important role in hippocampal network function. Disruption of this region has been implicated in neuropsychiatric disorders. It is well appreciated that cholinergic input to the

hippocampus plays an important role in learning and memory. While the effect of elevated cholinergic tone has been well studied in areas CA1 and CA3, it remains unclear how changes in cholinergic tone impact synaptic transmission and the intrinsic properties of neurons in area CA2. In this study, we applied the cholinergic agonist carbachol and performed on-cell, whole-cell, and extracellular recordings in area CA2. We observed that under conditions of high cholinergic tone, CA2 pyramidal neurons depolarized and rhythmically fired bursts of action potentials. This depolarization depended on the activation of M1 and M3 cholinergic receptors. Furthermore, we examined how the intrinsic properties and action-potential firing were altered in CA2 pyramidal neurons treated with 10 μM carbachol. While this intrinsic burst firing persisted in the absence of synaptic transmission, bursts were shaped by synaptic inputs in the intact network. We found that both excitatory and inhibitory synaptic transmission were reduced upon carbachol treatment. Finally, we examined the contribution of different channels to the cholinergic-induced changes in neuronal properties. We found that a conductance from Kv7 channels partially contributed to carbachol-induced changes in resting membrane potential and membrane resistance. We also found that D-type potassium currents contributed to controlling several properties of the bursts, including firing rate and burst kinetics. Furthermore, we determined that T-type calcium channels and small conductance calcium-activated potassium channels play a role in regulating bursting activity.

A hypothalamic novelty signal modulates hippocampal memory.
The ability to recognize information that is incongruous with previous experience is critical for survival. Novelty signals have therefore evolved in the mammalian brain to enhance attention, perception and memory. Although the importance of regions such as the ventral tegmental area and locus coeruleus in broadly signalling novelty is well-established, these diffuse monoaminergic transmitters have yet to be shown to convey specific information on the type of stimuli that drive them. Whether distinct types of novelty, such as contextual and social novelty, are differently processed and routed in the brain is unknown. Here we identify the supramammillary nucleus (SuM) as a novelty hub in the hypothalamus. The SuM region is unique in that it not only responds broadly to novel stimuli, but also segregates and selectively routes different types of information to discrete cortical targets-the dentate gyrus and CA2 fields of the hippocampus-for the modulation of mnemonic processing. Using a new transgenic mouse line, SuM-Cre, we found that SuM neurons that project to the dentate gyrus are activated by contextual novelty, whereas the SuM-CA2 circuit is preferentially activated by novel social encounters. Circuit-based manipulation showed that divergent novelty channelling in these projections modifies hippocampal contextual or social memory. This content-specific routing of novelty signals represents a previously unknown mechanism that enables the hypothalamus to flexibly modulate select components of cognition.

Local circuit allowing hypothalamic control of hippocampal area CA2 activity and consequences for CA1.
The hippocampus is critical for memory formation. The hypothalamic supramammillary nucleus (SuM) sends long-range projections to hippocampal area CA2. While the SuM-CA2 connection is critical for social memory, how this input acts on the local circuit is unknown. Using transgenic mice, we found that SuM axon stimulation elicited mixed excitatory and inhibitory responses in area CA2 pyramidal neurons (PNs). Parvalbumin-expressing basket cells were largely responsible for the feedforward inhibitory drive of SuM over area CA2. Inhibition recruited by the SuM input onto CA2 PNs increased the precision of action potential firing both in conditions of low and high cholinergic tone. Furthermore, SuM stimulation in area CA2 modulated CA1 activity, indicating that synchronized CA2 output drives a pulsed inhibition in area CA1. Hence, the network revealed here lays basis for understanding how SuM activity directly acts on the local hippocampal circuit to allow social memory encoding.

Assessing Local and Branch-specific Activity in Dendrites.
Dendrites are elaborate neural processes which integrate inputs from various sources in space and time. While decades of work have suggested an independent role for dendrites in driving nonlinear computations for the cell, only recently have technological advances enabled us to capture the variety of activity in dendrites and their coupling dynamics with the soma. Under certain circumstances, activity generated in a given dendritic branch remains isolated, such that the soma or even sister dendrites are not privy to these localized signals. Such branch-specific activity could radically increase the capacity and flexibility of coding for the cell as a whole. Here, we discuss these forms of localized and branch-specific activity, their functional relevance in plasticity and behavior, and their supporting biophysical and circuit-level mechanisms. We conclude by showcasing electrical and optical approaches in hippocampal area CA3, using original experimental data to discuss

experimental and analytical methodology and key considerations to take when investigating the functional relevance of independent dendritic activity.

SEROTONERGIC MODULATION OF NEURAL ACTIVITY ACROSS THE MOUSE BRAIN

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Guido Meijer, Joana Catarino, Laura Freitas-Silva, Inês Laranjeira, International Brain Laboratory, Zachary Mainen Champalimaud Foundation, Champalimaud Neuroscience Programme, Lisbon, Portugal

Serotonin (5-HT) is a central neuromodulator which is implicated in the regulation of mood, motivation and cognitive flexibility. 5-HT is released from neurons in the dorsal raphe nucleus (DRN) which project throughout the entire brain. How serotonin release modulates neural dynamics across the brain remains a topic of debate. Previous fMRI and electrophysiological studies in rodents showed that optogenetically stimulating serotonin release resulted in a general suppression of neural activity. Brain-wide fMRI studies, however, lack single neuron resolution and are confounded by the vasoconstrictive effect of serotonin. To date, electrophysiological recording studies were performed under anesthesia or were limited in scope. Therefore, we present an extensive study investigating how serotonin modulates neural spiking activity across the mouse brain. We performed Neuropixel recordings in awake mice while optogenetically stimulating 5-HT neurons in the DRN. Acute Neuropixel recordings were targeted to eight locations, which were recorded in pairs in four recording sessions. We found that stimulating 5-HT release resulted in a substantial suppression of spiking activity in the thalamus, hippocampus and posterior parietal cortex. However, the amygdala, tail of the striatum, orbitofrontal, medial prefrontal, and piriform cortex showed balanced serotonergic enhancement and suppression of neuronal activity. Other target regions, like the superior colliculus, were unaffected. These findings shed light on the functional dynamics of the serotonergic projection system at a single neuron level, and have important implications for the computational role of serotonin in large-scale neural dynamics across the brain.

Neural Correlates of Multisensory Detection Behavior: Comparison of Primary and Higher-Order Visual Cortex.
We act upon stimuli in our surrounding environment by gathering the multisensory information they convey and by integrating this information to decide on a behavioral action. We hypothesized that the anterolateral secondary visual cortex (area AL) of the mouse brain may serve as a hub for sensorimotor transformation of audiovisual information. We imaged neuronal activity in primary visual cortex (V1) and AL of the mouse during a detection task using visual, auditory, and audiovisual stimuli. We found that AL neurons were more sensitive to weak uni- and multisensory stimuli compared to V1. Depending on contrast, different subsets of AL and V1 neurons showed cross-modal modulation of visual responses. During audiovisual stimulation, AL neurons showed stronger differentiation of behaviorally reported versus unreported stimuli compared to V1, whereas V1 showed this distinction during unisensory visual stimulation. Thus, neural population activity in area AL correlates more closely with multisensory detection behavior than V1.

The circuit architecture of cortical multisensory processing: Distinct functions jointly operating within a common anatomical network.
Our perceptual systems continuously process sensory inputs from different modalities and organize these streams of information such that our subjective representation of the outside world is a unified experience. By doing so, they also enable further cognitive processing and behavioral action. While cortical multisensory processing has been extensively investigated in terms of psychophysics and mesoscale neural correlates, an in depth understanding of the underlying circuit-level mechanisms is lacking. Previous studies on circuit-level mechanisms of multisensory processing have predominantly focused on cue integration, i.e. the mechanism by which sensory features from different modalities are combined to yield more reliable stimulus estimates than those obtained by using single sensory modalities. In this review, we expand the framework on the circuit-level mechanisms of cortical multisensory processing by highlighting that multisensory processing is a family of

functions - rather than a single operation - which involves not only the integration but also the segregation of modalities. In addition, multisensory processing not only depends on stimulus features, but also on cognitive resources, such as attention and memory, as well as behavioral context, to determine the behavioral outcome. We focus on rodent models as a powerful instrument to study the circuit-level bases of multisensory processes, because they enable combining cell-type-specific recording and interventional techniques with complex behavioral paradigms. We conclude that distinct multisensory processes share overlapping anatomical substrates, are implemented by diverse neuronal micro-circuitries that operate in parallel, and are flexibly recruited based on factors such as stimulus features and behavioral constraints.

Audiovisual Integration Enhances Stimulus Detection Performance in Mice.
The detection of objects in the external world improves when humans and animals integrate object features of multiple sensory modalities. Behavioral and neuronal mechanisms underlying multisensory stimulus detection are poorly understood, mainly because they have not been investigated with suitable behavioral paradigms. Such behavioral paradigms should (i) elicit a robust multisensory gain, (ii) incorporate systematic calibration of stimulus amplitude to the sensory capacities of the individual subject, (iii) yield a high trial count, and (iv) be easily compatible with a large variety of neurophysiological recording techniques. We developed an audiovisual stimulus detection task for head-fixed mice which meets all of these critical behavioral constraints. Behavioral data obtained with this task indicated a robust increase in detection performance of multisensory stimuli compared with unisensory cues, which was maximal when both stimulus constituents were presented at threshold intensity. The multisensory behavioral effect was associated with a change in the perceptual performance which consisted of two components. First, the visual and auditory perceptual systems increased their sensitivity meaning that low intensity stimuli were more often detected. Second, enhanced acuity enabled the systems to better classify whether there was a stimulus or not. Fitting our data to signal detection models revealed that the multisensory gain was more likely to be achieved by integration of sensory signals rather than by stimulus redundancy or competition. This validated behavioral paradigm can be exploited to reliably investigate the neuronal correlates of multisensory stimulus detection at the level of single neurons, microcircuits, and larger perceptual systems.

Conditioning sharpens the spatial representation of rewarded stimuli in mouse primary visual cortex.
Reward is often employed as reinforcement in behavioral paradigms but it is unclear how the visuospatial aspect of a stimulus-reward association affects the cortical representation of visual space. Using a head-fixed paradigm, we conditioned mice to associate the same visual pattern in adjacent retinotopic regions with availability and absence of reward. Time-lapse intrinsic optical signal imaging under anesthesia showed that conditioning increased the spatial separation of mesoscale cortical representations of reward predicting- and non-reward predicting stimuli. Subsequent in vivo two-photon calcium imaging revealed that this improved separation correlated with enhanced population coding for retinotopic location, specifically for the trained orientation and spatially confined to the V1 region where rewarded and non-rewarded stimulus representations bordered. These results are corroborated by conditioning-induced differences in the correlation structure of population activity. Thus, the cortical representation of visual space is sharpened as consequence of associative stimulus-reward learning while the overall retinotopic map remains unaltered.

Audiovisual Modulation in Mouse Primary Visual Cortex Depends on Cross-Modal Stimulus Configuration and Congruency.
The sensory neocortex is a highly connected associative network that integrates information from multiple senses, even at the level of the primary sensory areas. Although a growing body of empirical evidence supports this view, the neural mechanisms of cross-modal integration in primary sensory areas, such as the primary visual cortex (V1), are still largely unknown. Using two-photon calcium imaging in awake mice, we show that the encoding of audiovisual stimuli in V1 neuronal populations is highly dependent on the features of the stimulus constituents. When the visual and auditory stimulus features were modulated at the same rate (i.e., temporally congruent), neurons responded with either an enhancement or suppression compared with unisensory visual stimuli, and their prevalence was balanced. Temporally incongruent tones or white-noise bursts included in audiovisual stimulus pairs resulted in predominant response suppression across the neuronal population. Visual contrast did not influence multisensory processing when the audiovisual stimulus pairs were congruent; however, when white-noise bursts were used, neurons generally showed response suppression when the visual stimulus contrast was high whereas this effect was absent when the visual contrast was low. Furthermore, a small fraction of V1 neurons, predominantly those located near the lateral border of V1, responded to sound alone. These results show that V1 is involved in the encoding of cross-modal interactions in a more versatile way than previously thought. The neural substrate of cross-modal integration is not limited to specialized cortical association areas but extends to primary sensory areas. Using two-

photon imaging of large groups of neurons, we show that multisensory modulation of V1 populations is strongly determined by the individual and shared features of cross-modal stimulus constituents, such as contrast, frequency, congruency, and temporal structure. Congruent audiovisual stimulation resulted in a balanced pattern of response enhancement and suppression compared with unisensory visual stimuli, whereas incongruent or dissimilar stimuli at full contrast gave rise to a population dominated by response-suppressing neurons. Our results indicate that V1 dynamically integrates nonvisual sources of information while still attributing most of its resources to coding visual information.

Reward Expectancy Strengthens CA1 Theta and Beta Band Synchronization and Hippocampal-Ventral Striatal Coupling.
The use of information from the hippocampal memory system in motivated behavior depends on its communication with the ventral striatum. When an animal encounters cues that signal subsequent reward, its reward expectancy is raised. It is unknown, however, how this process affects hippocampal dynamics and their influence on target structures, such as ventral striatum. We show that, in rats, reward-predictive cues result in enhanced hippocampal theta and beta band rhythmic activity during subsequent action, compared with uncued goal-directed navigation. The beta band component, also labeled theta's harmonic, involves selective hippocampal CA1 cell groups showing frequency doubling of firing periodicity relative to theta rhythmicity and it partitions the theta cycle into segments showing clear versus poor spike timing organization. We found that theta phase precession occurred over a wider range than previously reported. This was apparent from spikes emitted near the peak of the theta cycle exhibiting large "phase precessing jumps" relative to spikes in foregoing cycles. Neither this phenomenon nor the regular manifestation of theta phase precession was affected by reward expectancy. Ventral striatal neuronal firing phase-locked not only to hippocampal theta, but also to beta band activity. Both hippocampus and ventral striatum showed increased synchronization between neuronal firing and local field potential activity during cued compared with uncued goal approaches. These results suggest that cue-triggered reward expectancy intensifies hippocampal output to target structures, such as the ventral striatum, by which the hippocampus may gain prioritized access to systems modulating motivated behaviors.

Population-Level Neural Codes Are Robust to Single-Neuron Variability from a Multidimensional Coding Perspective.
Sensory neurons are often tuned to particular stimulus features, but their responses to repeated presentation of the same stimulus can vary over subsequent trials. This presents a problem for understanding the functioning of the brain, because downstream neuronal populations ought to construct accurate stimulus representations, even upon singular exposure. To study how trial-by-trial fluctuations (i.e., noise) in activity influence cortical representations of sensory input, we performed chronic calcium imaging of GCaMP6-expressing populations in mouse V1. We observed that high-dimensional response correlations, i.e., dependencies in activation strength among multiple neurons, can be used to predict single-trial, single-neuron noise. These multidimensional correlations are structured such that variability in the response of single neurons is relatively harmless to population representations of visual stimuli. We propose that multidimensional coding may represent a canonical principle of cortical circuits, explaining why the apparent noisiness of neuronal responses is compatible with accurate neural representations of stimulus features.

Standardized and reproducible measurement of decision-making in mice.
Progress in science requires standardized assays whose results can be readily shared, compared, and reproduced across laboratories. Reproducibility, however, has been a concern in neuroscience, particularly for measurements of mouse behavior. Here, we show that a standardized task to probe decision-making in mice produces reproducible results across multiple laboratories. We adopted a task for head-fixed mice that assays perceptual and value-based decision making, and we standardized training protocol and experimental hardware, software, and procedures. We trained 140 mice across seven laboratories in three countries, and we collected 5 million mouse choices into a publicly available database. Learning speed was variable across mice and laboratories, but once training was complete there were no significant differences in behavior across laboratories. Mice in different laboratories adopted similar reliance on visual stimuli, on past successes and failures, and on estimates of stimulus prior probability to guide their choices. These results reveal that a complex mouse behavior can be reproduced across multiple laboratories. They establish a standard for reproducible rodent behavior, and provide an unprecedented dataset and open-access tools to study decision-making in mice. More generally, they indicate a path toward

achieving reproducibility in neuroscience through collaborative open-science approaches.

LAYER-SPECIFIC STIMULATIONS OF PARVALBUMIN-POSITIVE INTERNEURONS IN MICE ENTRAIN BRAIN RHYTHMS TO DIFFERENT FREQUENCIES

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Francois David[1], Mélodie Borel[2], Suleman Ayub[3], Patrick Ruther[3], Luc Gentet[4]
[1]CNRS, Incc, Paris, France, [2]CRNL, Neurocampus, Bron, France, [3]University of Freiburg, Department Of Microsystems Engineering (imtek), Freiburg, Germany, [4]Lyon Neuroscience Research Center, Neurocampus - C.h Le Vinatier, Bron, France

Neocortical interneurons provide inhibition responsible for organizing neuronal activity into brain oscillations that subserve cognitive functions such as memory, attention or prediction. However, little is known about the interneuron contribution to the entrainment of neocortical oscillations across different layers. Here, using layer-specific optogenetic stimulations with micro-Light-Emitting Diode (µLED) arrays, directed toward parvalbumin-expressing (PV) interneurons in non-anesthetized awake mice, we found that supragranular layer stimulations of PV neurons were most efficient at entraining supragranular local field potential (LFP) oscillations at gamma frequencies (g: 25 - 80 Hz), whereas infragranular layer stimulation of PV neurons better entrained the LFP at delta (d: 2 - 5 Hz) and theta (θ: 6 - 10 Hz) frequencies. At the level of neuronal AP activity, we observed that supragranular regular-spiking (RS) neurons better followed the imposed PV stimulation rhythm than their infragranular counterparts at most frequencies when the stimulation was delivered in their respective layer. Layer-specific intrinsic resonant properties of neurons are hypothesized as one plausible mechanism of the layer-specific rhythm entrainment by the performed brain stimulations.

ASTROCYTES AS ACTIVE CHANNEL FOR THE MOLECULAR CLOCK SYNCHRONIZATION AMONG SEGREGATED NEURAL POPULATIONS

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Lidia Giantomasi[1], Joao Ribeiro[1], Olga Barca-Mayo[2], Davide De Pietri Tonelli[2], Luca Berdondini[1]
[1]Istituto Italiano di Tecnologia, Microtechnology For Neuroelectronics Laboratory, Genova, Italy, [2]Istituto Italiano di Tecnologia, Neurobiology Of Mirna Laboratory, Genova, Italy

In mammals the suprachiasmatic nucleus of the hypothalamus is considered the master circadian pacemaker which synchronizes all the clocks in the central nervous system and periphery, thus orchestrating rhythms throughout the body. However, little is known about how so many cellular clocks can be effectively synchronized. Here, we investigated the implication of two possible pathways: i) paracrine factors-mediated synchronization and ii) astrocytes-mediated synchronization. We developed a lab-on-a-chip microfluidic device, which allows growing distinct neural populations connected through i) a cell-free channel allowing (or impeding by fluidic compartmentalization) the diffusion of paracrine factors; ii) a network of astrocytes, enabling direct cell-cell transfer of the signals. Results show that both pathways can be involved. Neurons release factors that can diffuse to synchronize a neuronal population. The same factors can also synchronize astrocytes that, in turn, can transmit molecular clocks to more distant neuronal populations. Interestingly, using microfluidic devices featuring different channel lengths, we found that paracrine factors-mediated synchronization occurs only in the case of a short distance between neuronal populations. On the contrary, interconnecting astrocytes define an active channel that can transfer molecular clocks to neural populations also at long distances. By taking advantage of such devices, we also started to investigate if reactive astrocytes affect this signaling. These findings strength the importance of the synergic regulation of clock genes among neurons and astrocytes, and suggest that the network of astrocytes in the brain might have a role in the distribution of regulatory signals for the expression of clock genes.

FUNCTIONAL INTERACTIONS OF THALAMIC CELLS

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Agnes Antal-Schnell, Éva Gulyás, Blanka Kozma, István Ulbert, Péter Barthó
Research Centre for Natural Sciences, Institute Of Cognitive Neuroscience And Psychology, Budapest, Hungary

The thalamic relay cell-reticular cell loop is the origin of diverse oscillations, most notably sleep spindles and absence seizures. Though well characterized in vitro, the direct excitatory and inhibitory connections between the two cell types have not been detected in extracellular population recordings. Here we performed high-density multichannel silicon probe recordings from primary- and higher order somatosensory thalamus of anesthetized and head-restrained mice. Thalamocortical (TC) cells and axon terminals of locally projecting thalamic reticular (nRT) cells were distinguished by their characteristic waveform and autocorrelogram (as reported in Barthó et. al. 2014). TC and nRT units most commonly showed and indirect relationship (nRT cells broadly increasing their firing ~20 ms from TC spikes) likely due to both cells taking part in spindle oscillations. We also found, however, short latency narrow peaks and troughs on several cross-correlograms, indicative of monosynaptic excitation and inhibition, respectively. Both monosynaptic excitation and inhibition occurred between TC and nRT units, not between cells of the same type. In some cases, reciprocal excitation-inhibition was observed between coupled units. On the other hand, TC-TC and nRT-nRT pairs usually showed synchronous activity on a varying time scale. The probability of monosynaptic connections and the degree of synchrony both decreased with physical distance, indicating a strict topography of these connections.

A COMPENSATORY ACCOUNT OF ALPHA-BAND REORGANIZATION WITH AGE.

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Anagh Pathak[1], Vivek Sharma[1], Dipanjan Roy[2], Arpan Banerjee[1]
[1]National Brain Research Centre, Neuroscience, gurgaon, India, [2]IIT Jodhpur, Neuroscience, Jodhpur, India

AIM: Healthy human ageing is marked by several changes in the properties of neuro-electrophysiological recordings. Some markers of ageing reflect underlying structural decline, while others signify secondary compensations that seek to minimize the deleterious consequences of structural loss. For example, white-matter changes are linked to reduced individual peak alpha frequency (IPAF) in ongoing EEG/MEG recordings. However, the causal relationship between white matter and IPAF slowing— whether adverse or compensatory— remains unknown. This work seeks to shed light on the mechanistic basis of frequency slowing with age. **METHOD:** First we analyze a large cohort of adult lifespan MEG data to test our compensatory hypothesis. Next, we employ computational modelling to suggest possible mechanisms of compensation. **RESULTS:** We show that phase-locking at the IPAF remains preserved while the IPAF slows with age. Subsequent in-silico modelling reveals that enhancing inter-areal coupling can cancel the effect of increased axonal transmission delays on network dynamics and preserve brain-wide synchrony at reduced synchronization frequency. **CONCLUSIONS:** Our results indicate that frequency slowing emerges from functional compensation in large-scale brain circuits rather than being a passive fallout of structural decline with age.

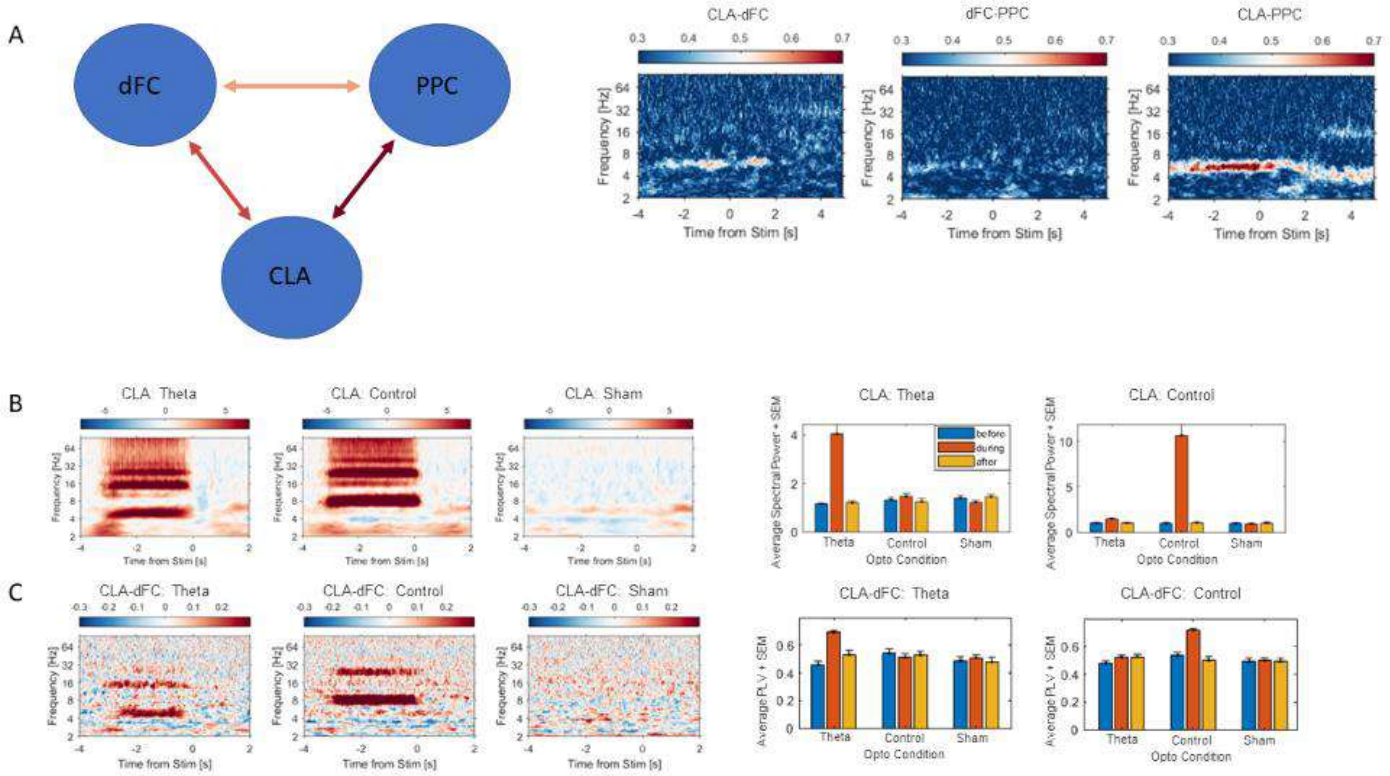
CAUSAL ROLE OF THE CLAUSTRUM IN COORDINATING THE DORSAL ATTENTION NETWORK DURING SUSTAINED ATTENTION

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Peyton Siekierski, Wei (Angel) Huang, Grace Ross, Qi Fang, Mengsen Zhang, Susanne Radtke-Schuller, Flavio Frohlich
University of North Carolina - Chapel Hill, Psychiatry, Chapel Hill, United States of America

The claustrum is a highly interconnected subcortical structure that has been posited to play a key role in higher order brain functions, such as attention and salience processing. The claustrum has reciprocal anatomical connections with the frontoparietal network which exhibits rhythmic synchronization during the top-down process sustained attention; however, the causal role of oscillations in the claustrum and their role in synchronizing cortical networks remains unknown. We investigated the functional connectivity of the claustrum, dorsal frontal cortex (dFC), and posterior parietal cortex (PPC) in ferrets during the five-choice serial reaction-time task (sustained attention task) by multisite electrophysiological recordings and optogenetic frequency-specific, excitatory stimulation (5 Hz for targeting peak functional connectivity, and 8 Hz as control) in the claustrum. Functional connectivity (CLA-PPC, CLA-dFC) exhibited a task-modulated theta (5 Hz) peak (Panel A). Optogenetic stimulation increased the targeted oscillation in the claustrum for both stimulation frequencies (theta: $F(2,42) = 62.99$, $p < 0.001$; control: $F(2,42) = 272.95$, $p < 0.001$, Panel B) and demonstrated frequency-specific engagement of the CLA-dFC connection (theta: $F(2,42) = 15.76$, $p < 0.001$; control: $F(2,42) = 183.90$, $p < 0.001$, Panel C). In contrast, only the theta stimulation increased behavioral performance by decreasing omission trials by 50% compared to control ($p=0.03$). Our results demonstrate that (1) functional connectivity of the claustrum with the frontoparietal network during a sustained attention task is mediated by theta oscillations and (2) theta oscillations in claustrum may play a causal role in increasing sustained attention by reducing

omissions.



(A) Functional connectivity in CLA-dFC-PPC network. (B) Optogenetic enhancement of oscillations (before, during, and after stimulation) and (C) Functional connectivity (Phase Locking Value, PLV).

Medial septal glutamatergic neurons are active during theta oscillation and locomotor activity. Prolonged optogenetic activation of medial septal glutamatergic neurons drives theta oscillation and locomotion for extended periods of time outlasting the stimulus duration. However, the cellular and circuit mechanisms supporting the maintenance of both theta oscillation and locomotion remain elusive. Specifically, it remains unclear whether theta-modulated stimulus of glutamatergic neurons is a necessary prerequisite for locomotion, and whether neuronal activity within the medial septum underlies its persistence. In the present study, we show that persistent theta oscillation can be induced in the hippocampus by a brief transient optogenetic activation of medial septal glutamatergic neurons. By blocking synaptic transmission pharmacologically in the medial septum, we observed persistent locomotion upon photoactivation of the glutamatergic neurons while theta oscillation was abolished in the hippocampus. We discovered persistent spiking of medial septal neurons that outlasts the stimulus for several seconds, both in vitro and in vivo. These results led to the conclusion that persistent activity is driven by the intrinsic excitability of medial septal glutamatergic neurons. Finally, using novel Neuropixels electrodes, we recorded a larger number of neurons and discuss how stimulus-evoked changes of a single cell type affects different groups of medial septum neurons, as well as their relation to theta rhythm and locomotion.

Single Bursts of Individual Granule Cells Functionally Rearrange Feedforward Inhibition.
The sparse single-spike activity of dentate gyrus granule cells (DG GCs) is punctuated by occasional brief bursts of 3-7 action potentials. It is well-known that such presynaptic bursts in individual mossy fibers (MFs; axons of granule cells) are often able to discharge postsynaptic CA3 pyramidal cells due to powerful short-term facilitation. However, what happens in the CA3 network after the passage of a brief MF burst, before the arrival of the next burst or solitary spike, is not understood. Because MFs innervate significantly more CA3 interneurons than pyramidal cells, we focused on unitary MF responses in identified interneurons in the seconds-long postburst period, using paired recordings in rat hippocampal slices. Single bursts as short as 5 spikes in <30 ms in individual presynaptic MFs caused a sustained, large increase (tripling) in the amplitude of the unitary MF-EPSCs for several seconds in ivy, axo-axonic/chandelier and basket interneurons. The postburst unitary MF-EPSCs in these feedforward interneurons reached amplitudes that were even larger than the MF-EPSCs during the bursts in the same cells. In contrast, no comparable postburst enhancement of MF-EPSCs could be observed in pyramidal cells or nonfeedforward interneurons. The robust postburst increase in MF-EPSCs in feedforward interneurons was associated with significant shortening of the unitary synaptic delay and large downstream increases in disynaptic IPSCs in pyramidal cells. These results reveal a new cell type-specific plasticity that enables even solitary brief bursts in single GCs to powerfully enhance inhibition at the DG-CA3 interface in the seconds-long time-scales of interburst intervals. The hippocampal formation is a brain region that plays key roles in spatial navigation and learning and memory. The first stage of information processing occurs in the dentate gyrus, where principal cells are remarkably quiet, discharging low-frequency single action potentials interspersed with occasional brief bursts of spikes. Such bursts, in particular, have attracted a lot of attention because they appear to be critical for efficient coding, storage, and recall of information. We show that single bursts of a few spikes in

individual granule cells result in seconds-long potentiation of excitatory inputs to downstream interneurons. Thus, while it has been known that bursts powerfully discharge ("detonate") hippocampal excitatory cells, this study clarifies that they also regulate inhibition during the interburst intervals.

CORTICO-HIPPOCAMPAL BILATERAL COHERENCE IS VARIABLE AND PATHWAY-SPECIFIC: A STUDY WITH FIELD POTENTIAL GENERATORS

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Sara Hernández Recio, Julia Samuseva, Oscar Herreras
Cajal Institute, Traslational Neuroscience, Madrid, Spain

Although most brain structures have one copy in each hemisphere growing evidence indicates that some perform unilaterally beyond the expected coordination of symmetric bodily functions. Particularly, imaging techniques show stronger unilateral activation of high order structures as the cortex and hippocampus. A detailed study will benefit from the unbeaten spatial and temporal resolution of pathway-specific field potentials (FPs). We recorded anesthetized rats with bilateral linear probes spanning the CA1 and Dentate Gyrus (DG). Evoked potentials served to localize the position of recordings. Pathway specific generators were obtained by Independent Component Analysis from depth series of FPs. This avoids strong distortion of FP waveforms from mutually contaminating pathways and uncovers true temporal dynamics. The activity of FP generators in both hemispheres was compared pairwise using cross-correlation and spectral coherence analyses. The cortical input to the DG (perforant pathway) showed intermingled bouts of high and low frequency gamma waves, some of which were bilateral and phase-locked, but others occurred in only one side. Abundant lateralized waves were observed. The FP generator in the stratum lacunosum-moleculare of the CA1 exhibited strong bilateral synchrony, whether it displayed theta or irregular activity. The CA3 input to CA1 showed tight bilateral synchrony during sharp-waves and some short bouts of gamma oscillations, but unilateral waves were frequent. These results indicate a complex bilateral organization of intrinsic and afferent hippocampal pathways that suggest time-varying and pathway-specific coordination of cortical and hippocampal regions. This mode of coordinated but independent operation may require re-defining current theories based on unilateral networks.

THE COACTIVATION OF NEURONS IN THE PREFRONTAL CORTICO-BASAL GANGLIA NETWORK DISTINGUISHES EFFORT, REWARD AND DECISION IN A NOVEL DECISION-MAKING TASK.

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Levels of effort and reward associated with a given behaviour are encoded by diverse populations of neurons across the forebrain, but it is unclear how this information is integrated across these brain areas for decision-making. In this study, animals were trained to decide whether or not to run to the end of a linear track with varying numbers of obstacles, to receive rewards of different sizes. This task allowed reward and effort to be manipulated independently. Behavioural data (n = 13) confirmed that increasing reward and effort were associated with a higher and lower probability of accepting the reward-effort offer, respectively. Electrophysiological recordings were made simultaneously across the prefrontal cortico-basal ganglia network (medial orbitofrontal cortex, anterior cingulate cortex, ventral pallidum, striatum and subthalamic nucleus) as rats performed this task. A machine learning strategy was used to identify neurons across this network with a statistically significant tendency to coactivate over short timescales (neural ensembles). The expression strengths of some identified coactivity patterns significantly distinguished the reward and effort offered to rats and/or their subsequent decisions on the task. The proportion of neurons in each structure that contributed to these ensembles was used to evaluate the contribution of different brain areas to reward and effort-based decisions. Coordinated activity across diverse populations of forebrain neurons may serve as a mechanism for encoding decision relevant information for effort-based decision making at the network level.

CHOLINERGIC INDUCTION OF SYNCHRONOUS OSCILLATION IN THE SLUG NEURONAL NETWORK IN VITRO.

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Suguru Kobayashi
Tokushima Bunri University, Kagawa School Of Pharmaceutical Sciences, Sanuki, Kagawa, Japan

Synchronous oscillatory network is important for cognitive functions of the brain in both vertebrates and invertebrates. In the central nervous system of the terrestrial slugs, spontaneous periodic oscillation (0.5 - 1.0 Hz) is recorded from the surface of the laminar structure of procerebrum (PC), and its frequency changes are suggested to encode the olfactory information and memory. We recently found oscillatory activity is generated spontaneously in dispersed cell culture of PC neurons. Application of acetylcholinesterase inhibitor or nicotine induced synchronous oscillation in *in vitro* network activity. To investigate how such synchronous oscillation is generated, we tested cholinergic activation and compared between synchronous and asynchronous networks. Previous results showed that acetylcholine could be function as a driving force on the synchronous oscillatory activity of the PC neuron network via nicotinic acetylcholine receptors activation *in vivo*. In present study, differences between synchronous and asynchronous network were examined in cultured PC neuron (7-21 days). First, we found a lower excitability and a higher sensibility to cholinergic activation of PC neurons in synchronous networks. Second, muscarinic receptor agonist, pilocarpine, did not induce synchronous oscillation and did not occlude the effects of physostigmine. It is suggested that: (1) *in vitro* synchronous oscillation was induced by activation of cholinergic synaptic transmission via nicotinic ACh receptors; (2) "synchronous *in vitro* networks" were characterized by higher ACh-sensitivity (than "asynchronous networks") together with the lateral inhibition of excessive activity in resting states.

INCLUDING THE LATERAL HABENULA IN THE STRESS-RELATED FUNCTIONAL NETWORK

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Laura Durieux[1], Karine Herbeaux[2], Monique Majchrzak[2], Nelson Totah[3], Lucas Lecourtier[2]
[1]Université of Strasbourg, Lnca Umr7364, Strasbourg, France, [2]Université of Strasbourg/ CNRS, Lnca Umr7364, Strasbourg, France, [3]University of Helsinki, Hilife, Helsinki Institute Of Lifescience And School Of Pharmacy, Helsinki, Finland

Aims: Stressful experiences induce cellular activation and engage specific plasticity mechanisms and gene expression within the lateral habenula (LHb), providing good insight into stress-related events in this structure. However, little is known about the place of the LHb within the broad network engaged during these types of experiences. **Methods:** Using restraint stress in male Long-Evans rats we performed two studies: one including a single 10-min restraint session and graph theory-based analyses of network activation following c-Fos immunostaining throughout the brain; one including local field potential recordings in the LHb before, during, and following two 3 hours apart 10-min restraint sessions. For the later study we focused our analyses on the different sleep-wake stages. **Results:** Graph theory-based analyses indicated that upon restraint LHb activation correlated with this of the medial prefrontal cortex (mPFC), lateral septum and medial habenula. In addition, the LHb belonged to a community (group of structures sharing more functional connections than with the others) including the mPFC, amygdala, periventricular hypothalamus and midbrain monoaminergic regions. During the electrophysiology experiment, rats could be clustered into two groups based on the intensity of their behavioral response to the first restraint (high and low responders); preliminary analyses revealed in the LHb, following the second restraint, decreased theta (6-9Hz) power during active wake in low responders, and decreased delta (1-3Hz) power during slow-wave sleep in high responders. **Conclusion:** Our results include the LHb in the broad stress-response network and suggest differential implication of LHb oscillations during coping with repeated stressful experience.

Involvement of the lateral habenula in fear memory.
Increasing evidence points to the engagement of the lateral habenula (LHb) in the selection of appropriate behavioral responses in aversive situations. However, very few data have been gathered with respect to its role in fear memory formation, especially in learning paradigms in which brain areas involved in cognitive processes like the hippocampus (HPC) and the medial prefrontal cortex (mPFC) are required. A paradigm of this sort is trace fear conditioning, in which an aversive event is preceded by a discrete stimulus, generally a tone, but without the close temporal contiguity allowing for their association based on amygdala-dependent information processing. In a first experiment, we analyzed cellular activations (c-Fos expression) induced by trace fear conditioning in subregions of the habenular complex, HPC, mPFC and amygdala using a factorial analysis to unravel functional networks through correlational analysis of data. This analysis suggested that distinct LHb subregions engaged in different aspects of conditioning, e.g. associative processes and onset of fear responses. In a second experiment, we performed chemogenetic LHb inactivation during the conditioning phase of the trace fear conditioning paradigm and subsequently assessed contextual and tone fear memories. Whereas LHb inactivation did not modify rat's behavior during conditioning, it induced contextual memory deficits and enhanced fear to the tone. These results demonstrate the involvement of the LHb in fear memory. They further suggest that the LHb is engaged in learning about threatening environments through the selection of relevant information predictive of a danger.

ALTERED NEURONAL SPATIOTEMPORAL DYNAMICS AND SENSORY INFORMATION PROCESSING BY ACTIVATION OF CORTICAL ASTROCYTE NETWORK

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Claudia Miguel-Quesada, Salvador Herrera, Marta Zaforas, Elena Fernández-López, Elena Alonso-Calviño, Juan Aguilar, Juliana M Rosa
Hospital Nacional de Parapléjicos, Experimental Neurophysiology And Neuronal Circuits, Toledo, Spain

The extraction of behaviouraly relevant sensory information at cortical levels is only possible due to the interaction of parallel neuronal circuitries. However, it is now clear that glial cells, especially astrocytes, form a second network capable to set the basis by which neuronal output is defined in time and space. Here, we used a combination of *in/ex vivo* electrophysiology, behaviour and genetic tools to explored how changes in the spatiotemporal patterns of astrocytic networks alter the integration and processing of sensory information at cellular, network and behavioral level. Our data show that up-regulation of astrocytic network by using Gfap-hMD3q-DREADD increased the duration of spontaneous network synchronization while decreasing the neuronal excitability at cortical level. Such effect was mediated by an enhanced activity of the inhibitory GABAergic transmission onto excitatory pyramidal neurons as shown by whole cell patch clamp recordings. In addition, altered astrocytic network also decreased the strength and propagation of spontaneous activity across layers of the somatosensory cortex, which strongly influenced the processing of sensory information. By using electrical stimulation of hindlimb, we found that Gfap-hM3Dq-DREADD mice exhibited decreased gain of evoked-potentials in response to high-stimulus intensity in L4/5/6 neurons. The altered excitability at cellular and network level was further corroborated at behavior level in which hM3Dq-DREADD mice exhibited increased threshold for temperature response in the hot plate assessment. These results indicate that changes in the spatiotemporal patterns astrocytic network strongly influence the integration and processing of sensory information at cortical levels with consequences to behavior output.

ROLE OF SST+ INTERNEURONS SCULPING DEVELOPMENTAL DYNAMICS

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Laura Modol-Vidal, Oscar Marín
King's College London, Centre For Developmental Neurobiology, London, United Kingdom

Spontaneous coordinated neuronal activity is a hallmark of the developing brain and plays a pivotal role in the formation of neuronal circuits. In contrast, how the interaction between different cell types leads to the complex formation of functional networks remains poorly understood. GABAergic interneurons critically contribute to cortical development starting from neurogenesis and migration, to activity-dependent circuit refinement. Particularly, SST+ interneurons (a subclass of interneurons derived from the medial ganglionic eminence (MGE)), have been suggested to play a prominent role in modulating the functional wiring of early cortical circuits. SST+ cells are among the first type of interneurons to populate and mature within the cortex. However, how these pioneer cells integrate into functional circuits and influence the flow of spontaneous and evoked activity during postnatal development, remains unknown. In this study, we address this issue using a combination of in vivo volumetric and longitudinal calcium imaging in the barrel cortex, to monitor the integration of SST+ cells into functional circuits and their role modulating cortical dynamics at different stages of postnatal development.

GABAergic Restriction of Network Dynamics Regulates Interneuron Survival in the Developing Cortex.
During neonatal development, sensory cortices generate spontaneous activity patterns shaped by both sensory experience and intrinsic influences. How these patterns contribute to the assembly of neuronal circuits is not clearly understood. Using longitudinal in vivo calcium imaging in un-anesthetized mouse pups, we show that spatially segregated functional assemblies composed of interneurons and pyramidal cells are prominent in the somatosensory cortex by postnatal day (P) 7. Both reduction of GABA release and synaptic inputs onto pyramidal cells erode the emergence of functional topography, leading to increased network synchrony. This aberrant pattern effectively blocks interneuron apoptosis, causing increased survival of parvalbumin and somatostatin interneurons. Furthermore, the effect of GABA on apoptosis is mediated by inputs from medial ganglionic eminence (MGE)-derived but not caudal ganglionic eminence (CGE)-derived interneurons. These findings indicate that immature MGE interneurons are fundamental for shaping GABA-driven activity patterns that balance the number of interneurons integrating into maturing cortical networks.

Assemblies of Perisomatic GABAergic Neurons in the Developing Barrel Cortex.
The developmental journey of cortical interneurons encounters several activity-dependent milestones. During the early postnatal period in developing mice, GABAergic neurons are transient preferential recipients of thalamic inputs and undergo activity-dependent migration arrest, wiring, and programmed cell-death. Despite their importance for the emergence of sensory experience and the role of activity in their integration into cortical networks, the collective dynamics of GABAergic neurons during that neonatal period remain unknown. Here, we study coordinated activity in GABAergic cells of the mouse barrel cortex using in vivo calcium imaging. We uncover a transient structure in GABAergic population dynamics that disappears in a sensory-dependent process. Its building blocks are anatomically clustered GABAergic assemblies mostly composed by prospective parvalbumin-expressing cells. These progressively widen their territories until forming a uniform perisomatic GABAergic network. Such transient patterning of GABAergic activity is a functional scaffold that links the cortex to the external world prior to active exploration. VIDEO ABSTRACT.

Spatial Embryonic Origin Delineates GABAergic Hub Neurons Driving Network Dynamics in the Developing Entorhinal Cortex.
Coordinated neuronal activity is essential for the development of cortical circuits. GABAergic hub neurons that function in

orchestrating early neuronal activity through a widespread net of postsynaptic partners are therefore critical players in the establishment of functional networks. Evidence for hub neurons was previously found in the hippocampus, but their presence in other cortical regions remains unknown. We examined this issue in the entorhinal cortex, an initiation site for coordinated activity in the neocortex and for the activity-dependent maturation of the entire entorhinal-hippocampal network. Using an unbiased approach that identifies "driver hub neurons" displaying a high number of functional links in living slices, we show that while almost half of the GABAergic cells single-handedly influence network dynamics, only a subpopulation of cells born in the MGE and composed of somatostatin-expressing neurons located in infragranular layers, spontaneously operate as "driver" hubs. This indicates that despite differences in the origin of interneuron diversity, the hippocampus and entorhinal cortex share similar developmental mechanisms for the establishment of functional circuits.

NKCC1 Activation Is Required for Myelinated Sensory Neurons Regeneration through JNK-Dependent Pathway.
After peripheral nerve injury, axons are able to regenerate, although specific sensory reinnervation and functional recovery are usually worse for large myelinated than for small sensory axons. The mechanisms that mediate the regeneration of different sensory neuron subpopulations are poorly known. The Na(+)-K(+)-Cl(-) cotransporter 1 (NKCC1) is particularly relevant in setting the intracellular chloride concentration. After axotomy, increased NKCC1 phosphorylation has been reported to be important for neurite outgrowth of sensory neurons; however, the mechanisms underlying its effects are still unknown. In the present study we used in vitro and in vivo models to assess the differential effects of blocking NKCC1 activity on the regeneration of different types of dorsal root ganglia (DRGs) neurons after sciatic nerve injury in the rat. We observed that blocking NKCC1 activity by bumetanide administration induces a selective effect on neurite outgrowth and regeneration of myelinated fibers without affecting unmyelinated DRG neurons. To further study the mechanism underlying NKCC1 effects, we also assessed the changes in mitogen-activated protein kinase (MAPK) signaling under NKCC1 modulation. The inhibition of NKCC1 activity in vitro and in vivo modified pJNK1/2/3 expression in DRG neurons. Together, our study identifies a mechanism selectively contributing to myelinated axon regeneration, and point out the role of Cl(-) modulation in DRG neuron regeneration and in the activation of MAPKs, particularly those belonging to the JNK family.

Neonatal allopregnanolone or finasteride administration modifies hippocampal K(+) Cl(-) co-transporter expression during early development in male rats.
The maintenance of levels of endogenous neurosteroids (NS) across early postnatal development of the brain, particularly to the hippocampus, is crucial for their maturation. Allopregnanolone (Allop) is a NS that exerts its effect mainly through the modulation of the GABAA receptor (GABAAR). During early development, GABA, acting through GABAAR, that predominantly produces depolarization shifts to hyperpolarization in mature neurons, around the second postnatal week in rats. Several factors contribute to this change including the progressive increase of the neuron-specific K(+)/Cl(-) co-transporter 2 (KCC2) (a chloride exporter) levels. Thus, we aimed to analyze whether a different profile of NS levels during development is critical and can alter this natural progression of KCC2 stages. We administrated sustained Allop (20mg/kg) or Finasteride (5α-reductase inhibitor, 50mg/kg) from the 5th postnatal day (PD5) to PD9 and assessed changes in the hippocampal expression of KCC2 at transcript and protein levels as well as its active phosphorylated state in male rats. Taken together data indicated that manipulation of NS levels during early development influence KCC2 levels and point out the importance of neonatal NS levels for the hippocampal development.
J Steroid Biochem Mol Biol, 2014; 143
24813295: Mòdol L, Cobianchi S, Navarro X
Prevention of NKCC1 phosphorylation avoids downregulation of KCC2 in central sensory pathways and reduces neuropathic pain after peripheral nerve injury.
Neuropathic pain after peripheral nerve injury is characterized by loss of inhibition in both peripheral and central pain pathways. In the adult nervous system, the Na(+)-K(+)-2Cl(-) (NKCC1) and neuron-specific K(+)-Cl(-) (KCC2) cotransporters are involved in setting the strength and polarity of GABAergic/glycinergic transmission. After nerve injury, the balance between these cotransporters changes, leading to a decrease in the inhibitory tone. However, the role that NKCC1 and KCC2 play in pain-processing brain areas is unknown. Our goal was to study the effects of peripheral nerve injury on NKCC1 and KCC2 expression in dorsal root ganglia (DRG), spinal cord, ventral posterolateral (VPL) nucleus of the thalamus, and primary somatosensory (S1) cortex. After sciatic nerve section and suture in adult rats, assessment of mechanical and thermal pain thresholds showed evidence of hyperalgesia during the following 2 months. We also found an increase in NKCC1 expression in the DRG and a downregulation of KCC2 in spinal cord after injury, accompanied by later decrease of KCC2 levels in higher projection areas (VPL and S1) from 2 weeks postinjury, correlating with neuropathic pain signs. Administration of bumetanide (30 mg/kg) during 2 weeks following sciatic nerve lesion prevented the previously observed changes in the spinothalamic

tract projecting areas and the appearance of hyperalgesia. In conclusion, the present results indicate that changes in NKCC1 and KCC2 in DRG, spinal cord, and central pain areas may contribute to development of neuropathic pain.

Differential effects on KCC2 expression and spasticity of ALS and traumatic injuries to motoneurons.
Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease manifested by progressive muscle atrophy and paralysis due to the loss of upper and lower motoneurons (MN). Spasticity appears in ALS patients leading to further disabling consequences. Loss of the inhibitory tone induced by downregulation of the potassium chloride cotransporter 2 (KCC2) in MN has been proposed to importantly contribute to the spastic behavior after spinal cord injury (SCI). The aim of the present study was to test whether the alterations in the expression of KCC2 are linked to the appearance of spasticity in the SOD(G93A) ALS murine model. We compared SOD(G93A) mice to wild type mice subjected to SCI to mimic the spinal MN disconnection from motor descending pathways, and to sciatic nerve lesion to mimic the loss of MN connectivity to muscle. Electrophysiological results show that loss of motor function is observed at presymptomatic stage (8 weeks) in SOD(G93A) mice but hyperreflexia and spasticity do not appear until a late stage (16 weeks). However, KCC2 was not downregulated despite MN suffered disconnection both from muscles and upper MNs. Further experiments revealed decreased gephyrin expression, as a general marker of inhibitory systems, accompanied by a reduction in the number of Renshaw interneurons. Moreover, 5-HT fibers were increased in the ventral horn of the lumbar spinal cord at late stage of disease progression in SOD1(G93A) mice. Taken together, the present results indicate that spasticity appears late in the ALS model, and may be mediated by a decrease in inhibitory interneurons and an increase of 5-HT transmission, while the absence of down-regulation of KCC2 could rather indicate an inability of MNs to respond to insults.

Neonatal finasteride administration alters hippocampal α4 and δ GABAAR subunits expression and behavioural responses to progesterone in adult rats.
Allopregnanolone is a neurosteroid that has been reported to fluctuate during early developmental stages. Previous experiments reported the importance of neonatal endogenous allopregnanolone levels for the maturation of the central nervous system and particularly for the hippocampus. Changes in neonatal allopregnanolone levels have been related to altered adult behaviour and with psychopathological susceptibility, including anxiety disorders, schizophrenia and drug abuse. However, the mechanism underlying these changes remains to be elucidated. In the present study we assessed changes in hippocampal expression of α4 and δ GABAA receptor (GABAAR) subunits as a consequence of neonatal finasteride (a 5-α reductase inhibitor) administration during early development (PD6 to PD15) in male rats. We observed that the treatment altered the temporal window of the natural peak in the expression of these subunits during development. Additionally, the level of these subunits were higher than in non-handled and control animals in the adult hippocampus. We observed that in adulthood, neonatal finasteride-treated animals presented an anxiogenic-like profile in response to progesterone administration which was absent in the rest of the groups. In conclusion, these results corroborate the relevance of neonatal maintenance of neurosteroid levels for behavioural anxiety responses in the adult, and point to some of the mechanisms involved in this alterations.

Alteration of neonatal Allopregnanolone levels affects exploration, anxiety, aversive learning and adult behavioural response to intrahippocampal neurosteroids.
Neurosteroids (NS) are well known to exert modulatory effects on ionotropic receptors. Recent findings indicate that NS could also act as important factors during development. In this sense, neonatal modifications of Allopregnanolone (Allop) levels during critical periods have been demonstrate to alter the morphology of the hippocampus but also other brain structures. The aim of the present work is to screen whether the alterations of Allop levels modify adult CA1 hippocampal response to NS administration. For this purpose, pups were injected with Allop (20 mg/kg s.c.), Finasteride (5α-reductase inhibitor that impedes Allop synthesis) (50 mg/kg s.c.) or Vehicle from postnatal day 5 (P5) to postnatal day 9 (P9). NS levels were tested at P5. To test the behavioural hippocampal response to NS in adulthood, animals were implanted with a bilateral cannula into the CA1 hippocampus at 80 days old and injected with Allop (0.2 µg/0.5 µl), Pregnenolone sulphate (5 ng/0.5 µl) or Vehicle in each hippocampus. After injections animals were tested in the Boisser test to assess exploratory behaviour, the elevated plus maze to assess anxiety and the passive avoidance to test aversive learning. Results indicate that alteration of neonatal Allop or pregnenolone levels (by Allop and Finasteride administration, respectively) suppressed intrahippocampal Allop anxiolytic effect in the EPM. Moreover our results also indicate that manipulation of neonatal Allop levels (Allop and Finast administration) alters exploratory and anxiety-like behaviour and impairs aversive learning in the adulthood. These data point out the role of Allop in the maturation of hippocampal function and behaviour.

Behav Brain Res, 2013; 241
21463656: Mòdol L, Darbra S, Pallarès M
Neurosteroids infusion into the CA1 hippocampal region on exploration, anxiety-like behaviour and aversive learning.
Neurosteroids (NS) are substances synthesised de novo in the brain that have rapid modulatory effects on ionotropic receptors. Specifically, NS can act as positive allosteric modulators of GABAA receptors as pregnanolone or allopregnanolone (Allop), or GABAA negative modulators and NMDA positive modulators as pregnenolone (PREG) or dehydroepiandrosterone (DHEA) and their sulphate esters (PREGS and DHEAS). Given this, their role in anxiety and emotional disturbances has been suggested. In addition, NS such as PREGS or DHEAS have demonstrated a promnesic role in several learning tests. The aim of the present work is to highlight the role that the dorsal (CA1) hippocampus plays in the behavioural profile of NS such as Allop and PREGS in tests assessing exploration, anxiety and aversive learning in rats. For this purpose, animals were administered intrahippocampally with Allop (0.2µg/0.5µl), PREGS (5ng/0.5µl) or vehicle in each hippocampus, and tested in the Boissier and elevated plus maze (EPM) tests. For learning test we have chosen the passive avoidance paradigm. Results indicate that intrahippocampal administration of Allop enhances exploration, reflected in an increase in the total and the inner number of head-dips. Allop-injected animals also showed an increase in the percentage of entries into the open arms of the EPM, suggesting an anxiolytic-like profile. In addition, post-acquisition PREGS administration enhanced passive avoidance retention, while post-acquisition Allop administration had no effects on aversive learning retention. These results point out the important role of the dorsal (CA1) hippocampus in several NS behavioural effects, such as exploration, anxiety, learning and memory.

THETA OSCILLATIONS AS A MECHANISM FOR COMMUNICATION BETWEEN CORTICAL SENSORY AREAS, PERIRHINAL CORTEX AND HIPPOCAMPUS DURING SENSORY DETECTION AND MEMORY RECOLLECTION.

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Thijs Ruikes[1], Julien Fiorilli[1], Gerjan Huis In 'T Veld[1], Jan Bjaalie[2], Ingrid Reiten[3], Cyriel Pennartz[4]

Memory consolidation and recall have been suggested to be driven by coordinated oscillatory activity, such as Hippocampal (HC) theta oscillations, of neuronal ensembles during memory-guided, spatial behaviour. Although multiple studies have demonstrated entrainment of neural assemblies on the hippocampal theta cycle (Vinck et al., 2016) , few investigations have investigated this phenomenon in brain-wide circuits by means of simultaneous multi-area ensemble recordings from distant regions. Additionally, it remains debatable which behavioural parameters most prominently relate to brain-wide coordinated oscillatory entrainment (Mizuseki & Buzsaki, 2014). Here we investigate coherency driven by oscillations between HC and the Visual (V2L), Somatosensory Barrel (S1BF) and Perirhinal (PER) cortices. These areas are interlinked trough anatomical projections and thought to form a cortical hierarchy facilitating the incorporation of sensory information into episodic memory (van Strien et al., 2009). Using a 36-tetrode hyperdrive, we recorded neural activity from four areas (V2, S1BF, PER, HC) simultaneously in freely behaving rats doing a multimodal–two alternative forced choice–object recognition task on a T-maze. The rats were shown one out of two objects under either tactile, visual or multimodal conditions and were rewarded if they responded on the arm of the T-maze associated with the object. Using the pairwise phase consistency we found increased spike-field coherency between HC theta cycles and neurons recorded in V2L (n=310), BR (n=118), PER (n=194) and HC (n=139), during behavioural epochs of sensory detection and memory recollection. Our results highlight the differences in processing between areas S1BF,V2L, PER and HC during the utilization of episodic memory.

HIGH-DENSITY MULTIELECTRODE ARRAY RECORDINGS REVEAL COMPUTATIONAL COMPLEXITY IN CEREBELLAR CORTICAL PROCESSING

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Alessandra Ottaviani[1], Thierry Neius[2], Anita Monteverdi[3], Yuhe Li[1], Lisa Mapelli[1], Marcello Massimini[2], Egidio D'Angelo[1,3]

The cerebellar cortex has a prominent forward architecture that was interpreted as a predictor of low complexity of spatiotemporal activities compared to the cerebral cortex. However, the complexity of the cerebellar responses has never been assessed experimentally. We quantified the *complexity* of the spatiotemporal responses to mossy-fibers (mfs) stimulation in mouse acute cerebellar slices with the Perturbational Complexity Index (PCI), an index which has been used to summarize the richness of TMS/EEG spatiotemporal patterns in conscious/unconscious human subjects. We computed PCI with an adapted version of the original PCI algorithm, applied to neuronal activity recorded using a high-density multielectrode array (HD–MEA), to study the cerebellar cortical processing at different activity ranges. The *complexity* of granule cells (GrC) layer and PCs responses was quantified for different mfs stimulation frequencies. Our data revealed that PCI increased with the stimulation frequency and it was more pronounced in coronal slices, presumably due to the intense spread of activity along the parallel fibres, with the involvement of molecular layer interneurons (MLI) filtering in shaping PC output. PCI for the GrC and PC populations revealed that complexity in the cerebellar circuit changes dynamically with orientation of the signal flow, revealing that PCs contribution is strikingly different in the sagittal and coronal planes, contrary to GrCs. Finally, the analysis of the temporal and spatial correlation of PCs firing completed the characterization of PCs contribution to shaping the features of the whole network.

Cerebellar Golgi cell models predict dendritic processing and mechanisms of synaptic plasticity.
The Golgi cells are the main inhibitory interneurons of the cerebellar granular layer. Although recent works have highlighted the complexity of their dendritic organization and synaptic inputs, the mechanisms through which these neurons integrate complex input patterns remained unknown. Here we have used 8 detailed morphological reconstructions to develop multicompartmental models of Golgi cells, in which Na, Ca, and K channels were distributed along dendrites, soma, axonal initial segment and axon. The models faithfully reproduced a rich pattern of electrophysiological and pharmacological properties and predicted the operating mechanisms of these neurons. Basal dendrites turned out to be more tightly electrically coupled to the axon initial segment than apical dendrites. During synaptic transmission, parallel fibers caused slow Ca-dependent depolarizations in apical dendrites that boosted the axon initial segment encoder and Na-spike backpropagation into basal dendrites, while inhibitory synapses effectively shunted backpropagating currents. This oriented dendritic processing set up a coincidence detector controlling voltage-dependent NMDA receptor unblock in basal dendrites, which, by regulating local calcium influx, may provide the basis for spike-timing dependent plasticity anticipated by theory.

ATTENTIONAL EFFECTS EMBEDDED IN LARGE-SCALE SYNCHRONIZED NETWORKS

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Julien Vezoli[1], André Bastos[1,2], Conrado Bosman[3], Henry Kennedy[4,5], Pascal Fries[1,6]
[1]Ernst Strüngmann Institute (ESI) for Neuroscience in cooperation with the Max Planck Society, Fries Lab, Frankfurt am Main, Germany, [2]Vanderbilt University, Psychological Sciences, Nashville, United States of America, [3]Swammerdam Institute for Life Sciences, Center For Neuroscience, Faculty Of Science, Amsterdam, Netherlands, [4]Inserm U1208, Stem Cell And Brain Research Institute, Bron, France, [5]Institute of Neuroscience, Chinese Academy of Sciences, Key Laboratory Of Primate Neurobiology, Shanghai, China, [6]Donders Institute for Brain, Cognition, and Behaviour, Radboud University, Nijmegen, Netherlands

We recently demonstrated that rhythmic neuronal oscillations form spatially distinct functional modules that are frequency-dependent but independent of oscillatory power (Vezoli et al., Neuron 2021). Here, we explore this functional heterogeneity with respect to inter-areal anatomical connectivity and in the context of attention. In particular, we explored attentional effects on the strength of rhythmic synchronizations for distinct frequency-specific networks. Two monkeys were trained to perform a visual attention task that required selectively responding to changes to a cued stimulus, while ignoring changes to the uncued stimulus. Recordings were made through high-density micro-electrocorticogram (micro-ECoG) electrode arrays implanted subdurally allowing simultaneous recordings of over 16 interconnected cortical areas distributed across occipital to prefrontal cortices. Attentional effects were characterized by contrasting trials in which the attended stimulus was presented in the hemifield contra- or ipsilateral to the recorded hemisphere (Attend controlateral vs. Attend ipsilateral) across four frequency-bands of interest (theta, beta, high-beta and gamma). This showed that the strength of top-down anatomical projections predicts the strength of attention effects at the top-down targets. We then investigated how rhythm-specific functional interaction networks subserve attention, and show that gamma- and beta-band networks display enhanced interareal influences when mediating behaviorally relevant signals whereas theta- and high-beta-band networks displayed mixed attentional effects. We discuss the implications of these attentional effects on the engagement of both top-down and bottom-up networks in hierarchical processing. JV, AMB and CAB contributed equally

Brain-Computer Interfaces (BCIs) constitute a promising tool, but mastering non-invasive BCI remains a poorly-understood learned skill (1), since the underlying brain processes and their reflection on brain signals are unknown. Brain dynamic is characterized by aperiodic perturbations (i.e. "Neuronal Avalanches") (2) preferentially spreading across the white-matter bundles (3). Different avalanche dynamics might underlie different behaviors. To test our hypothesis we applied the neuronal avalanches approach to MEG data recorded in 19 subjects (aged 28.1 3.6 years, 11 men) during a motor-imagery-based BCI training session (6). We characterized dynamics using avalanche transition matrices (ATM), containing the probability that region j would be active at time t+1 when region i was active at time t. Then, for each subject, we compared the ATMs for the two experimental conditions (Fig. 1). Our results show that all the significantly different edges cluster upon a limited number of brain regions. In particular, the premotor areas appear to differ, bilaterally, between the conditions. The involvement is prominent to the left. Furthermore, the cunei bilaterally are also shown to differ between the two conditions, which might be related to the role these regions play in visual processing. In conclusion, selectively focusing on higher-order dynamics, we pinpointed the regions whose recruitment is affected by the execution of a motor imagery task. Our results suggest that avalanches capture functionally-relevant processes of interest for alternative BCI designing.

Innate behaviours are vital for survival, however the neural dynamics that terminate and initiate them promptly are elusive. It is unclear whether the lateral hypothalamus (LH), a key region for the maintenance of innate behaviours, also codes for their progression. LH neurons change their firing rate according to behaviours and the timing of neuronal discharge during network oscillations according to the activity in afferent and efferent regions can be instrumental for engagement in innate behaviours. Here, using electrophysiological recordings in behaving mice, neural decoding, and optogenetics, we studied the dynamics of the neural circuitry entailing LH that underlies engagement in feeding and exploratory behaviours. We investigated the timing of LH neurons during network oscillations, including those in the gamma band (>30 Hz), during food intake and exploration. The timing of neuronal discharge during oscillations was found to be sufficient to reliably decode a relative stage of innate behaviours by the Support Vector Machines. We studied the behavioural necessity of this code using optogenetic re-entrainment of inhibition to LH cells and stimulation of excitatory inputs, and found opposing effects of these manipulations on behavioural progressions. Probabilistic modelling revealed interdependencies between behaviours in their sequential organization. Our results highlight the role of short-time-scale interactions in the organization of hypothalamic information processing and in the regulation of multiple innate behaviours, dysfunctions of which underlie some major neuropsychiatric disorders. Place fields of single spikes in hippocampus involve Kcnq3 channel-dependent entrainment of complex spike bursts. Hippocampal pyramidal cells encode an animal's location by single action potentials and complex spike bursts. These elementary signals are believed to play distinct roles in memory consolidation. The timing of single spikes and bursts is determined by intrinsic excitability and theta oscillations (5-10 Hz). Yet contributions of these dynamics to place fields remain elusive due to the lack of methods for specific modification of burst discharge. In mice lacking Kcnq3-containing M-type K channels, we find that pyramidal cell bursts are less coordinated by the theta rhythm than in controls during spatial navigation, but not alert immobility. Less modulated bursts are followed by an intact post-burst pause of single spike firing, resulting in a temporal discoordination of network oscillatory and intrinsic excitability. Place fields of single spikes in one- and two-dimensional environments are smaller in the mutant. Optogenetic manipulations of upstream signals reveal that neither medial septal GABA-ergic nor cholinergic inputs alone, but rather their joint activity, is required for entrainment of bursts. Our results suggest that altered representations by bursts and single spikes may contribute to deficits underlying cognitive disabilities associated with KCNQ3-mutations in humans.

LOCAL DYNAMICS AND DISTANT INTERACTIONS BETWEEN MEDIAL AND LATERAL PREFRONTAL CORTEX DURING PERFORMANCE MONITORING

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Clément Goussi-Dejean, Vincent Fontanier, Emmanuel Procyk
Inserm, U1208, Bron, France

Flexible cognition relies on flexible information processing and on dynamical interactions between multiple brain structures. Neural dynamics in and between medial and lateral frontal areas in primates reflect some aspects of flexible information processing, however the detailed mechanisms and dynamics of regional interactions during flexible decision making are still unknown. We acquired and analysed a unique set of simultaneous recordings in the lateral prefrontal cortex and midcingulate cortex in macaques using couples of linear probes. Monkeys performed a 3-arm bandit probabilistic task interacting with a realistic target design (skeuomorphic design) on a touchscreen, a task in which monkeys relied on negative and positive outcomes to make decisions. We analysed the local field potentials from 83 recordings with dual 16 contacts probes, as well as 2827 isolated units recorded across MCC and LPFC regions. We showed that while both LPFC and MCC encoded feedback with sustained coding bridging successive trials, MCC was recruited first and more strongly than LPFC. In addition, Granger causality measures revealed that for a majority of site couples, MCC signals forecasted LPFC, rarely the reverse. These preliminary analyses provide important evidence supporting a model of MCC driving LPFC at the time of adaptation.

From the perspective of synaptic input and spiking output, a morphologically complex neuron is (almost) equivalent to a single output multilayered artificial neural network. However, it is not known if they can perform equivalent computations. Recently Bicknell and Hausser (2021) showed that a single neuron of complex morphology can be trained to distinguish different synaptic patterns which previously were considered to require multilayer neural networks. Here, using the method of Bicknell and Hausser, we study minimal computational models of a dendritic tree trained on a classification task that requires complex, nonlinear computations. We show which aspects of dendritic morphology and synaptic locations influence feature differentiation and how to select them optimally. Bicknell, B. A., & Häusser, M. (2021). A synaptic learning rule for exploiting nonlinear dendritic computation. *Neuron*, *109*(24), 4001-4017.

CHARACTERIZATION OF BRAIN NETWORKS USING FUNCTIONAL ULTRASOUND IMAGING

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Flora Nelissen, Lorenzo De Angelis, Camilo Rojas, Christian Keysers, Valeria Gazzola
Netherlands Institute for Neuroscience, Social Brain Lab, Amsterdam, Netherlands

Aims We often feel bad when witnessing a painful scene, because observing an emotion of a conspecific triggers the same emotion in the observer (Lorenz, 1935; Han et al., 2019). This phenomenon, emotional contagion, has been observed in humans and other species, including rodents (Meyza et al., 2017). Human fMRI studies identified the involved brain circuitry, encompassing several brain regions (Gu et al., 2010). In rodents, invasive techniques can inform on single cell responses and specific connections (Carrillo et al., 2019), but identifying the whole circuit remains difficult. To validate social animal models and gain insight into the evolution of emotional contagion, we need the ability to read-out emotional circuitries in rodents and compare them to those found in humans. By using, as for fMRI, blood flow changes as indirect measure of brain activity, Functional Ultrasound Imaging (fUSI) can bridge this gap, by allowing imaging of big volumes of the brain of awake rodents (Macé et al., 2018). We started with a validation study. **Methods** Using a 128-channels linear ultrasound probe, 2D images of the mouse brain were acquired at Bregma -3 mm during presentation of 25 20 second drifting black-and-white gratings. **Results** Correlation analyses showed increased blood flow with stimulus presentation in the expected regions: the superior colliculi and primary visual cortices. Additionally, the signal was stronger for the contra-lateral hemisphere during stimulation of one eye. **Conclusions** These results show we are able to perform reliable fUSI experiments.

IS THE WHOLE BRAIN CRITICAL?

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Zoia Kharybina[1], Henrike Hartung[1,2], Tomi Taira[1]
[1]University of Helsinki, Faculty Of Veterinary Medicine, Helsinki, Finland, [2]University of Helsinki, Neuroscience Center, Helsinki, Finland

An increasing body of evidence suggests that healthy brain operates near critical state. Scale-free distributions of neuronal avalanches, the hallmark of criticality, have been described in cortical networks in a variety of species. Yet, the avalanche dynamics in deeper brain structures has remained unelucidated. Here we describe neural avalanches in the amygdala in comparison with the prefrontal cortex in the developing brain using *in vivo* multielectrode recordings in urethane anaesthetized juvenile rats (postnatal days 14-15). Scale-free statistics of neural avalanches in the cortex are expressed in power-law avalanche size distributions with cut-off corresponding to the maximum number of recording sites as also found in our study. However, in the amygdala the cut-off was preceded by a sharp peak at the maximum number of recording sites, meaning that the avalanches spanning over all the electrodes were most abundant in the amygdala. Smaller decay exponents indicated that small avalanches are less prevalent in the amygdala than in the cortex. We further characterized the spread of activity by calculating branching ratio. In critical systems the mean branching ratio is close to one. In line with previous findings in cortical networks, our results show that it is true for the prefrontal cortex whereas avalanches in the amygdala are characterized by higher branching ratio. Taken together, our results suggest that in the amygdala, unlike in the cortex, activity tends to stretch rapidly over the whole region indicating supercritical state.

GluA4 Dependent Plasticity Mechanisms Contribute to Developmental Synchronization of the CA3-CA1 Circuitry in the Hippocampus.
During the course of development, molecular mechanisms underlying activity-dependent synaptic plasticity change considerably. At immature CA3-CA1 synapses in the hippocampus, PKA-driven synaptic insertion of GluA4 AMPA receptors is the predominant mechanism for synaptic strengthening. However, the physiological significance of the developmentally restricted GluA4-dependent plasticity mechanisms is poorly understood. Here we have used microelectrode array (MEA) recordings in GluA4 deficient slice cultures to study the role of GluA4 in early development of the hippocampal circuit function. We find that during the first week in culture (DIV2-6) when GluA4 expression is restricted to pyramidal neurons, loss of GluA4 has no effect on the overall excitability of the immature network, but significantly impairs synchronization of the CA3 and CA1 neuronal populations. In the absence of GluA4, the temporal correlation of the population spiking activity between CA3-CA1 neurons was significantly lower as compared to wild-types at DIV6. Our data show that synapse-level defects in transmission and plasticity mechanisms are efficiently compensated for to normalize population firing rate at the immature hippocampal network. However, lack of the plasticity mechanisms typical for the immature synapses may perturb functional coupling between neuronal sub-populations, a defect frequently implicated in the context of developmentally originating neuropsychiatric disorders.

SPATIALLY CONFINED OPTOGENETIC PERTURBATIONS IN THE MOUSE MOTOR CORTEX FOR DECOMPOSING LOCAL FIELD POTENTIALS

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Andreas Genewsky, Anton Sirota
Ludwig-Maximilians-Universität München, Biozentrum; Dep. Biologie Ii, Planegg-Martinsried, Germany

Subdural micro electrocorticography (µECoG) arrays capture the superimposed electrical activity of ionic processes in the brain volume beneath. Compared to electroencephalography (EEG) recordings, µECoGs offer a higher spatial resolution and broader frequency range and thus allow a more sensitive readout of the spatio-temporal network dynamics, while remaining minimally invasive compared to intracortical electrodes. Therefore, µECoG recordings possess a great translational potential for the development of brain-computer interfaces (BCIs) and neuroprosthesis. However, a major caveat in interpreting µECoG data is the limited understanding of the physiological origin of the surface local field potential (LFP). The efficiency of future BCIs based on the decoding of ECoG data, requires a profound understanding of the cellular and morphological contribution of different signal sources to the LFP and the advantages of high-density µECoG recordings for the identification of intracortical dynamics. In order to overcome this drawback, we apply joint depth (Neuropixels) and high-resolution µECoG array recordings in the motor cortex of awake and behaving head-fixed mice which where trained to run through a virtual linear track while their 3D paw position was reconstructed using DeepLabCut. This approach allows linking the ongoing cortical dynamics across all layers with the surface LFP. Further, we apply depth-controlled optogenetic modulation of distinct layers of a cortical column using tapered optical fibers and soma-targeted opsins in order to address one isolated laminar source at a time and interrogate its contribution to the depth and surface LFP in a causal manner.

Coordinated waves of gene expression during neuronal differentiation of embryonic stem cells as basis for novel approaches to developmental neurotoxicity testing.
As neuronal differentiation of embryonic stem cells (ESCs) recapitulates embryonic neurogenesis, disturbances of this process may model developmental neurotoxicity (DNT). To identify the relevant steps of in vitro neurodevelopment, we implemented a differentiation protocol yielding neurons with desired electrophysiological properties. Results from focussed transcriptional profiling suggested that detection of non-cytotoxic developmental disturbances triggered by toxicants such as retinoic acid (RA) or cyclopamine was possible. Therefore, a broad transcriptional profile of the 20-day differentiation process was obtained. Cluster analysis of expression kinetics, and bioinformatic identification of overrepresented gene ontologies revealed waves of regulation relevant for DNT testing. We further explored the concept of superimposed waves as descriptor of ordered, but overlapping biological processes. The initial wave of transcripts indicated reorganization of chromatin and epigenetic changes. Then, a transient upregulation of genes involved in the formation and patterning of neuronal precursors followed. Simultaneously, a long wave of ongoing neuronal differentiation started. This was again superseded towards the end of the process by shorter waves of neuronal maturation that yielded information on specification, extracellular matrix formation, disease-associated genes and the generation of glia. Short exposure to lead during the final differentiation phase, disturbed neuronal maturation. Thus, the wave kinetics and the patterns of neuronal specification define the time windows and end points for examination of DNT.

Rapid, complete and large-scale generation of post-mitotic neurons from the human LUHMES cell line.
We characterized phenotype and function of a fetal human mesencephalic cell line (LUHMES, Lund human mesencephalic) as neuronal model system. Neurodevelopmental profiling of the proliferation stage (d0, day 0) of these conditionally-immortalized cells revealed neuronal features, expressed simultaneously with some early neuroblast and stem cell markers. An optimized 2-step differentiation procedure, triggered by shut-down of the myc transgene, resulted in uniformly post-mitotic neurons within 5 days (d5). This was associated with down-regulation of some precursor markers and further up-regulation of neuronal genes. Neurite network formation involved the outgrowth of 1-2, often > 500 µm long projections. They showed

dynamic growth cone behavior, as evidenced by time-lapse imaging of stably GFP-over-expressing cells. Voltage-dependent sodium channels and spontaneous electrical activity of LUHMES continuously increased from d0 to d11, while levels of synaptic markers reached their maximum on d5. The developmental expression patterns of most genes and of the dopamine uptake- and release-machinery appeared to be intrinsically predetermined, as the differentiation proceeded similarly when external factors such as dibutyryl-cAMP and glial cell derived neurotrophic factor were omitted. Only tyrosine hydroxylase required the continuous presence of cAMP. In conclusion, LUHMES are a robust neuronal model with adaptable phenotype and high value for neurodevelopmental studies, disease modeling and neuropharmacology.

Activation of endogenously expressed ion channels by active complement in the retinal pigment epithelium.
Defective regulation of the alternative pathway of the complement system is believed to contribute to damage of retinal pigment epithelial (RPE) cells in age-related macular degeneration. Thus we investigated the effect of complement activation on the RPE cell membrane by analyzing changes in membrane conductance via patch-clamp techniques and Ca(2+) imaging. Exposure of human ARPE-19 cells to complement-sufficient normal human serum (NHS) (25 %) resulted in a biphasic increase in intracellular free Ca(2+) ([Ca(2+)]i); an initial peak followed by sustained Ca(2+) increase. C5- or C7-depleted sera did not fully reproduce the signal generated by NHS. The initial peak of the Ca(2+) response was reduced by sarcoplasmic Ca(2+)-ATPase inhibitor thapsigargin, L-type channel blockers (R)-(+)-BayK8644 and isradipine, transient-receptor-potential (TRP) channel blocker ruthenium-red and ryanodine receptor blocker dantrolene. The sustained phase was carried by CaV1.3 L-type channels via tyrosine-phosphorylation. Changes in [Ca(2+)]I were accompanied by an abrupt hyperpolarization, resulting from a transient increase in membrane conductance, which was absent under extracellular Ca(2+)- or K(+)-free conditions and blocked by (R)-(+)-BayK8644 or paxilline, a maxiK channel inhibitor. Single-channel recordings confirmed the contribution of maxiK channels. Primary porcine RPE cells responded to NHS in a comparable manner. Pre-incubation with NHS reduced H2O2-induced cell death. In summary, in a concerted manner, C3a, C5a and sC5b-9 increased [Ca(2+)]i by ryanodine-receptor-dependent activation of L-type channels in addition to maxi-K channels and TRP channels absent from any insertion of a lytic pore.

Local Optogenetic Induction of Fast (20-40 Hz) Pyramidal-Interneuron Network Oscillations in the In Vitro and In Vivo CA1 Hippocampus: Modulation by CRF and Enforcement of Perirhinal Theta Activity.
The neurophysiological processes that can cause theta-to-gamma frequency range (4-80 Hz) network oscillations in the rhinal cortical-hippocampal system and the potential connectivity-based interactions of such forebrain rhythms are a topic of intensive investigation. Here, using selective Channelrhodopsin-2 (ChR2) expression in mouse forebrain glutamatergic cells, we were able to locally, temporally precisely, and reliably induce fast (20-40 Hz) field potential oscillations in hippocampal area CA1 in vitro (at 25°C) and in vivo (i.e., slightly anesthetized NEX-Cre-ChR2 mice). As revealed by pharmacological analyses and patch-clamp recordings from pyramidal cells and GABAergic interneurons in vitro, these light-triggered oscillations can exclusively arise from sustained suprathreshold depolarization (~200 ms or longer) and feedback inhibition of CA1 pyramidal neurons, as being mandatory for prototypic pyramidal-interneuron network (P-I) oscillations. Consistently, the oscillations comprised rhythmically occurring population spikes (generated by pyramidal cells) and their frequency increased with increasing spectral power. We further demonstrate that the optogenetically driven CA1 oscillations, which remain stable over repeated evocations, are impaired by the stress hormone corticotropin-releasing factor (CRF, 125 nM) in vitro and, even more remarkably, found that they are accompanied by concurrent states of enforced theta activity in the memory-associated perirhinal cortex (PrC) in vivo. The latter phenomenon most likely derives from neurotransmission via a known, but poorly studied excitatory CA1→PrC pathway. Collectively, our data provide evidence for the existence of a prototypic (CRF-sensitive) P-I gamma rhythm generator in area CA1 and suggest that CA1 P-I oscillations can rapidly up-regulate theta activity strength in hippocampus-innervated rhinal networks, at least in the PrC.

Enhanced anandamide signaling reduces flight behavior elicited by an approaching robo-beetle.
Our current knowledge of the implications of endocannabinoids in fear and anxiety is largely based on fear conditioning paradigms and approach-avoidance conflicts. Here we establish the ethobehavioral beetle mania task (BMT), which confronts mice with an erratically moving robo-beetle. With the help of this task we demonstrate decreased tolerance yet increased avoidance responses to an approaching beetle in high-anxiety behavior (HAB) and BALBc mice compared to C57BL/6N, CD1 and normal-anxiety behavior (NAB) mice. Also DBA/2N mice showed decreased passive and increased active behavior, but followed the robo-beetle more often than HAB and BALBc mice. Treatment with diazepam (1 mg/kg) increased tolerance without affecting avoidance behavior in HAB mice. Treatment with the MAGL inhibitor JZL184 (8 mg/kg) increased flight

behavior, but did not affect tolerance. The FAAH inhibitor URB597 (0.3 mg/kg), however, reduced flight behavior and enhanced tolerance to the robo-beetle. The latter effects were blocked by co-treatment with the CB1 receptor antagonist SR141716A (3 mg/kg), which failed to affect the behavior by itself. Taken together, we validate the BMT as a novel test for studying endocannabinoids beyond traditional paradigms and for assessing active fear responses in mice. Furthermore, we demonstrate panicolytic consequences of pharmacological enhancement of anandamide, but not 2-AG signaling.

The Endocannabinoid System Differentially Regulates Escape Behavior in Mice.
Among the behaviors, fear or survival responses certainly belong to the most evolutionary conserved ones. However, higher animals possess the ability to adapt to certain environments (e.g., novel foraging grounds), and, therefore, those responses need to be plastic. Previous studies revealed a cell-type specific role of the endocannabinoid system in novelty fear, conditioned fear and active vs. passive avoidance in a shuttle box paradigm. In this study we aim to investigate, whether knocking-out the cannabinoid receptor type-1 (CB1) on cortical glutamatergic (Glu-CB1) or GABAergic (GABA-CB1) neurons differentially affects the level of behavioral inhibition, which could ultimately lead to differences in escape behavior. In this context, we developed a novel behavioral paradigm, the (MWB). Using the MWB task we could show that Glu-CB1 mice have higher levels of behavioral inhibition over the course of repeated testing. GABA-CB1 mice, in contrast, showed significantly lower levels of behavioral inhibition compared to wild-type controls and more escape behavior. These changes in behavioral inhibition and escape behavior cannot be explained by altered levels of arousal, as repeated startle measurements revealed general habituation irrespective of the line and genotype of the animals. Taken together, we could show that CB1 on cortical glutamatergic terminals is important for the acquisition of active avoidance, as the absence of CB1 on these neurons creates a bias toward inhibitory avoidance. This is the case in situations without punishment such as electric footshocks. On the contrary CB1 receptors on GABAergic neurons mediate the acquisition of passive avoidance, as the absence of CB1 on those neurons establishes a strong bias toward escape behavior.

A simplified microwave-based motion detector for home cage activity monitoring in mice.
Locomotor activity of rodents is an important readout to assess well-being and physical health, and is pivotal for behavioral phenotyping. Measuring homecage-activity with standard and cost-effective optical methods in mice has become difficult, as modern housing conditions (e.g. individually ventilated cages, cage enrichment) do not allow constant, unobstructed, visual access. Resolving this issue either makes greater investments necessary, especially if several experiments will be run in parallel, or is at the animals' expense. The purpose of this study is to provide an easy, yet satisfying solution for the behavioral biologist at novice makers level.

29786085: Dedic N, Kühne C, Jakovcevski M, Hartmann J, Genewsky AJ, Gomes KS, Anderzhanova E, Pöhlmann ML, Chang S, Kolarz A, Vogl AM, Dine J, Metzger MW, Schmid B, Almada RC, Ressler KJ, Wotjak CT, Grinevich V, Chen A, Schmidt MV, Wurst W, Refojo D, Deussing JM
Chronic CRH depletion from GABAergic, long-range projection neurons in the extended amygdala reduces dopamine release and increases anxiety.
The interplay between corticotropin-releasing hormone (CRH) and the dopaminergic system has predominantly been studied in addiction and reward, while CRH-dopamine interactions in anxiety are scarcely understood. We describe a new population of CRH-expressing, GABAergic, long-range-projecting neurons in the extended amygdala that innervate the ventral tegmental area and alter anxiety following chronic CRH depletion. These neurons are part of a distinct CRH circuit that acts anxiolytically by positively modulating dopamine release.

Stimulation of the Nigrotectal Pathway at the Level of the Superior Colliculus Reduces Threat Recognition and Causes a Shift From Avoidance to Approach Behavior.
Defensive behavioral responses are essential for survival in threating situations. The superior colliculus (SC) has been implicated in the generation of defensive behaviors elicited by visual, tactile and auditory stimuli. Furthermore, substantia nigra pars reticulata (SNr) neurons are known to exert a modulatory effect on midbrain tectum neural substrates. However, the functional role of this nigrotectal pathway in threating situations is still poorly understood. Using optogenetics in freely behaving mice, we activated SNr projections at the level of the SC, and assessed consequences on behavioral performance in an open field test (OFT) and the beetle mania task (BMT). The latter confronts a mouse with an erratic moving robo-beetle and allows to measure active and passive defensive responses upon frequent encounter of the threatening object. Channelrhodopsin-2 (ChR2)-mediated activation of the inhibitory nigrotectal pathway did not affect anxiety-like and

exploratory behavior in the OFT, but increased the number of contacts between robo-beetle and test mouse in the BMT. Depending on the size of the arena, active avoidance responses were reduced, whereas tolerance and close following of the robo-beetle were significantly increased. We conclude from the data that the nigrotectal pathway plays holds the potential to modulate innate fear by attenuating threat recognition and causing a shift from defensive to approach behavior.

The stress susceptibility factor FKBP51 controls S-ketamine-evoked release of mBDNF in the prefrontal cortex of mice.
We report here the involvement of the stress-responsive glucocorticoid receptor co-chaperone FKBP51 in the mechanism of secretion of mature BDNF (mBDNF). We used a novel method combining brain microdialysis with a capillary electrophoresis-based immunoassay, to examine mBDNF secretion in the medial prefrontal cortex (mPFC) in freely moving mice. By combining optogenetic, neurochemical (KCl-evoked depolarization), and transgenic (conditional BDNF knockout mice) means, we have shown that the increase in extracellular mBDNF is determined by neuronal activity. Withal, mBDNF secretion in the mPFC of mice was stimulated by a systemic administration of S-ketamine (10 or 50 mg/kg) or S-hydroxynorketamine (10 mg/kg). KCl- and S-ketamine-evoked mBDNF secretion was strongly dependent on the expression of FKBP51. Moreover, the inability of S-ketamine to evoke a transient secretion in mBDNF in the mPFC in FKBP51- knockout mice matched the lack of antidepressant-like effect of S-ketamine in the tail suspension test. Our data reveal a critical role of FKBP51 in mBDNF secretion and suggest the involvement of mBDNF in the realization of immediate stress-coping behavior induced by acute S-ketamine.

CORTICAL NEURONAL ASSEMBLIES COORDINATE WITH EEG MICROSTATE DYNAMICS DURING RESTING WAKEFULNESS

POSTER SESSION 05 - SECTION: NEURONAL INTERACTIONS AND SYNCHRONIZATION

Richard Boyce, Robin Dard, Rosa Cossart
INSERM, Inmed, Umr1249, Marseille, France

Cortical assemblies have been studied in the context of sensory processing, learning, and memory. However, their relation to conscious experience and dynamics across different natural vigilance states remain poorly understood despite their disruption being associated with induced loss of consciousness. To help address this gap in our knowledge, we employed 2-photon calcium imaging of sensorimotor cortex across the full sleep-wake cycle in a head-fixed mouse model. We found no difference in the structural characteristics of assemblies occurring during quiet wakefulness (QW), NREMs, or REMs, despite the latter two vigilance states being associated with significantly reduced levels of consciousness. To determine whether association of local assembly activity with macroscale brain dynamics could help explain this lack of consistent difference between assembly structure in wake versus sleep states, we combined the above imaging techniques with global EEG microstate analysis derived from multi-EEG recordings. When directly compared, evidence of a significant coordination between global EEG microstate dynamics and local cortical assembly activity was found during periods of resting wakefulness, but not sleep. These results suggest that the coordination of cortical assembly activity with global brain dynamics could be a key factor of sustained conscious experience and that a disengagement of local assemblies with global brain states occurs during sleep. More generally, this data suggests that EEG microstates could be an important mechanism for promoting coordination and temporary binding between local activity patterns in physically segregated neural populations in the awake resting brain.

NEURONAL MECHANISMS OF VISUO-TACTILE INTEGRATION IN MOUSE ASSOCIATIVE CORTICES

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Maëlle Guyoton, Giulio Matteucci, Lucile Favero, Sami El-Boustani
University of Geneva, Department Of Basic Neuroscience, Geneva, Switzerland

Objects are defined by physical properties that can stimulate different sensory modalities. Multisensory integration (MI) refers to the neural computations that transform signals originating from distinct sensory systems into a unified multimodal representation. However, the cortical circuits involved in producing coherent perceptual experiences of multimodal stimuli remain largely unexplored. In the mouse posterior parietal cortex, the rostrolateral area (RL) of the primary visual cortex (V1) receives direct inputs from both V1 and the primary somatosensory cortex but it is not clear if this is the siege of all visuo-tactile processing. We investigated how visuo-tactile signals are mapped in associative cortical regions and how these representations are used during goal-directed behaviours. Transgenic mice expressing fluorescent calcium indicator GCaMP6f in superficial cortical layers were implanted with a cranial window covering the left posterior hemisphere, providing a large optical access to somatosensory and visual cortical areas. Combining wide-field and two-photon calcium imaging, we recorded at both population and single-cell level in head-fixed mice during passive exposure to combinations of visuo-tactile stimuli. Calcium signals evoked by these stimulations helped to identify non-linear summations of visual and tactile responses in several cortical territories with different functional organizations. We further developed a Go/No-Go visuo-tactile discrimination paradigm where mice were trained to report perceptions of simultaneous visual and tactile stimuli while ignoring unisensory stimuli. We observed that mice exhibited frequent switches between strategies favouring specific sensory modalities during the task. These results illustrate how multiple cortical regions are involved in visuo-tactile MI and potentially support flexible visuo-tactile decision-making.

POSITION ESTIMATION AT VARYING SENSORY CONFLICTS IN THE HIPPOCAMPUS

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Andrey Sobolev[1], Evgeny Resnik[2], Dustin Fetterhoff[3], Kay Thurley[3], Christian Leibold[4], Anton Sirota[5]
[1]Ludwig-Maximilians University, Neurobiology, Planegg-Martinsried, Germany, [2]Ludwig-Maximilians University, Cognition And Neural Plasticity, Planegg-Martinsried, Germany, [3]Ludwig-Maximilians University, Computational Neuroscience, Planegg-Martinsried, Germany, [4]Albert-Ludwigs University Freiburg, Theoretical Systems Neuroscience, Freiburg, Germany, [5]Ludwig Maximillian University Munchen, Biology Ii, Planegg, Germany

Estimation of an actual location in space involves simultaneous assessment of information coming from different sensory systems. Multiple behavioral studies demonstrated that independent estimations given by different sensory modalities are combined in an optimal manner. Moreover, while integration of coherent estimations increases response precision, it is reasonable to abandon a less reliable estimation if it is highly conflicting with others. The neural correlates of these mechanisms are still not fully described. We asked if position estimation performed by the hippocampal place cells follows these principles. Using the freely-moving 3D virtual reality for rodents we introduced a translational conflict between the virtual visual and the physical boundary-defined reference frames involved in position estimation and recorded hippocampal neural population in freely-foraging gerbils. Most of the place cells represented position using a weighted combination of sensory estimations, consistent with the concepts of the optimal coding framework. As a population, hippocampal neurons showed mixed representation of both reference frames, balanced between visual and physical environmental geometry depending on the proximity to the boundary and saliency of the visual stimulus. The activity of place fields in small / large conflicts followed the integration / abandonment of position estimations predicted by behavioral studies. Integration of the conflicting sensory information was continuous and led to recalibration of the hippocampal map, producing a new, morphed spatial representation. Finally, patterns of animal behavior parallelled resolution of the conflict predicted by the hippocampal representation in all conflicting conditions connecting altered spatial perception and the corresponding navigation in a mixed environment.

Graded remapping of hippocampal ensembles under sensory conflicts.
Hippocampal place cells are thought to constitute a cognitive map of space derived from multimodal sensory inputs. Alteration of allocentric (visual) cues in a fixed environment is known to induce modulations of place cell activity to varying degrees from rate changes to global remapping. To determine how hippocampal ensembles combine multimodal sensory cues, we examine hippocampal CA1 remapping in Mongolian gerbils in a 1D virtual reality experiment, during which self-motion cues (locomotor, vestibular, and optic flow information) and allocentric visual cues are altered. We observe that self-motion cues are over-represented, but responsiveness to allocentric visual cues, although task-irrelevant, elicits both rate and global remapping in the hippocampal ensemble. We propose that remapping can be reconciled by considering global, partial, and rate remapping on a continuous scale on which the graded change of activity in the entire CA1 population can be interpreted as the expectancy about the animal's spatial environment.

Integrated platform and API for electrophysiological data.
Recent advancements in technology and methodology have led to growing amounts of increasingly complex neuroscience data recorded from various species, modalities, and levels of study. The rapid data growth has made efficient data access and flexible, machine-readable data annotation a crucial requisite for neuroscientists. Clear and consistent annotation and organization of data is not only an important ingredient for reproducibility of results and re-use of data, but also essential for collaborative research and data sharing. In particular, efficient data management and interoperability requires a unified approach that integrates data and metadata and provides a common way of accessing this information. In this paper we describe GNData, a data management platform for neurophysiological data. GNData provides a storage system based on a data representation that is suitable to organize data and metadata from any electrophysiological experiment, with a

functionality exposed via a common application programming interface (API). Data representation and API structure are compatible with existing approaches for data and metadata representation in neurophysiology. The API implementation is based on the Representational State Transfer (REST) pattern, which enables data access integration in software applications and facilitates the development of tools that communicate with the service. Client libraries that interact with the API provide direct data access from computing environments like Matlab or Python, enabling integration of data management into the scientist's experimental or analysis routines.

Data management routines for reproducible research using the G-Node Python Client library.
Structured, efficient, and secure storage of experimental data and associated meta-information constitutes one of the most pressing technical challenges in modern neuroscience, and does so particularly in electrophysiology. The German INCF Node aims to provide open-source solutions for this domain that support the scientific data management and analysis workflow, and thus facilitate future data access and reproducible research. G-Node provides a data management system, accessible through an application interface, that is based on a combination of standardized data representation and flexible data annotation to account for the variety of experimental paradigms in electrophysiology. The G-Node Python Library exposes these services to the Python environment, enabling researchers to organize and access their experimental data using their familiar tools while gaining the advantages that a centralized storage entails. The library provides powerful query features, including data slicing and selection by metadata, as well as fine-grained permission control for collaboration and data sharing. Here we demonstrate key actions in working with experimental neuroscience data, such as building a metadata structure, organizing recorded data in datasets, annotating data, or selecting data regions of interest, that can be automated to large degree using the library. Compliant with existing de-facto standards, the G-Node Python Library is compatible with many Python tools in the field of neurophysiology and thus enables seamless integration of data organization into the scientific data workflow.

Sensory Island Task (SIT): A New Behavioral Paradigm to Study Sensory Perception and Neural Processing in Freely Moving Animals.
A central function of sensory systems is the gathering of information about dynamic interactions with the environment during self-motion. To determine whether modulation of a sensory cue was externally caused or a result of self-motion is fundamental to perceptual invariance and requires the continuous update of sensory processing about recent movements. This process is highly context-dependent and crucial for perceptual performances such as decision-making and sensory object formation. Yet despite its fundamental ecological role, voluntary self-motion is rarely incorporated in perceptual or neurophysiological investigations of sensory processing in animals. Here, we present the Sensory Island Task (SIT), a new freely moving search paradigm to study sensory processing and perception. In SIT, animals explore an open-field arena to find a sensory target relying solely on changes in the presented stimulus, which is controlled by closed-loop position tracking in real-time. Within a few sessions, animals are trained via positive reinforcement to search for a particular area in the arena ("target island"), which triggers the presentation of the target stimulus. The location of the target island is randomized across trials, making the modulated stimulus feature the only informative cue for task completion. Animals report detection of the target stimulus by remaining within the island for a defined time ("sit-time"). Multiple "non-target" islands can be incorporated to test psychometric discrimination and identification performance. We exemplify the suitability of SIT for rodents (Mongolian gerbil,) and small primates (mouse lemur,) and for studying various sensory perceptual performances (auditory frequency discrimination, sound source localization, visual orientation discrimination). Furthermore, we show that pairing SIT with chronic electrophysiological recordings allows revealing neuronal signatures of sensory processing under ecologically relevant conditions during goal-oriented behavior. In conclusion, SIT represents a flexible and easily implementable behavioral paradigm for mammals that combines self-motion and natural exploratory behavior to study sensory sensitivity and decision-making and their underlying neuronal processing.

27486397: Zehl L, Jaillet F, Stoewer A, Grewe J, Sobolev A, Wachtler T, Brochier TG, Riehle A, Denker M, Grün S
Handling Metadata in a Neurophysiology Laboratory.
To date, non-reproducibility of neurophysiological research is a matter of intense discussion in the scientific community. A crucial component to enhance reproducibility is to comprehensively collect and store metadata, that is, all information about the experiment, the data, and the applied preprocessing steps on the data, such that they can be accessed and shared in a consistent and simple manner. However, the complexity of experiments, the highly specialized analysis workflows and a lack of knowledge on how to make use of supporting software tools often overburden researchers to perform such a detailed documentation. For this reason, the collected metadata are often incomplete, incomprehensible for outsiders or ambiguous.

Based on our research experience in dealing with diverse datasets, we here provide conceptual and technical guidance to overcome the challenges associated with the collection, organization, and storage of metadata in a neurophysiology laboratory. Through the concrete example of managing the metadata of a complex experiment that yields multi-channel recordings from monkeys performing a behavioral motor task, we practically demonstrate the implementation of these approaches and solutions with the intention that they may be generalized to other projects. Moreover, we detail five use cases that demonstrate the resulting benefits of constructing a well-organized metadata collection when processing or analyzing the recorded data, in particular when these are shared between laboratories in a modern scientific collaboration. Finally, we suggest an adaptable workflow to accumulate, structure and store metadata from different sources using, by way of example, the odML metadata framework.

Neo: an object model for handling electrophysiology data in multiple formats.
Neuroscientists use many different software tools to acquire, analyze and visualize electrophysiological signals. However, incompatible data models and file formats make it difficult to exchange data between these tools. This reduces scientific productivity, renders potentially useful analysis methods inaccessible and impedes collaboration between labs. A common representation of the core data would improve interoperability and facilitate data-sharing. To that end, we propose here a language-independent object model, named "Neo," suitable for representing data acquired from electroencephalographic, intracellular, or extracellular recordings, or generated from simulations. As a concrete instantiation of this object model we have developed an open source implementation in the Python programming language. In addition to representing electrophysiology data in memory for the purposes of analysis and visualization, the Python implementation provides a set of input/output (IO) modules for reading/writing the data from/to a variety of commonly used file formats. Support is included for formats produced by most of the major manufacturers of electrophysiology recording equipment and also for more generic formats such as MATLAB. Data representation and data analysis are conceptually separate: it is easier to write robust analysis code if it is focused on analysis and relies on an underlying package to handle data representation. For that reason, and also to be as lightweight as possible, the Neo object model and the associated Python package are deliberately limited to representation of data, with no functions for data analysis or visualization. Software for neurophysiology data analysis and visualization built on top of Neo automatically gains the benefits of interoperability, easier data sharing and automatic format conversion; there is already a burgeoning ecosystem of such tools. We intend that Neo should become the standard basis for Python tools in neurophysiology.

PROPRIOCEPTIVE DEFICITS AND VISUAL COMPENSATION IN STROKE PATIENTS: A THEORETICAL APPROACH TO REINTERPRET UPPER-LIMB SENSORY ASSESSMENTS.

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Jules Bernard-Espina, Mathieu Beraneck, Marc Maier, Michele Tagliabue
Université de Paris, CNRS, Incc, Umr8002, Paris, France

Aim: Recent findings suggest that, when reaching or grasping an object, sensory information is encoded in multiple, parallel reference frames. For example, in some proprioceptive assessments, such as the thumb localization task with eyes closed, proprioceptive signals tend to be re-encoded in visual-space. The process of re-encoding sensory signals, from proprioceptive to visual space, is referred to as “cross-reference transformation”. We propose to apply this concept to the study of proprioceptive deficits post-stroke, distinguishing between proprioceptive inputs available for a given assessment, and the potential cross-reference transformations that ensue during task execution. **Methods and Results:** We reviewed and reinterpreted the outcomes of the most common tests used to assess proprioceptive function in stroke survivors. We identified four main categories of clinical tests, each characterized by a specific processing of proprioceptive signals that may, or may not be re-encoded in different sensory spaces (see

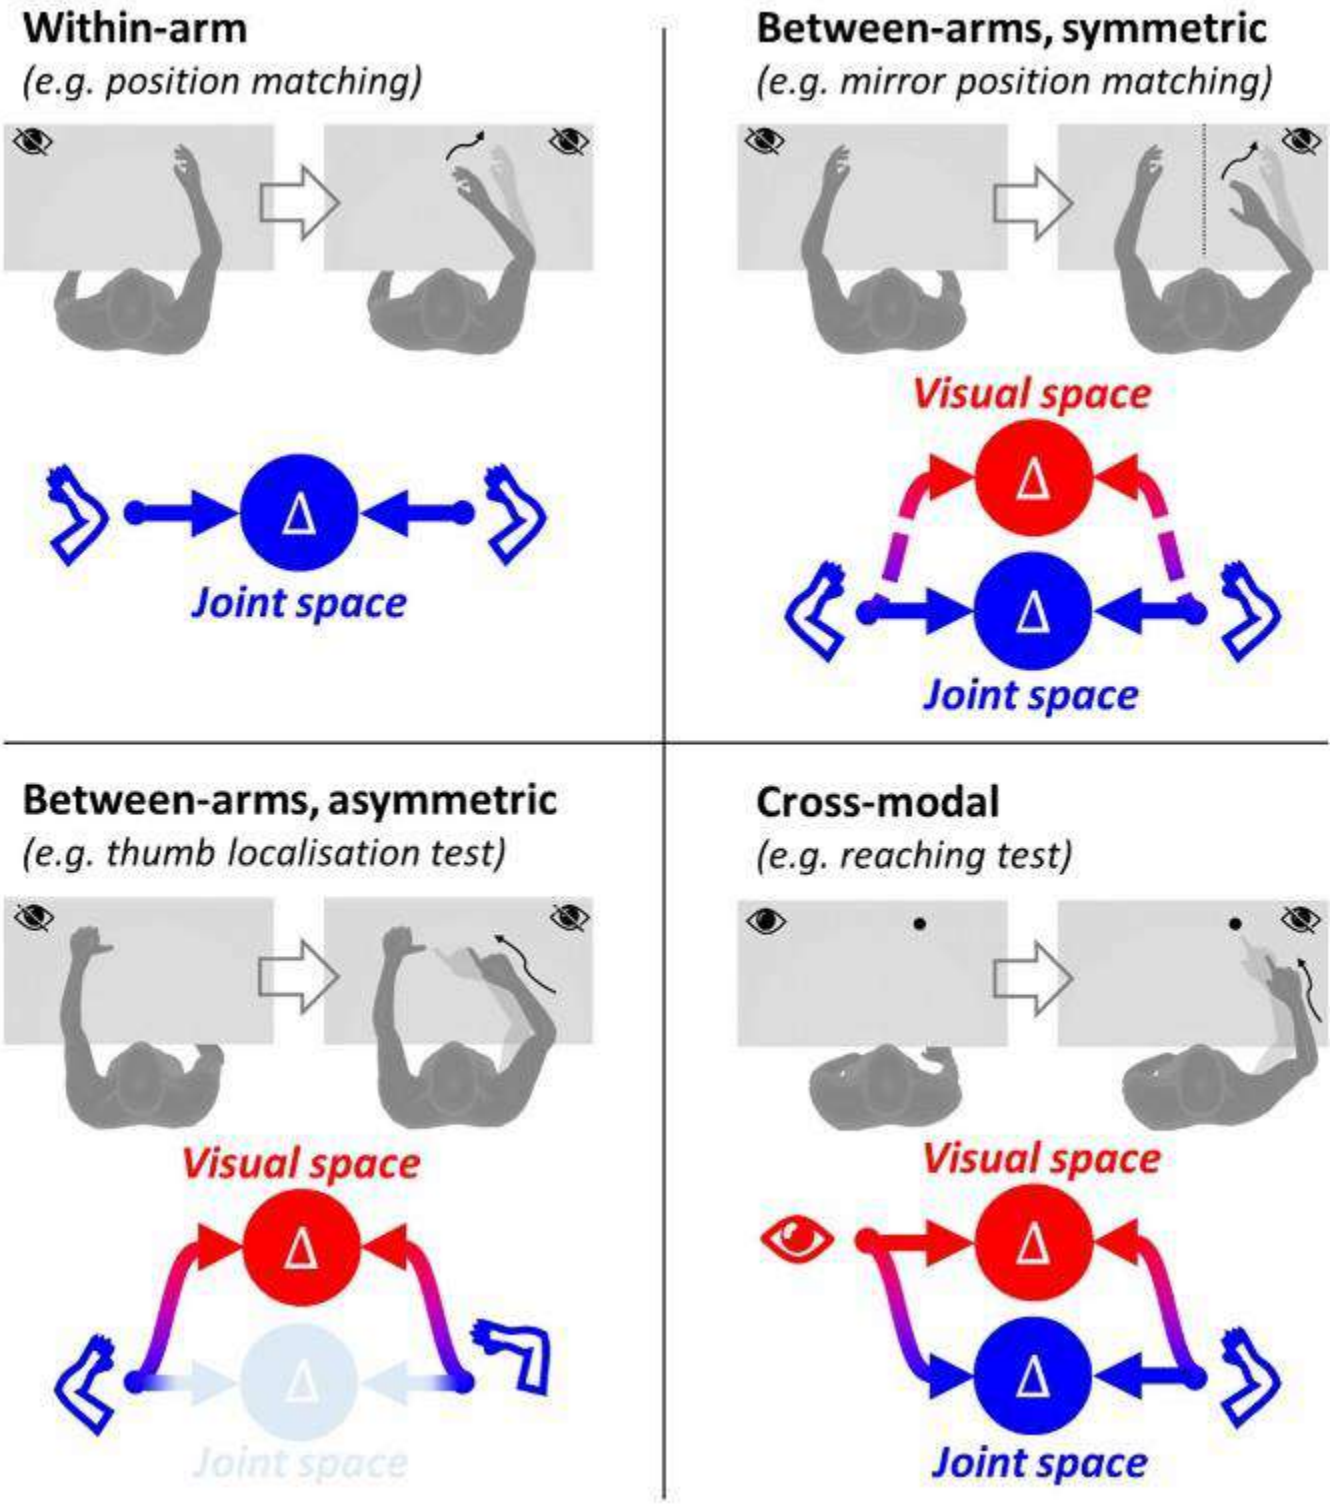

figure). This categorization, together with optimal sensory integration modeling, can reconcile the apparently contradictory results of a large number of clinical studies and can explain functionally why different tests lead, in the same patients, to different outcomes. Similarly, reinterpreting the relation between cerebral structures and proprioceptive functions in the light of our theoretical approach provides a novel rationale for an improved stratification of stroke patients. **Conclusions:** This novel classification of post-stroke sensory deficits may lead to innovative approaches to stroke assessment and rehabilitation.

Targeted training of proprioception and/or cross-reference transformations, depending on the patient's specific of sensory deficit, may be key to improved recovery.

VISUAL AND TACTILE INTEGRATION OF OBJECT LOCATIONS IN THE MOUSE CORTEX

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Adrian Hoffmann[1,2], Fritjof Helmchen[1,2]
[1]University of Zurich, Brain Research Institute, Zurich, Switzerland, [2]University of Zurich, Neuroscience Center Zurich, Zurich, Switzerland

For a stable and coherent perception of the world, the brain combines sensory information from different modalities using distinct reference frames. In the mouse brain, tactile information from the snout's vibrissae passes through the thalamus to the somatotopically organized primary whisker somatosensory cortex (wS1) while the primary visual cortex (V1) contains a retinotopic map of the visual field. For nearby objects, these two sensory streams likely converge in the rostro-lateral (RL) area of the posterior parietal cortex. How such converging multisensory inputs are integrated on a single-cell level, especially for naturalistic stimuli, remains unclear. Here, we investigated how neurons in mouse wS1, V1, and RL integrate visuotactile information about a pole in reach of the whiskers that can be seen and/or felt. Using two-photon calcium imaging, we recorded neurons in L2/3 of head-fixed mice while tracking whisker-pole interactions. Simultaneously, we recorded neural spikes and local field potentials from the primary and secondary thalamus (VPM, PO) by chronically implanting a 64-channel linear array of flexible electrodes. By comparing average activities at different pole locations, we find that subsets of neurons in RL and wS1 show selectivity for specific locations in the near space based on tactile and/or visual input. Using Generalized Linear Models, we find neural activity in RL better predicted by object locations than by whisker kinematics, whereas the opposite holds for wS1. Together, these findings corroborate the notion of RL representing object locations based on visual and tactile information, potentially in a more modality-invariant manner.

[1]Istituto Italiano di Tecnologia, Unit For Visually Impaired People (u-vip), Genova, Italy, [2]University of Genoa, Department Of Informatics, Bioengineering, Robotics And Systems Engineering (dibris), Genova, Italy

Occipital activation has been shown to selectively support spatial information processing independently of the sensory modality involved, suggesting a domain-specific multisensory architecture of the visual cortex. The present study investigates whether this domain specificity is also influenced by the complexity of the spatial representations to be processed. We tested healthy participants in an EEG study involving: i) a spatial bisection task, in which three audio-visual stimuli were reproduced at different spatial locations and participants estimated whether the second stimulus (S2) was spatially farther from the first or the third; ii) a spatial localization task, in which only S2 was presented at specific spatial positions and participants localized it at the left or the right of themselves. To investigate whether the different spatial representations elicited by the audio-visual stimuli in the two tasks modulated the neural activation of visual areas, we measured participants' Event-Related Potentials (ERPs) during their performance. S2 evoked typical visual, auditory and multisensory ERP components in occipital, temporal, and central areas in both tasks. However, occipital ERPs in the initial 200ms after S2 onset were explicitly modulated by the nature of the spatial tasks. A contralateral early occipital component (50-90ms) supported more the representation of complex multisensory spatial information (i.e., the spatial bisection), while a later contralateral occipital response (110-160ms) more strongly sustained the processing of simple spatial representations (i.e., the spatial localization). These results suggest that the neural modulation of visual areas depends on the different spatial factors involved in multisensory processing.

Auditory speed processing in sighted and blind individuals.
Multisensory experience is crucial for developing a coherent perception of the world. In this context, vision and audition are essential tools to scaffold spatial and temporal representations, respectively. Since speed encompasses both space and time, investigating this dimension in blindness allows deepening the relationship between sensory modalities and the two representation domains. In the present study, we hypothesized that visual deprivation influences the use of spatial and temporal cues underlying acoustic speed perception. To this end, ten early blind and ten blindfolded sighted participants performed a speed discrimination task in which spatial, temporal, or both cues were available to infer moving sounds' velocity. The results indicated that both sighted and early blind participants preferentially relied on temporal cues to determine stimuli speed, by following an assumption that identified as faster those sounds with a shorter duration. However, in some cases, this temporal assumption produces a misperception of the stimulus speed that negatively affected participants' performance. Interestingly, early blind participants were more influenced by this misleading temporal assumption than sighted controls, resulting in a stronger impairment in the speed discrimination performance. These findings demonstrate that the absence of visual experience in early life increases the auditory system's preference for the time domain and, consequentially, affects the perception of speed through audition.

General Enhancement of Spatial Hearing in Congenitally Blind People.
Vision is thought to support the development of spatial abilities in the other senses. If this is true, how does spatial hearing develop in people lacking visual experience? We comprehensively addressed this question by investigating auditory-localization abilities in 17 congenitally blind and 17 sighted individuals using a psychophysical minimum-audible-angle task that lacked sensorimotor confounds. Participants were asked to compare the relative position of two sound sources located in central and peripheral, horizontal and vertical, or frontal and rear spaces. We observed unequivocal enhancement of spatial-hearing abilities in congenitally blind people, irrespective of the field of space that was assessed. Our results conclusively demonstrate that visual experience is not a prerequisite for developing optimal spatial-hearing abilities and that, in striking contrast, the lack of vision leads to a general enhancement of auditory-spatial skills.

Somatosensory-guided tool use modifies arm representation for action.
Tool-use changes both peripersonal space and body representations, with several effects being nowadays termed tool embodiment. Since somatosensation was typically accompanied by vision in most previous tool use studies, whether somatosensation alone is sufficient for tool embodiment remains unknown. Here we address this question via a task assessing arm length representation at an implicit level. Namely, we compared movement's kinematics in blindfolded healthy participants when grasping an object before and after tool-use. Results showed longer latencies and smaller peaks in the arm transport component after tool-use, consistent with an increased length of arm representation. No changes were found in the hand grip component and correlations revealed similar kinematic signatures in naturally long-armed participants. Kinematics changes did not interact with target object position, further corroborating the finding that somatosensory-guided tool use may increase the represented size of the participants' arm. Control experiments ruled out alternative interpretations based upon altered hand position sense. In addition, our findings indicate that tool-use effects are specific for the implicit level of arm representation, as no effect was observed on the explicit estimate of the forearm length. These findings demonstrate for the first time that somatosensation is sufficient for incorporating a tool that has never been seen, nor used before.

LATERAL LINE HAIR CELLS INTEGRATE MECHANICAL AND CHEMICAL CUES TO STEER NAVIGATION

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Julian Roussel[1], Laura Desban[2], Ludovic Keiser[3], Claire Wyart[4], François-Xavier Lejeune[4], Nicolas Michalski*[5]
[1]Institut du Cerveau (ICM), Wyart Lab, PARIS , France, [2]University of Oregon, Eisen And Guillemin Labs, Eugene, United States of America, [3]Ecole Polytechnique Fédérale de Lausanne, Laboratory Of Fluid Mechanics And Instabilities, Lausanne, Switzerland, [4]Institut du Cerveau (ICM), Wyart Lab, PARIS, France, [5]Institut Pasteur, Institut De L'audition, Paris, France

The lateral line is a superficial sensory system known to respond to hydrodynamic changes in the environment of aquatic vertebrates, thereby contributing to schooling, predation, and rheotaxis. Whether lateral line hair cells respond to external chemical cues is unknown. Here, we uncover a novel role of the lateral line as a versatile sensory system controlling fish innate locomotion. We find that zebrafish lateral line hair cells express over 45 chemoreceptors capable of detecting diverse chemicals including, among the most enriched ones, ionotropic receptors for serotonin. Serotonin is accumulated in skin neuroepithelial cells, direct neighbors of neuromast hair cells, and we find that this monoamine is released in the water upon injury. We show that lateral line hair cells exhibit large calcium responses to environmental serotonin. The lateral line affects behavior both via its mechanical and chemical sensory functions. First, we reveal that the spontaneous mechanosensory-dependent activity of neuromast hair cells sets the basal rate and speed of bouts during spontaneous swimming. Second, the activation of lateral line hair cells by serotonin shapes the navigation of larval zebrafish by increasing speed and swimming away from the serotonin source. Our results show that lateral line integrates both mechanical and chemical cues to orient navigation. As multiple chemoreceptors are conserved in the inner ear, our study suggests that chemoreception may be a fundamental property of hair cells that could modulate the essentials functions of mechanotransduction or regeneration.

How the brain operates with different sensory modalities is an essential question in order to understand how sensory feedback engages motor responses. Deficits in multisensory integration have been documented in several neurological problems, such as Parkinson's disease or the attention-deficit and hyperactivity disorder, which involve both the striatum and dopamine transmission. The striatum is the input layer of the basal ganglia and it is associated to sensorimotor functions. The 95% of the striatal neurons are GABAergic projection neurons known as Medium Spiny Neurons (MSNs), which are divided into two subpopulations according to their axonal projections and their different dopamine receptor expression: the direct and indirect pathway. Single MSNs located in the dorsomedial region of the striatum can be activated by different sensory stimuli, such as tactile and visual (Reig & Silberberg, 2014). In this work we studied how dopamine modulates the integration of multisensory inputs. To that end, we obtained in vivo whole-cell recordings in the dorsomedial striatum of anesthetized mice during the presentation of tactile, visual and multisensory stimuli while dopamine is released by optogenetic stimulation. We show that dopamine boosts the synchronization of visual and tactile information specifically in direct pathway MSNs. This synchronization relies on the disinhibition of direct MSNs and is supported by a type-specific corticostriatal pathway. Altogether, our in vivo and in silico results propose a new mechanism underlying the synchronization of sensory information from different modalities mediated by dopamine release that can contribute to the understanding of sensorimotor interactions that occur during fine movements.

The retrosplenial cortex (RSC) is known to have a key role in a range of cognitive functions, including episodic memory, navigation, imagination, and planning for the future. Based on the RSC connections with sensory regions and hippocampal formation, an integrative processing regime is expected for this area to involve in visuospatial behaviors. However, how the RSC neurons encode multimodal information is poorly understood. We combined acute electrophysiology recording and a head-fixed locomotion assay to characterize the sensory and cognitive signals in different sub-regions of the RSC. Using Neuropixel probes, we recorded single units' activity of the RSC cells from behaving animals during a navigation task in three different conditions including, bright, dark and in the presence of visual stimuli. We used full-field drifting sinusoidal gratings as visual stimuli with different directions, spatial and temporal frequencies. We report the response properties of multiple single units to different stimuli and across behavioral states. In 536 neurons we recorded from different parts of the RSC, we found multiple variables' encoding, including visual selectivity, somatosensory responses, locomotion speed tuning, and behavior-related signals. The number of simultaneously recorded neurons and the high temporal resolution of the recording enabled us to characterize the population and the individual cell's dynamic. We conclude that neuronal activity in the RSC conveys different information about the environment and the animal's behavioral state, as was expected due to previous anatomical and physiological reports. Our study highlights the importance of investigating deep structures of the RSC, which are rarely studied in the literature.

SEPARATE AUDITORY AND MOVEMENT CONTRIBUTIONS TO SOUND-EVOKED ACTIVITY IN VISUAL CORTEX

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Matthijs Oude Lohuis, Pietro Marchesi, Umberto Olcese, Cyriel Pennartz
University of Amsterdam, Swammerdam Institute Of Life Sciences, Amsterdam, Netherlands

To enable appropriate behavioral responses to visual inputs, contextual signals are already integrated with visual signals in primary visual cortex (V1). For example, V1 is also strongly influenced by crossmodal inputs and motor movement. To what extent these two non-visual influences on V1 activity are correlated is nevertheless controversial. Here we show that in awake mice the occurrence of frequency-tuned sound-evoked activity in primary visual cortex is explained to a large extent, but not completely, by instructed and uninstructed orofacial movements. Through task manipulations, pharmacological interventions, multi-area recordings, and optogenetics, we identify two distinct components underlying sound-evoked activity in V1. A sound-related component originates from auditory cortex, has an onset latency of about 27 ms, is transient, and is found predominantly in deep layers of V1. In both naive and trained mice, another motor-related component of V1 activity results from rapid sound-evoked orofacial movements that are both instructed and uninstructed (i.e., licking and whisking). Motor-related activity was found as early as 80-100 ms, mostly in superficial layers of V1, and accounted for most sound-evoked neural activity changes in visual cortex (but, intriguingly, not in auditory cortex). During a multisensory change detection task, these two components profoundly shape visual cortical activity, but in a manner that preserves visual orientation coding. Our study provides a key contribution towards dissociating crossmodal from behavioral signals in V1. This is central to the correct interpretation of multisensory evoked activity and to understanding how distinct sensory modalities interact in visual cortex to support vision.

Sensory Processing Across Conscious and Nonconscious Brain States: From Single Neurons to Distributed Networks for Inferential Representation.
Neuronal activity is markedly different across brain states: it varies from desynchronized activity during wakefulness to the synchronous alternation between active and silent states characteristic of deep sleep. Surprisingly, limited attention has been paid to investigating how brain states affect sensory processing. While it was long assumed that the brain was mostly disconnected from external stimuli during sleep, an increasing number of studies indicates that sensory stimuli continue to be processed across all brain states-albeit differently. In this review article, we first discuss what constitutes a brain state. We argue that-next to global, behavioral states such as wakefulness and sleep-there is a concomitant need to distinguish bouts of oscillatory dynamics with specific global/local activity patterns and lasting for a few hundreds of milliseconds, as these can lead to the same sensory stimulus being either perceived or not. We define these short-lasting bouts as micro-states. We proceed to characterize how sensory-evoked neural responses vary between conscious and nonconscious states. We focus on two complementary aspects: neuronal ensembles and inter-areal communication. First, we review which features of ensemble activity are conducive to perception, and how these features vary across brain states. Properties such as heterogeneity, sparsity and synchronicity in neuronal ensembles will especially be considered as essential correlates of conscious processing. Second, we discuss how inter-areal communication varies across brain states and how this may affect brain operations and sensory processing. Finally, we discuss predictive coding (PC) and the concept of multi-level representations as a key framework for understanding conscious sensory processing. In this framework the brain implements conscious representations as inferences about world states across multiple representational levels. In this representational hierarchy, low-level inference may be carried out nonconsciously, whereas high levels integrate across different sensory modalities and larger spatial scales, correlating with conscious processing. This inferential framework is used to interpret several cellular and population-level findings in the context of brain states, and we briefly compare its implications to two other theories of consciousness. In conclusion, this review article, provides foundations to guide future studies aiming to uncover the mechanisms of sensory processing and perception across brain states.

Inference-Based Decisions in a Hidden State Foraging Task: Differential Contributions of Prefrontal Cortical Areas.
Essential features of the world are often hidden and must be inferred by constructing internal models based on indirect evidence. Here, to study the mechanisms of inference, we establish a foraging task that is naturalistic and easily learned yet can distinguish inference from simpler strategies such as the direct integration of sensory data. We show that both mice and humans learn a strategy consistent with optimal inference of a hidden state. However, humans acquire this strategy more than an order of magnitude faster than mice. Using optogenetics in mice, we show that orbitofrontal and anterior cingulate cortex inactivation impacts task performance, but only orbitofrontal inactivation reverts mice from an inference-based to a stimulus-bound decision strategy. These results establish a cross-species paradigm for studying the problem of inference-based decision making and begins to dissect the network of brain regions crucial for its performance.

Higher Order Visual Areas Enhance Stimulus Responsiveness in Mouse Primary Visual Cortex.
Over the past few years, the various areas that surround the primary visual cortex (V1) in the mouse have been associated with many functions, ranging from higher order visual processing to decision-making. Recently, some studies have shown that higher order visual areas influence the activity of the primary visual cortex, refining its processing capabilities. Here, we studied how in vivo optogenetic inactivation of two higher order visual areas with different functional properties affects responses evoked by moving bars in the primary visual cortex. In contrast with the prevailing view, our results demonstrate that distinct higher order visual areas similarly modulate early visual processing. In particular, these areas enhance stimulus responsiveness in the primary visual cortex, by more strongly amplifying weaker compared with stronger sensory-evoked responses (for instance specifically amplifying responses to stimuli not moving along the direction preferred by individual neurons) and by facilitating responses to stimuli entering the receptive field of single neurons. Such enhancement, however, comes at the expense of orientation and direction selectivity, which increased when the selected higher order visual areas were inactivated. Thus, feedback from higher order visual areas selectively amplifies weak sensory-evoked V1 responses, which may enable more robust processing of visual stimuli.

Activation of serotonin neurons promotes active persistence in a probabilistic foraging task.
The neuromodulator serotonin (5-HT) has been implicated in a variety of functions that involve patience or impulse control. Many of these effects are consistent with a long-standing theory that 5-HT promotes behavioral inhibition, a motivational bias favoring passive over active behaviors. To further test this idea, we studied the impact of 5-HT in a probabilistic foraging task, in which mice must learn the statistics of the environment and infer when to leave a depleted foraging site for the next. Critically, mice were required to actively nose-poke in order to exploit a given site. We show that optogenetic activation of 5-HT neurons in the dorsal raphe nucleus increases the willingness of mice to actively attempt to exploit a reward site before giving up. These results indicate that behavioral inhibition is not an adequate description of 5-HT function and suggest that a unified account must be based on a higher-order function.

The head direction (HD) system functions as the brain's compass system. Vestibular based HD signals combine with visual signals to permit orientation coding with respect to external landmarks. Here we examined the encoding of angularly tuned signals in populations of dorsal postsubicular and ventral presubicular neurons, that can be dominated by HD and/or visual cue position. Head-fixed mice were passively rotated on a motorized stage to cover 360°, in a room, or surrounded by a dome with a white bar. The stage was rotated in a pseudorandom fashion, in clockwise and counterclockwise directions with peak speeds of 140°/sec and accelerations up to 200°/sec^2. We recorded extracellular spiking activity using Neuropixels probes positioned in post- and presubicular cortex. Spikes were sorted using kilosort3 and manually curated with Phy. Angular tuning was quantified by dividing the number of spikes by the occupancy per bin, and the Rayleigh vector (R) was calculated. Bursting index indicated interspike intervals <6ms. We found a total of 380 well-separated units in pre- and postsubiculum (n=5 mice), out of which 61% were directionally tuned (R value >0.3). Typically preferred angular directions of the population covered 360° in the room condition quite uniformly. The presence of a single visual cue could transiently skew the distribution. We examine how the population activity of tuned units allows to decode direction. Most directionally tuned units were non-bursting cells. In conclusion, visual cues can affect angular tuning of pre-and postsubicular cells in head-fixed condition.

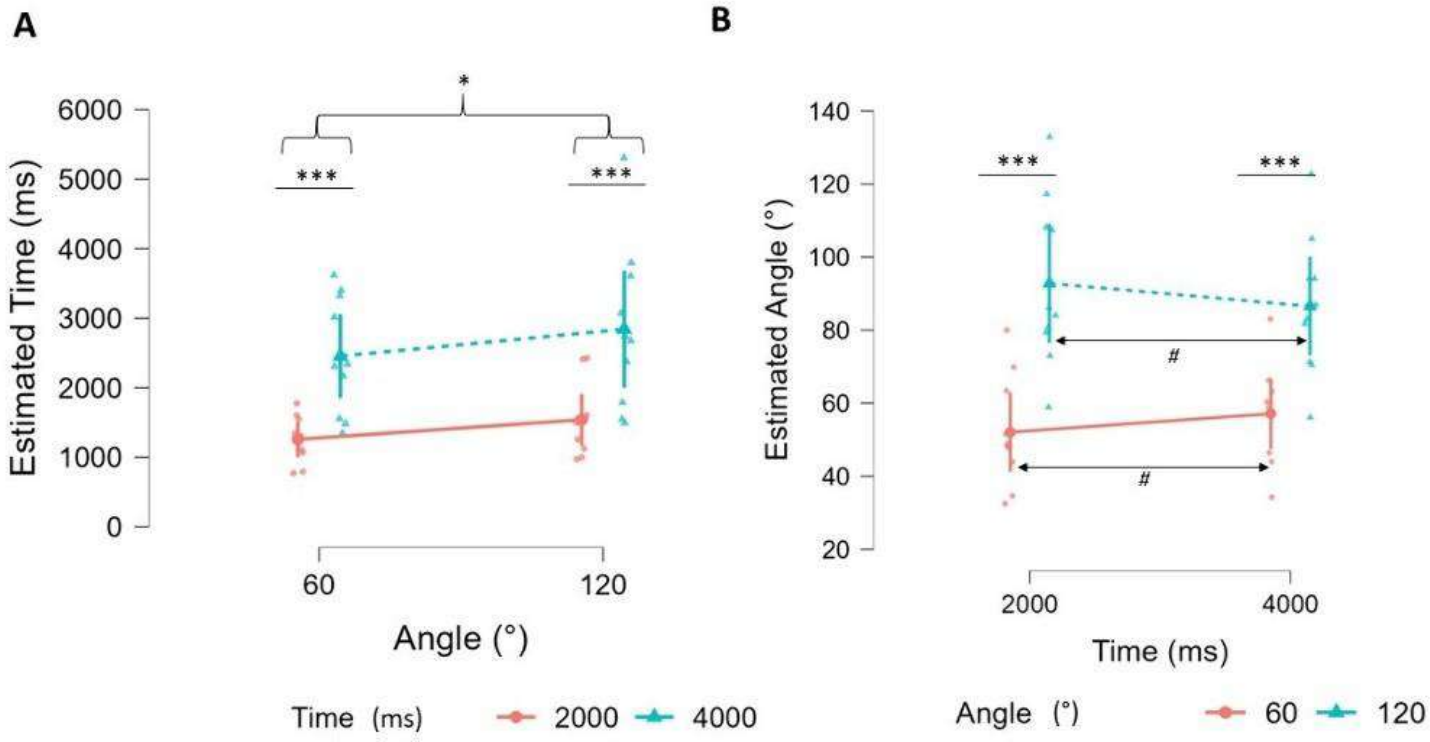
Introduction The interaction between time and space dimensions in human brain remains uncertain. Theories suggest an asymmetrical interaction: space perception influences time perception but not the opposite. However, this relationship has never been evaluated in real movement. We aim to study the interaction between time and space perception during rotations. ***Methods*** 25 healthy participants in total darkness performed two tasks after rotation (in random order: 2 or 4 seconds; 60 or 120°; right or left): (1) reproduction of the duration of rotation by pushing a button for the same amount of time or (2) reproduction of the amplitude of the rotation by pushing a button that drove the chair in the same direction. ***Results***



*Preliminary results of Lineal Mixed Model (10 of 25 participants) A) Estimated time based on the angle of rotation (60° or 120°). Rotations of 120° caused an overestimation of time compared to rotations of 60° (p=0.023). B) Estimated angle based on the time of rotation (2 or 4 seconds). Interaction (*p≤0.001*) leaded us to study 60° and 120° separately. For rotations of 60°, amplitude was overestimated comparing 4 to 2 seconds of rotations (p = 0.014). The opposite occurred for rotations of 120°(p=0.018). ***** p≤0.05, ******* p≤0.001, $^{\#}$p≤0.05 (ANOVA repeated measures).* ***Conclusions*** Preliminary results suggest a bidirectional interaction between the two estimates.

Feedback projections from higher-order processing areas to lower-order areas within the visual system have been observed in several species. While much is known about the function of feedforward connections in the visual processing pathway, feedback connections are not as well studied. They are thought to cause behaviors such as (selective) attention or expectations, but the exact mechanism and underlying neural connectivity is still unknown. The perirhinal cortex (PRH) forms the intersection between perceptual and mnemonic areas of the visual processing pathway. Evidence from rats, monkeys and humans suggests that it is involved in both object memory and perceptual tasks, which is reflected in its connectivity. PRH forms numerous feedforward and feedback projections with other areas of the visual processing pathway. However, little is known about the function and organization of feedback projections from PRH, and other parahippocampal regions, to visual areas in mice. Given the widespread availability of genetic and molecular tools, novel opportunities to investigate the function of these feedback projections would be enabled by mapping them in mice. Here we present preliminary data from anterograde and retrograde tract tracing experiments showing feedback projections from PRH, and other parahippocampal regions, to visual areas. We have found first evidence for feedback projections from PRH to lower-order visual areas that were assumed to be exclusive to higher-developed animals such as monkeys or humans. Further, we have identified feedback projections from other parahippocampal regions with specific subregional distribution. Funded from EU Horizon 2020, Specific Grant Agreement No. 945539 (Human Brain Project SGA3).

[Aims] Many studies suggest that all cortical sensory areas, including primary ones, are multisensory. For instance, mouse primary visual cortex (V1) appears to be influenced by auditory signals. These effects may be due to auditory projections to the visual cortex. However, sounds also change internal state and elicit uninstructed body movements, and both effects have brainwide correlates. It is thus possible that sounds affect visual cortex and other brain regions mainly through changes in state or behavior rather than through direct auditory projections. **[Methods]** We used Neuropixels probes to record the responses of hundreds of neurons in V1 and hippocampus of awake mice to audiovisual stimuli, while filming the mouse. To explore the role of direct projections from auditory to visual cortex, in 3 mice we cut auditory fibers to visual cortex and recorded sound-evoked responses on the cut and uncut sides of the brain. **[Results]** V1 encoded a low-dimensional representation of sounds. The same representation was also present in hippocampus, which barely receives any auditory input. The apparently auditory responses of neurons in V1 and hippocampus were highly correlated with the temporal patterns of movement evoked by the sounds, which were stereotyped across trials and across mice. They were independent of the presence of direct projections from auditory cortex, as they were unaffected by cutting these projections. **[Conclusions]** These results indicate that a large fraction of the multisensory activity that has been widely observed across the brain may have a simpler, behavioral origin.

A NOVEL EXPERIMENTAL SETUP TO STUDY MULTISENSORY INTEGRATION OF FREELY-SWIMMING ZEBRAFISH DURING RHEOTAXIS

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Orhun Koc[1], Alp Demirel[1], Sevval Izel Solmaz[2], Fatmagül Ibişoğlu[2], Ismail Uyanik[1]
[1]Hacettepe University, Electrical And Electronics Engineering, Ankara, Turkey, [2]Hacettepe University, Bioengineering Division, Ankara, Turkey

Separate sensory structures capture information in physically distinct domains. The CNS integrates multimodal information to obtain a unique representation of the environment. Our goal is to identify the dynamics of multisensory integration during free behavior of the animals. We developed a novel experimental setup to study multisensory integration during free rheotaxis behavior of adult *Danio rerio*. The setup is a speed-controlled flow tunnel that allows independent stimulation for visual and mechanosensory systems of zebrafish. Zebrafish orient themselves toward the flow due to their positive-rheotaxis behavior for position holding with minimal energy. Different from classical rheotaxis, our setup involves a transparent cylindrical tube placed within the setup to obscure the flow in its neighborhood. The obstacle forms a low gradient regime, motivating the fish to swim there to reduce its energetic cost during rheotaxis. This tube is attached to a linear actuator that moves horizontally, changing the position of the low gradient regime. Besides, we placed a dark stick inside the cylindrical tube for visual stimulation. Thus, the outer tube and inner stick provide mechanosensory and visual cues, respectively. The key feature of this design is that the movements of the inner stick can be controlled independently from that of the outer tube. We experimented with N=5 adult zebrafish using synchronous and conflicting stimuli. We estimated frequency response functions associated with each sensory structure, assuming a superposition model for the multisensory integration. We are currently examining Bayesian and Kalman filtering models to capture the multisensory behavioral response of the fish.

DYNAMIC SENSORY REWEIGHTING IN WEAKLY ELECTRIC FISH DURING REFUGE TRACKING IN A FLOW TUNNEL

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Alp Demirel[1], Orhun Koc[1], Emin Yusuf Aydin[2], Necip Gurler[1], Ismail Uyanik[1]
[1]Hacettepe University, Electrical And Electronics Engineering, Ankara, Turkey, [2]Graduate School of Science and Engineering, Bioengineering, Ankara, Turkey

Animals are equipped with diverse sensory organs that capture various sensory signals. The CNS integrates such multimodal information to increase reliability and disambiguate complex signals. Our goal is to reveal the filtering mechanisms adopted by CNS to perform multisensory integration under dynamic sensory conditions. We built an experimental setup to identify the dynamics of multisensory integration during refuge tracking behavior of *Apteronotus albifrons*. These fish hide inside refuges and track their movements to remain hidden. To achieve this, *Apteronotus* integrates visual and electrosensory information but (likely) not mechanosensory cues. Our experimental setup examines multisensory behavioral control of *Apteronotus* during refuge tracking considering the effects of these three sensory signals. The setup is a speed-controlled flow tunnel that allows an individual fish to perform refuge tracking under various mechanosensory stimulation levels. We built a transparent refuge attached to a linear actuator. In the dark, this refuge is invisible to the fish, but its longitudinal movements stimulate electrosensory receptors of the fish. We mounted a projector on the linear actuator to project a pattern of vertical stripes onto the refuge, generating visual cues. The refuge is sufficiently translucent so that the fish can see projected stripes from inside the refuge. The key feature is that visual and electrosensory cues can be controlled independently. We conducted experiments with N=5 fish under different sensory conditions and identified the weights associated with each sensory system. We currently investigate models that capture the dynamics of sensory reweighting in relation to the quality of sensory information.

THE EFFECTS OF SENSORY SALIENCE ON SMOOTH-PURSUIT TRACKING PERFORMANCE OF ZEBRAFISH DURING RHEOTAXIS

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Sevval Izel Solmaz[1], Orhun Koc[2], Alp Demirel[2], Fatmagül Ibişoğlu[1], Ismail Uyanik[2]
[1]Hacettepe University, Bioengineering Division, Ankara, Turkey, [2]Hacettepe University, Electrical And Electronics Engineering, Ankara, Turkey

The sensory salience plays a critical role in multisensory behavioral control. Our goal is to investigate the impact of sensory salience on the behavioral performance of *Danio rerio* during a new behavioral assay—target tracking during rheotaxis. We built a speed-controlled swim tunnel for an individual zebrafish to perform rheotaxis. During rheotaxis, zebrafish orient their bodies toward the flow and hold their position to avoid getting dragged. We placed a cylindrical plexiglass tube with a dark inner stick inside the setup to obscure the flow around its neighborhood. The tube is attached to a linear actuator that moves the tube horizontally. When moved, the outer transparent tube generates mechanosensory cues and the dark inner stick generates visual cues. Zebrafish track the movement of the tube to remain around the low gradient regime behind the tube. We varied the sensory salience by changing the diameter of the inner stick (1-5 cm) and the flow speed (10-20 cm/s). We conducted experiments with N=10 adult zebrafish by sinusoidally moving the tubes in 0-2 Hz range. We estimated frequency response functions between the movements of the fish and the tube. Our results show that tracking performance was better for 3cm-tube with a monotonic decrease in both directions. The flow speed did not have a significant effect in tracking. Our results suggest that the tracking behavior might be dominated by vision in light. Thus, we are currently expanding our experiments to dark and testing target objects in different shapes to improve mechanosensory stimulation.

MULTISENSORY INTEGRATION IN SUPERIOR COLLICULUS AND PRIMARY VISUAL CORTEX OF AWAKE BEHAVING MICE

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Kerstin Doerenkamp[1,2], Peter Graff[1,2], Gerion Nabbefeld[1,2], Thomas Rüland[1,2], Sandra Brill[1], Björn Kampa[1,2], Simon Musall[2,3]
[1]RWTH Aachen University, Molecular And Systemic Neurophysiology - Institute Of Biology 2, Aachen, Germany, [2]RWTH Aachen University, Rtg 2416 - Multisenses Multiscales, Aachen, Germany, [3]Forschungszentrum Jülich, Bioelectronics - Institute Of Biological Information Processing, Jülich, Germany

The Superior Colliculus (SC) is a key area for the integration of multisensory stimuli and involved in numerous cognitive functions. Inputs from different modalities reach the SC either directly or via the cortex. Yet, how multisensory integration in SC differs from cortex is not well understood. We therefore performed Neuropixels recordings in visual cortex (V1) and SC of awake mice while presenting visual, auditory and tactile stimuli. A majority of V1 neurons responded to visual stimuli but a large fraction also responded to auditory and tactile stimulation. In SC, responses showed a clear preference for contralateral visual stimuli in the superficial layers, similar to V1, while responses in deeper layers were more evenly distributed across modalities. To quantify multisensory integration, we compared responses to unisensory stimuli and multisensory combinations. Here, multisensory were mostly larger than unisensory responses for all stimulus combinations. Interestingly, multisensory enhancement was more common in V1 while SC neurons showed a larger variety in either enhancement or depression, suggesting a more detailed representation of multisensory stimuli. Lastly, we tested how multisensory integration is affected by behavior. We thus trained mice in a multisensory discrimination task and compared multisensory responses in naive versus trained animals. Here, trained mice showed an increased fraction of tactile neurons and more frequent occurrences of multisensory depression in both V1 and SC. Our results show that multisensory integration happens as early as primary sensory cortex. However, there seemed to be less variability and specificity in the multisensory responses in V1 compared to SC.

ROLE OF NORADRENERGIC NEURONS IN SHAPING MOTOR PATTERNS DURING AVOIDANCE RESPONSE

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Mahalakshmi Dhanasekar, Adeline Orts-Del'Immagine, Martin Carbo-Tano, Claire Wyart
Paris Brain Institute, Icm, Inserm U 1127, Cnrs Umr 7725, Sorbonne Université, Paris, France

To ensure their survival, animals need to avoid threats in their environment. Upon encountering aversive cues, animals rapidly integrate sensory information and deploy avoidance responses consisting of freezing and/or semi-automatic motor patterns to flee. The role of noradrenergic modulation in shaping such avoidance responses remains elusive due to the difficulty of accessing these neurons in the brainstem. To tackle this question, we exploit the transparency, genetic accessibility, and high throughput behavioral recordings of larval zebrafish. We first ascertained the recruitment of noradrenergic neurons upon aversive chemosensory and mechanosensory stimulation. Brief unilateral applications of acidic pH and pressure applications of water in the otic vesicle recruited effectively noradrenergic neurons in the medulla oblongata, which triggered a large calcium wave in glial cells descending in the spinal cord and ascending in the brain. We then tested the behavioral relevance of noradrenergic neuron recruitment in free swimming larvae. Pharmacological activation of the adrenergic system drastically reduced the mobility of larval zebrafish, indicating their ability to induce freezing. To dissect the circuit mechanism by which noradrenergic neurons operate, we examined the distribution of alpha-1a adrenergic receptor distribution. We found in the ventromedial medulla punctate clusters of alpha-1A adrenergic receptors onto descending axons projecting to the spinal cord. 2D optogenetic stimulation combined with single-cell electrophysiological recordings will be performed to dissect neuronal versus glial contribution in the induction of freezing. Altogether, this work reveals an essential neuromodulatory pathway to control the arrest of locomotion.

THE CELLULAR CODING OF TEMPERATURE IN THE MAMMALIAN CORTEX

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Mario Carta[1], Mikkel Vestergaard[2], James Poulet[2]
[1]CNRS / Université de Bordeaux, Iins - Umr 5297, BORDEAUX, France, [2]MDC, Neuroscience, Berlin, Germany

Temperature is a fundamental sensory modality separate from touch, with dedicated receptor channels and primary afferent neurons for cool and warm (Blix, 1882; Filingeri, 2016; Vriens et al., 2014). Unlike other modalities, however, the cortical encoding of temperature remains mysterious, with very few cortical neurons reported that respond to non-painful temperature and the presence of a 'thermal cortex' is debated (Bokiniec et al., 2018; Craig et al., 2000; Hellon et al., 1973; Milenkovic et al., 2014; Tsuboi et al., 1993). Using widefield and two-photon calcium imaging in the mouse forepaw system, here we identify cortical neurons that respond to cooling and/or warming with distinct spatial and temporal response properties. Surprisingly, we observed a representation of cool, but not warm, in the primary somatosensory cortex, but cool and warm in the posterior insular cortex (pIC). The representation of thermal information in pIC is robust, somatotopically-arranged and reversible manipulations show a profound impact on thermal perception. Intriguingly, despite being positioned along the same one-dimensional sensory axis, the encoding of cool and warm is distinct, both in highly- and broadly- tuned neurons. Together, our results show that pIC contains the primary cortical representation of skin temperature and may help explain how the thermal system generates sensations of cool and warm.

[1]University of Pisa, Department Of Surgical, Medical, Molecular And Critical Area Pathology, Pisa, Italy, Pisa, Italy, [2]ETH Zürich, Department Of Health Sciences And Technology, Zürich, Switzerland, [3]university of pisa, department Of Surgical, Medical And Molecular Pathology And Critical Care Medicine, Pisa, Italy, [4]University of Pisa, department Of Surgical, Medical And Molecular Pathology And Critical Care Medicine, Pisa, Italy, [5]ETH Zurich, D-hest, Zurich, Switzerland

Aims The prevailing theories of consciousness claim that multisensory stimuli cannot be integrated without emerging to consciousness: to empirically test the validity of this assumption, evidence of subliminal visuotactile integration has been checked. **Methods** 6 healthy volunteers were stimulated – unimodally or bimodally, and subliminally or supraliminally – with tactile and/or visual stimuli administered in virtual reality (VR). Tactile stimuli were delivered through Transcutaneous Electrical Nerve Stimulation (TENS) to the right foot dorsum; visual stimuli (semi-transparent circles) appeared on the same location. The multisensory integration of the stimuli was measured through electroencephalography (EEG) and through robust psychophysical models (optimal integration following the MLE model in a 2-Alternative Forced Choice task). **Results** Participants followed the MLE model in the suprathreshold condition. This was not the case in the subliminal condition. Here however, only in the bimodal condition their performance was higher than the chance level. Coherently, EEG analysis showed that bimodal stimuli both in the supra- and subliminal conditions elicited event-related potentials (ERPs) significantly different from those elicited by subliminal unimodal stimuli. **Conclusions** Contrasting popular theories of consciousness, we found evidence of multisensory integration also for subliminal stimuli. The methodological robustness of these results will impact the debate on consciousness and will have relevant implications on the newest frontiers of bionic neurosciences.

Unconscious processing of subliminal stimuli in panic disorder: A systematic review and meta-analysis.
Attentional biases to threat exist in panic disorder (PD), probably related to altered subliminal processing. We systematically reviewed studies investigating subliminal processing in PD. Studies were retrieved from MEDLINE and Scopus®. We meta-analytically compared PD (n = 167) and healthy controls (HC, n = 165) for processing of masked panic-related and neutral words. We also compared subliminal and supraliminal presentations of panic-related words relative to neutral words within PD subjects and HC. We found a significantly enhanced Stroop interference to masked panic-related words in PD vs HC (Hedges' g = 0.60, p = 0.03; Q = 14.83, I = 66.3 %, p = 0.01). While both PD subjects and HC tended to be slower to respond to supraliminal threat words than to neutral words, PD subjects only showed a marginally significant slower response to subliminal panic-related words vs neutral words. Findings remain inconclusive regarding comparison to other mental disorders, neural correlates, and the effect of psychotherapy. Even if possibly flawed by methodological weaknesses, our findings support the existence of a sensitivity to subliminal threat cues in PD, which could be targeted to improve treatment.

Lavender aromatherapy: A systematic review from essential oil quality and administration methods to cognitive enhancing effects.
Modern society is reviving the practice of aromatherapy, and lavender is reported being the most worldwide purchased plant for essential oil (EO) extraction. Since recent studies reported cognitive enhancing effects of lavender besides the hypno-inducing effects, a literature review is needed. Considering EO quality and diffusion devices, we conducted a systematic review on the effects of lavender EO inhalation on arousal, attention and memory in healthy subjects. Starting from this new multidisciplinary perspective, cognitive effects were reviewed to link outcomes to effective and reproducible protocols. A systematic search on MEDLINE, ERIC, PsycInfo, Google Scholar, and Scopus databases using Cognitive Atlas and plant-related keywords was conducted. Among the 1,203 articles yielded, 11 met eligibility criteria. Subjects administered with lavender EO displayed arousal decrease and sustained attention increase. Controversial results emerged regarding memory.

Lack of EO quality assessment and protocols heterogeneity did not allow assessing whether different EO composition differentially modulates cognition and whether placebo effect can be discerned from EO effect itself. However, GABAergic pathway modulation exerted by linalool, a major lavender EO constituent, might explain cognitive functions empowerment. We speculate aromatherapy could be a burgeoning cognition enhancing tool, although further investigation is required to reach robust conclusions.

The neurophysiological basis of excessive daytime sleepiness: suggestions of an altered state of consciousness.
Excessive daytime sleepiness (EDS) is characterized by difficulty staying awake during daytime, though additional features may be present. EDS is a significant problem for clinical and non-clinical populations, being associated with a range of negative outcomes that also represent a burden for society. Extreme EDS is associated with sleep disorders, most notably the central hypersomnias such as narcolepsy, Kleine-Levin syndrome, and idiopathic hypersomnia (IH). Although investigation of these conditions indicates that EDS results from diminished sleep quality, the underlying cause for this impairment remains uncertain. One possibility could be that previous research has been too narrow in scope with insufficient attention paid to non-sleep-related aspects. Here, we offer a broader perspective in which findings concerning the impact of EDS on cortical functioning are interpreted in relation to current understanding about the neural basis of consciousness. Alterations in the spatial distribution of cortical activity, in particular reduced connectivity of frontal cortex, suggest that EDS is associated with an altered state of consciousness.

Systematic Review of Studies on Subliminal Exposure to Phobic Stimuli: Integrating Therapeutic Models for Specific Phobias.
We systematically review 26 papers investigating subjective, behavioral, and psychophysiological correlates of subliminal exposure to phobic stimuli in phobic patients. Stimulations were found to elicit: (1) cardiac defense responses, (2) specific brain activations of both subcortical (e.g., amygdala) and cortical structures, (3) skin conductance reactions, only when stimuli lasted >20 ms and were administered with intertrial interval >20 s. While not inducing the distress caused by current (supraliminal) exposure therapies, exposure to subliminal phobic stimuli still results in successful extinction of both psychophysiological and behavioral correlates: however, it hardly improves subjective fear. We integrate those results with recent bifactorial models of emotional regulation, proposing a new form of exposure therapy whose effectiveness and acceptability should be maximized by a preliminary subliminal stimulation. Systematic Review Registration: identifier [CRD42021129234].

Interior Color and Psychological Functioning in a University Residence Hall.
The research exploited a unique architectural setting of a university residence hall composed by six separate buildings that matched for every architectural detail and differed only for the interior color (violet, blue, green, yellow, orange, and red). Four hundred and forty-three students living in the six buildings for an average of 13.33 months participated in a study that assessed color preference (hue and lightness), lightness preference, and the effects of color on studying and mood. The results showed a preference for blue interiors, followed by green, violet, orange, yellow, and red. A preference bias was found for the specific color in which the student lived. Gender differences emerged for the preference of blue and violet. Room-lightness was significantly affected by the interior color. Room ceiling was preferred white. Blue as interior color was considered to facilitate studying activity. The use of differentiated colors in the six buildings was evaluated to significantly facilitate orienting and wayfinding. A significant relation was found between a calm mood and preference for blue.

Much effort has focused on studying how the brain processes information from individual senses. Yet, the neural mechanisms that allow for multimodal integration aren't well understood. To study how neural circuits integrate visual and tactile information, we developed a multisensory discrimination task for head-fixed mice. Here, sequences of visual, tactile or visuotactile stimuli are presented on both sides of the mouse. After a short delay the mouse has to indicate the side with the higher stimulus rate to obtain a water reward. Mice achieved high accuracy in all conditions, with improved performance in multisensory trials. Using widefield-imaging, we measured cortex-wide activity in transgenic mice, expressing the Ca^{2+}-indicator GCaMP6s in excitatory neurons. Multisensory stimuli evoked higher neuronal activity compared to unisensory stimulation, particularly in the rostrolateral association area RL and the medial frontal cortex (mFC). To better isolate sensory responses we used a linear encoding model. Including a multisensory interaction term explained significantly more information than unisensory regressors alone, especially in parietal and frontal areas. This suggests that cortical multisensory responses are not simply a linear summation of unisensory responses. To causally test the relation between cortical activity and perceptual decisions, we used the inhibitory opsin stGtACR2 to silence excitatory neurons in RL and mFC at different times during the task. Inhibiting mFC during the delay resulted in robust impairments in all conditions, whereas inactivating RL mainly affected visual performance, despite robust multisensory activity. Our results show distributed cortical sensory processing and a convergence of sensory streams in mFC guiding behavior.

DISTINCT ENCODING OF SELF AND EXTERNAL MOTION IN CORTICAL AND COLLICULAR NETWORKS INVOLVED IN SPATIAL ORIENTATION

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Sepiedeh Keshavarzi[1], Hugo Soulat[2], Maneesh Sahani[2], Troy Margrie[1]
[1]Sainsbury Wellcome Centre, University College London, London, United Kingdom, [2]Gatsby Unit, University College London, London, United Kingdom

While self-motion information can be directly derived from the vestibular system, its combination with external visual signals allows the brain to discern the location and motion status of one's self relative to the surrounding world. Recently, vestibular and visual inputs have been shown to converge onto individual neurons in areas involved in spatial navigation, such as visual and retrosplenial cortices in the rodent brain. Yet, the respective contribution of these sensory cues to motion signalling in different brain regions remains unclear. To address this, we performed high-density single-unit recordings from several interconnected areas involved in spatial orientation (the retrosplenial cortex, primary visual cortex, subicular complex, and the superior colliculus (SC)) while head-fixed mice were horizontally rotated and/or presented with a full-field visual motion stimulus. By applying our recently described probabilistic tensor decomposition model to neural spike trains, we extracted motion related variables from the population activity in an unsupervised manner. We observed signals that reflected the temporal dynamics of angular speed and direction of the mouse or the visual scene as well as the animal's acceleration and accumulated angular displacement. The distribution of these signals across different areas was not homogeneous and revealed that motion representation in cortical regions is largely dominated by internally-generated cues. In contrast, the superficial SC mainly encoded external visual motion while deep layers of SC were dominated by self-motion variables. These findings suggest that internally and externally generated motion signals are utilised in different ways by cortical and collicular networks engaged in spatial navigation.

Multisensory coding of angular head velocity in the retrosplenial cortex.
To successfully navigate the environment, animals depend on their ability to continuously track their heading direction and speed. Neurons that encode angular head velocity (AHV) are fundamental to this process, yet the contribution of various motion signals to AHV coding in the cortex remains elusive. By performing chronic single-unit recordings in the retrosplenial cortex (RSP) of the mouse and tracking the activity of individual AHV cells between freely moving and head-restrained conditions, we find that vestibular inputs dominate AHV signaling. Moreover, the addition of visual inputs onto these neurons increases the gain and signal-to-noise ratio of their tuning during active exploration. Psychophysical experiments and neural decoding further reveal that vestibular-visual integration increases the perceptual accuracy of angular self-motion and the fidelity of its representation by RSP ensembles. We conclude that while cortical AHV coding requires vestibular input, where possible, it also uses vision to optimize heading estimation during navigation.

A deep learning algorithm for 3D cell detection in whole mouse brain image datasets.
Understanding the function of the nervous system necessitates mapping the spatial distributions of its constituent cells defined by function, anatomy or gene expression. Recently, developments in tissue preparation and microscopy allow cellular populations to be imaged throughout the entire rodent brain. However, mapping these neurons manually is prone to bias and is often impractically time consuming. Here we present an open-source algorithm for fully automated 3D detection of neuronal somata in mouse whole-brain microscopy images using standard desktop computer hardware. We demonstrate the applicability and power of our approach by mapping the brain-wide locations of large populations of cells labeled with cytoplasmic fluorescent proteins expressed via retrograde trans-synaptic viral infection.

A Circuit for Integration of Head- and Visual-Motion Signals in Layer 6 of Mouse Primary Visual Cortex.

To interpret visual-motion events, the underlying computation must involve internal reference to the motion status of the observer's head. We show here that layer 6 (L6) principal neurons in mouse primary visual cortex (V1) receive a diffuse, vestibular-mediated synaptic input that signals the angular velocity of horizontal rotation. Behavioral and theoretical experiments indicate that these inputs, distributed over a network of 100 L6 neurons, provide both a reliable estimate and, therefore, physiological separation of head-velocity signals. During head rotation in the presence of visual stimuli, L6 neurons exhibit postsynaptic responses that approximate the arithmetic sum of the vestibular and visual-motion response. Functional input mapping reveals that these internal motion signals arrive into L6 via a direct projection from the retrosplenial cortex. We therefore propose that visual-motion processing in V1 L6 is multisensory and contextually dependent on the motion status of the animal's head.

Dendritic Organization of Olfactory Inputs to Medial Amygdala Neurons.
The medial amygdala (MeA) is a central hub in the olfactory neural network. It receives vomeronasal information directly from the accessory olfactory bulb (AOB) and main olfactory information largely via odor-processing regions such as the olfactory cortical amygdala (CoA). How these inputs are processed by MeA neurons is poorly understood. Using the GAD67-GFP mouse, we show that MeA principal neurons receive convergent AOB and CoA inputs. Somatically recorded AOB synaptic inputs had slower kinetics than CoA inputs, suggesting that they are electrotonically more distant. Field potential recording, pharmacological manipulation, and Ca(2+) imaging revealed that AOB synapses are confined to distal dendrites and segregated from the proximally located CoA synapses. Moreover, unsynchronized AOB inputs had significantly broader temporal summation that was dependent on the activation of NMDA receptors. These findings show that MeA principal neurons process main and accessory olfactory inputs differentially in distinct dendritic compartments. Significance statement: In most vertebrates, olfactory cues are processed by two largely segregated neural pathways, the main and accessory olfactory systems, which are specialized to detect odors and nonvolatile chemosignals, respectively. Information from these two pathways ultimately converges at higher brain regions, one of the major hubs being the medial amygdala. Little is known about how olfactory inputs are processed by medial amygdala neurons. This study shows that individual principal neurons in this region receive input from both pathways and that these synapses are spatially segregated on their dendritic tree. We provide evidence suggesting that this dendritic segregation leads to distinct input integration and impact on neuronal output; hence, dendritic mechanisms control olfactory processing in the amygdala.
J Neurosci, 2015; 35

Functional properties and projections of neurons in the medial amygdala.
The medial nucleus of the amygdala (MeA) plays a key role in innate emotional behaviors by relaying olfactory information to hypothalamic nuclei involved in reproduction and defense. However, little is known about the neuronal components of this region or their role in the olfactory-processing circuitry of the amygdala. Here, we have characterized neurons in the posteroventral division of the medial amygdala (MePV) using the GAD67-GFP mouse. Based on their electrophysiological properties and GABA expression, unsupervised cluster analysis divided MePV neurons into three types of GABAergic (Types 1-3) and two non-GABAergic cells (Types I and II). All cell types received olfactory synaptic input from the accessory olfactory bulb and, with the exception of Type 2 GABAergic neurons, sent projections to both reproductive and defensive hypothalamic nuclei. Type 2 GABAergic cells formed a chemically and electrically interconnected network of local circuit inhibitory interneurons that resembled neurogliaform cells of the piriform cortex and provided feedforward inhibition of the olfactory-processing circuitry of the MeA. These findings provide a description of the cellular organization and connectivity of the MePV and further our understanding of amygdala circuits involved in olfactory processing and innate emotions.

Behavioral and histological assessment of the effect of intermittent feeding in the pilocarpine model of temporal lobe epilepsy.
Temporal lobe epilepsy (TLE) is the most resistant type of epilepsy. Currently available drugs for epilepsy are not antiepileptogenic. A novel treatment for epilepsy would be to block or reverse the process of epileptogenesis. We used intermittent feeding (IF) regimen of the dietary restriction (DR) to study its effect on epileptogenesis and neuroprotection in the pilocarpine model of TLE in rats. The effect of IF regimen on the induction of status epilepticus (SE), the duration of latent period, and the frequency, duration, severity and the time of occurrence of Spontaneous Recurrent Seizures (SRS) were investigated. We also studied the effect of IF regimen on hippocampal neurons against the excitotoxic damage of prolonged SE (about 4h) induced by pilocarpine. The animals (Wistar, male, 200-250g) were divided into four main groups: AL-AL (ad libitum diet throughout), AL-IF (PfS) [IF post-first seizure], AL-IF (PSE) [IF post-SE] and IF-IF (IF diet throughout), and two AL and IF control groups. SE was induced by pilocarpine (350mg/kg, i.p.) and with diazepam (6mg/kg, i.p.) injected after 3h, the behavioral signs of SE terminated at about 4h (AL animals, n=29, 260.43+/-8.74min; IF animals, n=19, 224.32+/-20.73min).

Behavioral monitoring was carried out by 24h video recording for 3 weeks after the first SRS. Rat brains were then prepared for histological study with Nissl stain and cell counting was done in CA1, CA2 and CA3 regions of the hippocampus. The results show that the animals on IF diet had significantly less SE induction and significantly longer duration of latent period (the period of epileptogenesis) was seen in IF-IF group compared to the AL-AL group. The severity of SRS was significantly more in AL-IF (PfS) compared to the AL-IF (PSE) group. These results indicate that IF diet can make rats resistant to the induction of SE and can prolong the process of epileptogenesis. The results of the histological study show that the number of pyramidal neurons was statistically less in CA1, CA2 and CA3 of the hippocampus in the experimental groups compared to the control groups. However, IF regimen could not protect the hippocampal neurons against the excitotoxic injury caused by a prolonged SE. We conclude that IF regimen can significantly influence various behavioral characteristics of pilocarpine model of TLE. Further studies can elaborate the exact mechanisms as well as its possible role in the treatment of human TLE.

17465369: Keshavarzi S, Nejat F, Kazemi H
Double spinal dysraphism. Report of three cases.
The simultaneous presence of multiple spinal neural tube defects is unusual. There have been only a few of these cases reported in the literature. The authors report on three cases of double spina bifida cystica. One patient had two myelomeningoceles (MMCs) at the cervical and lumbosacral regions, one was noted to have both thoracolumbar and sacral defects, and the third presented with double MMCs at lumbar and lumbosacral levels. All three neonates in these cases underwent surgical treatment and ventriculoperitoneal (VP) shunt insertion for associated hydrocephalus. One child died at the age of 2 months despite a well-functioning VP shunt. The other two patients had no complications. Current models of neural tube closure do not thoroughly explain the mechanisms of multiple spinal dysraphism, but the multisite closure model provides a better understanding of caudal neural tube closure than other closure-site models.

ASSESSING SENSE OF EMBODIMENT: ITS DIRECT AND INDIRECT EFFECT ON PHYSIOLOGICAL MEASURES

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Sara Falcone[1,2], Gwenn Englebienne[1], Jan Van Erp[1,2], Dirk Heylen[1]
[1]University of Twente, Human Media Interaction, Enschede, Netherlands, [2]TNO, Human Studies On Perception And Behaviour, Soesterberg, Netherlands

We explore the assessment of Sense of Embodiment (SoE), namely the extent to which a surrogate is perceived as one's own. The Rubber Hand Illusion is the pioneer study in this direction. It is hypothesized that physiological measures reflect SoE in a direct and indirect way. If individuals feel strongly embodied, presenting an emotional stimulus like a threat to the surrogate will produce a strong response, as if the stimulus would be presented to their own body. This would lead to a positive correlation between SoE and the measure value during the presentation of emotional stimuli. There may also be an indirect effect. It is postulated that higher degrees of embodiment reduce workload when controlling a surrogate. This indirect effect of embodiment through lower workload would result in a negative correlation between SoE and the measure value, since lower workload results in lower physiological values. We investigated these effects in five experiments, comparing different physiological measures (such as skin conductance response, heart rate, pupil dilation). Our hypothesis was partially accepted, since we did not observe consistent results among the different measures. Pupil dilation, that we propose as novel measure of SoE, resulted in the most sensitive measure. We observed that pupil dilation and SoE are positive and direct correlated in case of emotional stimuli subjected to the surrogate (e.g. a threat), and that the pupil diameter tended to be smaller for participants who experienced a condition designed to provide high SoE compared to one designed to provide low SoE.

NEURAL ENCODING OF SENSORY "SURPRISE" IN THE MOUSE CORTEX

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Diego Benusiglio[1], Richard Somervail[2], Giandomenico Iannetti[2], Hiroki Asari[1]
[1]European Molecular Biology Laboratory, Epigenetics And Neurobiology Unit, Monterotondo, Italy, [2]Istituto Italiano di Tecnologia, Neuroscience And Behaviour Laboratory, Clns, Rome, Italy

The brain generates predictions of future sensory inputs based on the statistics of recent sensory information. A mismatch between expected and perceived sensory stimuli elicits a "prediction error" or "surprise" signal that is used to update the mental model of the sensory world. Indeed, "surprise" is a major driving force for learning. For example, surprising isolated sensory stimuli triggers a large and widespread electrocortical activity in the mammal brain (the vertex potential) which is coupled with marked changes in behavioral output. However, it is still unclear how "surprise" signals are represented at different hierarchical levels of cortical processing, as well as at different spatiotemporal scales, ranging from individual neurons to large cortical areas. Also, if and how surprise at individual neuron level relates to the widespread surprise-related vertex potential widely studied in humans remains elusive. To answer those questions, we recorded single neuron activity from different hierarchical levels of cortical processing in the mouse brain, i.e. from primary visual or auditory cortices to parietal and prefrontal cortical areas, in response to unexpected visual and auditory sensory stimuli. Our data suggest that neural activity in primary sensory cortices is highly sensitive to abrupt changes in stimulus intensity or pattern, both at the level of single cell and average population activity. These results indicate that detection mechanisms for quick changes in the environment already exist at early stages of sensory processing. Comparing data across different scales and species will lead to a better understanding of how the brain detects and responds to surprising environmental events.

Viral vectors for opto-electrode recording and photometry-based imaging of oxytocin neurons in anesthetized and socially interacting rats.
Here, we present a step-by-step protocol to target, record, and manipulate the activity of oxytocin neurons in awake rats. The protocol includes a procedure to record the activity of oxytocin neurons from awake and socially interacting rats using opto-electrodes for simultaneous electrophysiological recording and virally based cell-type-specific opto-tagging with Channelrhodopsin 2. Furthermore, we illustrate a procedure for optically guided implantation of optic fiber and imaging of oxytocin neuron population activity expressing calcium indicator GCaMP6s with the fiber photometry technique. For complete details on the use and execution of this protocol, please refer to Tang et al., 2020.

Oxytocinergic Feedback Circuitries: An Anatomical Basis for Neuromodulation of Social Behaviors.
Oxytocin (OT) is a neuropeptide produced by hypothalamic neurons and is known to modulate social behavior among other functions. Several experiments have shown that OT modulates neuronal activity in many brain areas, including sensory cortices. OT neurons thus project axons to various cortical and subcortical structures and activate neuronal subpopulations to increase the signal-to-noise ratio, and in turn, increases the saliency of social stimuli. Less is known about the origin of inputs to OT neurons, but recent studies show that cells projecting to OT neurons are often located in regions where the OT receptor (OTR) is expressed. Thus, we propose the existence of reciprocal connectivity between OT neurons and extrahypothalamic OTR neurons to tune OT neuron activity depending on the behavioral context. Furthermore, the latest studies have shown that OTR-expressing neurons located in social brain regions also project to other social brain regions containing OTR-expressing neurons. We hypothesize that OTR-expressing neurons across the brain constitute a common network coordinated by OT.

Astrocytes mediate the effect of oxytocin in the central amygdala on neuronal activity and affective states in rodents.
Oxytocin (OT) orchestrates social and emotional behaviors through modulation of neural circuits. In the central amygdala, the release of OT modulates inhibitory circuits and, thereby, suppresses fear responses and decreases anxiety levels. Using astrocyte-specific gain and loss of function and pharmacological approaches, we demonstrate that a morphologically distinct subpopulation of astrocytes expresses OT receptors and mediates anxiolytic and positive reinforcement effects of OT in the central amygdala of mice and rats. The involvement of astrocytes in OT signaling challenges the long-held dogma that OT acts exclusively on neurons and highlights astrocytes as essential components for modulation of emotional states under normal and chronic pain conditions.

Social touch promotes interfemale communication via activation of parvocellular oxytocin neurons.
Oxytocin (OT) is a great facilitator of social life but, although its effects on socially relevant brain regions have been extensively studied, OT neuron activity during actual social interactions remains unexplored. Most OT neurons are magnocellular neurons, which simultaneously project to the pituitary and forebrain regions involved in social behaviors. In the present study, we show that a much smaller population of OT neurons, parvocellular neurons that do not project to the pituitary but synapse onto magnocellular neurons, is preferentially activated by somatosensory stimuli. This activation is transmitted to the larger population of magnocellular neurons, which consequently show coordinated increases in their activity during social interactions between virgin female rats. Selectively activating these parvocellular neurons promotes social motivation, whereas inhibiting them reduces social interactions. Thus, parvocellular OT neurons receive particular inputs to control social behavior by coordinating the responses of the much larger population of magnocellular OT neurons.

Chemogenetic activation of oxytocin neurons: Temporal dynamics, hormonal release, and behavioral consequences.
Chemogenetics provides cell type-specific remote control of neuronal activity. Here, we describe the application of chemogenetics used to specifically activate oxytocin (OT) neurons as representatives of a unique class of neuroendocrine cells. We injected recombinant adeno-associated vectors, driving the stimulatory subunit hM3Dq of a modified human muscarinic receptor into the rat hypothalamus to achieve cell type-specific expression in OT neurons. As chemogenetic activation of OT neurons has not been reported, we provide systematic analysis of the temporal dynamics of OT neuronal responses in vivo by monitoring calcium fluctuations in OT neurons, and intracerebral as well as peripheral release of OT. We further provide evidence for the efficiency of chemogenetic manipulation at behavioral levels, demonstrating that evoked activation of OT neurons leads to social motivation and anxiolysis. Altogether, our results will be profitable for researchers working on the physiology of neuroendocrine systems, peptidergic modulation of behaviors and translational psychiatry.

Distinct Types of Feeding Related Neurons in Mouse Hypothalamus.
The last two decades of research provided evidence for a substantial heterogeneity among feeding-related neurons (FRNs) in the hypothalamus. However, it remains unclear how FRNs differ in their firing patterns during food intake. Here, we investigated the relationship between the activity of neurons in mouse hypothalamus and their feeding behavior. Using tetrode-based in vivo recording technique, we identified various firing patterns of hypothalamic FRNs, which, after the initiation of food intake, can be sorted into four types: sharp increase (type I), slow increase (type II), sharp decrease (type III), and sustained decrease (type IV) of firing rates. The feeding-related firing response of FRNs was rigidly related to the duration of food intake and, to a less extent, associated with the type of food. The majority of these FRNs responded to glucose and leptin and exhibited electrophysiological characteristics of putative GABAergic neurons. In conclusion, our study demonstrated the diversity of neurons in the complex hypothalamic network coordinating food intake.

The Scaling of Human Contacts and Epidemic Processes in Metapopulation Networks.
We study the dynamics of reaction-diffusion processes on heterogeneous metapopulation networks where interaction rates scale with subpopulation sizes. We first present new empirical evidence, based on the analysis of the interactions of 13 million users on Twitter, that supports the scaling of human interactions with population size with an exponent γ ranging between 1.11 and 1.21, as observed in recent studies based on mobile phone data. We then integrate such observations into a reaction- diffusion metapopulation framework. We provide an explicit analytical expression for the global invasion threshold

which sets a critical value of the diffusion rate below which a contagion process is not able to spread to a macroscopic fraction of the system. In particular, we consider the Susceptible-Infectious-Recovered epidemic model. Interestingly, the scaling of human contacts is found to facilitate the spreading dynamics. This behavior is enhanced by increasing heterogeneities in the mobility flows coupling the subpopulations. Our results show that the scaling properties of human interactions can significantly affect dynamical processes mediated by human contacts such as the spread of diseases, ideas and behaviors.

SALIENCE OF MULTISENSORY FEEDBACK MODULATES ACTIVE SENSING MOVEMENTS OF WEAKLY ELECTRIC FISH DURING REFUGE TRACKING IN A FLOW TUNNEL

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Emin Yusuf Aydin[1], Alp Demirel[2], Orhun Koc[2], Necip Gurler[2], Ismail Uyanik[2]
[1]Hacettepe University, Bioengineering Division, Ankara, Turkey, [2]Hacettepe University, Electrical And Electronics Engineering, Ankara, Turkey

An amazing phenomenon in biological systems is that sensing and motor systems are inherently coupled. Despite its seemingly adverse nature, animals benefit from this coupling by utilizing motor actions to alter the spatiotemporal patterns of sensory information they perceive from the environment—a process known as active sensing. Our goal is to examine the effects of active sensing on sensorimotor control performance during natural behavior of animals. To achieve this, we built an experimental setup to study active sensing in *Apteronotus albifrons* during their refuge tracking behavior. This behavior is a form of image stabilization, where fish swim to remain within a moving refuge. We built a speed-controlled flow tunnel to imitate the natural Amazonian habitats of these fish. We use a cylindrical refuge without flooring to allow video recordings from below. The refuge is attached to a linear actuator that moves longitudinally to provide visual and electrosensory stimulation for the fish. We experimented with N=5 fish using sum-of-sines type stimulus, sweeping 0-2 Hz range. The experiments were repeated with various flow speeds (0-20 cm/s), illumination (0-300 lux), and refuge structures (with and without windows). We recorded the kinematic response of the fish under each sensory condition. We first segregated the tracking response of the fish. Then, we identified the stereotyped active sensing movements. Our results show that active sensing movements increase as the quality of the sensory information decreases. We are currently investigating how these movements help the fish to improve their behavioral performance using a control-theoretic approach.

Fabrication of a multi-layered decellularized amniotic membranes as tissue engineering constructs.
As a promising approach in tissue engineering, decellularization has become one of the mostly-studied research areas in tissue engineering thanks to its potential to bring about several advantages over synthetic materials since it can provide a 3-dimensional ECM structure with matching biomechanical properties of the target tissue. Amniotic membranes are the tissues that nurture the embryos during labor. Similarly, these materials have also been proposed for tissue regeneration in several applications. The main drawback in using amniotic membranes is the limited thickness of these materials since most tissues require a 3D matrix for an enhance regeneration. In order to prevent this limitation, here we report a facile fabrication methodology for multilayered amniotic membrane-based tissue constructs. The amniotic membranes of Wistar albino rats were first decellularized with the physical and chemical methods and utilized as scaffolds. Secondly, the prepared decellularized membranes were sutured to form a multilayered 3D structure. Within the study, 7 groups including control (PBS), were prepared based on physical and chemical decellularization methods. UV exposure and freezing techniques were used as a physical decellularization methods while hypertonic medium and SDS (sodium dodecyl sulfate) protocols were used as chemical decellularization methods. The combinations of both protocols were also used. In groups, A was the control and group B was applied just UV. In group C was applied UV and freezing. In addition to UV and freezing, in group D was applied hypertonic solution while group E was applied SDS (0.03 %). In group F was applied UV, freezing, hypertonic solution and SDS (0.03 %). In group G was applied UV, hypertonic solution, SDS (0.03 %) and freezing, respectively. Based on the histological and quantitative analyses, F and G groups were found as the most efficient decellularization protocols in rat amniotic membranes. Then, group F and G decellularized amniotic membranes were used to form scaffolds and thus-formed matrices were further characterized in vitro cell culture studies and mechanical tests. Cytotoxicity analyses performed using MTT showed a good cell viability in F and G groups scaffolds. The percentage viability rate was higher in G group (81.3 %) compared to F (75.33 %) and also cell viability in G group was found more meaningful according to p value which was obtained 0.007. Cellular adhesions after in vitro cell culture and morphology of scaffolds were evaluated by scanning electron

microscopy (SEM). It was observed that the cells cultivated in equal amounts of tissue scaffolds were higher in the F compared to that observed in group G. The mechanical testing with 40 N force revealed 0.77 mm displacement in group F while it was 0.75 mm in group G. Moreover, according to force-controlled test, 2.9 mm displacement of F group and 1.2 mm displacement of G group was measured. As a result, this study shows that the multilayered decellularized amniotic membrane scaffolds support cell survival and adhesion and can form a flexible biomaterial with desired handling properties. AUDIOVISUAL INTEGRATION IN MOUSE SUPERIOR COLLICULUS IS ADDITIVE AND RARE

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

[Aims] The superior colliculus (SC) receives auditory and visual inputs and is thought to combine them to form a representation of audiovisual space. However, the computational rules behind audiovisual integration are unclear: while electrophysiological studies in SC have emphasized super- & subadditivity, mouse behavior seems consistent with additive integration. We thus asked whether audiovisual integration in the mouse SC might be primarily additive in the majority of neurons. [Methods] We used Neuropixels 1.0 and 2.0 probes to record the responses of ~2,600 SC neurons in awake mice to checkerboard images and pink noise sound bursts presented at varying azimuths, alone or in combination. We then fitted six models to each neuron's response time courses using cross-validation. Models varied in aspects such as spatial selectivity and linearity. Five models were linear and a sixth allowed for nonlinearities. [Results] Neurons responding to both images and sounds were rare (19% of neurons). Most of them had spatial selectivity for images but not for sounds: they responded to sound onsets regardless of position. Only 4% of neurons, mostly in deeper layers, were selective for both auditory and visual position. Practically all audiovisual neurons (98%) were best fitted by an additive model. [Conclusions] We conclude that integration of auditory and visual position in mouse SC is rare, but many neurons additively integrate visual stimuli and sound onsets. We speculate that such sound onset responses may be related to changes in behavioral state.

MOUSE FRONTAL CORTEX MEDIATES ADDITIVE MULTISENSORY DECISIONS

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Timothy Sit[1], Philip Coen[2], Miles Wells[2], Matteo Carandini[3], Kenneth Harris[2]

[Introduction] To make accurate perceptual decisions, the brain must combine information across sensory modalities. Probability theory suggests that evidence from independent cues should be combined additively, but it is unclear whether mice do this. Here we show that to localize a stimulus, mice combine auditory and visual spatial cues additively, a computation supported by unisensory processing in auditory and visual cortex and additive multisensory integration in frontal cortex. [Methods] We developed an audiovisual localization task where mice turn a wheel to indicate the joint position of an image and a sound. We performed optogenetic inactivation of different spots across dorsal cortex while mice performed this task. We then recorded from >10,000 neurons in the frontal cortex during behaviour. [Results] In this task, mice integrated auditory and visual cues independently. An additive model predicted the mean response of mice to all cue combinations. Optogenetic inactivation of different spots across dorsal cortex demonstrated that auditory and visual areas contribute unisensory information, whereas frontal cortex (secondary motor area, MOs) contributes multisensory information to the mouse's decision. Of the frontal areas recorded, only MOs activity could predict the mouse's upcoming choice. Consistent with the mice's additive behavior, neural activity in MOs reflected an additive combination of visual and auditory signals. Furthermore, an accumulator model applied to the sensory representations of MOs neurons reproduced behaviourally observed choices and reaction times. [Conclusions] Frontal area MOs integrates information from sensory cortices additively, providing a signal that is then transformed into a binary decision by a downstream accumulator.

BEHAVIOUR-DEPENDENT MODULATION OF INHIBITION IN THE PRIMARY SOMATOSENSORY CORTEX

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Marcel Van Velze, Dhanasak Dhanasobhon, Nelson Rebola
Paris Brain Institute ICM, Cnrs, Inserm, Paris, France

In primary sensory areas stimuli evoked responses are particular sensitive to alterations in behavioural states associated with variations in arousal or locomotion. Recruitment of disinhibitory circuits has been proposed to be important for such behavioural-dependent control of neuronal activity. However, it is unclear if the recruitment of local interneurons during such behaviour transitions is similar across sensory areas and whether it affects responses to sensory stimuli similarly across sensory modalities. In particular, rodents heavily use their whiskers during navigation, however, how locomotion modulates activity in the primary somatosensory cortex (S1) is not well understood. To address this issue, we performed *in vivo* two-photon calcium imaging of somatostatin-positive (SST-INs) and vasoactive intestinal peptide positive (VIP-INs) interneurons, key elements of cortical disinhibitory circuits, in awake head-fixed mice in S1 spontaneously transitioning between rest and running periods. We found in the dark, locomotion strongly recruited SST-INs in the barrel cortex while having no effect in SST-INs in the visual cortex. This difference in SST-INs activity occurred despite the strong recruitment of VIP-INs in the two brain areas. In addition, neither the strength of inhibition provided by VIP-INs nor the sensitivity of SST-INs to cholinergic signalling was different across sensory modalities. We are presently investigating the contribution of thalamic activity to the differential recruitment of SST-INs in V1 and S1 by locomotion. The present results indicate that the recruitment of local inhibitory neurons is different across sensory areas for the same behavioural transition suggesting that impact of arousal in sensory cortices is modality specific.

THE TEMPORAL DYNAMICS OF AUDIOVISUAL EVIDENCE ACCUMULATION IN HUMANS AND MICE

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Rosanne Tuip[1,2], Reinder Dorman[3], Wessel Van Der Ham[3], Cyriel Pennartz[3], Filip Van Opstal[2], Jeannette Lorteije[3,4]
[1]Swammerdam Institute for Life Sciences, University Of Amsterdam, Amsterdam, Netherlands, [2]Brain and Cognition, University Of Amsterdam, Amsterdam, Netherlands, [3]University of Amsterdam, Swammerdam Institute Of Life Sciences, Amsterdam, Netherlands, [4]Animal Welfare Body, Radboud University/umc, Nijmegen, Netherlands

Integration of information from multiple sensory modalities over time is necessary for the brain to create a unified percept of the outside world and to perform functions such as decision-making. In natural settings (multi)sensory evidence is not always instantaneously clear, but instead it can be noisy as it can consist of very subtle and sometimes even contradictory stimuli that vary dynamically. A currently unexplored question is how time-varying visual and auditory information is integrated over time during audiovisual decision-making. To study this question we instructed human subjects and trained mice to discriminate between two visual gratings and/or two sound sources based on contrast and loudness that fluctuated in intensity every 50ms. We report that humans and mice based their decisions on early incoming information. Additionally, we demonstrate that audiovisual decision-making in humans was associated with modality dominance switching. The first visual and auditory evidence samples were equally integrated followed by second integration phase of visual dominance after which humans briefly switched to auditory dominance. Mice relied heavily on auditory evidence throughout the stimulus period. This suggests that mice and humans dynamically and differentially use time-varying audiovisual information during decision-making. We further present single-unit activity and local field potentials recorded from the primary visual cortex of task-performing mice. We correlate this neural activity with stimulus fluctuations and behavioral outcome, aiming to identify neural responses during visual processing, cross-modal and multimodal processing reflecting the decision of an animal. Our findings bring us one step closer to revealing the dynamics of multisensory decision-making.

DO CHANGES ON THE PLANTAR SYSTEM IMPACT THE BINOCULAR FUSION ?

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Sophie Loureau[1], Rachel Poulain-Chekroun[2], Celine Cappe[3], Marc Janin[4]
[1]MSP Val Drouette, Podiatrist, epernon, France, [2]Université de Toulouse, Cerpps / Cerco, Toulouse, France, [3]Université de Toulouse, Cnrs Cerco Umr 5549, Toulouse, France, [4]Université de Pau et des Pays de l'Adour, Laboratoire Meps 4445, Tarbes, France

Background: Multisensory integration is a fundamental brain mechanism, allowing integration and convergences, between a multitude of inputs from the different senses. The purpose of this study is to assess sensory reweighting of the plantar modality on the binocular fusion. Method: Plantar modality contribution was investigated by infection of the foot sole afferent by foams (reduction) and texture (increase). Binocular disruption vision was assessed by the Perceptive Maddox through Vertical Heterophoria (VH) and their Lability (L), because ocular motor compensation is very weak in this plane (only proprioception variations). 40 subjects (28 adults 12 children) with VH were included. VH was randomly scored on foam Crispon Diabet® (CD) and Airgom® (AG) and Black Pyramid (BP, Crispin France). Result: CD and BP induce significant reduction of VH and increase L. These effects did not vary with age. Discussion: Feedback, lack CD AG or upgrade BP of plantar information induce a new sensory situation. Then, somatosensory information is reweighted and impact the binocular fusion with reduction of VH and intensification of L. Only CD inducing reduction depends on the mechanical foam proprieties. We confirm that it is possible to modify visual perception by reducing or increasing, sensory plantar information. Independently of the age, we suggest that the plantar system could affect the visual integration and could influence the visual proprioception correspondingly the binocular fusion. These findings support the hypothesis that plantar sensory variation may be an effective tool for evaluating the relationship between plantar and visual integration.

Children with Dyslexia Have Altered Cross-Modal Processing Linked to Binocular Fusion. A Pilot Study.
The cause of dyslexia, a reading disability characterized by difficulties with accurate and/or fluent word recognition and by poor spelling and decoding abilities, is unknown. A considerable body of evidence shows that dyslexics have phonological disorders. Other studies support a theory of altered cross-modal processing with the existence of a pan-sensory temporal processing deficit associated with dyslexia. Learning to read ultimately relies on the formation of automatic multisensory representations of sounds and their written representation while eyes fix a word or move along a text. We therefore studied the effect of brief sounds on vision with a modification of binocular fusion at the same time (using the Maddox Rod test).

Regular rhythmic and audio-visual stimulations enhance procedural learning of a perceptual-motor sequence in healthy adults: A pilot study.
Procedural learning is essential for the effortless execution of many everyday life activities. However, little is known about the conditions influencing the acquisition of procedural skills. The literature suggests that sensory environment may influence the acquisition of perceptual-motor sequences, as tested by a Serial Reaction Time Task. In the current study, we investigated the effects of auditory stimulations on procedural learning of a visuo-motor sequence. Given that the literature shows that regular rhythmic auditory rhythm and multisensory stimulations improve motor speed, we expected to improve procedural learning (reaction times and errors) with repeated practice with auditory stimulations presented either simultaneously with visual stimulations or with a regular tempo, compared to control conditions (e.g., with irregular tempo). Our results suggest that both congruent audio-visual stimulations and regular rhythmic auditory stimulations promote procedural perceptual-motor learning. On the contrary, auditory stimulations with irregular or very quick tempo alter learning. We discuss how regular rhythmic multisensory stimulations may improve procedural learning with respect of a multisensory rhythmic integration process.

Alteration in binocular fusion modifies audiovisual integration in children.
In the field of multisensory integration, vision is generally thought to dominate audiovisual interactions, at least in spatial tasks, but the role of binocular fusion in audiovisual integration has not yet been studied. Using the Maddox test, a classical ophthalmological test used to subjectively detect a latent unilateral eye deviation, we checked whether an alteration in binocular vision in young patients would be able to change audiovisual integration. The study was performed on a group of ten children (five males and five females aged 11.3±1.6 years) with normal binocular vision, and revealed a visual phenomenon consisting of stochastic disappearanceof part of a visual scene caused by auditory stimulation. Indeed, during the Maddox test, brief sounds induced transient visual scotomas (VSs) in the visual field of the eye in front of where the Maddox rod was placed. We found a significant correlation between the modification of binocular vision and VS occurrence. No significant difference was detected in the percentage or location of VS occurrence between the right and left eye using the Maddox rod test orbetween sound frequencies. The results indicate a specific role of the oculomotor system in audiovisual integration in children. This convenient protocol may also have significant interest for clinical investigations of developmental pathologies where relationships between vision and hearing are specifically affected.

The effects of unilateral medial arch support stimulation on plantar pressure and center of pressure adjustment in young gymnasts.
The purpose of this study was to examine the contribution of tactile afferents from the medial arch of the foot on postural control. The center of pressure (CoP) position and right/left plantar pressure distributions of 13 gymnasts, with and without a medial arch support, were recorded by a force platform coupled with a baropedometry analysis. Stimulation of the subject's plantar sole was accomplished using a 3mm thick medial arch insert. Right arch stimulation induced an ipsilateral increase of plantar pressure and a contralateral displacement of the CoP to the left. Left arch support also resulted in an ipsilateral increase in plantar pressure and displacement of the CoP to the right. Stimulation of the plantar arch may induce a perception that the body's center of mass has shifted toward the stimulated foot. To maintain stability, individuals may then shift their CoP in the opposite direction. This response may involve compensatory muscle activation strategies to adjust posture. Clinicians may apply these results in their use of foot orthoses to address postural anomalies in patients.

THE CENTRAL COMPLEX OF DROSOPHILA LARVA

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Laura Lungu[1], Albert Cardona[1,2], Elizabeth Barsotti[1]
[1]University of Cambridge, Department Of Physiology, Development And Neuroscience, Cambridge, United Kingdom, [2]Medical Research Council - Laboratory of Molecular Biology, Neurobiology, Cambridge, United Kingdom

The Central Complex (CX) is a highly conserved set of neuropils found in insects, that is responsible for integrating sensory inputs (visual, mechanosensory and olfactory) towards spatial navigation decisions (e.g. heading direction, angular velocity and forward velocity), directed locomotion and sleep. In Drosophila, as in other holometabolous insects the central complex is formed during late larval and metamorphic stages. Nevertheless, this brain area has only been characterized in the adult stage of the fruit fly with little attention to its function in earlier stages of development. In this project, we aim at exploring - at synaptic level - whether a simplified version of the central complex exists in Drosophila larvae. Using the mapped electron microscopy volume of the L1 larva, we find that many central complex neuropils extant in the adult are also present in L1, including the noduli (NO), the protocerebral bridge(PB), and a substructure that seems to be the precursor for both the elipsoid body(EB) and the fan-shaped body(FB). Importantly, when describing these structures, we observed that patterns of connecivity characteristic to the adult CX are also present in the larva: (i) strong, direct connections from MBONs to the FB and NO, (ii) high levels of visual input into the PB and EB, but also (iii) strong connnectivity between FB and NO. Interestingly, we find that some lineages contributing to the CX of the larva seem to switch function in the adult, whilst others remain conserved.

The time course of synaesthetic colour perception.
Grapheme-colour synaesthesia is a neurodevelopmental condition wherein perception of numbers and letters consistently and involuntarily elicits concurrent experiences of colour photisms. Accumulating evidence suggests that heterogeneity in the visuospatial phenomenology of synaesthesia is attributable to the operation of top-down processes underlying photisms experienced as representations in associator synaesthetes and bottom-up processes subserving photisms experienced as spatially localized in projector synaesthetes. An untested corollary of this hypothesis is that bottom-up mechanisms will actuate earlier photism perception in projector than associator synaesthetes. We tested this prediction in a pre-registered study wherein associators and projectors completed adaptive temporal order judgement tasks for graphemes, colours, and photisms. In corroboration of the hypothesis of differential photism access across subtypes, projectors displayed lower photism colour thresholds than associators whereas the two subtypes did not significantly differ in veridical colour thresholds. Synaesthetes did not differ in grapheme or colour thresholds relative to non-synaesthete controls. These results are consistent with the proposal of differential neural mechanisms underlying photism perception in subtypes of grapheme-colour synaesthesia and warrant renewed attention to heterogeneity in the mechanisms and phenomenology of this condition.

SYNAPTIC PROCESSING IN EURYDENDROID NEURONS IN LARVAL ZEBRAFISH CEREBELLUM DURING ASSOCIATIVE MOTOR LEARNING

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Marion Najac, David Mclean, Indira Raman
Northwestern University, Neurobiology, Evanston, United States of America

Aims: Our goal was to identify changes in activity in cerebellar output neurons, during the acquisition of a motor behavior. Methods: We recorded Olig2(+) eurydendroid neurons (ENs) in whole-cell and loose-cell attached configurations, in immobilized larvae (dpf 6-8) while monitoring fictive swimming. The unconditioned stimulus, a mild electric tail shock, was repeatedly paired to the offset of the conditioned stimulus, a 2-s blue light. Results: Half fish acquired conditioned swimming responses to the light (CR), results reported below are from learners. Olig2(+) ENs showed robust excitatory and inhibitory synaptic activity, as well as increased firing, during unconditioned and conditioned fictive swimming, with inhibition always far exceeding excitation. Strikingly, at the population level, firing rates of ENs correlated with both EPSC and IPSC amplitude. Most Olig2(+) ENs had a purely motor-associative response and few had a mixed sensory-motor response; we have not seen a topographical distribution of those cells so far. Light-evoked synaptic inputs and an increase in firing preceded conditioned swimming by ~100 ms whereas tactile-related activity was concomitant to unconditioned swimming. Over the course of learning we did not observe modifications in synaptic inputs, only the presence or absence of CRs affected synaptic inputs. Conclusions: Olig2(+) ENs may participate in generating acquired motor responses. However, synaptic inputs from granule cell correlate with motor outcome, suggesting that the synaptic changes at the origin of CRs emergence occur upstream. Our results also suggest that a temporal patterning of EPSCs and IPSCs may allow ENs to fire action potentials despite the overwhelming inhibition.

INTER- AND INTRA-HEMISPHERIC SOURCES OF VESTIBULAR SIGNALS TO V1

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Sensations often trigger movements, but one's movements also generate sensory experience. Vestibular organs monitor head movements and contribute to the brain's ability to distinguish between self- and externally-generated sensory stimuli. Signals from the vestibular organs are broadcasted throughout the brain, including primary sensory regions such as the primary visual cortex (V1). However, what type of signals relative to head movements reach V1 and what the upstream sources of these signals are, remains poorly understood. Here we show that, in the absence of visual input, V1 neurons encode the direction of head movements as well as the angular velocity and acceleration in a layer specific manner. Moreover, we discovered that the ipsilateral latero-posterior thalamus (LP) and the contralateral visual cortex are key sources of vestibular input to V1. The ipsilateral LP provides the main head movement signal and this signal is biased toward contraversive head movements (i.e. clockwise head movements when recording from left V1). Instead, the contralateral visual cortex provides head-movement signals during ipsiversive head movements. Thus, this study reveals a direction specific recruitment of intra- and inter-hemispheric sources of vestibular signals to V1.

NMDARs in granule cells contribute to parallel fiber-Purkinje cell synaptic plasticity and motor learning.
Long-term synaptic plasticity is believed to be the cellular substrate of learning and memory. Synaptic plasticity rules are defined by the specific complement of receptors at the synapse and the associated downstream signaling mechanisms. In young rodents, at the cerebellar synapse between granule cells (GC) and Purkinje cells (PC), bidirectional plasticity is shaped by the balance between transcellular nitric oxide (NO) driven by presynaptic -methyl-D-aspartate receptor (NMDAR) activation and postsynaptic calcium dynamics. However, the role and the location of NMDAR activation in these pathways is still debated in mature animals. Here, we show in adult rodents that NMDARs are present and functional in presynaptic terminals where their activation triggers NO signaling. In addition, we find that selective genetic deletion of presynaptic, but not postsynaptic, NMDARs prevents synaptic plasticity at parallel fiber-PC (PF-PC) synapses. Consistent with this finding, the selective deletion of GC NMDARs affects adaptation of the vestibulo-ocular reflex. Thus, NMDARs presynaptic to PCs are required for bidirectional synaptic plasticity and cerebellar motor learning.

Head Movements Control the Activity of Primary Visual Cortex in a Luminance-Dependent Manner.
The vestibular system broadcasts head-movement-related signals to sensory areas throughout the brain, including visual cortex. These signals are crucial for the brain's ability to assess whether motion of the visual scene results from the animal's head movements. However, how head movements affect visual cortical circuits remains poorly understood. Here, we discover that ambient luminance profoundly transforms how mouse primary visual cortex (V1) processes head movements. While in darkness, head movements result in overall suppression of neuronal activity; in ambient light, the same head movements trigger excitation across all cortical layers. This light-dependent switch in how V1 processes head movements is controlled by somatostatin-expressing (SOM) inhibitory neurons, which are excited by head movements in dark, but not in light. This study thus reveals a light-dependent switch in the response of V1 to head movements and identifies a circuit in which SOM cells are key integrators of vestibular and luminance signals.

Cerebellar learning using perturbations.
The cerebellum aids the learning of fast, coordinated movements. According to current consensus, erroneously active parallel

fibre synapses are depressed by complex spikes signalling movement errors. However, this theory cannot solve the of processing a global movement evaluation into multiple cell-specific error signals. We identify a possible implementation of an algorithm solving this problem, whereby spontaneous complex spikes perturb ongoing movements, create eligibility traces and signal error changes guiding plasticity. Error changes are extracted by adaptively cancelling the average error. This framework, (SGDEGE), predicts synaptic plasticity rules that apparently contradict the current consensus but were supported by plasticity experiments in slices from mice under conditions designed to be physiological, highlighting the sensitivity of plasticity studies to experimental conditions. We analyse the algorithm's convergence and capacity. Finally, we suggest SGDEGE may also operate in the basal ganglia.

Burst-Dependent Bidirectional Plasticity in the Cerebellum Is Driven by Presynaptic NMDA Receptors.
Numerous studies have shown that cerebellar function is related to the plasticity at the synapses between parallel fibers and Purkinje cells. How specific input patterns determine plasticity outcomes, as well as the biophysics underlying plasticity of these synapses, remain unclear. Here, we characterize the patterns of activity that lead to postsynaptically expressed LTP using both in vivo and in vitro experiments. Similar to the requirements of LTD, we find that high-frequency bursts are necessary to trigger LTP and that this burst-dependent plasticity depends on presynaptic NMDA receptors and nitric oxide (NO) signaling. We provide direct evidence for calcium entry through presynaptic NMDA receptors in a subpopulation of parallel fiber varicosities. Finally, we develop and experimentally verify a mechanistic plasticity model based on NO and calcium signaling. The model reproduces plasticity outcomes from data and predicts the effect of arbitrary patterns of synaptic inputs on Purkinje cells, thereby providing a unified description of plasticity.

Contribution of postsynaptic T-type calcium channels to parallel fibre-Purkinje cell synaptic responses.
At the parallel fibre-Purkinje cell glutamatergic synapse, little or no Ca(2+) entry takes place through postsynaptic neurotransmitter receptors, although postsynaptic calcium increases are clearly involved in the synaptic plasticity. Postsynaptic voltage-gated Ca(2+) channels therefore constitute the sole rapid postsynaptic Ca(2+) signalling mechanism, making it essential to understand how they contribute to the synaptic signalling. Using a selective T-type calcium channel antagonist, we describe a T-type component of the EPSC that is activated by the AMPA receptor-mediated depolarization of the spine and thus will contribute to the local calcium dynamics. This component can amount up to 20% of the EPSC, and this fraction is maintained even at the high frequencies sometimes encountered in sensory processing. Modelling based on our biophysical characterization of T-type calcium channels in Purkinje cells suggests that the brief spine EPSCs cause the activated T-type channels to deactivate rather than inactivate, enabling repetitive activation.

Properties and molecular identity of NMDA receptors at synaptic and non-synaptic inputs in cerebellar molecular layer interneurons.
N-methyl-D-aspartate receptors (NMDARs) in cerebellar molecular layer interneurons (MLIs) are expressed and activated in unusual ways: at parallel fibre (PF) synapses they are only recruited by repetitive stimuli, suggesting an extrasynaptic location, whereas their activation by climbing fibre is purely mediated by spillover. NMDARs are thought to play an important role in plasticity at different levels of the cerebellar circuitry. Evaluation of the location, functional properties and physiological roles of NMDARs will be facilitated by knowledge of the NMDAR isoforms recruited. Here we show that MLI-NMDARs activated by both PF and climbing fibre inputs have similar kinetics and contain GluN2B but not GluN2A subunits. On the other hand, no evidence was found of functional NMDARs in the axons of MLIs. At the PF-Purkinje cell (PF-PC) synapse, the activation of GluN2A-containing NMDARs has been shown to be necessary for the induction of long-term depression (LTD). Our results therefore provide a clear distinction between the NMDARs located on MLIs and those involved in plasticity at PF-PC synapses.

T-type channel blockade impairs long-term potentiation at the parallel fiber-Purkinje cell synapse and cerebellar learning.
CaV3.1 T-type channels are abundant at the cerebellar synapse between parallel fibers and Purkinje cells where they contribute to synaptic depolarization. So far, no specific physiological function has been attributed to these channels neither as charge carriers nor more specifically as Ca(2+) carriers. Here we analyze their incidence on synaptic plasticity, motor behavior, and cerebellar motor learning, comparing WT animals and mice where T-type channel function has been abolished either by gene deletion or by acute pharmacological blockade. At the cellular level, we show that CaV3.1 channels are required for long-term potentiation at parallel fiber-Purkinje cell synapses. Moreover, basal simple spike discharge of the

Purkinje cell in KO mice is modified. Acute or chronic T-type current blockade results in impaired motor performance in particular when a good body balance is required. Because motor behavior integrates reflexes and past memories of learned behavior, this suggests impaired learning. Indeed, subjecting the KO mice to a vestibulo-ocular reflex phase reversal test reveals impaired cerebellum-dependent motor learning. These data identify a role of low-voltage activated calcium channels in synaptic plasticity and establish a role for CaV3.1 channels in cerebellar learning.

Persistent posttetanic depression at cerebellar parallel fiber to Purkinje cell synapses.
Plasticity at the cerebellar parallel fiber to Purkinje cell synapse may underlie information processing and motor learning. In vivo, parallel fibers appear to fire in short high frequency bursts likely to activate sparsely distributed synapses over the Purkinje cell dendritic tree. Here, we report that short parallel fiber tetanic stimulation evokes a ~7-15% depression which develops over 2 min and lasts for at least 20 min. In contrast to the concomitantly evoked short-term endocannabinoid-mediated depression, this persistent posttetanic depression (PTD) does not exhibit a dependency on the spatial pattern of synapse activation and is not caused by any detectable change in presynaptic calcium signaling. This persistent PTD is however associated with increased paired-pulse facilitation and coefficient of variation of synaptic responses, suggesting that its expression is presynaptic. The chelation of postsynaptic calcium prevents its induction, suggesting that post- to presynaptic (retrograde) signaling is required. We rule out endocannabinoid signaling since the inhibition of type 1 cannabinoid receptors, monoacylglycerol lipase or vanilloid receptor 1, or incubation with anandamide had no detectable effect. The persistent PTD is maximal in pre-adolescent mice, abolished by adrenergic and dopaminergic receptors block, but unaffected by adrenergic and dopaminergic agonists. Our data unveils a novel form of plasticity at parallel fiber synapses: a persistent PTD induced by physiologically relevant input patterns, age-dependent, and strongly modulated by the monoaminergic system. We further provide evidence supporting that the plasticity mechanism involves retrograde signaling and presynaptic diacylglycerol.

MULTISENSORY TRAINING INDUCED RECOVERY FROM HEMIANOPIA IN HUMAN PATIENTS

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Benjamin Rowland[1], Cheryl Bushnell[2], Pamela Duncan[2], Atalie Thompson[3], Barry Stein[1]
[1]Wake Forest School of Medicine, Neurobiology And Anatomy, Winston-Salem, United States of America, [2]Wake Forest School of Medicine, Neurology, Winston-Salem, United States of America, [3]Wake Forest School of Medicine, Ophthalmology, Winston-Salem, United States of America

Contralateral blindness (hemianopia) is a common consequence of stroke or trauma that unilaterally damages visual cortex. We previously demonstrated in an animal model that vision is rapidly restored to the blinded hemifield by a noninvasive multisensory training paradigm (see Stein & Rowland, 2020). The paradigm involves repeatedly presenting congruent visual-auditory stimulus pairs in the blinded hemifield. Here we show this paradigm is effective in two human patients whose hemianopia was a consequence of right PCA occlusion. Over the course of several weekly sessions of multisensory training, both regained the ability to detect, verbally report, and accurately point to light flashes in the left hemifield while maintaining fixation. The recovery pattern was like that observed in the animal model: beginning at the sighted field margin and expanding to encompass all locations across the entire hemifield. The recovered vision was robust even when challenged with competitive stimuli in the opposite hemifield and both patients commented on the intensity and color of the stimuli. One could describe the shapes of stationary, flashed, or moving (high contrast) objects everywhere within the formerly blinded field, while the other did so only in more central locations. Both patients reported significant quality of life improvements. Recovery was consistent with a model in which spatiotemporally congruent visual-auditory stimulation engages the brain's mechanisms for multisensory plasticity, through which convergent cross-modal signals enhance the visual sensitivity of multisensory neurons. Supported by NIH R01 EY026916 and a pilot grant from the Wake Forest School of Medicine Clinical Trials and Innovation Center.

BRAIN MORPHOMETRIC CHANGES IN CONGENITALLY BLIND SUBJECTS - A 7 TESLA MRI STUDY

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Ron Kupers, Beatrice De Gelder, Minye Zhan, Maarten Vaessen
University of Maastricht, Department Of Cognitive Neuroscience, Maastricht, Netherlands

Aims: To get a more comprehensive view of cerebral, subcortical and cerebral changes related to congenital blindness using ultra-high field magnetic resonance imaging (MRI). **Methods:** 12 congenitally blind (CB) and 11 matched sighted control (SC) subjects were scanned using 7 Tesla MRI at submillimeter resolution. Data were analyzed using Freesurfer. We assessed changes in cortical grey matter (GM) and white matter (WM) volume, cortical thickness (CT), cortical curvature and subcortical volumes. We segmented subcortical structures into their constituent nuclei. We used “volbrain” to assessed for regional changes in cerebellum. **Results:** CB had overall lower GM and WM volume for whole brain and cerebellum compared to SC. A region-of-interest analysis revealed GM reductions in various visual areas in striate and inferior temporal cortices, (post)central and superior frontal gyri, and right subcallosal gyrus. No significant group differences in CT were found. WM showed a similar pattern of volumetric reductions as those for GM but with additional reductions in precuneus and orbitofrontal cortex. Changes in cortical curvature were mostly situated in occipital cortex. Subcortically, caudate nucleus, putamen, globus pallidum, thalamus and nucleus accumbens were smaller in CB. Within thalamus, there were volumetric reductions in lateral geniculate, ventroposterior, centromedian and ventromedian nuclei. Within hippocampus, left presubiculum and right CA1 were smaller in CB. Reductions in cerebellar GM, WM and CT were also found in CB. **Conclusion:** Our data reveal a multitude of GM and WM reductions in CB, covering occipital, temporal, parietal, prefrontal, subcortical and cerebellar areas.

A META-ANALYSIS OF STRUCTURAL CHANGES IN CONGENITAL AND LATE-ONSET BLINDNESS

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Samuel Paré[1], Maxime Bleau[2], Ismaël Djerourou[3], Laurence Dricot[4], Maurice Ptito[2], Ron Kupers[5]
[1]Université de Montréal, Ecole D'optométrie, Montréal, Canada, [2]Université de Montréal, Ecole D'optométrie, Montreal, Canada, [3]Université de Montréal, Optometry, Montréal, Canada, [4]Université Catholique de Louvain, Neuroscience, Woluwe-Saint-Lambert, Belgium, [5]University of Copenhagen, Panum Institute, Copenhagen, Denmark

Aim: Numerous reports have described structural brain changes in congenitally blind (CB) and late blind (LB) subjects. However, there is a large variability in reported outcomes. Here, we present results of a meta- analysis of brain morphological changes due to blindness. **Methods:** We performed a complete literature search of five databases (Pubmed, Embase, MEDLINE, Psychinfo, Global Health) in conjunction with an ALE coordinate-based-meta-analysis in early and late-onset blindness in human. Out of 4140 studies screened, 279 were considered eligible. Of these, 65 studies were finally withheld, including 979 CB, 532 LB and 1333 sighted controls (SC). **Results:** Close to half of the studies reported voxel-based or surface-based morphometry data. Diffusion studies accounted for one third. For CB, ALE analysis revealed 3 clusters of reduced volume in cuneus, lentiform and precuneus, and one cluster of increased volume in temporal pole. In addition, CB had decreased cortical thickness (CT) in postcentral gyrus and increased CT in lingual gyrus. CB also had decreased fractional anisotropy (FA) in fusiform, lingual and middle occipital gyri. For LB, ALE revealed two clusters of reduced volume in bilateral cuneus, two of increased volume in the superior temporal and parahippocampal (PHG) gyri and three clusters of reduced FA (sub-gyral, sub-lobar and lingual gyrus). **Conclusion:** Despite the large variability in outcomes across studies, ALE revealed a consistent pattern of changes in CB and LB, consisting of volumetric reductions mostly in visual areas and decreases in FA in visual areas extending into PHG. We found little evidence for “adaptive” changes.

OPTOGENETIC PROSTHETIC STIMULATION IN THE LATERAL GENICULATE NUCLEUS CAN INDUCE VISUAL-LIKE DETECTION BEHAVIOR IN TREE SHREWS

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Jing Wang, Hamid Azimi, Melanie Kaeser, Michael Harvey, Gregor Rainer
University of Fribourg, Department Of Medicine, Fribourg, Switzerland

The visual thalamic lateral geniculate nucleus (LGN) is a potentially attractive target for visual prosthetics due to its laminar, retinotopic organization. Here we are interested in studying how visual stimulation and optogenetic activation of the LGN impact visually based behavior. We chose the northern tree shrew *T. belangeri*, a small diurnal mammal with a highly developed visual apparatus. In a visual detection paradigm, we used an opaque globe containing a nose-poke at its center to deliver visual stimuli in a retinotopic fashion using a projector in freely moving animals without food or water restriction. Tree shrews had to enter a nose-poke, and remain there until a visual stimulus, a cloud of moving dots resembling a phosphene, was presented at a particular visual field location. They quickly acquired this detection task, achieving over 70% correct performance for stimuli of 2° diameter in size after one week training. Following injection of AAV2-CaMKIIα-ChR2 in LGN, we then studied target detection of brief optogenetic LGN stimulation at various stimulation frequencies by tree shrews, using a battery- and cable-free RF powered light stimulator. Preliminary data suggest that frequencies of 10Hz and 50Hz are more easily detected than other frequencies. Optogenetic target detection was compromised by the addition of a visually presented masking stimulus (moving dot phosphene cloud 60°x75° in size). Our findings suggest that the tree shrew could be a useful animal model system to systematically study how optogenetic interventions in the LGN impact activations across the visual pathways, visual percepts and visually-based behaviors.

Washed Microbiota Transplantation Accelerates the Recovery of Abnormal Changes by Light-Induced Stress in Tree Shrews.
The gut and brain interact constantly in a complex fashion. Its intricacy and intrigue is progressively being revealed in the study of the "gut-brain axis". Among many factors, abnormal light exposure is a potential powerful stressor, which is becoming ever more pervasive in our modern society. However, little is known about how stress, induced by staying up late by light, affects the gut-brain axis. We addressed this question by extending the normal circadian light for four hours at night in fifteen male tree shrews to simulate the pattern of staying up late in humans. The behavior, biochemical tests, microbiota dynamics, and brain structure of tree shrews were evaluated. The simple prolongation of light in the environment resulted in substantial changes of body weight loss, behavioral differences, total sleep time reduction, and an increased level of urine cortisol. These alterations were rescued by the treatment of either ketamine or washed microbiota transplantation (WMT). Importantly, the sustainability of WMT effect was better than that of ketamine. Magnetic Resonance Imaging analysis indicated that ketamine acted on the hippocampus and thalamus, and WMT mainly affected the piriform cortex and lateral geniculate nucleus. In conclusion, long-term light stimulation could change the behaviors, composition of gut microbiota and brain structure in tree shrews. Targeting microbiota thus certainly holds promise as a treatment for neuropsychiatric disorders, including but not limited to stress-related diseases.

Aspects of tree shrew consolidated sleep structure resemble human sleep.
Understanding human sleep requires appropriate animal models. Sleep has been extensively studied in rodents, although rodent sleep differs substantially from human sleep. Here we investigate sleep in tree shrews, small diurnal mammals phylogenetically close to primates, and compare it to sleep in rats and humans using electrophysiological recordings from frontal cortex of each species. Tree shrews exhibited consolidated sleep, with a sleep bout duration parameter, τ, uncharacteristically high for a small mammal, and differing substantially from the sleep of rodents that is often punctuated by wakefulness. Two NREM sleep stages were observed in tree shrews: NREM, characterized by high delta waves and spindles, and an intermediate stage (IS-NREM) occurring on NREM to REM transitions and consisting of intermediate delta waves with concomitant theta-alpha activity. While IS-NREM activity was reliable in tree shrews, we could also detect it in

human EEG data, on a subset of transitions. Finally, coupling events between sleep spindles and slow waves clustered near the beginning of the sleep period in tree shrews, paralleling humans, whereas they were more evenly distributed in rats. Our results suggest considerable homology of sleep structure between humans and tree shrews despite the large difference in body mass between these species.

Mapping of c-Fos expression in male tree shrew forebrain.
The tree shrew is susceptible to stimuli. However, mapping of c-Fos expression in male tree shrew forebrain has not been explored. The present results provided the first detailed mapping of c-Fos expression in the forebrain of the tree shrew (Tupaia belangeri chinensis). Acute restraint stress rapidly increased the density of c-Fos-immunoreactive (-ir) neurons in the medial orbital cortex (MO), infralimbic cortex, intermediate part of the lateral septal nucleus (LSi), ventral part of the lateral septal nucleus (LSv), anterior part of the bed nucleus of the stria terminalis, posterior part of the bed nucleus of the stria terminalis (STP), paraventricular nucleus of the hypothalamus, supraoptic nucleus, lateral hypothalamic area, ventromedial hypothalamic nucleus (VMH), and medial amygdaloid nucleus (MeA). Furthermore, a significant increase in c-Fos expression was observed in the MO, LSi, LSv, STP, VMH, arcuate hypothalamic nucleus, anterior amygdaloid area, MeA, and cortical amygdaloid nucleus immediately after acute footshock stress. In addition, the distinct patterns of c-Fos expression in the forebrain were shown in context-, restraint-, or footshock-treated tree shrews. In general, the present study provides the first detailed maps of c-Fos expression in male tree shrew forebrain immediately after various stimuli.

A protein phosphatase 2A deficit in the hippocampal CA1 area impairs memory extinction.
Protein phosphorylation plays an important role in learning and memory. Protein phosphatase 2A (PP2A) is a serine/threonine phosphatase involved in the regulation of neural synaptic plasticity. Here, to determine if PP2A is necessary for successful learning and memory, we have utilized a Tg (Camk2a-cre) T29-2Stl mice to specific knock down the expression of hippocampal PP2A in mice. By analysing behavioural, we observed that loss of PP2A in the hippocampal CA1 area did not affect the formation of memory but impaired contextual fear memory extinction. We use the electrophysiological recording to find the synaptic mechanisms. The results showed that the basic synapse transmission and synaptic plasticity of PP2A conditional knockout (CKO) mice were impaired. Moreover, PP2A CKO mice exhibited a saturating long-term potentiation inducted by strong theta burst stimulation but no depotentiation after low-frequency stimulation. Taken together, our results provide the evidence that PP2A is involved in synaptic transmission and hippocampus-dependent memory extinction.

Hippocampal Wdr1 Deficit Impairs Learning and Memory by Perturbing F-actin Depolymerization in Mice.
WD repeat protein 1 (Wdr1), known as a cofactor of actin-depolymerizing factor (ADF)/cofilin, is conserved among eukaryotes, and it plays a critical role in the dynamic reorganization of the actin cytoskeleton. However, the function of Wdr1 in the central nervous system remains elusive. Using Wdr1 conditional knockout mice, we demonstrated that Wdr1 plays a significant role in regulating synaptic plasticity and memory. The knockout mice exhibited altered reversal spatial learning and fear responses. Moreover, the Wdr1 CKO mice showed significant abnormalities in spine morphology and synaptic function, including enhanced hippocampal long-term potentiation and impaired long-term depression. Furthermore, we observed that Wdr1 deficiency perturbed actin rearrangement through regulation of the ADF/cofilin activity. Taken together, these results indicate that Wdr1 in the hippocampal CA1 area plays a critical role in actin dynamics in associative learning and postsynaptic receptor availability.

Rapid-onset antidepressant efficacy of glutamatergic system modulators: the neural plasticity hypothesis of depression.
Depression is a devastating psychiatric disorder widely attributed to deficient monoaminergic signaling in the central nervous system. However, most clinical antidepressants enhance monoaminergic neurotransmission with little delay but require 4-8

weeks to reach therapeutic efficacy, a paradox suggesting that the monoaminergic hypothesis of depression is an oversimplification. In contrast to the antidepressants targeting the monoaminergic system, a single dose of the N-methyl-D-aspartate receptor (NMDAR) antagonist ketamine produces rapid (within 2 h) and sustained (over 7 days) antidepressant efficacy in treatment-resistant patients. Glutamatergic transmission mediated by NMDARs is critical for experience-dependent synaptic plasticity and learning, processes that can be modified indirectly by the monoaminergic system. To better understand the mechanisms of action of the new antidepressants like ketamine, we review and compare the monoaminergic and glutamatergic antidepressants, with emphasis on neural plasticity. The pathogenesis of depression may involve maladaptive neural plasticity in glutamatergic circuits that may serve as a new class of targets to produce rapid antidepressant effects.
Neurosci Bull, 2015; 31

Chronic clomipramine treatment reverses core symptom of depression in subordinate tree shrews.
Chronic stress is the major cause of clinical depression. The behavioral signs of depression, including anhedonia, learning and memory deficits, and sleep disruption, result from the damaging effects of stress hormones on specific neural pathways. The Chinese tree shrew (Tupaia belangeri chinensis) is an aggressive non-human primate with a hierarchical social structure that has become a well-established model of the behavioral, endocrine, and neurobiological changes associated with stress-induced depression. The tricyclic antidepressant clomipramine treats many of the core symptoms of depression in humans. To further test the validity of the tree shrew model of depression, we examined the effects of clomipramine on depression-like behaviors and physiological stress responses induced by social defeat in subordinate tree shrews. Social defeat led to weight loss, anhedonia (as measured by sucrose preference), unstable fluctuations in locomotor activity, sustained urinary cortisol elevation, irregular cortisol rhythms, and deficient hippocampal long-term potentiation (LTP). Clomipramine ameliorated anhedonia and irregular locomotor activity, and partially rescued the irregular cortisol rhythm. In contrast, weight loss increased, cortisol levels were even higher, and in vitro LTP was still impaired in the clomipramine treatment group. These results demonstrate the unique advantage of the tree shrew social defeat model of depression.

The human brain can form mental maps of an environment, which can support wayfinding. In such a cognitive map, spatial information such as distances between familiar locations are stored. The hippocampus and entorhinal cortex are essential regions for spatial orientation and navigation. They have been shown to encode distances to goals during navigation, and to store distances in a map-like representation. Most of this research was performed using visual information. In our study, we assessed map formation using tactile information in visually impaired and sighted persons. Furthermore, we explored the role of allocentric and egocentric navigation strategies. We let participants perform an object-location task in a tactile city-like environment, and combined functional magnetic resonance imaging (fMRI) with voxel pattern analysis to assess distance representations in the hippocampus and entorhinal cortex. Behavioural analyses show that both visually impaired and sighted participants have a good mental map of that tactile environment. When testing across all participants in the fMRI results, we found trend level distance representations in the right hippocampus. We found no differential representations between visually impaired and sighted participants. Furthermore, our analyses reveal representations of distances in the right hippocampus and entorhinal cortex in allocentric navigators, but not egocentric navigators. These results suggest map formation in the hippocampus and entorhinal cortex using tactile information. This is in line with ideas of modality-independent coding of space. Furthermore, our findings highlight the importance of implicating navigational strategies in cognitive map research.

EEG EVOKED ACTIVITY SUGGESTS AMODAL EVIDENCE INTEGRATION IN MULTISENSORY DECISION-MAKING

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Thomas Schaffhauser, Alain De Cheveigné, Yves Boubenec, Pascal Mamassian
Ecole Normale Superieure, PSL University, CNRS, Lsp, Paris, France

Recent works in neuroimaging have revealed neural signatures of evidence integration (O'Connell et al., 2012, Nat Neuro; Philiastides et al., 2014, J Neuro) that reflect the ramping activity of neurons in the parietal cortex. While these experiments focused on unisensory visual and auditory perceptual decision-making, it is unclear to what extent the neural correlates of multisensory evidence integration are shared with their unisensory counterparts. To address this issue, we designed a change detection paradigm in which twenty-one participants monitored a continuous stream of visual random dot motion and auditory tone clouds. The random dot motion was displayed within a circular aperture and consisted of 200 small dots repositioned every 50 ms. The tone clouds consisted of 10 simultaneous 50 ms pure tones drawn from a range of 6 octaves with a resolution of 12 semitones per octave. Participants had to detect unisensory or bimodal changes while continuous EEG was acquired. EEG activity was denoised with spatial filtering techniques to isolate components that capture neural activity most reproducibly evoked by stimulus change onset (de Cheveigné & Simon, 2008, J Neuro Methods). EEG evoked activity could be discriminated between visual and auditory target stimuli highlighting separable encoding of visual and auditory coherence changes. Further analyses revealed a component rising before participants response that echoes evidence accumulation and appeared to be common for both unisensory and redundant audio-visual changes. These results point to a single amodal accumulator that integrates evidence coming from each sensory modality in isolation or a combined bimodal signal.

ONE-MONTH AUDIO-MOTOR TRAINING IMPROVES SOME SPATIAL ABILITIES OF LATE-BLIND PEOPLE.

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Maria Bianca Amadeo, Chiara Martolini, Claudio Campus, Giulia Cappagli, Monica Gori
Istituto Italiano di Tecnologia, Unit For Visually Impaired People (u-vip), Genova, Italy

Late blindness represents a unique model to study how spatial abilities develop with visual feedback early in life and subsequently visual deprivation. Research showed that experiencing prolonged visual deprivation in adulthood compromises some complex spatial abilities and underlying neural correlates. We investigated whether training based on audio-motor coupling improved audio-proprioceptive spatial abilities of long-term late blind individuals at behavioral and neurophysiological levels. Six long-term late-blind adults took part in the study. Half participants performed a four-week training with ABBI (Audio Bracelet for Blind Interaction), a wearable device that has been clinically validated as rehabilitative technology to enhance spatial perception in visually impaired people. The other participants were recruited as a control sample performing everyday activities without any training. The training consisted of spatial exercises based on upper-limb movements to be performed in peripersonal and extrapersonal coordinates by relying on the auditory feedback from the bracelet. Before and after one month, a battery of spatial tasks was administrated to all participants consisting of 1) one auditory spatial bisection task with coherent and conflicting spatiotemporal information performed during EEG recording, 2) two auditory localization tasks, and 3) two proprioceptive-motor tasks. Results showed that some auditory and proprioceptive abilities of the late-blind participants who performed the training improved. Moreover, the audio-motor training induced adaptive changes in the early recruitment of visual and auditory areas during the spatial bisection task. To conclude, multimodal rehabilitation seems to help late blind individuals to overcome some of their spatial perception challenges.

Reduced flash lag illusion in early deaf individuals.
When a brief flash is quickly presented aligned with a moving target, the flash typically appears to lag behind the moving stimulus. This effect is widely known in the literature as a flash-lag illusion (FLI). The flash-lag is an example of a motion-induced position shift. Since auditory deprivation leads to both enhanced visual skills and impaired temporal abilities, both crucial for the perception of the flash-lag effect, here we hypothesized that lack of audition could influence the FLI. 13 early deaf and 18 hearing individuals were tested in a visual FLI paradigm to investigate this hypothesis. As expected, results demonstrated a reduction of the flash-lag effect following early deafness, both in the central and peripheral visual fields. Moreover, only for deaf individuals, there is a positive correlation between the flash-lag effect in the peripheral and central visual field, suggesting that the mechanisms underlying the effect in the center of the visual field expand to the periphery following deafness. Overall, these findings reveal that lack of audition early in life profoundly impacts early visual processing underlying the flash-lag effect.

Masking Emotions: Face Masks Impair How We Read Emotions.
To date, COVID-19 has spread across the world, changing our way of life and forcing us to wear face masks. This report demonstrates that face masks influence the human ability to infer emotions by observing facial configurations. Specifically, a mask obstructing a face limits the ability of people of all ages to infer emotions expressed by facial features, but the difficulties associated with the mask's use are significantly pronounced in children aged between 3 and 5 years old. These findings are of essential importance, as they suggest that we live in a time that may potentially affect the development of social and emotion reasoning, and young children's future social abilities should be monitored to assess the true impact of the use of masks.

Visual representations of time elicit early responses in human temporal cortex.
Time perception is inherently part of human life. All human sensory modalities are always involved in the complex task of

creating a temporal representation of the external world. However, when representing time, people primarily rely on auditory information. Since the auditory system prevails in many audio-visual temporal tasks, one may expect that the early recruitment of the auditory network is necessary for building a highly resolved and flexible temporal representation in the visual modality. To test this hypothesis, we asked 17 healthy participants to temporally bisect three consecutive flashes while we recorded EEG. We demonstrated that visual stimuli during temporal bisection elicit an early (50-90 ms) response of an extended area of the temporal cortex, likely including auditory cortex too. The same activation did not appear during an easier spatial bisection task. These findings suggest that the brain may use auditory representations to deal with complex temporal representation in the visual system.

Spatial metric in blindness: behavioural and cortical processing.
Visual modality dominates spatial perception and, in lack of vision, space representation might be altered. Here we review our work showing that blind individuals have a strong deficit when performing spatial bisection tasks (Gori et al., 2014). We also describe the neural correlates associated with this deficit, as blind individuals do not show the same ERP response mimicking the visual C1 reported in sighted people during spatial bisection (Campus et al., 2019). Interestingly, the deficit is not always evident in late blind individuals, and it is dependent on blindness duration. We report that the deficit disappears when one presents coherent temporal and spatial cues to blind people. This suggests that they may use time information to infer spatial maps (Gori et al., 2018). Finally, we propose a model to explain why blind individuals are impaired in this task, speculating that a lack of vision drives the construction of a multi-sensory cortical network that codes space based on temporal, rather than spatial, coordinates.
Neurosci Biobehav Rev, 2020; 109

Time attracts auditory space representation during development.
Vision is the most accurate sense for spatial representation, whereas audition is for temporal representation. However, how different sensory modalities shape the development of spatial and temporal representations is still unclear. Here, 45 children aged 11-13 years were tested to investigate the abilities to evaluate spatial features of auditory stimuli during bisection tasks, while conflicting or non-conflicting spatial and temporal information was delivered. Since audition is fundamental for temporal representation, the hypothesis was that temporal information could influence auditory spatial representation development. Results show a strong interaction between the temporal and the spatial domain. Younger children are not able to build complex spatial representations when the temporal domain is uninformative about space. However, when the spatial information is coherent with the temporal information children of all age are able to decode complex spatial relationships. When spatial and temporal cues are conflicting, younger children are strongly attracted by the temporal instead of spatial information, while older participants result unaffected by the cross-domain conflict. These findings suggest that during development temporal representation of events is used to infer spatial coordinates of the environment, offering important opportunities for new teaching and rehabilitation strategies.

Spatial Cues Influence Time Estimations in Deaf Individuals.
Recent studies have reported a strong interaction between spatial and temporal representation when visual experience is missing: blind people use temporal representation of events to represent spatial metrics. Given the superiority of audition on time perception, we hypothesized that when audition is not available complex temporal representations could be impaired, and spatial representation of events could be used to build temporal metrics. To test this hypothesis, deaf and hearing subjects were tested with a visual temporal task where conflicting and not conflicting spatiotemporal information was delivered. As predicted, we observed a strong deficit of deaf participants when only temporal cues were useful and space was uninformative with respect to time. However, the deficit disappeared when coherent spatiotemporal cues were presented and increased for conflicting spatiotemporal stimuli. These results highlight that spatial cues influence time estimations in deaf participants, suggesting that deaf individuals use spatial information to infer temporal environmental coordinates.
iScience, 2019; 19
31406158: Amadeo MB, Störmer VS, Campus C, Gori M
Peripheral sounds elicit stronger activity in contralateral occipital cortex in blind than sighted individuals.
Previous research has shown that peripheral, task-irrelevant sounds elicit activity in contralateral visual cortex of sighted people, as revealed by a sustained positive deflection in the event-related potential (ERP) over the occipital scalp contralateral to the sound's location. This Auditory-evoked Contralateral Occipital Positivity (ACOP) appears between 200-450 ms after sound onset, and is present even when the task is entirely auditory and no visual stimuli are presented at all. Here, we investigate whether this cross-modal activation of contralateral visual cortex is influenced by visual experience. To

this end, ERPs were recorded in 12 sighted and 12 blind subjects during a unimodal auditory task. Participants listened to a stream of sounds and pressed a button every time they heard a central target tone, while ignoring the peripheral noise bursts. It was found that task-irrelevant noise bursts elicited a larger ACOP in blind compared to sighted participants, indicating for the first time that peripheral sounds can enhance neural activity in visual cortex in a spatially lateralized manner even in visually deprived individuals. Overall, these results suggest that the cross-modal activation of contralateral visual cortex triggered by peripheral sounds does not require any visual input to develop, and is rather enhanced by visual deprivation.
Sci Rep, 2019; 9

30760758: Campus C, Sandini G, Amadeo MB, Gori M
Stronger responses in the visual cortex of sighted compared to blind individuals during auditory space representation.
It has been previously shown that the interaction between vision and audition involves early sensory cortices. However, the functional role of these interactions and their modulation due to sensory impairment is not yet understood. To shed light on the impact of vision on auditory spatial processing, we recorded ERPs and collected psychophysical responses during space and time bisection tasks in sighted and blind participants. They listened to three consecutive sounds and judged whether the second sound was either spatially or temporally further from the first or the third sound. We demonstrate that spatial metric representation of sounds elicits an early response of the visual cortex (P70) which is different between sighted and visually deprived individuals. Indeed, only in sighted and not in blind people P70 is strongly selective for the spatial position of sounds, mimicking many aspects of the visual-evoked C1. These results suggest that early auditory processing associated with the construction of spatial maps is mediated by visual experience. The lack of vision might impair the projection of multi-sensory maps on the retinotopic maps used by the visual cortex.
Sci Rep, 2019; 9

30710679: Amadeo MB, Campus C, Gori M
Impact of years of blindness on neural circuits underlying auditory spatial representation.
Early visual deprivation impacts negatively on spatial bisection abilities. Recently, an early (50-90 ms) ERP response, selective for sound position in space, has been observed in the visual cortex of sighted individuals during the spatial but not the temporal bisection task. Here, we clarify the role of vision on spatial bisection abilities and neural correlates by studying late blind individuals. Results highlight that a shorter period of blindness is linked to a stronger contralateral activation in the visual cortex and a better performance during the spatial bisection task. Contrarily, not lateralized visual activation and lower performance are observed in individuals with a longer period of blindness. To conclude, the amount of time spent without vision may gradually impact on neural circuits underlying the construction of spatial representations in late blind participants. These findings suggest a key relationship between visual deprivation and auditory spatial abilities in humans.

Temporal Cues Influence Space Estimations in Visually Impaired Individuals.
Many works have highlighted enhanced auditory processing in blind individuals, suggesting that they compensate for lack of vision with greater sensitivity of the other senses. Few years ago, we demonstrated severely impaired auditory precision in congenitally blind individuals performing an auditory spatial metric task: their thresholds for bisecting three consecutive spatially distributed sounds were seriously compromised, ranging from three times typical thresholds to total randomness. Here, we show that the deficit disappears if blind individuals are presented with coherent temporal and spatial cues. More interestingly, when the audio information is presented in conflict for space and time, sighted individuals are unaffected by the perturbation, whereas blind individuals are strongly attracted by the temporal cue. These results highlight that temporal cues influence space estimations in blind participants, suggesting for the first time that blind individuals use temporal information to infer spatial environmental coordinates.

MULTI-AREA NEURONAL POPULATION DYNAMICS IN MOUSE NEOCORTEX DURING SENSORY DISCRIMINATION

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Shuting Han[1,2], Fritjof Helmchen[1,2]
[1]University of Zurich, Brain Research Institute, Zurich, Switzerland, [2]University of Zurich / ETH Zurich, Neuroscience Center Zurich, Zurich, Switzerland

Animals adapt to the constantly changing world by learning and predicting the environment and the consequences of their actions. The predictive coding hypothesis states that the brain generates predictions that flow down the hierarchy of neocortical regions, continually comparing them with the actual sensory inputs, and that mismatches are sent up as prediction errors to correct the internal models and generate better predictions. To test this hypothesis, we simultaneously imaged the activity of neuronal populations in mouse somatosensory (S1) cortex and posterior parietal cortex (RL part of PPC) during texture discrimination behavior. Mice were trained to discriminate two textures and then to gradually associate each texture with a distinct auditory cue before texture onset. In expert mice, we randomly introduced trials where the cue and texture are mismatched. We measured GCaMP6f calcium signals in S1 and PPC neurons with a custom-built two-area two-photon microscope. We found that cue-texture mismatch results in erroneous sensory and choice coding of both populations, through disrupted population firing pattern as well as shifted tuning in task-responsive neurons. Furthermore, cross-area interaction is altered when mice shift their predictions to the earlier cue. We will present further results of our ongoing analysis of cross-area interactions.

ORGANIZATION OF AUDITORY AND AUDIO-VISUAL SPACE IN THE VISUAL CORTEX

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Camille Mazo, Margarida Baeta, Leopoldo Petreanu
Champalimaud Foundation, Champalimaud Research, Lisbon, Portugal

Binding different physical features of objects requires linking multiple sensory stimuli when they are congruent in time and space. The auditory cortex (AC) sends projections to the primary visual cortex (V1), thereby providing a substrate for binding audio-visual stimuli according to their spatiotemporal congruency. While AC neurons show spatial auditory receptive fields, it is not known if information about the spatial location of sounds is relayed to V1, and whether they target neurons with similar receptive fields as themselves. We employed dual-color two-photon calcium imaging and used a 3D array of speakers and LEDs to 1) measure the auditory spatial information that the AC relays to V1 with regard to the visual map of space, and 2) investigate whether multisensory interactions depend on the spatial congruency of auditory and visual stimuli. We found that many AC axons convey information about the location of a sound source to V1. However, unlike visual feedback from the lateral visual cortex, the spatial tuning of AC axons in V1 does not match that of V1 neurons. Consistent with this, audio-visual modulations of both AC axons and V1 neurons did not depend on the spatial congruence of the sound and light stimuli. Nevertheless, we found that audio-visual modulations are projection-specific: visual modulation of auditory responses was only present in AC projections to V1, but not to S1. Our results suggest that inter- and intra-modal cortico-cortical projections follow different organizational rules, and modulation of these inter-modal inputs depends on the modality of the targeted region.

INTELLIGIBILITY OF AUDIOVISUAL SPEECH DRIVES MULTIVOXEL RESPONSE PATTERNS IN HUMAN SUPERIOR TEMPORAL CORTEX

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Yue Zhang[1], Johannes Rennig[2], John Magnotti[1], Michael Beauchamp[1]
[1]UNIVERSITY OF PENNSYLVANIA, Neurosurgery, Philadelphia, United States of America, [2]University of Tübingen, Division Of Neuropsychology, Tübingen, Germany

Regions of the human posterior superior temporal gyrus and sulcus (pSTG/S) respond to the visual mouth movements that constitute visual speech and the auditory vocalizations that constitute auditory speech. We examined visual benefit in noisy speech through the lens of multivoxel pattern responses in pSTG/S. fMRI data was collected with from 37 participants. Stimuli consisted of sentences or single words presented in five formats: clear audiovisual (AcV); noisy audiovisual (AnV); clear auditory-only (Ac); noisy auditory-only (An); and visual-only (V). Following the presentation of each item, participants rated intelligibility with a button press. Noisy auditory speech was more intelligible when it was paired with a face video (76% for AnV *vs.* 45% for An). For these conditions, the fMRI data was *post hoc* sorted into intelligible and unintelligible trials. For audiovisual speech, the activity pattern in pSTG/S evoked by intelligible AnV speech was more similar to that evoked by AcV speech (mean r = 0.38) while the activity pattern evoked by unintelligible AnV speech was less similar to AcV speech (mean r = -0.09). A linear mixed-effects model showed this intelligibility difference to be significantly different ($p = 10^{-10}$). Overall, the correlation between patterns was greater for single words (mean r = 0.283) than sentences (mean r = -0.006, $p = 10^{-5}$) without a significant interaction. The successful integration of visual and auditory speech into an intelligible percept produces a characteristic neural signature in pSTG/S for both sentence and word stimuli.

AGE DIFFERENCES IN VISUO-PROPRIOCEPTIVE ADAPTATION

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Kaan Karan[1,2], Kathleen Kang[1,2], Shu-Chen Li[1,2], Jakub Limanowski[2,3]
[1]TU Dresden, Chair Of Lifespan Developmental Neuroscience, Dresden, Germany, [2]TU Dresden, Centre For Tactile Internet With Human-in-the-loop (ceti), Dresden, Germany, [3]TU Dresden, Human Perception And Action Lab, Dresden, Germany

The processing of multisensory signals plays a crucial role in how humans interact with their environment. This key function goes through substantial changes as we age, however, these performance differences also vary depending on the type of stimuli and paradigm. Most virtual reality (VR) environments rely on multisensory integration to appear plausible and realistic. Yet, there is a gap in research regarding the neural correlates of age differences in multisensory integration of visual and proprioceptive stimuli in VR environments. To address this point, we designed an experiment in which groups of older and younger adults control a virtual hand with a data glove during a set of experimental tasks. The first task requires tracking a target with grasping hand movements, and depending on the attentional modality, visual information is either task-relevant or distractor, creating visuo-proprioceptive incongruence. With an additional task we investigate age differences in delay-detection using a version of the same task. During both tasks, we employ functional near-infrared spectroscopy (fNIRS) to measure neural activity in the visual and temporo-parietal areas. Preliminary data of the hand movement trajectories indicate that although there are no age differences in congruent conditions, younger and older adults adapt their movements differently in incongruent conditions. With the assessment of the remaining experimental work, we are aiming to shed light onto the age effects on mechanisms regulating perceptual processing of visuo-proprioceptive stimuli and how this reflects on the development of VR technologies.

NEURONAL CIRCUIT MECHANISMS OF MULTISENSORY CONTEXT AND INTERNAL STATE INTEGRATION IN DROSOPHILA LARVA

POSTER SESSION 05 - SECTION: MULTISENSORY INTEGRATION

Dylan Manceau[1], Eloïse De Tredern[1], Sandra Autran[1], Tihana Jovanic[2]
[1]Institut des Neurosciences Paris-Saclay, Cognitive And Neural Network, Saclay, France, [2]Paris-Saclay Institute of Neuroscience, Cognitive And Neural Network, Saclay, France

Neuromodulation changes properties of neurons, resulting in a reconfiguration of neural circuits and modulation of behavior. The neural circuit mechanisms responsible for behavioral adaptation to changes in sensory context or internal-state remain unknown. Combining behavior quantification methods and calcium-imaging functional imaging in different feeding-states, we show that short Neuropeptide F, a neuropeptide involved namely in feeding behavior and locomotion, signaling modulates the output of a well-characterized decision circuit in Drosophila larvae according to their feeding state thanks to a differential action on two inhibitory interneurons: Handle-B and Griddle-2. Moreover, we found in the connectome of Drosophila larva a pair of Neuropeptide F releasing neurons that make direct synapses on the Handle-B interneuron. Dense core vesicles can be found in close proximity to these synapses in electron-microscopy images of this neuron, suggesting that neuropeptidergic transmission may be involved in the modulation of Handle-B. Finally, we found numerous 2-hops connexions between peripheric mechanosensory Chordotonal neurons and central feeding-related sensory neurons in the brain, using the connectome data. To study the impact of multisensory integration on decision-making, we developed an assay that allows for the delivery of an appetitive odor on top of an aversive air puff, from the same side of the test arena. First testing of this assay showed that we are able to detect some behavioral disturbances caused by the addition of odor to the air puff.

CATEGORISING ATTRACTOR DYNAMICS IN NEURAL DATA

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Abel Sagodi[1], Benjamin Dunn[2], Yasser Roudi[3]
[1]Champalimaud Foundation, Champalimaud Neuroscience Programme, Lisboa, Portugal, [2]NTNU, Department Of Mathematical Sciences, Trondheim, Norway, [3]NTNU, Kavli Institute For Systems Neuroscience And Centre For Neural Computation, Trondheim, Norway

Persistent neural activity is observed in many systems, and is thought to be a neural substrate for holding memories over time delays of a few seconds. When neural activity is not only stimulus-selective but also persistent, outlasting the stimulus that initially drove it, it can be used as a (short-term) memory representation of the stimulus. Such persistent, stimulus-dependent activity is thought to be the neural substrate for memories that last anywhere up to tens of seconds. Attractor networks are models which are used to explain (or at least describe) persistent activity. Attractor dynamics are thought to play a central role in the representation of information and computation in the brain. While many observed phenomena are consistent with their existence, direct proof in the brain remains elusive. In this work, pairwise maximum entropy models are inferred from both real and simulated neural activity. We infer a maximum entropy model from a network of head direction tuned cell recorded from the antero-dorsal thalamic nucleus and the post-subiculum from a freely behaving mouse. The inferred attractor does not however align well with a continuous circle attractor as one would expect for the head direction network. We show that this discrepancy can be explained by the fact that the recorded neurons from this system are sampled from a larger population and we show that the sub-sampling of model neurons leads to similar attractor landscapes.

Zuckerman Mind Brain Behavior Institute, New York, United States of America, [5]Columbia University, Department Of Neuroscience, New York, United States of America

The hippocampus is widely hypothesized to guide navigation by forming a cognitive map of the surrounding environment. Recent studies show that cells along the CA1 radial axis present differences not only in the molecular and electrophysiological profile but also in the synaptic distributions and the morphology of their dendritic trees. These differences are considered with growing interest because of their potential effect on the computations performed within individual CA1 pyramidal neurons and therefore on the integration of CA3 and EC to produce place fields, building blocks of this cognitive map. To investigate these questions, we developed a computational tool that automatically generates biophysical models of CA1 pyramidal neurons given any reconstructed morphology and allows the user to distribute voltage and calcium gated channels along the somato-dendritic axis. Using an advanced 3D cell reconstruction technique, we experimentally mapped the spatial distribution of all excitatory and inhibitory synapses, obtaining also detailed data about their morphology. Next, we established the neuronal model output baseline of our different morphologies, keeping for all of them the same ionic channel distributions, in line with a previously published model (Poirazi et al., 2003). We simulated grid-like (from EC) and place-like (from CA3) inputs and assessed the differences in dendritic and neuronal responses, including the properties of resulting place cells. In the end, modifying the synaptic distribution and/or the associated weights, we tested how such manipulations could impact the integration of the different input pathways and therefore, the resulting neuronal output.

Aims: Huntington's disease (HD) is a monogenic devastating neurodegenerative disorder without available treatment. Evidence indicates that subtle effects during development may lead to impairments in the cellular homeostasis of evolving regional neuronal subpopulations, which in turn may produce adult-onset cell death from normally non-lethal environmental stressors. However, available evidence on the disease onset at cellular level is scarce, especially for the striatum. Thus, our aim is to assess the impact of HD on striatal neurodevelopment and the consequences at a cellular level of HD induced alterations. **Methods:** To investigate human striatal development in both control and HD models, we differentiate three control and three HD human pluripotent stem cell (PSC) lines (two embryonic stem cell lines and four induced PSC lines) in vitro towards a striatal medium spiny neuronal fate. A range of analyses including bulk RNA-seq, single cell RNA-seq (scRNA-seq), and functional assays are performed during differentiation to evaluate the progression of striatal development and how it is altered in HD. **Results:** To integrate and analyze the complete dataset, we apply and implement bioinformatic and machine learning strategies. Concretely, scRNA-seq analysis supports the identification of two main neuroblast populations and differential biomarkers for control and HD cell lines in specific cell clusters. **Conclusions:** Analysis of this diverse range of data sets are integrated to develop a predictive model of striatal development. Using this approach, we anticipate that we will identify genes, signaling pathways and developmental modules to improve our understanding of HD onset and potential therapeutic targets.

ODOR BACKGROUND INCREASES THE PHEROMONE CODING EFFICIENCY IN MOTH OLFACTORY NEURONS

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Rimjhim Tomar[1,2], Elodie Demondion[3], Christelle Montsempès[3], Philippe Lucas[3], Lubomir Kostal[2]
[1]Charles University, Second Medical Faculty, Prague, Czech Republic, [2]Institute of Physiology, Department Of Computational Neuroscience, Prague, Czech Republic, [3]Institute of Ecology and Environmental Sciences, INRAE, Department Of Sensory Ecology, Versailles, France

Insects detect odorants with olfactory receptor neurons (ORNs), located on their antennae. Male moths specifically depend on pheromone-responding neurons (Phe-ORNs) to find females for reproduction purposes, using sex pheromones emitted by female moths. These sex pheromones are a small part of a complex olfactory world and some of the volatile plant compounds (VPCs) found in the environment interfere with the Phe-ORNs. Male moths use VPCs to locate food sources and potential habitats of female moths. Insect olfactory tracking behavior generally results from the integration of multiple information sources, however the effects of VPCs as they naturally appear in the environment have not been studied extensively yet. To this end, we stimulated the ORNs of male *Agrotis ipsilon* with short puffs of pheromone against VPC backgrounds of different concentrations, to mimic the natural environment. We found that the Phe-ORNs have a variable response to different concentrations of the VPC (Z)-3-hexenyl acetate. Of particular interest is a high concentration of the VPC, where we observe an improved coding efficiency per spike of the Phe-ORNs. We confirmed, using regression analysis and other statistical methods, that the accuracy of the stimulus prediction is consistently higher with VPC background. It has been frequently observed that VPC background often suppresses the Phe-ORNs reaction when pheromone is introduced, our research shows that certain VPC concentrations increase the information transmission in Phe-ORNs.

Alzheimer's disease (AD) is a neurodegenerative disorder with complex pathological manifestations and is the leading cause of cognitive decline and dementia in elderly individuals. Given the lack of treatment options, understanding the molecular and cellular changes in AD is essential to identify new therapeutic pathways. In this study, we present a comprehensive investigation of cellular heterogeneity from the temporal cortex region of 40 individuals, comprising healthy donors and individuals with different stages of tau pathology. Using single-nucleus transcriptome analysis of 463,988 nuclei from both gray and white matter of these individuals. We identified cell type-specific subclusters in both neuronal and glial cell types with varying degrees of association with AD pathology. In particular, these associations are present in some layer specific glutamatergic (excitatory) neuronal types, along with other GABAergic (inhibitory) neurons, as well as a few glial cell subtypes. These associations were observed in early as well late pathological progression. To put these findings in broader context, we also integrated our new dataset with other published single nucleus RNA-seq studies that profiled other brain regions such as the entorhinal cortex, prefrontal cortex, and superior frontal gyrus. The integrated analysis of 959,237 total nuclei across 9 different studies/regions identified region-specific subpopulations and associations in these brain regions. Together, our findings start to prioritize specific cell types and pathways for targeted interventions at early and middle stages of pathological spread in AD.

WWW.HUMOUS.ORG: FRIENDLY AND INTERACTIVE SINGLE-CELL TRANSCRIPTOMIC ONLINE RESOURCE FOR COMPARISON OF GENE EXPRESSION IN DIFFERENT SPECIES AND CONDITIONS ACROSS CORTICOGENESIS

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Lucia Gomez, Esther Klingler, Denis Jabaudon
University of Geneva, Department Of Basic Neuroscience, Geneva, Switzerland

Recent advances in single-cell transcriptomics have led to the exponentially increasing publications of datasets, which, despite being publicly available, require certain expertise in bioinformatics to be used for further studies. Comparisons of distinct datasets also raise the issue of data normalization. Depending on the experimental design, the sequencing depth can vary, as well as the number of genes detected, which can represent a bias for comparative studies. Recent advances in human and human-derived organoid transcriptomics further ask the question of inter-species comparisons: to which extent can we compare human cells with animal or *in vitro* model cells? To which degree are the cell types conserved across species and conditions? And to which extent are the transcriptional landscapes of corresponding cell types comparable between species and conditions? To address these questions, here, we propose an approach to compare the sequential steps of corticogenesis between different species (mouse and human) and different conditions (*in vivo* and *in vitro*) using recently published single-cell transcriptomic datasets.

THE EVENT TIMING-DEPENDENT PLASTICITY RULE CORROBORATES THE KEY ROLE OF DENDRITIC SPIKES FOR LTP INDUCTION AT DISTAL APICAL SYNAPSES IN THE CA1 PYRAMIDAL CELL MODEL

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Matus Tomko[1], Lubica Benuskova[2], Peter Jedlicka[3]
[1]Institute of Molecular Physiology and Genetics, Centre of Biosciences, SAS, Department Of Biophysics And Electrophysiology, Bratislava, Slovak Republic, [2]Centre for Cognitive Science, Faculty of Mathematics, Physics and Informatics, Comenius University in Bratislava, Department Of Applied Informatics, Bratislava, Slovak Republic, [3]Faculty of Medicine, Justus-Liebig-University, Icar3r—interdisciplinary Centre For 3rs In Animal Research, Giessen, Germany

Aims: It has been shown the Na_v-dSpikes are required for LTP at distal synapses of the CA1 neurons (Kim et al. 2015, doi: 10.7554/eLife.06414). Our goal was to investigate generalization of our synaptic plasticity rule (Jedlicka et al. *2015,* doi: 10.1371/journal.pcbi.1004588) and reduced-morphology computational model of the CA1 cell (Tomko et al. 2021, doi: 10.1038/s41598-021-87002-7) to Kim et al.'s experimental data. *Methods*: Excitatory synapses were distributed on the model CA1 neuron according to experimental data. Synapses changed efficacy according to the Event Timing-Dependent Plasticity (ETDP) rule, in which the presynaptic event is the presynaptic spike, and the postsynaptic event happens when the local PSP exceeds a certain voltage threshold. Four theta-burst stimulation (TBS) protocols were used: (1) TBS alone (2) TBS plus brief somatic current injections (3) TBS plus somatic voltage-clamp (4) modified (weak) TBS. Local application of TTX was simulated by reducing the conductance of dendritic Na_v channels by 50%. *Results:* All four protocols induced LTP of distal apical synapses in our model. The size of LTP was smaller for weak TBS than for the non-modified TBS. After reducing the conductance of Na_v channels so that no dSpikes were generated, we observed no LTP with neither of stimulation protocols. *Conclusions*: Our computational simulations corroborate experimental findings that LTP at the distal apical synapses of the CA1 cells requires Na_v-dSpikes. Thus, we have successfully validated our ETDP rule and the CA1 cell model on these experimental data. *Acknowledgment:* Supported by APVV-19-0435 and BMBF (No. 031L0229) grants.

A new reduced-morphology model for CA1 pyramidal cells and its validation and comparison with other models using HippoUnit.
Modeling long-term neuronal dynamics may require running long-lasting simulations. Such simulations are computationally expensive, and therefore it is advantageous to use simplified models that sufficiently reproduce the real neuronal properties. Reducing the complexity of the neuronal dendritic tree is one option. Therefore, we have developed a new reduced-morphology model of the rat CA1 pyramidal cell which retains major dendritic branch classes. To validate our model with experimental data, we used HippoUnit, a recently established standardized test suite for CA1 pyramidal cell models. The HippoUnit allowed us to systematically evaluate the somatic and dendritic properties of the model and compare them to models publicly available in the ModelDB database. Our model reproduced (1) somatic spiking properties, (2) somatic depolarization block, (3) EPSP attenuation, (4) action potential backpropagation, and (5) synaptic integration at oblique dendrites of CA1 neurons. The overall performance of the model in these tests achieved higher biological accuracy compared to other tested models. We conclude that, due to its realistic biophysics and low morphological complexity, our model captures key physiological features of CA1 pyramidal neurons and shortens computational time, respectively. Thus, the validated reduced-morphology model can be used for computationally demanding simulations as a substitute for more complex models.

A Voltage-Based STDP Rule Combined with Fast BCM-Like Metaplasticity Accounts for LTP and Concurrent "Heterosynaptic" LTD in the Dentate Gyrus In Vivo.
Long-term potentiation (LTP) and long-term depression (LTD) are widely accepted to be synaptic mechanisms involved in learning and memory. It remains uncertain, however, which particular activity rules are utilized by hippocampal neurons to induce LTP and LTD in behaving animals. Recent experiments in the dentate gyrus of freely moving rats revealed an

unexpected pattern of LTP and LTD from high-frequency perforant path stimulation. While 400 Hz theta-burst stimulation (400-TBS) and 400 Hz delta-burst stimulation (400-DBS) elicited substantial LTP of the tetanized medial path input and, concurrently, LTD of the non-tetanized lateral path input, 100 Hz theta-burst stimulation (100-TBS, a normally efficient LTP protocol for in vitro preparations) produced only weak LTP and concurrent LTD. Here we show in a biophysically realistic compartmental granule cell model that this pattern of results can be accounted for by a voltage-based spike-timing-dependent plasticity (STDP) rule combined with a relatively fast Bienenstock-Cooper-Munro (BCM)-like homeostatic metaplasticity rule, all on a background of ongoing spontaneous activity in the input fibers. Our results suggest that, at least for dentate granule cells, the interplay of STDP-BCM plasticity rules and ongoing pre- and postsynaptic background activity determines not only the degree of input-specific LTP elicited by various plasticity-inducing protocols, but also the degree of associated LTD in neighboring non-tetanized inputs, as generated by the ongoing constitutive activity at these synapses.

Enhanced polychronization in a spiking network with metaplasticity.
Computational models of metaplasticity have usually focused on the modeling of single synapses (Shouval et al., 2002). In this paper we study the effect of metaplasticity on network behavior. Our guiding assumption is that the primary purpose of metaplasticity is to regulate synaptic plasticity, by increasing it when input is low and decreasing it when input is high. For our experiments we adopt a model of metaplasticity that demonstrably has this effect for a single synapse; our primary interest is in how metaplasticity thus defined affects network-level phenomena. We focus on a network-level phenomenon called polychronicity, that has a potential role in representation and memory. A network with polychronicity has the ability to produce non-synchronous but precisely timed sequences of neural firing events that can arise from strongly connected groups of neurons called polychronous neural groups (Izhikevich et al., 2004). Polychronous groups (PNGs) develop readily when spiking networks are exposed to repeated spatio-temporal stimuli under the influence of spike-timing-dependent plasticity (STDP), but are sensitive to changes in synaptic weight distribution. We use a technique we have recently developed called Response Fingerprinting to show that PNGs formed in the presence of metaplasticity are significantly larger than those with no metaplasticity. A potential mechanism for this enhancement is proposed that links an inherent property of integrator type neurons called spike latency to an increase in the tolerance of PNG neurons to jitter in their inputs.

Mapping sensorimotor sequences to word sequences: a connectionist model of language acquisition and sentence generation.
In this article we present a neural network model of sentence generation. The network has both technical and conceptual innovations. Its main technical novelty is in its semantic representations: the messages which form the input to the network are structured as sequences, so that message elements are delivered to the network one at a time. Rather than learning to linearise a static semantic representation as a sequence of words, our network rehearses a sequence of semantic signals, and learns to generate words from selected signals. Conceptually, the network's use of rehearsed sequences of semantic signals is motivated by work in embodied cognition, which posits that the structure of semantic representations has its origin in the serial structure of sensorimotor processing. The rich sequential structure of the network's semantic inputs also allows it to incorporate certain Chomskyan ideas about innate syntactic knowledge and parameter-setting, as well as a more empiricist account of the acquisition of idiomatic syntactic constructions.

Evolving spiking neural networks for audiovisual information processing.
This paper presents a new modular and integrative sensory information system inspired by the way the brain performs information processing, in particular, pattern recognition. Spiking neural networks are used to model human-like visual and auditory pathways. This bimodal system is trained to perform the specific task of person authentication. The two unimodal systems are individually tuned and trained to recognize faces and speech signals from spoken utterances, respectively. New learning procedures are designed to operate in an online evolvable and adaptive way. Several ways of modelling sensory integration using spiking neural network architectures are suggested and evaluated in computer experiments.

"Heterosynaptic" LTD in the dentate gyrus of anesthetized rat requires homosynaptic activity.
Heterosynaptic long-term depression (LTD) is conventionally defined as occurring at synapses that are inactive during a time when neighboring synapses are activated by high-frequency stimulation. A new model that combines computational properties of both the Bienenstock, Cooper and Munro model and spike timing-dependent plasticity, however, suggests that such LTD actually may require presynaptic activity in the depressed pathway. We tested experimentally whether presynaptic

activity is in fact necessary for previously described heterosynaptic LTD in lateral perforant path synapses in the dentate gyrus of urethane-anesthetized rats. As predicted by the model, procaine infusion into the lateral path fibers, sufficient to transiently block neural activity in this pathway, prevented the induction of LTD in the lateral path following medial path high-frequency stimulation. These data indicate that the previously described heterosynaptic LTD in the dentate gyrus in vivo is actually a form of homosynaptic LTD, requiring presynaptic activity in the depressed pathway.

Theory for normal and impaired experience-dependent plasticity in neocortex of adult rats.
We model experience-dependent plasticity in the cortical representation of whiskers (the barrel cortex) in normal adult rats, and in adult rats that were prenatally exposed to alcohol. Prenatal exposure to alcohol (PAE) caused marked deficits in experience-dependent plasticity in a cortical barrel-column. Cortical plasticity was induced by trimming all whiskers on one side of the face except two. This manipulation produces high activity from the intact whiskers that contrasts with low activity from the cut whiskers while avoiding any nerve damage. By a computational model, we show that the evolution of neuronal responses in a single barrel-column after this sensory bias is consistent with the synaptic modifications that follow the rules of the Bienenstock, Cooper, and Munro (BCM) theory. The BCM theory postulates that a neuron possesses a moving synaptic modification threshold, theta(M), that dictates whether the neuron's activity at any given instant will lead to strengthening or weakening of its input synapses. The current value of theta(M) changes proportionally to the square of the neuron's activity averaged over some recent past. In the model of alcohol impaired cortex, the effective theta(M) has been set to a level unattainable by the depressed levels of cortical activity leading to "impaired" synaptic plasticity that is consistent with experimental findings. Based on experimental and computational results, we discuss how elevated theta(M) may be related to (i) reduced levels of neurotransmitters modulating plasticity, (ii) abnormally low expression of N-methyl-d-aspartate receptors (NMDARs), and (iii) the membrane translocation of Ca(2+)/calmodulin-dependent protein kinase II (CaMKII) in adult rat cortex subjected to prenatal alcohol exposure.

Computational study of experience-dependent plasticity in adult rat cortical barrel-column.
We model experience-dependent plasticity in the adult rat S1 cortical representation of the whiskers (the barrel cortex) which has been produced by trimming all whiskers on one side of the snout except two. This manipulation alters the pattern of afferent sensory activity while avoiding any direct nerve damage. Our simplified model circuitry represents multiple cortical layers and inhibitory neurons within each layer of a barrel-column. Utilizing a computational model we show that the evolution of the response bias in the barrel-column towards spared whiskers is consistent with synaptic modifications that follow the rules of the Bienenstock, Cooper and Munro (BCM) theory. The BCM theory postulates that a neuron possesses a dynamic synaptic modification threshold, thetaM, which dictates whether the neuron's activity at any given instant will lead to strengthening or weakening of the synapses impinging on it. However, the major prediction of our model is the explanation of the delay in response potentiation in the layer-IV neurons through a masking effect produced by the thresholded monotonically increasing inhibition expressed by either the logarithmic function, h(x) = mu log(1 + x), or by the power function, h(x) = mu x(0.8-0.9), where mu is a constant. Furthermore, simulated removal of the supragranular layers (layers II/III) reduces plasticity of neurons in the remaining layers (IV-VI) and points to the role of noise in synaptic plasticity.

SENSITIVITY OF ELECTRICAL PROPERTIES TO ALTERATIONS OF THE OBLIQUE DENDRITIC ARBOUR IN A DETAILED PYRAMIDAL CELL MODEL

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Francesca Barcellini, Alexis Arnaudon, Maria Reva, Werner Van Geit, Henry Markram
Ecole polytechnique fédérale de Lausanne, Blue Brain Project, Geneva, Switzerland

Morphological properties of a neuron affect its electrical signaling, contributing to the variability of the neuronal responses. Even assigned to the same functional type, neurons can significantly vary in their morphological characteristics. We use detailed electrical models to explore how variability of oblique dendritic tree in layer 5 pyramidal cell can affect its passive and active electrical properties in both soma and apical dendrite. In particular, we assessed the sensitivity of electrical features by applying local alterations of branch oblique diameters. Then, at the soma we measured a set of electrical features and along the apical trunk we recorded calcium transients and voltages generated by back-propagating action potentials. From our preliminary results we observe that the somatic input resistance has a decreased sensitivity to diameters as a function of path distance to soma. With increase in oblique diameters (up to 10%), the firing rate, interspike interval and after hyperpolarization potential increases (up to 20%), while action potential amplitude decreased up to 30%. Moreover, we perform in-silico dendrotomy of oblique branches and show that it can lead to decrease of calcium concentration up to 50% along the trunk during bAP propagation. Surprisingly, contribution to the total calcium concentration in the trunk of each oblique branch can be either positive and negative, and depends on its position within the oblique tree and arborization. These results indicate the impact of oblique tree on the electrical properties of the cell and nonlinear summation of the active dendritic currents along the oblique tree.

THE IMPACT OF LIGHT SOURCE PROPERTIES, NEURAL MORPHOLOGY AND THE DISTRIBUTION OF LIGHT-GATED ION CHANNELS ON THE EFFECTIVE SPATIAL RESOLUTION OF OPTOGENETIC STIMULATION

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

David Berling, Luca Baroni, Ján Antolík
Charles University, Faculty Of Mathematics And Physics, Prague, Czech Republic

Optogenetic stimulation is a powerful tool for studying the brain with a clinical application in neural prostheses [1]. Crucial for the success of optogenetics-based brain-interfaces is the spatial resolution at which they can control neural activity. Major effort is being invested into improving this aspect through dense arrays of light elements [2] and subcellularly precise expression of light-gated ion channels [3]. However, there is a lack of quantitative understanding on how light source properties, neuron morphology, and the expression of light-gated ion channels constrain the spatial resolution of stimulation. This knowledge is a key for guiding the development of stimulation devices, optogenetic constructs, and for designing and interpreting experiments utilizing optogenetic stimulation. Based on existing computational work [4], we address this question by simulating optogenetic stimulation of channelrhodopsin-2 expressing pyramidal neurons (layer 2 and 5). The simulated scenario resembles illumination with an optical fiber placed on top of the cortex. We find that the spatial stimulation profile strongly depends on the extent of the neuron's morphology unless the expression of channelrhodopsin is somatically confined. Furthermore, the number of expressed channels and the light power affect the spatial stimulation profile similarly. It evolves with increasing magnitude of the two variables from a sparse set of off-center stimulation locations to a centered, laterally decaying stimulation, to a ring-like off-center stimulation. THE LATERAL ENTORHINAL CORTEX MODULATES DENDRITIC EXCITABILITY IN THE CA1 BY RECRUITING A LOCAL DISINHIBITORY MICROCIRCUIT.

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Spyridon Chavlis[1], Olesia Bilash[2], Jayeeta Basu[2], Panayiota Poirazi[1]
[1]Foundation for Research and Technology Hellas, Institute Of Molecular Biology And Biotechnology, Heraklion, Crete, Greece, [2]New York University, Neuroscience Institute, New York, United States of America

The lateral entorhinal cortex (LEC) has been suggested to provide nonspatial contextual information to the hippocampus via direct connections to the distal dendrites of CA1 pyramidal cells. It has been shown that LEC inputs are vital for episodic memory processing, as they encode context-dependent environmental cues in an environment. However, little is known about the circuit interactions between the LEC and the CA1 hippocampal subregion. In this study[1], we combined experimental and computational approaches to reveal the role of LEC inputs in compartment-specific excitation-inhibition dynamics in the CA1 subregion. In particular, we developed a biophysical microcircuit model consisting of a multicompartmental CA1 pyramidal neuron innervated by LEC-driven interneurons, i.e., cholecystokinin (CCK), vasoactive intestinal peptide (VIP), and somatostatin (SST)-expressing cells. All model neurons were heavily validated against experimental evidence through targeted experiments (in the Basu lab). Simulation of LEC-driven input induced local dendritic spikes in the distal dendrites of CA1 pyramidal neurons, as observed in our experiments. To unravel the role of specific interneuron subtypes in dendritic spiking, we simulated their selective deletion. We found that local VIP interneurons in CA1 act as a disinhibitory gate that promotes local dendritic spiking in pyramidal neurons, and this finding was verified experimentally. Furthermore, our model predicts that CCK interneurons act as a potent suppressor of dendritic spikes. These results provide new insight into a LEC-driven GABAergic microcircuit mechanism that gates local, non-linear dendritic computations, which may support dendrite-specific coding of multi-sensory contextual features within the hippocampus. 1. Large-Scale 3D Two-Photon Imaging of Molecularly Identified CA1 Interneuron Dynamics in Behaving Mice.
Cortical computations are critically reliant on their local circuit, GABAergic cells. In the hippocampus, a large body of work has identified an unprecedented diversity of GABAergic interneurons with pronounced anatomical, molecular, and physiological differences. Yet little is known about the functional properties and activity dynamics of the major hippocampal interneuron classes in behaving animals. Here we use fast, targeted, three-dimensional (3D) two-photon calcium imaging coupled with immunohistochemistry-based molecular identification to retrospectively map in vivo activity onto multiple classes of interneurons in the mouse hippocampal area CA1 during head-fixed exploration and goal-directed learning. We find examples of preferential subtype recruitment with quantitative differences in response properties and feature selectivity during key behavioral tasks and states. These results provide new insights into the collective organization of local inhibitory circuits supporting navigational and mnemonic functions of the hippocampus.

Breakdown of spatial coding and interneuron synchronization in epileptic mice.
Temporal lobe epilepsy causes severe cognitive deficits, but the circuit mechanisms remain unknown. Interneuron death and reorganization during epileptogenesis may disrupt the synchrony of hippocampal inhibition. To test this, we simultaneously recorded from the CA1 and dentate gyrus in pilocarpine-treated epileptic mice with silicon probes during head-fixed virtual navigation. We found desynchronized interneuron firing between the CA1 and dentate gyrus in epileptic mice. Since hippocampal interneurons control information processing, we tested whether CA1 spatial coding was altered in this desynchronized circuit, using a novel wire-free miniscope. We found that CA1 place cells in epileptic mice were unstable and

completely remapped across a week. This spatial instability emerged around 6 weeks after status epilepticus, well after the onset of chronic seizures and interneuron death. Finally, CA1 network modeling showed that desynchronized inputs can impair the precision and stability of CA1 place cells. Together, these results demonstrate that temporally precise intrahippocampal communication is critical for spatial processing.

Drawing inspiration from biological dendrites to empower artificial neural networks.
This article highlights specific features of biological neurons and their dendritic trees, whose adoption may help advance artificial neural networks used in various machine learning applications. Advancements could take the form of increased computational capabilities and/or reduced power consumption. Proposed features include dendritic anatomy, dendritic nonlinearities, and compartmentalized plasticity rules, all of which shape learning and information processing in biological networks. We discuss the computational benefits provided by these features in biological neurons and suggest ways to adopt them in artificial neurons in order to exploit the respective benefits in machine learning.

Pattern separation in the hippocampus through the eyes of computational modeling.
Pattern separation is a mnemonic process that has been extensively studied over the years. It entails the ability -of primarily hippocampal circuits- to distinguish between highly similar inputs, via generating different neuronal activity (output) patterns. The dentate gyrus (DG) in particular has long been hypothesized to implement pattern separation by detecting and storing similar inputs as distinct representations. The ways in which these distinct representations can be generated have been explored in a number of theoretical and computational modeling studies. Here, we review two categories of pattern separation models: those that address the phenomenon in an abstract mathematical fashion and those that delve into the underlying biological mechanisms by taking into account the anatomy and/or physiology of hippocampal circuits. We summarize the strategies, findings and limitations of these modeling approaches in the light of new experimental findings and propose a unifying framework whereby different network, cellular and sub-cellular mechanisms converge to a common goal: controlling sparsity, the key determinant of pattern separation in the DG.

Evolutionary models of amino acid substitutions based on the tertiary structure of their neighborhoods.
Intra-protein residual vicinities depend on the involved amino acids. Energetically favorable vicinities (or interactions) have been preserved during evolution, while unfavorable vicinities have been eliminated. We describe, statistically, the interactions between amino acids using resolved protein structures. Based on the frequency of amino acid interactions, we have devised an amino acid substitution model that implements the following idea: amino acids that have similar neighbors in the protein tertiary structure can replace each other, while substitution is more difficult between amino acids that prefer different spatial neighbors. Using known tertiary structures for α-helical membrane (HM) proteins, we build evolutionary substitution matrices. We constructed maximum likelihood phylogenies using our amino acid substitution matrices and compared them to widely-used methods. Our results suggest that amino acid substitutions are associated with the spatial neighborhoods of amino acid residuals, providing, therefore, insights into the amino acid substitution process.

Vasoactive Intestinal Polypeptide-Expressing Interneurons in the Hippocampus Support Goal-Oriented Spatial Learning.
Diverse computations in the neocortex are aided by specialized GABAergic interneurons (INs), which selectively target other INs. However, much less is known about how these canonical disinhibitory circuit motifs contribute to network operations supporting spatial navigation and learning in the hippocampus. Using chronic two-photon calcium imaging in mice performing random foraging or goal-oriented learning tasks, we found that vasoactive intestinal polypeptide-expressing (VIP), disinhibitory INs in hippocampal area CA1 form functional subpopulations defined by their modulation by behavioral states and task demands. Optogenetic manipulations of VIP INs and computational modeling further showed that VIP disinhibition is necessary for goal-directed learning and related reorganization of hippocampal pyramidal cell population dynamics. Our results demonstrate that disinhibitory circuits in the hippocampus play an active role in supporting spatial learning. VIDEO ABSTRACT.

In Vivo Imaging of Dentate Gyrus Mossy Cells in Behaving Mice.
Mossy cells in the hilus of the dentate gyrus constitute a major excitatory principal cell type in the mammalian hippocampus;

however, it remains unknown how these cells behave in vivo. Here, we have used two-photon Ca imaging to monitor the activity of mossy cells in awake, behaving mice. We find that mossy cells are significantly more active than dentate granule cells in vivo, exhibit spatial tuning during head-fixed spatial navigation, and undergo robust remapping of their spatial representations in response to contextual manipulation. Our results provide a functional characterization of mossy cells in the behaving animal and demonstrate their active participation in spatial coding and contextual representation.

Dendrites of dentate gyrus granule cells contribute to pattern separation by controlling sparsity.

The hippocampus plays a key role in pattern separation, the process of transforming similar incoming information to highly dissimilar, nonverlapping representations. Sparse firing granule cells (GCs) in the dentate gyrus (DG) have been proposed to undertake this computation, but little is known about which of their properties influence pattern separation. Dendritic atrophy has been reported in diseases associated with pattern separation deficits, suggesting a possible role for dendrites in this phenomenon. To investigate whether and how the dendrites of GCs contribute to pattern separation, we build a simplified, biologically relevant, computational model of the DG. Our model suggests that the presence of GC dendrites is associated with high pattern separation efficiency while their atrophy leads to increased excitability and performance impairments. These impairments can be rescued by restoring GC sparsity to control levels through various manipulations. We predict that dendrites contribute to pattern separation as a mechanism for controlling sparsity.

LEARNING A BIOPHYSICAL NEURAL MODEL DURING THE TIME FRAME OF AN EXPERIMENT

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Thiago Burghi[1], Ekaterina Morozova[2], Sonal Kedia[2], Eve Marder[2], Timothy O'Leary[1]
[1]University of Cambridge, Department Of Engineering, Cambridge, United Kingdom, [2]Brandeis University, Volen Center For Complex Systems, Waltham, United States of America

State-of-the art methods for estimating biophysical neuronal models are typically based on *offline* algorithms that require considerable time and computational resources to run. Consequently, it is currently difficult to estimate models during the relatively short time frame of an electrophysiology experiment. Under moderate uncertainty regarding ion channel kinetics (neglected by some methods), this task is currently unattainable. Solving this challenge is important: rapid or real-time model estimates would open the doors to innovative *closed-loop* experiments incorporating model-based prediction in experiment design. Aims: To develop a data-driven method for rapidly learning a predictive and interpretable model of a single neuron and its synapses, from pre- and post-synaptic voltage measurements, with minimal prior ion channel knowledge. Methods: We exploit novel data-driven neuronal models and adaptive algorithms from control theory. The models respect the neurobiological structure of living neurons (allowing for interpretability) but employ artificial neural networks to capture ion channel dynamics (allowing for rapid estimation). To train our models, we recorded membrane potentials intracellularly from two neurons in the *Cancer borealis* stomatogastric ganglion *in vitro*. In our experimental configuration, we recorded the presynaptic drive in PD neurons simultaneously with postsynaptic cholinergic inhibitory potentials and intervening activity in LP neurons. Results: We consistently obtained accurate biophysical-like models of the LP neuron, from intracellular recordings, in a few minutes using a personal laptop and its embedded GPU. Conclusions: Our results demonstrate that a predictive biophysical-like neuronal model can be rapidly learned during an experiment. The applications to closed-loop experiments involving dynamic clamp are

manifold.

CALCIUM DYNAMICS SIMULATIONS WITH MORPHOLOGICALLY-DETAILED RECONSTRUCTION OF BERGMANN GLIAL CELL MODEL

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Laura Keto, Tiina Manninen
Tampere University, Faculty Of Medicine And Health Technology, Tampere, Finland

Calcium dynamics occurring within the highly heterogeneous morphological compartments of Bergmann glial cells play a major role in the functioning of the whole cerebellum. The aim of this research was to build a morphologically-detailed model for a Bergmann glial cell in order to decipher the patterns of calcium signaling in the different morphological compartments. The model consisted of a stem tree, nanoscopic processes attached to the stem tree, and mathematical equations for biophysical properties. The stem tree was built with the NEURON CellBuilder tool based on values found from the literature. For the nanoscopic processes, a 3D reconstruction of a Bergmann glial appendage was recreated based on a video file (Grosche et al. 1999) with AgiSoft Metashape and Blender. A new computational tool ASTRO (Savtchenko et al., 2018) was used to define statistical properties from the reconstructed appendage, assemble the final model, and run the simulations. In this work, for the first time a whole Bergmann glial cell was modeled in the detail of nanoscopic processes that characterize these cells. The spatiotemporal pattern of calcium dynamics across the morphology was influenced by the shape and localization of the lateral processes. Simulations with and without mobile buffers present elucidated the highly variable spatiotemporal dynamics of calcium within the specialized morphological structures of Bergmann glial cells.
Acknowledgements We are very grateful to Prof. Helmut Kettenmann for providing us the video file of Bergmann glia appendage. The work was supported by the Academy of Finland (Nos. 326494, 326495, 345280).

PERMUTATION TEST FOR COVARIATE SELECTION

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Fredrik Nevjen, Benjamin Dunn
NTNU, Department Of Mathematical Sciences, Trondheim, Norway

Proper selection of covariates is a critical problem with the ever-growing accessibility to data. The statistical dependencies between the many behavioral covariates and the activity of a neuron make this a non-trivial problem, and there is a need in the field for statistically sound methods. The generalized linear model (GLM) is a common framework to investigate the underlying relationship between the firing of neurons and, in essence, everything else. We address issues that occur when using the GLM framework with neural data. The spike data and our tracked covariates are correlated in time, and there inevitably exist unobserved covariates that affect the activity of the neuron in question. Conditional independence, a core assumption of the GLM, is not fulfilled, and the model is likely misspecified. The problems relate to so called "Nonsense correlations", which are concerns raised initially by Yule (1926) and in modern Neuroscience by Harris (2020). The consequence is that statistical inference and covariate selection methods that build on the GLM assumptions, such as likelihood ratio tests and the Akaike information criterion, are flawed. We utilize a permutation test to construct a forward selection procedure, avoiding the strict dependency on unfulfilled GLM assumptions. Studies on simulated data and electrophysiological recordings with multiple covariates suggest that the method is statistically robust where certain methods prove to be invalid, and also more powerful than methods commonly used in the field.

BIOPHYSICAL MECHANISMS SUPPORTING MAINTENANCE OF COMPLEX TUNING

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Andrew Landau, Bernardo Sabatini
Howard Hughes Medical Institute - Harvard Medical School, Department Of Neurobiology, Boston, MA, United States of America

Neural tuning properties are shaped by synaptic plasticity rules that govern the strength of each synaptic input. Hebbian plasticity rules strengthen the connections to correlated inputs that more effectively drive postsynaptic action potentials. While this supports feature detection, it simplifies tuning functions such that neural activity can be described as a mere relay of information already present in correlated inputs. We performed experimental measurements of the calcium signals underlying STDP in cortical L2/3 cells and found that STDP-mediated depression signals are selectively reduced in a subset of dendrites while STDP-mediated potentiation signals are preserved. Using these results as motivation, we constructed STDP models that have a reduction in synaptic depression in a subset of dendrites. We observed that dendrites with less depression can learn and maintain tuning properties that are not observed under conventional Hebbian learning algorithms. We show that this increases the complexity of neural tuning functions by permiting neurons to encode informative features in input with weaker correlations. We conclude by drawing connections between our findings and mutual information.

Classical creativity: A functional magnetic resonance imaging (fMRI) investigation of pianist and improviser Gabriela Montero. Improvisation is sometimes described as instant composition and offers a glimpse into real-time musical creativity. Over the last decade, researchers have built up our understanding of the core neural activity patterns associated with musical improvisation by investigating cohorts of professional musicians. However, since creative behavior calls on the unique individuality of an artist, averaging data across musicians may dilute important aspects of the creative process. By performing case study investigations of world-class artists, we may gain insight into their unique creative abilities and achieve a deeper understanding of the biological basis of musical creativity. In this experiment, functional magnetic resonance imaging and functional connectivity were used to study the neural correlates of improvisation in famed Classical music performer and improviser, Gabriela Montero. GM completed two control tasks of varying musical complexity; for the Scale condition she repeatedly played a chromatic scale and for the Memory condition she performed a given composition by memory. For the experimental improvisation condition, she performed improvisations. Thus, we were able to compare the neural activity that underlies a generative musical task like improvisation to 'rote' musical tasks of playing pre-learned and pre-memorized music. In GM, improvisation was largely associated with activation of auditory, frontal/cognitive, motor, parietal, occipital, and limbic areas, suggesting that improvisation is a multimodal activity for her. Functional connectivity analysis suggests that the visual network, default mode network, and subcortical networks are involved in improvisation as well. While these findings should not be generalized to other samples or populations, results here shed insight into the brain activity that underlies GM's unique abilities to perform Classical-style musical improvisations.

Background: T-type Ca^{2+} channels are known to play an essential role in the development and maintenance of the peripheral diabetic neuropathy (PDN). However, no particular mechanisms relating diabetes-induced upregulation of T-channels in soma of nociceptive DRG neurons to the pathological pain processing in PDN have been suggested. The **aim** of this study is to establish mechanisms that relate diabetes-induced upregulation of T-type channels to hyperexcitability of nociceptive DRG neurons and thus to PDN. **Methods:** Computation experiments were performed on a single-compartment model of isolated DRG neuron soma developed in the NEURON simulation environment. Parameters of simulated voltage-gated Ca^{2+}, Na^{+} and K^{+} currents were fitted by experimental recordings from somas of nociceptive DRG neurons, isolated from control and streptozotocin diabetic rats. **Results**: Computation experiments showed that an increased density of somatic T-type current and a depolarizing shift of its steady-state inactivation, observed in these neurons under diabetic conditions, transforms a single AP in the soma into a burst of multiple APs; thus far, the peripheral nociceptive input can be strongly amplified. This amplification may account for mechanical hyperalgesia observed in diabetic rats. Further increase in the T-type conductivity resulted in sustained AP firing occurred in the absence of external stimulation that might be a mechanism underlying spontaneous pain observed at later stages of diabetes. **Conclusions**: Computation experiments have confirmed causative link between changes in the properties of the T-type current and increased excitability of the DRG neurons under diabetes. 3D CELL ATLAS OF MOUSE SPINAL CORD

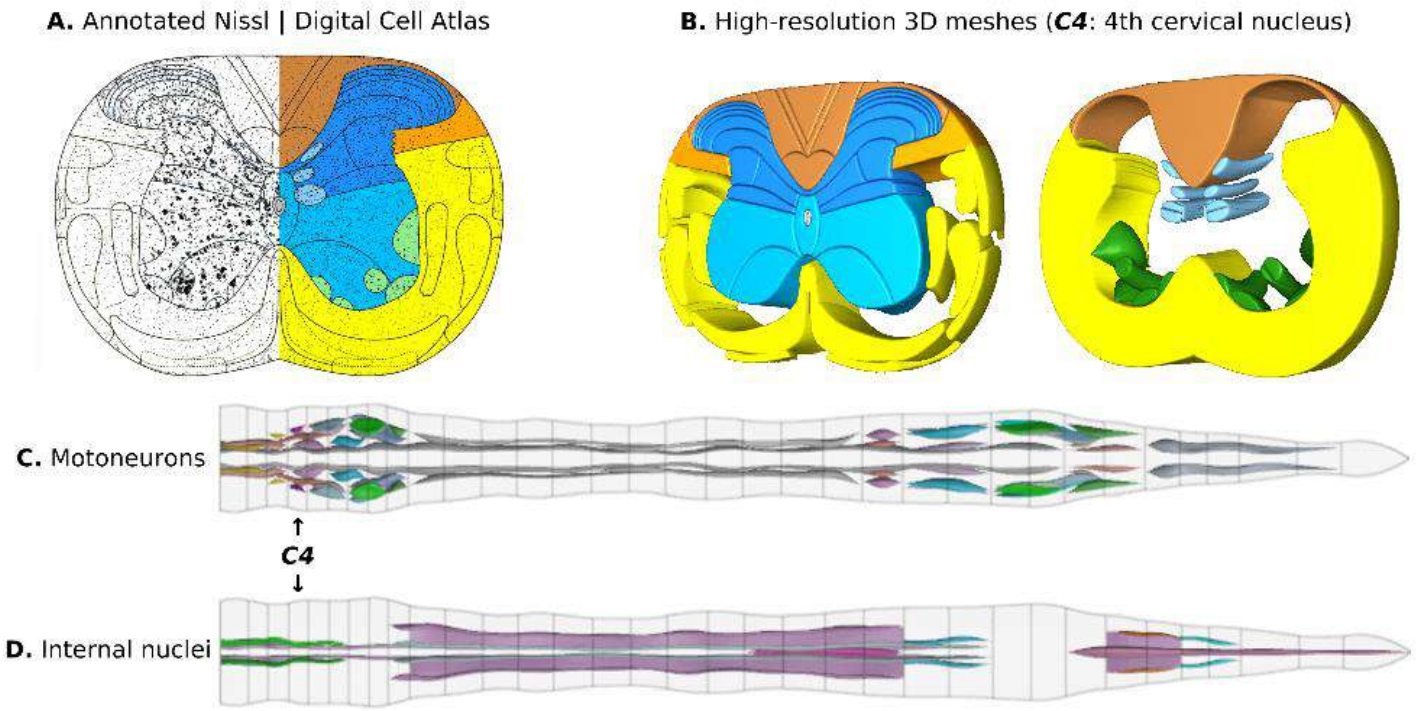
POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Ihor Kuras, Henry Markram, Marc-Oliver Gewaltig
EPFL, Blue Brain Project, Geneva, Switzerland



The spinal cord is an elongated nervous structure that together with the brain forms the central nervous system.It relays sensory and motor information between the brain and the body, thus controlling most somatic and autonomic body functions. In recent years, great progress has been made in creating digital atlasses for the mouse brain, convering, regions, cellular composition and connectivity. For the spinal cord, however, such atlasses do not yet exist. Here we present a first step towards a comprehensive digital atlas of the mouse spinal cord, based on annotated Nissl images from the Allen Institute of Brain Science. Our atlas has two parts: the first part is a reference volume, comprising high-resolution 3D meshes for 78 regions across all 34 spinal nuclei. The second part is a cell atlas with the number, densities, and positions of neurons, motoneurons and non-neurons in all regions. We estimate that the mouse spinal cord contains 11,735,398 cells in total with 2,653,186 neurons, 31,280 motoneurons and 9,082,212 glial cells. The neuron-glia ratio in each region depends on the average size of its neurons: in the dorsal horn, where we find the smallest interneurons, the ratio is up to 1:1, while in regions with the largest neurons (motoneurons) the ratio is as low as 1:4. This is consistent with the neuron-glia ratio in the brain. Our atlas will be made available as an online ressource and will be of great value for modelers and anatomists.

DYNAMIC MODELING OF EYE-HEAD GAZE SHIFTS BY A SPIKING NEURAL NETWORK MODEL OF THE SUPERIOR COLLICULUS

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Arezoo Alizadeh, John Van Opstal
Donders Institute for Brain, Cognition and Behaviour, Radboud University, Department Of Biophysics, Nijmegen, Netherlands

Recent single-unit recordings in head-unrestrained monkeys revealed that saccadic eye-head gaze trajectories and kinematics are encoded by deep-layer midbrain Superior Colliculus (SC) neurons through their cumulative number of spikes and firing rates, respectively.
A previously proposed model for eye-head gaze-control[1] can account for many of the observed properties of eye-head gaze shifts and the SC role. However, in the lumped model, the SC burst profile was described by a simple rectangular pulse that issued a constant desired gaze-velocity signal. We here extended the model by incorporating a spiking neural network of the SC motor map, the output of which is based on the linear summation of individual vectorial spike effects of each recruited neuron. The more realistic spiking activity of the population of recruited SC neurons thus drives eye and head to the target location within a dynamic gaze-velocity feedback loop. In our extended model, we also included a neural mechanism on the cells that explains the small modulatory influence of the initial eye-in-head position on the spiking activity of the neurons, and on the detailed kinematics of gaze shifts. Further, our SC model was made robust to large spatial-temporal variations in its input stimulation by cortical inputs, by tuning its top-down and lateral synaptic connections. Our gaze-control model can thus generate gaze shifts with properties observed in electrophysiological experiments.

NEURONAL AND ASTROCYTIC INTERACTIONS IN SCHIZOPHRENIA: A COMPUTATIONAL MODELLING STUDY

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Lea Fritschi[1], Johanna Lindmar[2], Florian Scheidl[3], Kerstin Lenk[4]
[1]ETH Zurich, Department Of Mathematics, Zurich, Switzerland, [2]ETH Zurich, Institute Of Neuroinformatics, Zurich, Switzerland, [3]ETH Zurich, Department Of Computer Science, Zurich, Switzerland, [4]Graz University of Technology, Institute Of Neural Engineering, Graz, Austria

Astrocytes have been associated with psychiatric disorders such as schizophrenia in several studies. However, there are several different hypotheses regarding the pathological mechanisms of neurons and astrocytes in schizophrenia. In Lenk et al. (2020), we developed a mathematical neuron-astrocyte network model to investigate the influence of astrocytes on neuronal activity. In this study, we used this model to investigate several hypotheses about schizophrenia. In our simulations, reducing the number of astrocytes or neurons leads to decreased glutamate concentration in astrocytes and reduced neuronal network activity. Increased release of ATP (adenosine triphosphate) by astrocytes toward postsynapses also decreased neuronal activity but temporarily increased glutamate concentration. A reduction in the release of the neurotransmitter glutamate and the decreased uptake by astrocytes each resulted in increased network activity. Also, the increase in synaptic weights, i.e., the coupling strength, of excitatory and inhibitory neurons respectively inhibitory neurons led to this result. Our simulations suggest, that the interaction of neurons and astrocytes in schizophrenia should be further should be investigated in more detail.

A COMPUTATIONAL MODEL OF SLOW WAVE OSCILLATION PROPAGATION ACROSS CORTICAL NETWORKS

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Javier Alegre-Cortes[1,2], Maurizio Mattia[1], Ramon Reig[2]
[1]Istituto Superiore di Sanità, Centro Nazionale Per La Protezione Dalle Radiazioni E Fisica, Roma, Italy, [2]Instituto de Neurociencias UMH-CSIC, Cellular And Systems Neurobiology, San Juan de Alicante, Spain

The activity of every neural circuit is limited by anatomical and functional constrains, which will restrict its repertoire of activity patterns. Therefore, the knowledge obtained from the study of the brain spontaneous activity is a valuable resource to understand how those circuits operate during behaviour. We present a computational model of cortical populations under the Slow Wave Oscillation (SWO) regime. This spontaneous brain state is characterized by periods of high spontaneous activity (Up states) intermingled with silent periods (Down states) at the frequency of ~ 1 Hz. It originates in the cortex and from there propagates to other brain regions. While traditional SWO models are focused on single and isolated cortical areas. our study aims to provide a theoretical understating of the contribution of local and long range connections to the properties of the SWO in multiple connected neuronal populations. This includes the study of the neuronal and circuit substrates behind the different Up state attributes across cortical regions and the rostrocaudal preferential directionality of the SWO propagation. With this, we will provide an explanation to the differences in the SWO recorded in slices or brain slabs compared to the intact brain. In conclusion, we have designed a model of SWO propagation along cortical. With this tool, we studied the neuronal and circuit substrates of the propagation of this wave along these networks, unifying the previous knowledge based on *in vivo* and *ex vivo* recordings.

Multiscale dynamics of interstimulus interval integration in visual cortex.
Although the visual cortex receives information at multiple temporal patterns, much of the research in the field has focused only on intervals shorter than 1 second. Consequently, there is almost no information on what happens at longer temporal intervals. We have tried to address this question recording neuronal populations of the primary visual cortex during visual stimulation with repetitive grating stimuli and intervals ranging from 1 to 7 seconds. Our results showed that firing rate and response stability were dependent of interval duration. In addition, there were collective oscillations with different properties in response to changes in intervals duration. These results suggest that visual cortex could encode visual information at several time scales using oscillations at multiple frequencies.

Time-frequency analysis of neuronal populations with instantaneous resolution based on noise-assisted multivariate empirical mode decomposition.
Linear analysis has classically provided powerful tools for understanding the behavior of neural populations, but the neuron responses to real-world stimulation are nonlinear under some conditions, and many neuronal components demonstrate strong nonlinear behavior. In spite of this, temporal and frequency dynamics of neural populations to sensory stimulation have been usually analyzed with linear approaches.

Toward an Improvement of the Analysis of Neural Coding.
Machine learning and artificial intelligence have strong roots on principles of neural computation. Some examples are the structure of the first perceptron, inspired in the retina, neuroprosthetics based on ganglion cell recordings or Hopfield networks. In addition, machine learning provides a powerful set of tools to analyze neural data, which has already proved its efficacy in so distant fields of research as speech recognition, behavioral states classification, or LFP recordings. However, despite the huge technological advances in neural data reduction of dimensionality, pattern selection, and clustering during the last years, there has not been a proportional development of the analytical tools used for Time-Frequency (T-F) analysis in neuroscience. Bearing this in mind, we introduce the convenience of using non-linear, non-stationary tools, EMD

algorithms in particular, for the transformation of the oscillatory neural data (EEG, EMG, spike oscillations…) into the T-F domain prior to its analysis with machine learning tools. We support that to achieve meaningful conclusions, the transformed data we analyze has to be as faithful as possible to the original recording, so that the transformations forced into the data due to restrictions in the T-F computation are not extended to the results of the machine learning analysis. Moreover, bioinspired computation such as brain-machine interface may be enriched from a more precise definition of neuronal coding where non-linearities of the neuronal dynamics are considered.

A New Micro-holder Device for Local Drug Delivery during In Vivo Whole-cell Recordings.
Focal administration of pharmacological agents during in vivo recordings is a useful technique to study the functional properties of neural microcircuits. However, the lack of visual control makes this task difficult and inaccurate, especially when targeting small and deep regions where spillover to neighboring regions is likely to occur. An additional problem with recording stability arises when combining focal drug administration with in vivo intracellular recordings, which are highly sensitive to mechanical vibrations. To address these technical issues, we designed a micro-holder that enables accurate local application of pharmacological agents during in vivo whole-cell recordings. The holder couples the recording and drug delivery pipettes with adjustable distance between the respective tips adapted to the experimental needs. To test the efficacy of the micro-holder we first performed whole-cell recordings in mouse primary somatosensory cortex (S1) with simultaneous extracellular recordings in S1 and motor cortex (M1), before and after local application of bicuculline methiodide (BMI 200 µM). The blockade of synaptic inhibition resulted in increased amplitudes and rising slopes of "Up states", and shortening of their duration. We then checked the usability of the micro-holder in a deeper brain structure, the striatum. We applied tetrodotoxin (TTX 10 µM) during whole-cell recordings in the striatum, while simultaneously obtaining extracellular recordings in S1 and M1. The focal application of TTX in the striatum blocked Up states in the recorded striatal neurons, without affecting the cortical activity. We also describe two different approaches for precisely releasing the drugs without unwanted leakage along the pipette approach trajectory.

33599609: Alegre-Cortés J, Sáez M, Montanari R, Reig R
Medium spiny neurons activity reveals the discrete segregation of mouse dorsal striatum.
Behavioral studies differentiate the rodent dorsal striatum (DS) into lateral and medial regions; however, anatomical evidence suggests that it is a unified structure. To understand striatal dynamics and basal ganglia functions, it is essential to clarify the circuitry that supports this behavioral-based segregation. Here, we show that the mouse DS is made of two non-overlapping functional circuits divided by a boundary. Combining in vivo optopatch-clamp and extracellular recordings of spontaneous and evoked sensory activity, we demonstrate different coupling of lateral and medial striatum to the cortex together with an independent integration of the spontaneous activity, due to particular corticostriatal connectivity and local attributes of each region. Additionally, we show differences in slow and fast oscillations and in the electrophysiological properties between striatonigral and striatopallidal neurons. In summary, these results demonstrate that the rodent DS is segregated in two neuronal circuits, in homology with the caudate and putamen nuclei of primates.

INCORPORATION OF INTERNEURONS IN A NETWORK MODEL TO EXPLAIN THE EFFECTS OF SCHIZOPHRENIA-ASSOCIATED GENES ON DELTA OSCILLATIONS

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Jan Fredrik Kismul[1], Torbjørn Ness[2], Gaute Einevoll[2], Marja-Leena Linne[1], Tuomo Mäki-Marttunen[3]
[1]Tampere University, Faculty Of Medicine And Health Technology, Tampere, Norway, [2]Norwegian University of Life Sciences, Faculty Of Science And Technology, Ås, Norway, [3]Tampere University, Faculty Of Medicine And Health Technology, Tampere, Finland

Recent genome-wide association studies have identified many variants associated with schizophrenia[1]. These genetic variants were suggested to be able to account for the increased power of delta-oscillation, a common biomarker of schizophrenia[2]. In[2] a network of model pyramidal neurons with reduced morphological reconstructions were connected to an inhibitory population of point neurons. In the present study this network model is expanded upon; the interneurons will be replaced with model neurons of simplified morphologies, and a new population of neuroglial cells are added to study the effects of GABA_B receptors. In previous studies GABA_B receptors have been shown to decrease the delta-oscillation power of sleeping rats [3]. In our work, the interneurons are first obtained from the Blue Brain database, and subsequently reduced to 3-compartmental models of the same neurons. They show the same behavior in response to stimulation with a somatic current as the full-morphology level neurons. These additions to the model presented in [2] allow a larger set of model variants of schizophrenia risk genes to be studied in a physiologically more realistic model of cortical circuitry.

Aims: Rodent barrel cortex receives and processes whisker information. The network dynamics of the barrel cortex is strongly impacted by the cortical structure and cell-type specificity. However, the mechanisms of how structural details and cell-type specificity impact the network dynamics have not yet been fully understood. In the context of the visual cortex, stabilized supralinear network (SSN) models have been suggested as a way to include orientation selectivity and contrast invariance, which makes it a suitable model to study the somatosensory cortex dynamics. Can a connectomically constrained SSN model of the rat barrel cortex be used to interpret the role of cell-type specificity? **Methods:** Here we present an SSN model which incorporates anatomically detailed barrel cortex data which reflects multiple cell types and their neuron-to-neuron connectivity. Our SSN model is consistent with the spiking network activity of approximately 4000 neurons where a single neuron is modelled as a leaky-integrate-and-fire model (LIF). The parameters of LIF neurons are based on biologically plausible data for each specific cell type. The connectivity of LIF neurons is based on an empirically observed statistical connectome model. **Results and Conclusion:** We can now use the model to derive predictions for future experiments and identify cell-type specific activity patterns that contribute to sensory perception.

CORE NEURONS ARE STRUCTURAL CROSSROADS OF CORTICAL DYNAMICS

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Domenico Guarino, Anton Filipchuk, Alain Destexhe
NeuroPSI, Icn, Saclay, France

Two-photon calcium imaging of the behaving mouse cortex shows spiking correlations - called ensembles - thought to underlie perceptual, motor, and higher cognitive functions. The functional specificity and reproducibility of these ensembles would be ensured by distinctive regularly participating cells, called core neurons (here simply ‘cores’). It is assumed that cores' strong interconnections underlie pattern completion and reproducibility. Here we show that this hypothesis is incorrect. Using electron microscopy and 2-photon calcium imaging data of the same cortical tissue, we studied spiking correlations between cell motifs - i.e. significant connectivity patterns. We found that strong interconnection is not the characterizing feature of cores. The majority of cores belong to converging and diverging motifs, and they do not connect preferentially to other cores (low assortativity). On the contrary, cores lie onto many different paths (high betweenness), longer than those passing by other neurons (high eccentricity), making them structural “crossroads”. Based on the strong interconnection assumption, several models have been previously proposed, where strong paths were artificially imposed to obtain ensembles and cores. We present the first model where core neurons are not imposed by ad-hoc wiring. We show instead that topological connectivity - distance-dependent random sampling of connections - is the only necessary and sufficient requirement to reproduce the statistics of spontaneous and evoked ensembles, containing core neurons, recorded across several cortices. Taken together, our analysis of electron microscopy and two-photon data, and our modeling work show that recurrence of cortical dynamics is not a direct consequence of strong structural interconnectivity.

HUMAN DATA STATE OF THE ART: TOWARDS A HUMAN CORTICAL MICROCIRCUIT

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Natali Barros Zulaica, Srikanth Ramaswamy, Michael Reimann
Campus Biotech, Blue Brain Project, Geneva, Switzerland

The human neocortex is the brain area thought to differentiate us most from other species because it gives us some unique abilities, as speaking. Although the human neocortex has been studied for many years since Ramon y Cajal started last century, little is known about its cell anatomical structure and its cell and circuit functionality. One proven approach to speed up the process of understanding neurons and brain circuits that has been successfully used before, is the use of computational models and simulations. Another approach that aims to make the most out of the little data available for human, is to explicitly compare to and contrast it with better studied cortices from other species, such as rodents. In this study we collected, integrated, and analyzed data on human that were available in the literature and propose various strategies to overcome the missing data, such as generalizing data from other species. We then used it to build a human cortical microcircuit, based on the modelling approach we previously developed to model a rat microcircuit. We found that the literature provided a sufficient amount of data to generate a first draft of a model of microcircuit anatomy, neuronal morphology, connectivity and physiology, when combined with data generalizations. While gaps in data on cell morphologies and electrophysiology had to be filled by adapting corresponding data from other species, in the resulting model still a number of anatomical features emerged that were not present in the rodent model and are thus potentially human-specific.

MULTI-COMPARTMENTAL RECONSTRUCTION AND SIMULATION OF AN ENTIRE MODULE OF THE MOUSE CEREBELLAR CORTEX

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Robin De Schepper[1], Alice Geminiani[1], Stefano Masoli[1], Martina Rizza[1], Alberto Antonietti[1], Egidio D'Angelo[1,2], Claudia Casellato[1]

Data-driven modelling of the brain requires a neuroinformatic framework implementing a general strategy to accommodate experimental data at different scales. To this end, we have developed the Brain Scaffold Builder (BSB), a tool for structural and functional microcircuit modelling. The BSB provides an organized staged workflow, multiple strategies for cell placement and connectivity, a configuration system capable of including detailed neuronal and synaptic models and the support for multiple simulators with transparent parallel processing. It is provided as an open-source package, applicable for multi-scale modelling of different brain areas. The interfaces with several simulators (NEURON, NEST, Arbor) allow to investigate the same brain region at different levels of resolution, depending on the scientific question. The BSB's effectiveness was tested on the cerebellar network, which has a complex geometry and raises a broad set of modelling challenges. For the first time, an entire module of the mouse cerebellar cortex was reconstructed using morphologically realistic conductance-based multi-compartmental neuron models of granule, Golgi, Purkinje, stellate and basket cells. Different connection rules, such as convergence-divergence, touch detection and voxel intersection, were used to generate the connectome, unifying a collection of scattered experimental data into a coherent construct. Baseline and sensory-burst stimulation were used for functional validation against in vivo recordings, monitoring the impact of subcellular and cellular mechanisms on signal propagation and spatio-temporal processing in the cerebellum. The integration of structural and functional properties through the model provides a new "ground truth" about cerebellar circuit organization capable of predicting neural dynamics in vivo.

A DETAILED BIOPHYSICAL MODEL OF THE INFERIOR OLIVE

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Elie Oriol[1], Vincent Hakim[1], Boris Barbour[2]
[1]Ecole Normale Superieure, Lpens, Paris, France, [2]Ecole Normale Supérieure, Ibens, PARIS, France

The cerebellum is known to play an essential role in the supervised learning of accurately executed and coordinated movements. Cerebellar Purkinje cells (PCs) receive movement-related information at their plastic input synapses, classically thought to be modulated after a movement by error signals. These originate from the Inferior Olive (IO) through the unique climbing fiber to each PC. However, signals coming from the IO during learning have been shown to be more diverse than post-movement errors only, with for instance consistent anticipatory activity being observed in classical conditioning experiments. This plurality of signals may thus contribute to different plasticity mechanisms in the cerebellum. In this context, an accurate description of the IO seems key to understand and model cerebellar learning.
The IO is constituted of a single cell type, assembled in clustered networks highly coupled via electrical gap junctions. Previous work has focused mainly on the experimentally observed synchronous spontaneous oscillations, but individual cell recordings display various complex behaviors contributing to IO excitability that are poorly reproduced by the few models that exist. We thereby aim at developing a more precise biophysical model of networks of IO cells accounting for most of their experimentally measured properties, based on data obtained from the literature and patch-clamp experiments currently in progress. This should deepen our understanding of this key structure and help to understand how it relates to learning in the cerebellum.

A NOVEL COMPUTATIONAL PLATFORM FOR MIMICKING NEURAL NETWORK ACTIVITY IN ADVANCED IN VITRO NEURAL CONSTRUCTS

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Rachele Fabbri[1,2], Stefano Rizzo[2], Ermes Botte[1,2], Arti Ahluwalia[1,2], Chiara Magliaro[1,2]
[1]University of Pisa, Department Of Information Engineering, Pisa, Italy, [2]University of Pisa, Centro Di Ricerca “e. Piaggio”, Pisa, Italy

To date, the computational models of biological neural networks do not include the oxygen concentration as a variable influencing the electrical activity of neurons. However, in three-dimensional (3D) vessel-free cell cultures, e.g., brain organoids and assembloids, oxygen may represent a limiting factor for neuron viability and function. We developed a novel model of neuron firing in 3D constructs which accounts for oxygen reaction and diffusion. The model simulates the functional activity of an organoid slice and was developed in Matlab. A single neuron is represented by a Simulink block. The blocks are connected each other to simulate the signal transmission through synapses. Oxygen diffuses through the network according to Fick’s second law and is taken up by neurons fuelling both their metabolic and electrophysiological activities. Specifically, metabolic consumption is modelled with Michaelis-Menten kinetics, while firing activity is simulated with a modified Hodgkin-Huxley model, where the dynamics of sodium and potassium ions, whose activity is oxygen-dependent, are introduced. The outputs of the model (i.e., the spiking activity of the neurons constituting the network) are dependent on the local oxygen concentration within the construct and are consistent with the electrophysiological activity recorded in cerebral organoids. The computational platform can be used to guide experiments, optimising organoid generation and maintenance protocols. It can also help to gain insights into cerebral organoid growth and function. Future developments will include new model configurations, i.e. higher number of neurons, spatial 3D arrangement and different connections, in order to fully resemble the neural network of an organoid.

A Machine Learning Decision Support System (DSS) for Neuroendocrine Tumor Patients Treated with Somatostatin Analog (SSA) Therapy.
The application of machine learning (ML) techniques could facilitate the identification of predictive biomarkers of somatostatin analog (SSA) efficacy in patients with neuroendocrine tumors (NETs). We collected data from 74 patients with a pancreatic or gastrointestinal NET who received SSA as first-line therapy. We developed three classification models to predict whether the patient would experience a progressive disease (PD) after 12 or 18 months based on clinic-pathological factors at the baseline. The dataset included 70 samples and 15 features. We initially developed three classification models with accuracy ranging from 55% to 70%. We then compared ten different ML algorithms. In all but one case, the performance of the Multinomial Naïve Bayes algorithm (80%) was the highest. The support vector machine classifier (SVC) had a higher performance for the recall metric of the progression-free outcome (97% vs. 94%). Overall, for the first time, we documented that the factors that mainly influenced progression-free survival (PFS) included age, the number of metastatic sites and the primary site. In addition, the following factors were also isolated as important: adverse events G3-G4, sex, Ki67, metastatic site (liver), functioning NET, the primary site and the stage. In patients with advanced NETs, ML provides a predictive model that could potentially be used to differentiate prognostic groups and to identify patients for whom SSA therapy as a single agent may not be sufficient to achieve a long-lasting PFS.

PROBING THE ROLE OF CUNEATE NUCLEUS AND PRIMARY SOMATOSENSORY CORTEX USING TASK-OPTIMIZED NEURAL NETWORK MODELS

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Axel Bisi[1], Alessandro Marin Vargas[1], Alberto Chiappa[1,2], Chris Versteeg[3], Lee Miller[3], Alexander Mathis[1]
[1]EPFL, Brain Mind Institute, Center Of Neuroprosthetics, Center Of Intelligent Systems, School Of Life Sciences, Lausanne, Switzerland, [2]EPFL, Brain Mind Institute, Center Of Neuroprosthetics, School Of Life Sciences, Geneva, Switzerland, [3]Northwestern University, Department Of Biomedical Engineering, Chicago, IL, United States of America

Adaptive motor control requires proprioception. However, the principles that govern the processing of proprioception are poorly understood. Here, we employ a task-driven neural network modeling approach to quantitatively test hypotheses about the functional role of proprioceptive neurons in both cuneate nucleus (CN) and somatosensory cortex (area 2). We simulated muscle spindle signals for a large, diverse movement repertoire (following Sandbrink et al., bioRxiv, 2020), and used them to train hundreds of deep neural networks (DNNs) in three behavioral tasks: action recognition, hand localization, and redundancy reduction. We tested these tasks as hypotheses about the function of the ascending proprioceptive pathway by predicting neuronal spiking activity in CN and area 2 from macaques performing a center-out reaching task. To do so, we tracked limb movements using DeepLabCut and inferred the proprioceptive signals via musculoskeletal modeling. We used these as inputs to the task-trained DNNs to linearly regress single-neuron activity. Firstly, we found that network models that perform better on their tasks explain the neural data better, for all tasks and monkeys. This correlation was most pronounced for models trained on action recognition. Secondly, network features of specific tasks explained CN and area 2 neurons differently, while combining representations from different tasks yielded strongly improved predictions, outperforming classical tuning curve and GLMs. Our results suggest that these tasks are sufficient to develop brain-like representations along the proprioceptive pathway. Overall, our work consolidates task-driven modeling as an optimization-based framework to understand sensory systems beyond vision, audition, and touch.

RETINAL WAVES ALIGN THE CONCENTRIC ORIENTATION MAP IN MOUSE SUPERIOR COLLICULUS TO THE CENTER OF VISION

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Kai Lun Teh, Jérémie Sibille, Jens Kremkow
Charite Universitatsmedizin Berlin, Neuroscience Research Center, Berlin, Germany

Neurons in the mouse superior colliculus (SC) are arranged in an orientation preference map (OPM) that has a concentric organization, which is aligned to the center of vision and the optic flow (Ahmadlou and Heimel, 2015). The developmental mechanisms that underlie this functional map remain unclear. During development, the stage III (S3) retinal waves are known to play important roles in circuit formation. The S3 waves that tend to propagate towards the caudal direction (Gribizis et al., 2019) have impacts on the direction selectivity of the SC neurons (Ge et al., 2021). Besides, the OFF retinal ganglion cells (RGCs) are recruited with a time-delay relative to ON RGCs (Kerschensteiner and Wong, 2008). Here, we propose that these S3 wave properties provide a scaffold to establish the concentric OPM in the mouse SC and its alignment to the optic flow. We test this hypothesis by modeling the orientation-tuned SC neurons that receive ON/OFF retinal inputs. Our results suggest that the OFF delay and the wave direction bias are key factors that regulate the spatial organization of the SC OPM. Specifically, the OFF delay mediates the establishment of orientation-tuned SC neurons, the wave-like activities facilitate the formation of a concentric pattern, and the wave direction biases align the OPM to the center of vision. Taken together, our model suggests that retinal waves may play an instructive role in establishing functional properties of SC neurons and provides a promising mechanism for explaining the correlations between the optic flow and the SC OPM.

SINGLE-AXON DYNAMICS OF SEROTONERGIC NEURONS IN EX VIVO SYSTEMS

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Melissa Hingorani[1], Ryan Stowers[2], Chris Bates[3], Skirmantas Janusonis[1]
[1]University of California, Santa Barbara, Psychological & Brain Sciences, -, United States of America, [2]University of California, Santa Barbara, Mechanical Engineering, -, United States of America, [3]University of California, Santa Barbara, Materials Science, -, United States of America

Our group has shown that the self-organization of the brain serotonergic matrix depends in part on the spatiotemporal dynamics of individual serotonergic axons (fibers). The trajectories of these axons are strongly stochastic and can be described by step-wise random walks or fractional Brownian motion (a time-continuous process). The success of these modeling efforts depends on experimental data that can validate their mathematical frameworks and constrain the values of model parameters. However, visualizing this dynamic behavior in vivo is currently extremely difficult. In this study, we developed an ex vivo system of primary mouse brainstem neurons. Using a combination of methods such as confocal microscopy, digital holotomography, STED super-resolution microscopy, and novel 3D hydrogel systems, we investigated serotonergic axons with unprecedented spatiotemporal precision. The dynamics of axon growth cones, branching events, and other key processes were analyzed with respect to the properties of the tunable extracellular environment and to intracellular movements reflected in refractive index changes. These experimental data include the first holotomographic images of serotonergic neurons and axons and provide essential information for predictive modeling of the serotonergic matrix. In addition to the importance of these findings for fundamental neuroscience, they can also support future efforts in the restoration of brain tissue (serotonergic fibers are almost unique in the mammalian brain in their ability to robustly regenerate). The novel approaches developed in this study may be applicable to other "stochastic" axons in the ascending reticular activating system.

BRIDGING THE GAP BETWEEN ARTIFICIAL MODELS AND CORTICAL CIRCUITS

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

[1]Institute of Science and Technology Austria, Computational Neuroscience And Neurotheory, Klosterneuburg, Austria, [2]Neurolentech, Neurolentech, Klosterneuburg, Austria, [3]Institute of Science and Technology, Life Sciences, Klosterneuburg, Austria

Artificial neural networks simplify complex biological circuits into tractable models for computational exploration and experimentation. However, the simplification of artificial models also undermines their applicability to real brain dynamics. Typical efforts to address this mismatch add complexity to increasingly unwieldy models. Here, we take a different approach; by reducing the complexity of a biological cortical culture, we aim to distil the essential factors of neuronal dynamics and plasticity. We leverage recent advances in growing neurons from human induced pluripotent stem cells (hiPSCs) to analyse *ex vivo* cortical cultures with only two distinct excitatory and inhibitory neuron populations. Over 6 weeks of development, we record from thousands of neurons using high-density microelectrode arrays (HD-MEAs). We compare these dynamics to two-population artificial networks of single-compartment neurons with random sparse connections. Moreover, integrating models and cultures allows us to evaluate the impact of changing architectures over weeks of development, with and without external stimuli. Broadly, the use of simplified cortical cultures enables us to use the repertoire of theoretical neuroscience techniques established over the past decades on artificial network models. Our approach of deriving neural networks from human cells also allows us to directly compare neural dynamics of disease and control. We found that cultures from epilepsy patients have increasingly more synchronous activity over weeks of development. Next, we will test possible interventions, *in silico* and *in vitro*, in a drive for personalised medical care. This work starts bridging an important theoretical-experimental neuroscience gap for advancing our understanding of mammalian neuron

dynamics.

Chloride dynamics alter the input-output properties of neurons.
Fast synaptic inhibition is a critical determinant of neuronal output, with subcellular targeting of synaptic inhibition able to exert different transformations of the neuronal input-output function. At the receptor level, synaptic inhibition is primarily mediated by chloride-permeable Type A GABA receptors. Consequently, dynamics in the neuronal chloride concentration can alter the functional properties of inhibitory synapses. How differences in the spatial targeting of inhibitory synapses interact with intracellular chloride dynamics to modulate the input-output function of neurons is not well understood. To address this, we developed computational models of multi-compartment neurons that incorporate experimentally parametrised mechanisms to account for neuronal chloride influx, diffusion, and extrusion. We found that synaptic input (either excitatory, inhibitory, or both) can lead to subcellular variations in chloride concentration, despite a uniform distribution of chloride extrusion mechanisms. Accounting for chloride changes resulted in substantial alterations in the neuronal input-output function. This was particularly the case for peripherally targeted dendritic inhibition where dynamic chloride compromised the ability of inhibition to offset neuronal input-output curves. Our simulations revealed that progressive changes in chloride concentration mean that the neuronal input-output function is not static but varies significantly as a

function of the duration of synaptic drive. Finally, we found that the observed effects of dynamic chloride on neuronal output were mediated by changes in the dendritic reversal potential for GABA. Our findings provide a framework for understanding the computational effects of chloride dynamics on dendritically targeted synaptic inhibition.

Biophysical models reveal the relative importance of transporter proteins and impermeant anions in chloride homeostasis. Fast synaptic inhibition in the nervous system depends on the transmembrane flux of Cl ions based on the neuronal Cl driving force. Established theories regarding the determinants of Cl driving force have recently been questioned. Here, we present biophysical models of Cl homeostasis using the pump-leak model. Using numerical and novel analytic solutions, we demonstrate that the Na/K-ATPase, ion conductances, impermeant anions, electrodiffusion, water fluxes and cation-chloride cotransporters (CCCs) play roles in setting the Cl driving force. Our models, together with experimental validation, show that while impermeant anions can contribute to setting [Cl] in neurons, they have a negligible effect on the driving force for Cl locally and cell-wide. In contrast, we demonstrate that CCCs are well-suited for modulating Cl driving force and hence inhibitory signaling in neurons. Our findings reconcile recent experimental findings and provide a framework for understanding the interplay of different chloride regulatory processes in neurons.

Early ethanol exposure and vinpocetine treatment alter learning- and memory-related proteins in the rat hippocampus and prefrontal cortex.
This study investigates the effects of early exposure to ethanol on cognitive function and neural plasticity-related proteins in the rat brain. Sprague-Dawley rats were administered 12% ethanol solution (4 g/kg/day i.p.) or saline from P4 to P9. Vinpocetine, a phosphodiesterase type 1 inhibitor, was tested to determine whether it could reverse any changes induced by early ethanol exposure. Hence, from P25 to P31, ethanol-exposed male rats were injected with vinpocetine (20 mg/kg/day i.p.) or vehicle (DMSO) prior to undergoing behavioral testing in the open field and Morris water maze (MWM) tests. Ethanol exposure did not adversely affect spatial memory in the MWM. A key finding in this study was a significant ethanol-induced change in the function of the phosphorylated extracellular signal-related kinase (P-ERK) signaling pathway in the prefrontal cortex (PFC) and dorsal hippocampus (DH) of rats that did not display overt behavioral deficits. The P-ERK/ERK ratio was decreased in the PFC and increased in the DH of ethanol-exposed rats compared with controls. Rats that received vinpocetine in addition to ethanol did not display any behavioral changes but did show alterations in neural plasticity-related proteins. Mitogen-activated protein kinase phosphatase was increased, whereas brain-derived neurotrophic factor was decreased, in the PFC of vinpocetine-treated ethanol-exposed rats, and phosphorylated-glycogen synthase kinase β and synaptophysin were increased in the DH of these rats. This study provides insight into the long-term effects of early ethanol exposure and its interaction with vinpocetine in the rat brain. © 2016 Wiley Periodicals, Inc.

NOT IN SHAPE: NEURONAL CELL TYPE CLASSIFICATION USING SPIKE TIMING OR SPATIAL FEATURES

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Lior Sukman[1,2], Eran Stark[1,2]
[1]Tel Aviv University, Department Of Physiology And Pharmacology, Tel Aviv, Israel, [2]Tel Aviv University, Sagol School Of Neuroscience, tel aviv, Israel

Brain circuits are composed of different cell types with distinct roles in neuronal network dynamics. Previous work showed that it is possible to distinguish between pyramidal cells and parvalbumin-immunoreactive (PV) interneurons based on features derived from spike waveforms recorded extracellularly. Whether pyramidal and PV cells can be distinguished solely based on features independent of the spike waveform remains unknown. Here, we combined high-density silicon probe recordings from hippocampal region CA1 of freely-moving PV mice with optogenetic tagging. We used the ground truth data to construct cross-validated random-forest models for binary classification, combined with a new chunking approach we created to optimize performance. Features derived from waveforms (morphological features), spike timing (temporal), and the distribution of signals across recording sites (spatial), were used as input to distinct models. Consistent with previous work, the cross-validated morphological model reached near-perfect results with an area-under-the-curve (AUC) of 0.99, considerably above chance level of 0.5. The model based on spike timing alone reached an AUC of 0.95, and the model based on purely spatial features yielded an AUC of 0.89. The results show that both spike timing and the distribution of the signals in space provide unique information about pyramidal and PV cells. The models allow accurate and robust classification of data from animals without ground truth, furthering our understanding of neuronal network dynamics. **Funding: CIHR-IDRC-ISF #2558/18; CRCNS NSF-BSF #2015577; Zimin Institute**

Patterns of endogenous activity in the brain reflect a stochastic exploration of the neuronal state space that is constrained by the underlying assembly organization of neurons. Yet it remains to be shown that this interplay between neurons and their assembly dynamics indeed suffices to generate whole-brain data statistics. Here we recorded the activity from ~ 40, 000 neurons simultaneously in zebrafish larvae, and show that a data-driven network model of neuron-assembly interactions can accurately reproduce the mean activity and pairwise correlation statistics of their spontaneous activity. This model, the compositional Restricted Boltzmann Machine, unveils ~ 200 neural assemblies, which compose neurophysiological circuits and whose various combinations form successive brain states. From this, we mathematically derived an interregional functional connectivity matrix, which is conserved across individual animals and correlates well with structural connectivity. This novel, assembly-based generative model of brain-wide neural dynamics enables physiology-bound perturbation experiments in silico.

ACTIVITY-DRIVEN DEEP MODELS FOR LEARNING SOUND TRANSFORMATIONS ACROSS THE AUDITORY PATHWAY

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Simone Azeglio, Allan Muller, Sophie Bagur, Brice Bathellier
Institut Pasteur, Institut De L'audition, Paris, France

Auditory system neurons present striking nonlinear features in their activity patterns which are difficult to model. To take advantage of model optimization tools now offered by deep networks we recorded a large sample of neurons, using two-photon imaging and electrophysiology, across different stages of the auditory pathway including the cochlea, inferior colliculus, thalamus, and auditory cortex. Based on this dataset, we aimed at capturing stage-to-stage non-linear transformation of auditory information. Given the large number of different stimuli presented and recorded neurons across several trials, we could employ an *activity-driven* framework to map the neuronal activity across stages with multilayer models (multi-layer perceptron) of different complexities, which are trained based on a subset of the dataset and cross-validated on another subset. This allowed us to identify which features of neuronal responses are captured by linear or nonlinear models while preventing overfitting issues. Based on these principles, we derive a scheme to extract nonlinear transformations from data, shedding light on the properties of different stages of the auditory pathway.

MARKOV CHAIN MONTE CARLO AND DETAILED ELECTRICAL MODELS OF NEURONS: CORRELATIONS AND GENERALISATION

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Alexis Arnaudon[1], Maria Reva[2], Mickael Zbili[1], Lida Kanari[1], Werner Van Geit[1], Henry Markram[1]
[1]École polytechnique fédérale de Lausanne, Blue Brain Project, Geneva, Switzerland, [2]EPFL, Bbp, Geneva, Switzerland

Detailed electrical models of neurons consist of several ion channels in various compartments yielding models with as many as 35 parameters.
These parameters, such as ion channel conductances, have to be fitted to experimental data via a cost function, but robustness under external perturbations, an important property of biological cells, is rarely studied.
To address this problem, we go beyond methods based on optimisation and use Markov Chain Monte Carlo sampling of the parameters of the electrical models with probability proportional to the cost function.
We show that this approach provides detailed information about the properties of the parameter space, such as the shape of the high dimensional subspace of valid electrical models, or, equivalently, correlations between conductances.
For example, the maximum conductance of sodium in the axon initial segment and soma must not both be small or the threshold current will dramatically increase.
The shape of parameter space allows us to assess stability under perturbations such as morphological changes or current blockades.
We then propose algorithms for selecting a population of robust and low score models.
In addition, we show that by adjusting the size of axon initial segment and soma to match their respective input resistance with one of the dendrites, we further improve the generalisability and consistency of the models. We apply this procedure to various electrical types as means to produce a heterogeneous and robust population of single neuron models, which, in network simulations can provide further insight into how neuronal variability impacts circuit computations.

SPATIAL AND TEMPORAL CONSTRAINS ON THE EXCITATORY EFFECT OF DEPOLARIZING GABAERGIC INPUTS

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Werner Kilb, Aniello Lombardi, Heiko Luhmann
University Medicine of the J. Gutenberg University Mainz, Institute Of Physiology, Mainz, Germany

The inhibitory neurotransmitter GABA (γ-amino butyric acid) mediates via ionotropic $GABA_A$ receptors hyperpolarizing or depolarizing membrane responses. While in the healthy adult brain hyperpolarizing responses dominate, depolarizing responses occur during development or after neuropathological insults. Because GABAergic actions depend on membrane potential changes, shunting inhibition and spatiotemporal filtering, the net effect of depolarizing GABAergic responses is hard to predict. To evaluate how the GABA reversal potential (E_{GABA}) influence the excitatory/inhibitory action of GABA, we performed a detailed in-silico study using simple neuronal topologies and distinct spatiotemporal relations between GABAergic and glutamatergic inputs. In these simulations we quantified E_{GABA} required for a net excitatory effect (E_{GABA}^{Thr}). For excitatory current injections E_{GABA}^{Thr} was close to action potential threshold (E_{AP}^{Thr}) for GABAergic synapses located at the soma, while with increasing dendritic distance E_{GABA}^{Thr} shifted to positive values. For excitatory synaptic inputs E_{GABA}^{Thr} was slightly negative to E_{AP}^{Thr} and was shifted to more negative values for dendritic AMPA synapses located proximally to the GABA input. For AMPA synapses located distally to the GABA synapse the dendritic distance had only a minor effect on E_{GABA}^{Thr}. In addition, E_{GABA}^{Thr} depended on the temporal relation between GABA and AMPA inputs, with E_{GABA}^{Thr} approximating resting membrane potential for delayed AMPA inputs. For tonic GABAergic conductances E_{GABA}^{Thr} was negative to E_{AP}^{Thr}. In summary, these results demonstrate that E_{GABA}^{Thr} is negative to E_{AP}^{Thr} for various physiologically relevant situations, suggesting that depolarizing GABAergic responses can mediate excitatory effects even if E_{GABA} does not reach E_{AP}^{Thr}.

Strong inhibitory recurrent connections can reduce the tendency for a neural network to become unstable. This is known as inhibitory stabilization and networks that combine unstable excitatory recurrent connections with strong inhibitory feedback are known as Inhibition Stabilized Networks (ISNs). One of the characteristics of ISNs is their “paradoxical response”, which refers to the case where perturbing the inhibitory interneurons by excitatory input results in a decrease in the activity of these neurons after a temporal delay, instead of increasing their activity. Here, we develop a model of populations of neurons across different layers of cortex. Within each layer, there is one population of inhibitory and one population of excitatory neurons. To investigate the presence of ISNs across different layers, we recorded the membrane potentials of neural populations after perturbing inhibitory populations. The perturbation applied was a step increase in the firing rate of the excitatory input. The results shows that layer 2/3 in the model does not operate in the ISN regime as the membrane potential of inhibitory interneurons increases when perturbation is applied to this population. However, layers 4 and 5 operate in the ISN regime as the membrane potential of the inhibitory interneurons decreases after a transition period. These results accord with neurophysiological findings that explored the presence of ISNs across different layers in the cortex. The model may be used to provide insights into how parameter changes may lead to bifurcations resembling epileptic seizures and the relationship of paradoxical response and seizure onset in epileptic brains.

THE ROLE OF REINFORCEMENT LEARNING IN THE CEREBELLUM BEYOND CLASSICAL THEORIES OF MOTOR CONTROL

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Mattia Della Vecchia, N Alex Cayco Gajic
École Normale Supérieure, Université Paris Sciences et Lettres, Département D'Études Cognitives, Paris, France

One of the most influential models of the cerebellar cortex ascribes to its ‘crystalline’ structure the role of an associative learning device in the context of motor control. Albus and Marr, more than 50 years ago, proposed this perceptron-like theory of supervised learning to correct motor outcomes based on sensorimotor predictions. We extend this model, which is characterized by a divergent-convergent architecture and error-gated plasticity, to test new perspectives of its functional repertoire. Our interest revolves around its ability to perform reinforcement learning (RL). This objective is inspired by recent studies that unveiled teaching signals in the cerebellum resembling a reward prediction error used in RL models of basal ganglia, rather than the typical sensory errors used in many computational models. We apply the model to classical cerebellar functions, such as pattern classification or sensorimotor predictions, as well as reinforcement learning tasks. These results demonstrate the ability of the cerebellar architecture to implement a wider range of learning rules than previously appreciated, in particular, in relation to its role beyond motor control and towards cognitive processing.

Of Anatomy, Budapest, Hungary

Cognition emerges by counterstream feedforward and feedback interactions in the large-scale hierarchical network of the cerebral cortex. The counterstream, as a topological feature, is captured by the convergence and divergence of paths through directed links. So defined, the convergence degree (CD) reveals hierarchically relevant integrative properties of areas through their inward and outward connections. Although cortical dynamics are rooted in the anatomical network, the relationship of structure and function is far from clear. To understand how topology shapes large-scale cortical functioning, we studied the role of CD in network resilience and Granger causal coupling in a model of hierarchical network dynamics. Our results indicate that topological synchronizability is highly vulnerable to attacking edges based on CD, while global network efficiency depends mostly on edge betweenness. Furthermore, similar to anatomical hierarchy determined by the laminar distribution of connections, CD-based topological hierarchy showed high correlation with causal coupling in feedforward gamma and feedback alpha-beta band synchronizations in a subnetwork including low-level visual cortical areas. In contrast, causal coupling did not correlate with edge betweenness. Considering the entire network, the CD-based hierarchy correlated well with both the anatomical and functional hierarchy for low-level areas that are hierarchically far apart. Conversely, in a large part of the anatomical network where hierarchical distances are small, correlations were not significant. These findings indicate that at lower levels of cortical hierarchy interareal connectivity closely shapes large-scale oscillatory dynamics. However, at higher levels flexibility in hierarchical interactions is maintained to cope with varying demands.

Alterations in cortical circuit parameters impact neural computation and cognition and have been implicated in brain disorders. Existing methods for interrogation of changes in neural circuit configuration are often based on recordings of neural mass signals, such as LFPs, ECoGs, MEGs and EEGs. However, microscopic neural parameters cannot be readily inferred from mass signals. Previous work has suggested that the aperiodic 1/f slope of the power spectrum of mass signals is a robust biomarker of excitation-inhibition (E/I) imbalance. Here we take a step forward from prior work by utilizing a multivariate inference method that accounts for joint changes in several relevant spectral features of mass signals (including aperiodic and periodic spectral components) to accurately predict microscopic neural circuit parameters from mass activity. Using a model of a recurrent cortical microcircuit of interacting excitatory and inhibitory neuronal populations, we systematically varied key neural model parameters to create a large dataset of spectral features that was used to train multivariate regression methods for inferring changes in E/I, mean firing rate of excitatory neurons and strength of the network input. Our model-based inference method was validated in-vivo with a combination of chemogenetic and optogenetic manipulations of E/I and firing rates with LFP and ECoG recordings from mice and ferrets, LFPs in mice at different stages of early development, and a combination of non-invasive pharmacological manipulations of E/I with MEG and EEG recordings in humans. Our results provide a method to estimate circuit parameters from spontaneous and stimulus-evoked activity recorded at different spatial scales.

EXTRACTING MOTOR COMMANDS FROM NATURAL BEHAVIOR: A CONTROL THEORY APPROACH

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Yoav Rubinstein[1], Sapir Shapira[1], Maayan Moshkovitz[1], Yogev Hendel[1], Stas Tiomkin[2], Lilach Avitan[1]
[1]The Hebrew University of Jerusalem, Edmond And Lily Safra Center For Brain Sciences, Jerusalem, Israel, [2]San Jose state University, Computer Engineering, San Jose, United States of America

Goal-directed behavior is a key feature of all biological systems. Whether searching for food or running away from a predator, an organism must choose a sequence of actions driven by a series of motor commands to achieve a desired goal. To study the principles shaping action selection, it is necessary to map the continuous space of motor commands forming the organism's behavioral repertoire. Here we record larval zebrafish during natural hunt and extract motor commands accounting for their behavior. Behavior is treated as the response of a dynamic system to an impulse function representing the command. The framework offers predictions of motor commands and properties of their neural representations, including command onset time and duration. Mapping the full space of motor commands will form the first milestone to study sequences of actions in natural behavior settings.

COMPRESSION-ENABLED INTERPRETABILITY OF VOXEL-WISE ENCODING MODELS

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Fatemeh Kamali[1], Amir Abolfazl Suratgar[1], Mohammadbagher Menhaj[1], Reza Abbasi-Asl[2]
[1]Amirkabir University of Technology, Electrical Engineering Department, Tehran, Iran, [2]University of California, San Francisco, Department Of Neurology, Department Of Bioengineering And Therapeutic Sciences, San Francisco, United States of America

Voxel-wise encoding models based on convolutional neural networks (CNNs) have emerged as state-of-the-art predictive models of brain activity evoked by natural movies. Despite the superior predictive performance of CNN-based models, the huge number of parameters in these models have made them difficult to interpret for domain experts. Here, we investigate the role of model compression in building more interpretable and more stable CNN-based voxel-wise models. We used (1) structural compression techniques to prune less important CNN filters and connections, (2) a receptive field compression method to choose the model receptive fields with optimal center and size, and (3) principal component analysis to reduce the dimensionality of the model. The compressed models reveal increased category-selectivity along the ventral visual pathway with higher stability compared to uncompressed models. Furthermore, we demonstrate that the optimal model receptive fields become larger along the ventral visual pathway, as the receptive fields become more centralized.

A GRAPH-BASED MODEL OF THE EFFECT OF DEEP BRAIN STIMULATION ON CORTICO-SUBCORTICAL NETWORKS IN THE CONTEXT OF FREEZING OF GAIT IN PARKINSON'S DISEASE

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Mariia Popova[1], Arnaud Messé[1], Alessandro Gulberti[2], Christian Gerloff[2], Monika Pötter-Nerger[2], Claus Hilgetag[1]
[1]University Medical Center Hamburg-Eppendorf, Institute Of Computational Neuroscience, Hamburg, Germany, [2]University Medical Center Hamburg-Eppendorf, Department Of Neurology, Hamburg, Germany

Currently available treatments of Parkinson's disease (PD) are restricted in their efficiency to alleviate freezing of gait (FoG). One potential therapeutical approach of FoG treatment, which is highlighted in the current literature, represents deep brain stimulation (DBS) of the subthalamic nucleus (STN) and the substantia nigra pars reticulata (SNr), however with clinically heterogeneous results. A computational model explaining the observed STN- or STN+SNr-DBS effects on cortical and brainstem excitability may unravel the complicated brain network interactions underlying the complex phenomenon of DBS. However, large-scale basal ganglia and brainstem models require frequently unavailable biological details or impractical computational capacity. Hence, to date, there is no model that is both computationally effective and accounts for the complex basal ganglia and brainstem circuitry. As an alternative approach, we propose a spontaneous-excitatory-refractory (SER) graph-based network model of the basal ganglia and brainstem. Here, the regions and connections involved in the current gait model and FoG are nodes and edges of the model graph. Every involved region undergoes a simplified, albeit biologically plausible SER dynamical cycle. We assess and compare all combinations of the emerging network dynamics in the healthy, parkinsonian, and DBS states. The network dynamics during the STN+SNr-DBS is markedly different from the standard STN-DBS dynamics. The pattern of the brainstem excitability is closer to the healthy one under the STN+SNr-DBS suggesting its positive effect on FoG. Thus, for the first time, a model accounts for the difference between two stimulation modes and suggests the network mechanism behind them.

PARAMETER INFERENCE ON BRAIN NETWORK MODELS WITH UNKNOWN NODE DYNAMICS AND SPATIAL HETEROGENEITY

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Viktor Sip[1], Spase Petkoski[1], Meysam Hashemi[1], Timo Dickscheid[2], Katrin Amunts[2], Viktor Jirsa[1]
[1]Aix-Marseille Université, Institut De Neurosciences Des Systèmes, Marseille, France, [2]Jülich Research Centre, Institute For Neuroscience And Medicine, Julich, Germany

Model-based data analysis of whole-brain dynamics links the observed data to model parameters in a network of neural masses. In recent years a special focus was placed on the role of regional variance of model parameters for the emergent activity. Such analyses however depend on the properties of the employed neural mass model, which is often obtained through a series of major simplifications or analogies. Here we propose a data-driven approach where the neural mass model needs not to be specified. Building on the recent progresses in identification of dynamical systems with neural networks, we propose a method to infer from the functional data both the neural mass model representing the regional dynamics as well as the region- and subject-specific parameters, while respecting the known network structure. We demonstrate on two synthetic data sets that our method is able to recover the original model parameters, and that the trained generative model produces dynamics resembling the training data both on the regional level and on the whole-brain level. We further apply the method to resting-state fMRI data from Human Connectome Project. We find that to achieve best fit, the model needs two dimensional state space and three regional parameters, one of which is strongly correlated with the map of genetic expression in human brain. The present approach opens a novel way to the analysis of resting-state fMRI with possible applications in understanding the changes of whole-brain dynamics during aging or in neurodegenerative diseases.

A MULTIVARIATE MODEL FOR THE ANALYSIS OF NEURAL SPIKE TRAINS

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Reza Ramezan[1], Bryn Crandles[1,2]
[1]University of Waterloo, Dept. Of Statistics And Actuarial Science, Waterloo, Canada, [2]University of Waterloo, Statistics And Actuarial Science, Waterloo, Canada

The current state-of-the-art technology in collecting neurophysiological data allows for simultaneous recording from hundreds of neurons. A proper modelling approach for such data is the point process framework. However, the existing point process models for simultaneous neural spike trains are computationally infeasible. In this work, we introduce a multi-neuron version of our previous work on Skellam process with resetting (SPR). Unlike other models, the multivariate SPR is flexible in capturing the correlation structure among spike trains, it is computationally efficient, and is also biologically justified due to mimicking a neural integration process. Through both simulations and real-data analyses we highlight the strengths and weaknesses of this model.

LEARNING HETERO-SYNAPTIC DELAYS OF SPIKING NEURONS FOR MOTION DETECTION

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Antoine Grimaldi[1], Laurent Perrinet[2]
[1]Institut de Neurosciences de la Timone, Faculté De Médecine, Marseille, France, [2]Aix-Marseille Université, Institut Des Neurosciences De La Timone, Marseille, France

The response of a biological neuron depends on the precise timing of afferent spikes. This temporal aspect of the neuronal code is essential in understanding information processing in neurobiology and applies particularly well to the output of neuromorphic hardware such as event-based cameras. However, most artificial neuronal models do not take advantage of this minute temporal dimension. Inspired by this neuroscientific observation, we develop a model for the efficient detection of temporal spiking motifs based on a layer of neurons with hetero-synaptic delays. Indeed, the connectivity of the dendritic tree allows to discriminate between different temporal sequences, and we show that this can be formalized as a time-invariant logistic regression that can be trained using labeled data. We apply this model to solve the specific computer vision problem of motion detection and demonstrate its application to synthetic nature videos transformed into event streams similar to the output of event-based cameras. In particular, we quantify how its accuracy can vary with the total computational load. This end-to-end event-driven computational brick could help improve the performance of future spiking neural network (SNN) solutions currently used in neuromorphic chips.

COMPUTATIONAL STUDY OF GAP JUNCTIONS IN A BIOPHYSICALLY DETAILED MODEL OF THE STRIATAL MICROCIRCUIT

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Johannes Hjorth[1], Kadri Pajo[2], Johanna Frost Nylén[2], Ilaria Carannate[1], Alexander Kozlov[1], Sten Grillner[2], Jeanette Hellgren Kotaleski[1]
[1]Royal Institute of Technology (KTH), School Of Electrical Engeneering And Computer Science, Solna, Sweden, [2]Karolinska Institutet, Neuroscience, Solna, Sweden

We have previously developed a biophysically detailed striatal simulation platform [Hjorth et al, 2020] containing striatal projection neurons of D1 and D2 dopamine subtypes, fast spiking interneurons (FS), cholinergic interneurons and low threshold spiking interneurons, including dopamine modulation [Frost Nylen 2021]. The connectivity of the synapses in the microcircuit is based on touch detection using the software Snudda [Hjorth et al 2021]. Also gap junctions between the FS are placed within the dendritic overlaps. The connection probability and coupling coefficients between gap-junction coupled FS in the model match what has been previously reported in experiments [Koos and Tepper 1999]. Using this in silico platform it becomes possible to investigate both dynamical features and function of the striatal network. For instance, different oscillatory components are seen both in the healthy and diseased basal ganglia, and such oscillatory entrainments may have a causal role in shaping the signal propagation through the basal ganglia [Fischer 2021]. However, the mechanisms behind these oscillations and their functional relevance to the striatum is unclear. We here investigate, in particular, the role of gap junctions between FS neurons for the striatal signal propagation. Our results confirm that when gap junctions are placed using touch detection algorithms the FS subnetwork can detect a change in how synchronous the input is [Hjorth et al 2009]. We furthermore investigate the effect of the embedded gap-junction coupled FS network on the local striatal surrounding microcircuit and activity.

THE OFT-FORGOTTEN GOLDMAN-HODGKIN-KATZ (GHK) CURRENT EQUATION PREDICTS STABLE SPIKE FIRING IN ULTRATHIN AXONS

POSTER SESSION 05 - SECTION: MODELING THE BRAIN

Oron Kotler[1], Michael Gutnick[2], Ilya Fleidervish[1]
[1]Ben-Gurion University of the Negev, Department Of Physiology And Cell Biology, Beer Sheva, Israel, [2]The Hebrew University of Jerusalem, Koret School Of Veterinary Medicine, Rehovot, Israel

In the 1940's and 50's, two constant electric field equations emerged that describe the relationships between voltage and current across a membrane. The more famous GHK *voltage* equation reconciles Nernst potentials of the various ion species with their partial permeabilities. The other, GHK *current* equation, describes the non-linear relationship between current and voltage for different concentration gradients. Hodgkin and Huxley used a simplified, linear model for their formalism, and this well fit the data from squid giant axon. However, when applied to the condition of rapid repetitive firing in ultra-thin axons, the linear HH equations (which have been used in most computational studies) predict that the marked decrease in Na gradient will have dire consequences for the fidelity of spike initiation and propagation. We now show that when the HH formalism is modified to use the GHK *current* equation, spikes are only minimally affected. Thus, whereas the linear model predicts that a 10-fold increase in [Na+]i leads to an 80% decrease in inward current at 0 mV and an equivalent slowing of the rate of rise of an action potential, the non-linear GHK *current* equation predicts only about a 20% change. The effect on propagation velocity is also minimal. These dramatic differences are significant because much neuropil includes axons with diameters smaller than .5 microns. In summary, action potential spans a voltage range that is largely resistant to changes in Na concentration gradient, which ensures stable neuronal interaction in highly active local networks.

Exploiting holographic control of light transport through a multimode fiber turns such single hair-thin glass filament into endoscopic instrument performing at submicron resolution. Multimode fiber-based holographic endoscopes (MMFE) thus represent a revolutionary tool for deep brain *in-vivo* imaging. While current state-of-the–art *in-vivo* brain imaging methods struggle from the fundamental trade-off between resolution and penetration depth, MMFE effectively bypasses this technological trap, allowing high resolution imaging in any depth within the brain in the most atraumatic manner. Here we review the performance of a high-speed MMFE system optimised for fluorescent imaging of brain tissue within various living mice models. The instrument is equipped with 110 µm side-view multimode probe, refocusing property, multi-wavelength detection and three-dimensional random access options allowing detection of high speed events. We demonstrate various modes of its application through the observation of fluorescently labelled blood vessels, neurons, neuronal bodies, processes and even subcellular structures such as dendritic spines and lysosomes. Further, exploiting the random access option the instrument allows functional imaging of high speed events as demonstrated by imaging of calcium signaling and red blood cell velocity measurements in single vessels. In conclusion, the present study pushed the technological development forward creating a multimode fiber-based holographic endoscope as a perspective tool for *in-vivo* deep brain imaging.

PAMAM dendrimers are 3-dimensional nanomolecules with multiple applications in biomedical sciences. These dendrimers can carry drugs and DNA/biomolecules to target systems, including those that necessitate the crossing of the blood brain barrier (BBB) to deliver its cargo to the brain. One of the advantages of PAMAM dendrimers, compared to the current viral-based delivery systems, is that these dendrimers can carry and deliver very large plasmids in addition to delivering drugs simultaneously (mixed-cargo). The **aim** of the current study was to analyze the drug delivery applications of our modified-surface PAMAM dendrimers (G4-90/10) in stroke and glioblastoma (GB) models in vitro and in vivo. **Methods:** (1) inject G4-90/10 dendrimers systemically in healthy mice via different routes to analyze their efficiency to cross the BBB; (2) characterize large dendrimer-plasmid complex and its delivery efficiency in healthy rats; (3) complex and deliver a therapeutic gene (hSOX2) in an ischemic stroke rat model; and (4) encapsulate curcumin (which has anti-cancer properties) and deliver this to models of human glioblastoma. **Results:** G4-90/10 dendrimers can: (1) cross the BBB following systemic injections in mice; (2) complex and carry large plasmids that were successfully delivered to the neurons and glial cells in vitro and in vivo in rats; (3) deliver the hSOX2 gene in stroke rats and reduce motor deficits; (4) l specifically target human GB cells for destruction and tended to improve the survivability of GB mice. **Conclusion:** PAMAM dendrimer is a promising versatile cargo delivery vehicle that has multiple applications to treat brain diseases, including GB.

DEVELOPMENT AND VALIDATION OF ARC NANOBODIES: NEW TOOLS FOR PROBING ARC DYNAMICS AND FUNCTION

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Tadiwos Mergiya[1,2], Yuta Ishizuka[1], Rodolfo Baldinotti[1,2], Ju Xu[1], Erik I. Hallin[1], Sigurbjörn Markússon[1], Petri Kursula[1,3,4], Clive Bramham[1,2]
[1]University of Bergen, Biomedicine, Bergen, Norway, [2]University of Bergen, Mohn Center For Research On The Brain, Bergen, Norway, [3]University of Oulu, Faculty Of Biochemistry And Molecular Medicine, Oulu, Finland, [4]University of Oulu, Biocenter Oulu, Oulu, Finland

Activity-regulated cytoskeleton-associated (Arc) protein plays key roles in long-term synaptic plasticity, memory, and cognitive flexibility. However, an integral understanding of Arc mechanisms is lacking. Arc is proposed to function as an interaction hub in neuronal dendrites and the nucleus, yet Arc can also form retrovirus-like capsids with proposed roles in intercellular communication. Here, we sought to develop anti-Arc nanobodies (ArcNbs) as new tools for probing Arc dynamics and function. Six ArcNbs representing different clonal lines were selected from immunized alpaca. Western blotting with recombinant ArcNbs fused to a small ALFA-epitope tag demonstrated binding to bacterially-expressed, purified Arc and endogenous Arc from rat cortical tissue. ALFA-ArcNb also provided efficient immunoprecipitation of stimulus-induced Arc after carbachol-treatment of SH-SY5Y neuroblastoma cells and induction of long-term potentiation (LTP) in the rat dentate gyrus in vivo. Epitope mapping showed that all Nbs recognize the Arc C-terminal region containing the retroviral Gag capsid homology domain, comprised of tandem N- and C-lobes. ArcNbs E5 and H11 selectively bound the N-lobe, which harbors a peptide ligand binding pocket specific to mammals. Four additional ArcNbs bound the region containing the C-lobe and terminal tail. For use as genetically-encoded fluorescent intrabodies, we show that ArcNbs fused to mScarlet-I are uniformly expressed, without aggregation, in the cytoplasm and nucleus of HEK293FT cells. Finally, mScarlet-ArcNb H11 expressed as intrabody selectively bound the N-lobe and enabled co-immunoprecipitation of full-length intracellular Arc. Arc nanobodies are versatile tools for live-cell labeling and purification of Arc and analysis of capsid domain specific functions.

[1]Vrije Universiteit Brussel (VUB), Pharmaceutical Chemistry, Drug Analysis And Drug Informatoin, Center For Neuroscience, Brussels, Belgium, [2]University of Pécs, Medical School, Department Of Anatomy, Pécs, Hungary, [3]University of Pécs, Center For Neuroscience & Szentagothai Research Center, Pécs, Hungary, [4]IGF, Université Montpellier, CNRS, Inserm, Molecular And Neural Coding Of Behavior (mncb)lab, Montpellier, France

Neuromedin U (NMU) is an evolutionary conserved neuropeptide that has been implicated in multiple physiological and pathophysiological processes, such as energy homeostasis, stress response and reward processing. Although central expression of NMU has been addressed previously, the lack of specific and sensitive research tools has prevented a comprehensive anatomical and functional characterization of NMU neurons in the brain. In the present study, we generated a knock-in mouse model constitutively expressing Cre recombinase under the *nmu* endogenous promoter. A multi-level approach using RT-qPCR, *in situ* hybridization, a cross with a reporter mouse line and an adenoviral vector driving Cre-dependent expression of a fluorescent protein successfully validated the mouse model. By using the newly developed Nmu-Cre knock-in mouse, we performed a complete mapping of NMU expression in both male and female adult mouse brain, unveiling a potential new brain circuit of NMU-expressing neurons, comprising areas involved in the modulation of the stress response, drug reward and appetitive motivational states. Taken together, our results strongly suggest that the newly developed Nmu-Cre knock-in mouse model largely and faithfully expresses Cre recombinase in NMU-expressing neurons in the adult mouse brain, without altering endogenous NMU expression. It is presented as a novel, powerful and sensitive tool to explore the role of NMU neurons in mice. Moreover, the neuroanatomical characterization supports the suggested role of NMU in the brain reward system.

Extra-Virgin Olive Oil and Its Minor Compounds Influence Apoptosis in Experimental Mammary Tumors and Human Breast Cancer Cell Lines.
Breast cancer is the most common malignancy among women worldwide. Modifiable factors such as nutrition have a role in its etiology. In experimental tumors, we have observed the differential influence of high-fat diets in metabolic pathways, suggesting a different balance in proliferation/apoptosis. In this work, we analyzed the effects of a diet high in n-6 polyunsaturated fatty acids (PUFA) and a diet high in extra-virgin olive oil (EVOO) on the histopathological features and different cell death pathways in the dimethylbenz(a)anthracene-induced breast cancer model. The diet high in n-6 PUFA had a stimulating effect on the morphological aggressiveness of tumors and their proliferation, while no significant differences were found in groups fed the EVOO-enriched diet in comparison to a low-fat control group. The high-EVOO diet induced modifications in proteins involved in several cell death pathways. In vitro analysis in different human breast cancer cell lines showed an effect of EVOO minor compounds (especially hydroxytyrosol), but not of fatty acids, decreasing viability while increasing apoptosis. The results suggest an effect of dietary lipids on tumor molecular contexts that result in the modulation of different pathways, highlighting the importance of apoptosis in the interplay of survival processes and how dietary habits may have an impact on breast cancer risk.

Discovery of a macromolecular complex mediating the hunger suppressive actions of cocaine: Structural and functional properties.
Cocaine not only increases brain dopamine levels but also activates the sigma receptor (σ R) that in turn regulates orexigenic receptor function. Identification of interactions involving dopamine D (D R), ghrelin (GHS-R), and σ receptors have been addressed by biophysical techniques and a complementation approach using interfering peptides. The effect of cocaine on

receptor functionality was assayed by measuring second messenger, cAMP and Ca , levels. The effect of acute or chronic cocaine administration on receptor complex expression was assayed by in situ proximity ligation assay. In silico procedures were used for molecular model building. σ R KO mice were used for confirming involvement of this receptor. Upon identification of protomer interaction and receptor functionality, a unique structural model for the macromolecular complex formed by σ R, D R, and GHS-R is proposed. The functionality of the complex, able to couple to both Gs and Gq proteins, is affected by cocaine binding to the σ R, as confirmed using samples from σ R mice. The expression of the macromolecular complex was differentially affected upon acute and chronic cocaine administration to rats. The constructed 3D model is consistent with biochemical, biophysical, and available structural data. The σ R, D R, and GHS-R complex constitutes a functional unit that is altered upon cocaine binding to the σ R. Remarkably, the heteromer can simultaneously couple to two G proteins, thus allowing dopamine to signal via Ca and ghrelin via cAMP. The anorexic action of cocaine is mediated by such complex whose expression is higher after acute than after chronic administration regimens.

Effects of neuromedin U-8 on stress responsiveness and hypothalamus-pituitary-adrenal axis activity in male C57BL/6J mice.
Neuromedin U (NMU) is a highly conserved neuropeptide that has been implicated in the stress response. To better understand how it influences various aspects of the stress response, we studied the effects of intracerebroventricular NMU-8 administration on stress-related behavior and activity of the hypothalamus-pituitary-adrenal (HPA) axis in male C57BL/6J mice. We investigated these NMU-8 effects when mice remained in their home cage and when they were challenged by exposure to forced swim stress. NMU-8 administration resulted in increased grooming behavior in mice that remained in their home cage and in a significant increase in c-Fos immunoreactivity in the paraventricular hypothalamus (PVH) and arcuate nucleus (ARC). Surprisingly, NMU-8 administration significantly decreased plasma corticosterone concentrations. Furthermore, NMU-8 administration increased immobility in the forced swim test in both naïve mice and mice that were previously exposed to swim stress. The effect of NMU-8 on c-Fos immunoreactivity in the PVH was dependent on previous exposure to swim stress given that we observed no significant changes in mice exposed for the first time to swim stress. In contrast, in the ARC we observed a significant increase in c-Fos immunoreactivity regardless of previous stress exposure. Interestingly, NMU-8 administration also significantly decreased plasma corticosterone concentrations in mice that were exposed to single forced swim stress, while this effect was no longer observed when mice were exposed to forced swim stress for a second time. Taken together, our data indicate that NMU-8 regulates stress responsiveness and suggests that its effects depend on previous stress exposure.

Differential effect of amphetamine over the corticotropin-releasing factor CRF receptor, the orexin OX receptor and the CRF-OX heteroreceptor complex.
Stress is one of the factors underlying drug seeking behavior that often goes in parallel with loss of appetite. We here demonstrate that orexin 1 receptors (OXR) may form complexes with the corticotropin releasing factor CRF receptor. Two specific features of the heteromer were a cross-antagonism and a blockade by CRF of OXR signaling. In cells expressing one of the receptors, agonist-mediated signal transduction mechanisms were potentiated by amphetamine. Sigma 1 (σ) and 2 (σ) receptors are targets of drugs of abuse and, despite sharing a similar name, the two receptors are structurally unrelated and their physiological role is not known. We here show that σ receptors interact with CRF receptors and that σ receptors interact with OXR. Moreover, we show that amphetamine effect on CRF receptors was mediated by σR whereas the effect on OX receptors was mediated by σR. Amphetamine did potentiate the negative cross-talk occurring within the CRF-OX receptor heteromer context, likely by a macromolecular complex involving the two sigma receptors and the two GPCRs. Finally, in vivo microdialysis experiments showed that amphetamine potentiated orexin A-induced dopamine and glutamate release in the ventral tegmental area (VTA). Remarkably, the in vivo orexin A effects were blocked by a selective CRFR antagonist. These results show that amphetamine impacts on the OXR-, CRFR- and OXR/CRFR-mediated signaling and that cross-antagonism is instrumental for in vivo detection of GPCR heteromers. This article is part of the Special Issue entitled 'Receptor heteromers and their allosteric receptor-receptor interactions'.

Cocaine Blocks Effects of Hunger Hormone, Ghrelin, Via Interaction with Neuronal Sigma-1 Receptors.
Despite ancient knowledge on cocaine appetite-suppressant action, the molecular basis of such fact remains unknown. Addiction/eating disorders (e.g., binge eating, anorexia, bulimia) share a central control involving reward circuits. However, we here show that the sigma-1 receptor (σR) mediates cocaine anorectic effects by interacting in neurons with

growth/hormone/secretagogue (ghrelin) receptors. Cocaine increases colocalization of σR and GHS-R1a at the cell surface. Moreover, in transfected HEK-293T and neuroblastoma SH-SY5Y cells, and in primary neuronal cultures, pretreatment with cocaine or a σR agonist inhibited ghrelin-mediated signaling, in a similar manner as the GHS-R1a antagonist YIL-781. Results were similar in G protein-dependent (cAMP accumulation and calcium release) and in partly dependent or independent (ERK1/2 phosphorylation and label-free) assays. We provide solid evidence for direct interaction between receptors and the functional consequences, as well as a reliable structural model of the macromolecular σR-GHS-R1a complex, which arises as a key piece in the puzzle of the events linking cocaine consumption and appetitive/consummatory behaviors.

Cocaine Effects on Dopaminergic Transmission Depend on a Balance between Sigma-1 and Sigma-2 Receptor Expression.
Sigma σ and σ receptors are targets of cocaine. Despite sharing a similar name, the two receptors are structurally unrelated and their physiological role is unknown. Cocaine increases the level of dopamine, a key neurotransmitter in CNS motor control and reward areas. While the drug also affects dopaminergic signaling by allosteric modulations exerted by σR interacting with dopamine D and D receptors, the potential regulation of dopaminergic transmission by σR is also unknown. We here demonstrate that σR may form heteroreceptor complexes with D but not with D receptors. Remarkably σ, σ, and D receptors may form heterotrimers with particular signaling properties. Determination of cAMP levels, MAP kinase activation and label-free assays demonstrate allosteric interactions within the trimer. Importantly, the presence of σR induces bias in signal transduction as σR ligands increase cAMP signaling whereas reduce MAP kinase activation. These effects, which are opposite to those exerted via σR, suggest that the D receptor-mediated signaling depends on the degree of trimer formation and the differential balance of sigma receptor and heteroreceptor expression in acute versus chronic cocaine consumption. Although the physiological role is unknown, the heteroreceptor complex formed by σ, σ, and D receptors arise as relevant to convey the cocaine actions on motor control and reward circuits and as a key factor in acquisition of the addictive habit.

Orexin A/Hypocretin Modulates Leptin Receptor-Mediated Signaling by Allosteric Modulations Mediated by the Ghrelin GHS-R1A Receptor in Hypothalamic Neurons.
The hypothalamus is a key integrator of nutrient-seeking signals in the form of hormones and metabolites originated in both the central nervous system and the periphery. The main autocrine and paracrine target of orexinergic-related hormones such as leptin, orexin/hypocretin, and ghrelin are neuropeptide Y neurons located in the arcuate nucleus of the hypothalamus. The aim of this study was to investigate the expression and the molecular and functional relationships between leptin, orexin/hypocretin and ghrelin receptors. Biophysical studies in a heterologous system showed physical interactions between them, with potential formation of heterotrimeric complexes. Functional assays showed robust allosteric interactions particularly different when the three receptors are expressed together. Further biochemical and pharmacological assays provided evidence of heterotrimer functional expression in primary cultures of hypothalamic neurons. These findings constitute evidence of close relationships in the action of the three hormones already starting at the receptor level in hypothalamic cells.

Singular Location and Signaling Profile of Adenosine A-Cannabinoid CB Receptor Heteromers in the Dorsal Striatum.
The dorsal striatum is a key node for many neurobiological processes such as motor activity, cognitive functions, and affective processes. The proper functioning of striatal neurons relies critically on metabotropic receptors. Specifically, the main adenosine and endocannabinoid receptors present in the striatum, ie, adenosine A receptor (AR) and cannabinoid CB receptor (CBR), are of pivotal importance in the control of neuronal excitability. Facilitatory and inhibitory functional interactions between striatal AR and CBR have been reported, and evidence supports that this cross-talk may rely, at least in part, on the formation of AR-CBR heteromeric complexes. However, the specific location and properties of these heteromers have remained largely unknown. Here, by using techniques that allowed a precise visualization of the heteromers in situ in combination with sophisticated genetically modified animal models, together with biochemical and pharmacological approaches, we provide a high-resolution expression map and a detailed functional characterization of AR-CBR heteromers in the dorsal striatum. Specifically, our data unveil that the AR-CBR heteromer (i) is essentially absent from corticostriatal projections and striatonigral neurons, and, instead, is largely present in striatopallidal neurons, (ii) displays a striking G protein-coupled signaling profile, where co-stimulation of both receptors leads to strongly reduced downstream signaling, and (iii) undergoes an unprecedented dysfunction in Huntington's disease, an archetypal disease that affects striatal neurons.

Altogether, our findings may open a new conceptual framework to understand the role of coordinated adenosine-endocannabinoid signaling in the indirect striatal pathway, which may be relevant in motor function and neurodegenerative diseases.

A Significant Role of the Truncated Ghrelin Receptor GHS-R1b in Ghrelin-induced Signaling in Neurons.
The truncated non-signaling ghrelin receptor growth hormone secretagogue R1b (GHS-R1b) has been suggested to simply exert a dominant negative role in the trafficking and signaling of the full and functional ghrelin receptor GHS-R1a. Here we reveal a more complex modulatory role of GHS-R1b. Differential co-expression of GHS-R1a and GHS-R1b, both in HEK-293T cells and in striatal and hippocampal neurons in culture, demonstrates that GHS-R1b acts as a dual modulator of GHS-R1a function: low relative GHS-R1b expression potentiates and high relative GHS-R1b expression inhibits GHS-R1a function by facilitating GHS-R1a trafficking to the plasma membrane and by exerting a negative allosteric effect on GHS-R1a signaling, respectively. We found a preferential Gi/o coupling of the GHS-R1a-GHS-R1b complex in HEK-293T cells and, unexpectedly, a preferential Gs/olf coupling in both striatal and hippocampal neurons in culture. A dopamine D1 receptor (D1R) antagonist blocked ghrelin-induced cAMP accumulation in striatal but not hippocampal neurons, indicating the involvement of D1R in the striatal GHS-R1a-Gs/olf coupling. Experiments in HEK-293T cells demonstrated that D1R co-expression promotes a switch in GHS-R1a-G protein coupling from Gi/o to Gs/olf, but only upon co-expression of GHS-R1b. Furthermore, resonance energy transfer experiments showed that D1R interacts with GHS-R1a, but only in the presence of GHS-R1b. Therefore, GHS-R1b not only determines the efficacy of ghrelin-induced GHS-R1a-mediated signaling but also determines the ability of GHS-R1a to form oligomeric complexes with other receptors, promoting profound qualitative changes in ghrelin-induced signaling.

Targeting CB2-GPR55 receptor heteromers modulates cancer cell signaling.
The G protein-coupled receptors CB2 (CB2R) and GPR55 are overexpressed in cancer cells and human tumors. Because a modulation of GPR55 activity by cannabinoids has been suggested, we analyzed whether this receptor participates in cannabinoid effects on cancer cells. Here we show that CB2R and GPR55 form heteromers in cancer cells, that these structures possess unique signaling properties, and that modulation of these heteromers can modify the antitumoral activity of cannabinoids in vivo. These findings unveil the existence of previously unknown signaling platforms that help explain the complex behavior of cannabinoids and may constitute new targets for therapeutic intervention in oncology.

NANOBODIES AS ALLOSTERIC MODULATORS OF MGLU RECEPTOR IN THE TREATMENT OF SCHIZOPHRENIA

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Léo Pion
IGF-CNRS, Neurosciences, Montpellier, France

Schizophrenia is a highly debilitating psychiatric disease with a prevalence of roughly 1%. Due to relatively ineffective treatment it currently has a very high societal cost.
In the current understanding of the physiopathology, the disease takes root in a combination of NMDA receptor hypofunction and general glutamatergic hyperstimulation. Current treatment does not address this perturbation and only alleviates symptoms.
Several propositions have been made for treatment that restore NMDA function, but the high side effects of direct glutamatergic stimulation cripple clinical trials and drug development. An alternative approach would be to target mGluR receptors, which are glutamate-responsive GPCR regulating neuronal excitability. These receptors are constituted by a family of 8 proteins that work as dimers. Amongst these, mGlu5 is particularly promising due to its positive action on the NMDA receptor. Unfortunately, the close genetic and structural proximity of mGluRs makes it challenging to develop specific drugs.
Nanobodies, the paratope of a subclass of Camelidae antibodies, are small, potent and very structure-specific peptides that are able to recognize and stabilize specific protein conformations. This property makes them uniquely potent as structural probes or allosteric modulators.
We hypothesized that nanobodies targeting mGluRs might act as modulators of the glutamate system and be viable therapeutic options. We developed nanobodies against different mGluR including mGlu5, and proceeded to improve their function through engineering. Here, we present several engineered nanobodies able to specifically influence mGluR5 activation, and are therefore promising candidates for treatment.

Aims: 5-methyl-cytosine (5mC) and 5-hydroxy-methyl-cytosine (5hmC) are epigenetic modifications that are dynamically regulated throughout neuronal development and function. The discovery of an active demethylation pathway created an increasing interest in these epigenetic marks also in the context of neuroscience. Our goal was to establish an easy, cost-efficient and rapid analysis pipeline allowing for the differential quantification of 5hmC and 5mC in different hippocampal subregions. **Methods:** We combined a hippocampal sub-dissection method using fine syringe needles to selectively isolate regions of interest from slide-mounted hippocampal tissue in a dark field microscope with a liquid-chromatography mass spectrometry (LC-MS) method capable of reliably identifying differential amounts of 5mC and 5hmC. We used mouse brain tissue from wildtype and NEIL3-deficient mice, with NEIL3 being a DNA repair enzyme potentially interacting with methylated DNA bases. We selectively dissected the hippocampal subregions CA1, CA3 and dentate gyrus, isolated nucleic acids (RNA and DNA), verified region specificity via an RNAseq-dataset based on the same samples, and subsequently quantified base modifications of interest via LC-MS. **Results:** Here we show that the differential quantification of DNA base modifications 5mC and 5hmC in subregion specific hippocampal tissue is possible within less than 24h and at reagent/material costs of ca. 5 EUR per sample for the dissection part. **Conclusion:** Our pipeline for the subregion specific quantitative analysis of DNA base modifications can help to add local network-relevance to neuro-epigenetic experiments currently relying on the analysis of e.g. whole-hippocampal tissue. The method appears transferrable to other brain regions or types of tissue.

Loss of Mediator complex subunit 13 (MED13) promotes resistance to alkylation through cyclin D1 upregulation.
Alkylating drugs are among the most often used chemotherapeutics. While cancer cells frequently develop resistance to alkylation treatments, detailed understanding of mechanisms that lead to the resistance is limited. Here, by using genome-wide CRISPR-Cas9 based screen, we identify transcriptional Mediator complex subunit 13 (MED13) as a novel modulator of alkylation response. The alkylation exposure causes significant MED13 downregulation, while complete loss of MED13 results in reduced apoptosis and resistance to alkylating agents. Transcriptome analysis identified cyclin D1 (CCND1) as one of the highly overexpressed genes in MED13 knock-out (KO) cells, characterized by shorter G1 phase. MED13 is able to bind to CCND1 regulatory elements thus influencing the expression. The resistance of MED13 KO cells is directly dependent on the cyclin D1 overexpression, and its down-regulation is sufficient to re-sensitize the cells to alkylating agents. We further demonstrate the therapeutic potential of MED13-mediated response, by applying combinatory treatment with CDK8/19 inhibitor Senexin A. Importantly, the treatment with Senexin A stabilizes MED13, and in combination with alkylating agents significantly reduces viability of cancer cells. In summary, our findings identify novel alkylation stress response mechanism dependent on MED13 and cyclin D1 that can serve as basis for development of innovative therapeutic strategies.

NEIL1 and NEIL2 DNA glycosylases modulate anxiety and learning in a cooperative manner in mice.

Oxidative DNA damage in the brain has been implicated in neurodegeneration and cognitive decline. DNA glycosylases initiate base excision repair (BER), the main pathway for oxidative DNA base lesion repair. NEIL1 and NEIL3 DNA glycosylases affect cognition in mice, while the role of NEIL2 remains unclear. Here, we investigate the impact of NEIL2 and its potential overlap with NEIL1 on behavior in knockout mouse models. Neil1Neil2 mice display hyperactivity, reduced anxiety and improved learning. Hippocampal oxidative DNA base lesion levels are comparable between genotypes and no mutator phenotype is found. Thus, impaired canonical repair is not likely to explain the altered behavior. Electrophysiology suggests reduced axonal activation in the hippocampal CA1 region in Neil1Neil2 mice and lack of NEIL1 and NEIL2 causes dysregulation of genes in CA1 relevant for synaptic function. We postulate a cooperative function of NEIL1 and NEIL2 in genome regulation, beyond canonical BER, modulating behavior in mice.

DNA repair enzyme NEIL3 enables a stable neural representation of space by shaping transcription in hippocampal neurons.
DNA repair enzymes are essential for the maintenance of the neuronal genome and thereby proper brain functions. Emerging evidence links DNA repair to epigenetic gene regulation; however, its contribution to different transcriptional programs required for neuronal functions remains elusive. In this study, we identified a role of the DNA repair enzyme NEIL3 in modulating the maturation and function of hippocampal CA1 neurons by shaping the CA1 transcriptome during postnatal development and in association with spatial behavior. We observed a delayed maturation in CA1 and identified differentially regulated genes required for hippocampal development. We revealed impaired spatial stability in CA1 place cells and found spatial experience-induced gene expression essential for synaptic plasticity. This is the first study that links molecular underpinnings of DNA repair to the neural basis of spatial cognition beyond animals' behavioral phenotypes, thus shedding light on the molecular determinants enabling a stable neural representation of space.

Alkyladenine DNA glycosylase associates with transcription elongation to coordinate DNA repair with gene expression.
Base excision repair (BER) initiated by alkyladenine DNA glycosylase (AAG) is essential for removal of aberrantly methylated DNA bases. Genome instability and accumulation of aberrant bases accompany multiple diseases, including cancer and neurological disorders. While BER is well studied on naked DNA, it remains unclear how BER efficiently operates on chromatin. Here, we show that AAG binds to chromatin and forms complex with RNA polymerase (pol) II. This occurs through direct interaction with Elongator and results in transcriptional co-regulation. Importantly, at co-regulated genes, aberrantly methylated bases accumulate towards the 3'end in regions enriched for BER enzymes AAG and APE1, Elongator and active RNA pol II. Active transcription and functional Elongator are further crucial to ensure efficient BER, by promoting AAG and APE1 chromatin recruitment. Our findings provide insights into genome stability maintenance in actively transcribing chromatin and reveal roles of aberrantly methylated bases in regulation of gene expression.

Parp3 promotes astrocytic differentiation through a tight regulation of Nox4-induced ROS and mTorc2 activation.
Parp3 is a member of the Poly(ADP-ribose) polymerase (Parp) family that has been characterized for its functions in strand break repair, chromosomal rearrangements, mitotic segregation and tumor aggressiveness. Yet its physiological implications remain unknown. Here we report a central function of Parp3 in the regulation of redox homeostasis in continuous neurogenesis in mice. We show that the absence of Parp3 provokes Nox4-induced oxidative stress and defective mTorc2 activation leading to inefficient differentiation of post-natal neural stem/progenitor cells to astrocytes. The accumulation of ROS contributes to the decreased activity of mTorc2 as a result of an oxidation-induced and Fbxw7-mediated ubiquitination and degradation of Rictor. In vivo, mTorc2 signaling is compromised in the striatum of naïve post-natal Parp3-deficient mice and 6 h after acute hypoxia-ischemia. These findings reveal a physiological function of Parp3 in the tight regulation of striatal oxidative stress and mTorc2 during astrocytic differentiation and in the acute phase of hypoxia-ischemia.

Ghrelin agonist does not foster insulin resistance but improves cognition in an Alzheimer's disease mouse model.
The orexigenic hormone ghrelin, a potential antagonist of the insulin system, ensures sufficient serum glucose in times of fasting. In the race for new therapeutics for diabetes, one focus of study has been antagonizing the ghrelin system in order to improve glucose tolerance. We provide evidence for a differential role of a ghrelin agonist on glucose homeostasis in an Alzheimer's disease mouse model fed a high-glycemic index diet as a constant challenge for glucose homeostasis. The ghrelin agonist impaired glucose tolerance immediately after administration but not in the long term. At the same time, the

ghrelin agonist improved spatial learning in the mice, raised their activity levels, and reduced their body weight and fat mass. Immunoassay results showed a beneficial impact of long-term treatment on insulin signaling pathways in hippocampal tissue. The present results suggest that ghrelin might improve cognition in Alzheimer's disease via a central nervous system mechanism involving insulin signaling.

Ghrelin modulates encoding-related brain function without enhancing memory formation in humans.
Ghrelin regulates energy homeostasis in various species and enhances memory in rodent models. In humans, the role of ghrelin in cognitive processes has yet to be characterized. Here we show in a double-blind randomized crossover design that acute administration of ghrelin alters encoding-related brain activity, however does not enhance memory formation in humans. Twenty-one healthy young male participants had to memorize food- and non-food-related words presented on a background of a virtual navigational route while undergoing fMRI recordings. After acute ghrelin administration, we observed decreased post-encoding resting state fMRI connectivity between the caudate nucleus and the insula, amygdala, and orbitofrontal cortex. In addition, brain activity related to subsequent memory performance was modulated by ghrelin. On the next day, however, no differences were found in free word recall or cued location-word association recall between conditions; and ghrelin's effects on brain activity or functional connectivity were unrelated to memory performance. Further, ghrelin had no effect on a cognitive test battery comprising tests for working memory, fluid reasoning, creativity, mental speed, and attention. In conclusion, in contrast to studies with animal models, we did not find any evidence for the potential of ghrelin acting as a short-term cognitive enhancer in humans.

BACTRACE A RETROGRADE TOOL FOR MAPPING NEURONAL CONNECTIVITY IN FLIES

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Sebastian Cachero, Marina Gkantia, Shahar Frechter, Gregory Jefferis
MRC Laboratory of Molecular Biology, Neurobiology, Cambridge, United Kingdom

The Drosophila brain contains 100,000 neurons with mostly stereotyped connections offering a rich array of well-characterised behaviours to study the basic principles of neural circuits. Extracting those principles relies on the availability of connectivity information. While generating electron microscopy-based connectomes have recently become feasible, they remain prohibitively expensive for many applications, especially those requiring information at the level of many individual flies, genetic backgrounds or live animals. For this reason, an efficient retrograde tracing method to reveal and manipulate inputs to any given neuron remains highly desirable. To address this need, we developed BAcTrace, a fully genetically encoded transsynaptic labelling system based on an engineered form of Clostridium botulinum neurotoxin A (BoNT/A). We re-engineered the toxin in such a way that it can be made in a neuron and transferred to connected partners where it triggers expression of an effector gene such as a fluorescent protein or a neuronal effector gene. We will present the validation of BAcTrace at three synapses along the fly olfactory system: 1. the connection between Olfactory Receptor Neurons and Projection Neurons (PNs), 2. the connection between Kenyon Cells of the mushroom body and PNs and 3. the weaker connections between PNs and Lateral Horn Neurons. We will also present improvements in the genetic implementation and functionality of the system. BAcTrace provides an easy, cheap and fast way to map inputs for any given neuron within living specimens, enabling assessment of changes in connectivity in multiple genetic backgrounds.

[1]Sorbonne Université, Inserm, Institut De La Vision, Paris, France, [2]CNRS, INSERM, PSL Université Paris, Ibens, Ecole Normale Supérieure, Paris, France

Site-specific recombination systems such as Cre/lox are widely used to label cells or control gene expression in model organisms. In Brainbow transgenes, multiple pairs of *lox* sites create mutually exclusive, divergent recombination pathways that trigger the expression of spectrally distinct fluorescent proteins (FPs). These genetic labels are ideal to mark and discriminate neural cells or clones when mapping circuits or studying their development. Transgene configurations that maximize the number and equilibrium of these labels are useful for this purpose, but their design is difficult to optimize. Here, we present a mathematical model based on Markov chains that predicts the recombination outcomes from any given array of lox sites and estimates their respective frequencies. This model accounts for excision and inversion between several types of heterospecific lox sites and distinguishes stable vs. unstable recombination outcomes. We used it to select an improved transgene configuration termed Brainbow-4 that drives stochastic, near-equiprobable and irreversible expression of trichromatic FP markers with only two types of heterospecific lox sites. In addition, all FPs are combined with a shared subcellular tethering sequence, hence solving the difficulty of fusing Brainbow FPs to large proteins. We demonstrate the usefulness of this new configuration to target FPs to a variety of subcellular compartments and express an expanded palette of combinatorial labels from episomal or genome-integrated transgenes. These experiments lay the ground for dense multiplexed single cell and clonal analyses in the developing nervous system. Furthermore, the proposed model may be used to identify other useful genetic barcoding configurations.

Aims: Cumulative clinical evidence supports the reliability of circulating extracellular vesicles (cEVs)-based biomarkers in Alzheimer's disease (AD) diagnosis. The substantial link between apolipoprotein E4 allele (*APOE* ε4) and oxidative stress may underlie enhanced AD risk. Here, we studied the impact of *APOE* ε4 on the level of apolipoproteins with antioxidant activities along with oxidative markers in circulating extracellular vesicles (cEVs) and plasma from cognitively impaired-not demented (CIND) individuals converted to AD (CIND-AD). **Methods:** Apolipoproteins E, J, and D and antioxidant response markers were determined in cEVs and plasma using electrochemical examination, spectrofluorimetry, and chemiluminescence immunoassay. **Results:** For the first time, our study evidences the presence of apoE, apoJ, and apoD in cEVs. The total antioxidant capacity and apoD levels in cEVs, as judged by ROC curves, regression analysis, and cognitive performance correlations, allowed to differentiate CIND *APOE* ε4 carriers from controls and to predict their progression to AD 5 years later. Our data revealed that the reduced antioxidant defense in *APOE* ε4 carriers may contribute to the early pathological cascade of neurodegeneration and that antioxidant supplementation might prevent AD development. **Conclusions:** Our findings support the pathological redox linkage between *APOE* ε4 and AD onset and suggest the use of cEVs oxidative signature in early AD diagnosis.

Apolipoprotein E4-driven effects on inflammatory and neurotrophic factors in peripheral extracellular vesicles from cognitively impaired, no dementia participants who converted to Alzheimer's disease.
In brain, extracellular vesicles (EVs) play an essential role in the neuron-glia interface and ensure the crosstalk between the brain and the periphery. Some studies now link the pathway dysfunction of the EVs to apolipoprotein E gene variant (ε4) and the risk of progression to Alzheimer's disease (AD). To better understand the role of ε4 in pre-clinical AD, we have determined levels of pathogenic, neurotrophic and inflammatory proteins in peripheral EVs (pEVs) and in plasma from cognitively impaired, no dementia (CIND) participants stratified upon the absence (ε4) or the presence (ε4) of the ε4 allele of .

Glutathione: An Old and Small Molecule with Great Functions and New Applications in the Brain and in Alzheimer's Disease.
Glutathione (GSH) represents the most abundant and the main antioxidant in the body with important functions in the brain related to Alzheimer's disease (AD). Oxidative stress is one of the central mechanisms in AD. We and others have demonstrated the alteration of GSH levels in the AD brain, its important role in the detoxification of advanced glycation end-products and of acrolein, a by-product of lipid peroxidation. Recent studies found a decrease of GSH in several areas of the brain from control, mild cognitive impairment, and AD subjects, which are correlated with cognitive decline. Several strategies

were developed to restore its intracellular level with the l-cysteine prodrugs or the oral administration of γ-glutamylcysteine to prevent alterations observed in AD. To date, no benefit on GSH level or on oxidative biomarkers has been reported in clinical trials. Thus, it remains uncertain if GSH could be considered a potential preventive or therapeutic approach or a biomarker for AD. We address how GSH-coupled nanocarriers represent a promising approach for the functionalization of nanocarriers to overcome the blood/brain barrier (BBB) for the brain delivery of GSH while avoiding cellular toxicity. It is also important to address the presence of GSH in exosomes for its potential intercellular transfer or its shuttle across the BBB under certain conditions. . 35, 270-292.

Levels of Receptor for Advanced Glycation End Products and Glyoxalase-1 in the Total Circulating Extracellular Vesicles from Mild Cognitive Impairment and Different Stages of Alzheimer's Disease Patients.
Growing evidence supports that receptor for advanced glycation end products (RAGE) and glyoxalase-1 (GLO-1) are implicated in the pathophysiology of Alzheimer's disease (AD). Extracellular vesicles (EVs) are nanovesicles secreted by almost all cell types, contribute to cellular communication, and are implicated in AD pathology. Recently, EVs are considered as promising tools to identify reliable biomarkers in AD.

Inhibition of Protein Glycation by Combined Antioxidant and Antiglycation Constituents from a Phenolic Fraction of Sage (Salvia officinalis L.).
Disturbed advanced glycation end products (AGEs)-oxidative stress axis is strongly linked to vascular complications observed in diabetes and other metabolic conditions. Salvia officinalis L. (sage) is a medicinal plant used as an ingredient in foods and beverages and displays a wide range of biological and pharmacological activities including anti-diabetic effects. However, no study has assessed its anti-glycative potential. The aim of this study is to determine the phenolic compounds associated with the anti-glycation and antioxidant potential of sage methanol extract (SME). SME shows similar effects to aminoguanidine on fluorescent AGEs inhibition. It protects albumin damage from glycation (52.9 vs. 50.3%, respectively) by preventing the loss of protein thiol groups (50.0 vs. 44.3%, respectively) and by reducing protein carbonyl accumulation (67.4 vs. 70.5%, respectively). Moreover, linear regression and multivariate analysis support the efficient contribution of SME antioxidant capacity, as judged by DPPH, TBARS and iron chelating tests, in AGEs suppression. Furthermore, HPLC analysis revealed the presence of verbascoside as a novel phenolic constituent identified in sage leaves and suggests that the protective activity is mostly assigned to the presence of rosmarinic acid, resveratrol, quercetin, rutin and luteolin-7-O-glucoside. Likewise, the screening of SME phenolic content supports the contribution of various antioxidant substances to the observed effects. Therefore, a polyphenol enriched sage extract was able to inhibit the formation of AGEs and protein glycation. Our data unveils the promising properties of sage and its bioactive principles in the management of AGEs-mediated vascular complications observed in diabetes and other metabolic disorders.

Methylglyoxal and Glyoxal as Potential Peripheral Markers for MCI Diagnosis and Their Effects on the Expression of Neurotrophic, Inflammatory and Neurodegenerative Factors in Neurons and in Neuronal Derived-Extracellular Vesicles.
Methylglyoxal (MG) and glyoxal (GO) are suggested to be associated with the development of neurodegenerative pathologies. However, their peripheral levels in relation to cognitive decline and their effects on key factors in neuronal cells are poorly investigated. The aim of this study was to determine their serum levels in MCI (mild cognitive impairment) and Alzheimer's disease (AD) patients, to analyze their effects on the neurotrophic and inflammatory factors, on neurodegenerative markers in neuronal cells and in neuronal derived-extracellular vesicles (nEVs). Our results show that MG and GO levels in serum, determined by HPLC, were higher in MCI. ROC (receiver-operating characteristic curves) analysis showed that the levels of MG in serum have higher sensitivity to differentiate MCI from controls but not from AD. Meanwhile, serum GO levels differentiate MCI from control and AD groups. Cells and nEVs levels of BDNF, PRGN, NSE, APP, MMP-9, ANGPTL-4, LCN2, PTX2, S100B, RAGE, Aβ peptide, pTau T181 and alpha-synuclein were quantified by luminex assay. Treatment of neuronal cells with MG or GO reduced the cellular levels of NSE, PRGN, APP, MMP-9 and ANGPTL-4 and the nEVs levels of BDNF, PRGN and LCN2. Our findings suggest that targeting MG and GO may be a promising therapeutic strategy to prevent or delay the progression of AD.

Chemical composition and biological activities of Salvia officinalis essential oil from Tunisia.
The aim of this study is to evaluate the chemical composition, antioxidant, antimicrobial, insecticidal and allelopathic activities of Tunisia essential oil (SoEO). The SoEO was characterized by the presence of 49 components with camphor (25.14 %), α-thujone (18.83 %), 1,8-cineole (14.14 %), viridiflorol (7.98 %), β-thujone (4.46 %) and β-caryophyllene (3.30 %) as the major components, determined by gas chromatography-mass spectrometry. The level of antioxidant activity, determined by complementary tests, namely 2,2-diphenyl-1-picrylhydrazyl radical-scavenging (IC= 6.7 mg/mL), linoleic acid peroxidation (IC= 9.6 mg/mL) and ferric reducing assays (IC= 28.4 mg/mL), was relatively moderate. The SoEO was also screened for its antimicrobial activity. Good to moderate inhibitions were recorded for most of tested microorganisms. It also exhibited important insecticidal activity against larvae and adults with LC values of 55.99 and 97.43 µl/L air, respectively. The effect of the SoEO on seeds germination and growth showed different activities against radical and hypocotyl elongation of the tested species. These results suggest the potential use of the SoEO as natural antimicrobial preservative in cosmetic, pharmaceutical industry and in pest management.

LIGHT AS AN INVERSE AGONIST INHIBITS CONSTITUTIVE G PROTEIN SIGNALLING OF THE ZEBRAFISH NON-VISUAL OPSIN OPN7B

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Raziye Karapinar
Francis Crick Institute, Neurophysiology, London, United Kingdom

Optogenetics combines the use of light-sensitive proteins and genetic targeting strategies to allow for precise light-controlled manipulation of cell function and signalling in living tissue. We discovered Opn7b, a non-visual G protein-coupled receptor (GPCR) expressed in zebrafish (*Danio rerio*), as a novel reverse optogenetic tool, which enables the constitutive activation of the $G_{i/o}$ coupled signalling pathway. Our photophysical characterisation shows that Opn7b expressed in HEK cells constitutively activates the $G_{i/o}$ coupled signalling pathway in darkness while illumination with blue/green light inactivates GIRK (G protein-coupled inwardly rectifying K^+) channels. Our patch-clamp studies indicate that light acts as an inverse agonist for Opn7b and can be used as an optogenetic tool to inhibit neuronal networks in the dark and interrupt constitutive inhibition during light stimulation. Consistent with this prediction, recordings in acute slices show that light activation of recombinant expressed Opn7b in cortical pyramidal cells increases neuronal activity. The constitutive activation of $G_{i/o}$ coupled signalling pathways leads to a homeostatic inhibition of neuronal networks, where light stimulation leads to a withdrawal from inhibition inducing generalised epileptiform activity. Indeed, in awake mice, light stimulation of Opn7b expressed in cortical pyramidal cells reliably induces generalised epileptiform activity within a short (<10 s) delay after onset of stimulation. Our study demonstrates a reversed mechanism for G protein-coupled receptor control and Opn7b as a tool for modulating neural circuit properties with the potential to study diseases related to constitutive activity of GPCRs.

Reverse optogenetics of G protein signaling by zebrafish non-visual opsin Opn7b for synchronization of neuronal networks. Opn7b is a non-visual G protein-coupled receptor expressed in zebrafish. Here we find that Opn7b expressed in HEK cells constitutively activates the G pathway and illumination with blue/green light inactivates G protein-coupled inwardly rectifying potassium channels. This suggests that light acts as an inverse agonist for Opn7b and can be used as an optogenetic tool to inhibit neuronal networks in the dark and interrupt constitutive inhibition in the light. Consistent with this prediction, illumination of recombinant expressed Opn7b in cortical pyramidal cells results in increased neuronal activity. In awake mice, light stimulation of Opn7b expressed in pyramidal cells of somatosensory cortex reliably induces generalized epileptiform activity within a short (<10 s) delay after onset of stimulation. Our study demonstrates a reversed mechanism for G protein-coupled receptor control and Opn7b as a tool for controlling neural circuit properties.

Design of an Ultrafast G Protein Switch Based on a Mouse Melanopsin Variant.
The primary goal of optogenetics is the light-controlled noninvasive and specific manipulation of various cellular processes. Herein, we present a hybrid strategy for targeted protein engineering combining computational techniques with electrophysiological and UV/visible spectroscopic experiments. We validated our concept for channelrhodopsin-2 and applied it to modify the less-well-studied vertebrate opsin melanopsin. Melanopsin is a promising optogenetic tool that functions as a selective molecular light switch for G protein-coupled receptor pathways. Thus, we constructed a model of the melanopsin G protein complex and predicted an absorption maximum shift of the Y211F variant. This variant displays a narrow blue-shifted action spectrum and twofold faster deactivation kinetics compared to wild-type melanopsin on G protein-coupled inward rectifying K (GIRK) channels in HEK293 cells. Furthermore, we verified the in vivo activity and optogenetic potential for the variant in mice. Thus, we propose that our developed concept will be generally applicable to designing optogenetic tools.

Lamprey Parapinopsin ("UVLamP"): a Bistable UV-Sensitive Optogenetic Switch for Ultrafast Control of GPCR Pathways.
Optogenetics uses light-sensitive proteins, so-called optogenetic tools, for highly precise spatiotemporal control of cellular states and signals. The major limitations of such tools include the overlap of excitation spectra, phototoxicity, and lack of sensitivity. The protein characterized in this study, the Japanese lamprey parapinopsin, which we named UVLamP, is a promising optogenetic tool to overcome these limitations. Using a hybrid strategy combining molecular, cellular, electrophysiological, and computational methods we elucidated a structural model of the dark state and probed the optogenetic potential of UVLamP. Interestingly, it is the first described bistable vertebrate opsin that has a charged amino acid interacting with the Schiff base in the dark state, that has no relevance for its photoreaction. UVLamP is a bistable UV-sensitive opsin that allows for precise and sustained optogenetic control of G protein-coupled receptor (GPCR) pathways and can be switched on, but more importantly also off within milliseconds via lowintensity short light pulses. UVLamP exhibits an extremely narrow excitation spectrum in the UV range allowing for sustained activation of the G pathway with a millisecond UV light pulse. Its sustained pathway activation can be switched off, surprisingly also with a millisecond blue light pulse, minimizing phototoxicity. Thus, UVLamP serves as a minimally invasive, narrow-bandwidth probe for controlling the G pathway, allowing for combinatorial use with multiple optogenetic tools or sensors. Because UVLamP activated G signals are generally inhibitory and decrease cellular activity, it has tremendous potential for health-related applications such as relieving pain, blocking seizures, and delaying neurodegeneration.

CaMello-XR enables visualization and optogenetic control of G signals and receptor trafficking in GPCR-specific domains.
The signal specificity of G protein-coupled receptors (GPCRs) including serotonin receptors (5-HT-R) depends on the trafficking and localization of the GPCR within its subcellular signaling domain. Visualizing traffic-dependent GPCR signals in neurons is difficult, but important to understand the contribution of GPCRs to synaptic plasticity. We engineered CaMello (Ca-melanopsin-local-sensor) and CaMello-5HT for visualization of traffic-dependent Ca signals in 5-HT-R domains. These constructs consist of the light-activated G coupled melanopsin, mCherry and GCaMP6m for visualization of Ca signals and receptor trafficking, and the 5-HT C-terminus for targeting into 5-HT-R domains. We show that the specific localization of the GPCR to its receptor domain drastically alters the dynamics and localization of the intracellular Ca signals in different neuronal populations in vitro and in vivo. The CaMello method may be extended to every GPCR coupling to the G pathway to help unravel new receptor-specific functions in respect to synaptic plasticity and GPCR localization.

Melanopsin Variants as Intrinsic Optogenetic On and Off Switches for Transient versus Sustained Activation of G Protein Pathways.
G-protein-coupled receptors (GPCRs) represent the major protein family for cellular modulation in mammals. Therefore, various strategies have been developed to analyze the function of GPCRs involving pharmaco- and optogenetic approaches [1, 2]. However, a tool that combines precise control of the activation and deactivation of GPCR pathways and/or neuronal firing with limited phototoxicity is still missing. We compared the biophysical properties and optogenetic application of a human and a mouse melanopsin variant (hOpn4L and mOpn4L) on the control of Gi/o and Gq pathways in heterologous expression systems and mouse brain. We found that GPCR pathways can be switched on/off by blue/yellow light. The proteins differ in their kinetics and wavelength dependence to activate and deactivate G protein pathways. Whereas mOpn4L is maximally activated by very short light pulses, leading to sustained G protein activation, G protein responses of hOpn4L need longer light pulses to be activated and decline in amplitude. Based on the different biophysical properties, brief light activation of mOpn4L is sufficient to induce sustained neuronal firing in cerebellar Purkinje cells (PC), whereas brief light activation of hOpn4L induces AP firing, which declines in frequency over time. Most importantly, mOpn4L-induced sustained firing can be switched off by yellow light. Based on the biophysical properties, hOpn4L and mOpn4L represent the first GPCR optogenetic tools, which can be used to switch GPCR pathways/neuronal firing on an off with temporal precision and limited phototoxicity. We suggest to name these tools moMo and huMo for future optogenetic applications.

GOLD AND SILVER NANOPARTICLE-BASED LOCALIZED SURFACE PLASMON RESONANCE SENSOR (LSPR) FOR THE DETECTION OF HISTIDINE AS A POTENTIAL BIOMARKER IN PARKINSON'S DISEASE.

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Elly Robles[1], Daniel Martinez-Ramirez[2]
[1]Instituto Tecnológico y de Estudios Superiores de Monterrey, Chemistry And Nanotechnology, Monterrey, Mexico, [2]Instituto Tecnológico y de Estudios Superiores de Monterrey, Medicine And Health Sciences, Monterrey, Mexico

Objective: Previous literature has proven that histamine has a crucial role in the process of neuroinflammation in Parkinson's Disease (PD) . We can indirectly detect histamine levels in fluid samples by quantifying levels of histidine. Therefore, we developed a gold and silver nanoparticle-based LSPR sensor for the detection of histidine. **Methods:** Au/Ag and Au, Ag nanoparticles were synthesized. Histidine was prepared at different concentrations: 10 mM, 25mM, and 100 mM. UV-Vis spectroscopy was used to determine the absorbance spectrums of the nanoparticles with histidine. Additionally, a spearman analysis was done for the absorbance values measured from 190 nm to 360 nm in all three concentrations in order to evaluate the significance of the study and to observe correlations between the variables. **Results:** In all concentrations a higher absorbance was obtained with the metallic systems. At 10 mM both Au and Ag generated a better signal than histidine alone, at a wavelength of 217 nm with an absorbance of 0.76 at 25 mM, Au emitted the highest signal at a wavelength of 221 with an absorbance of 0.39 and at 100 mM the system Au/Ag generated a better signal at a wavelength of 209.0 at an absorbance of 0.89. Additionally, the conducted spearman analysis indicated $p < 0.001$ in all concentrations. **Conclusions:** We successfully developed an LSPR sensor that improved the detection of histidine. Our findings could help to easily identify abnormal levels of relevant biomarkers in PD and contribute to early detection of this disease.

A FLEXIBLE AND VERSATILE SYSTEM FOR MULTICOLOR FIBER PHOTOMETRY AND OPTOGENETIC MANIPULATION

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Andrey Formozov, Alexander Dieter, J. Simon Wiegert
Universitätsklinikum Hamburg-Eppendorf, Center For Molecular Neurobiology Hamburg, Hamburg, Germany

Fiber photometry is a technique of growing popularity in neuroscience research. It is widely used to infer brain activity by recording calcium dynamics in genetically defined populations of neurons. Aside from the wide variety of calcium indicators, other genetically encoded biosensors have recently been engineered to measure membrane potential, neurotransmitter release, pH, or various cellular metabolites, such as ATP or cAMP. Due to the spectral characteristics of these tools, different assemblies of optical hardware are usually needed to reveal the full potential of different biosensors. In addition, combining multiple sensors in one experiment, often requires the investment in more complex equipment, which limits the flexibility of the experimental design. Such constraints often hamper a straightforward implementation of new molecular tools, evaluation of their performance in vivo, and construction of new experimental paradigms – especially if the financial budget is a limiting factor. Here, we propose a novel approach for fiber photometry recordings and optogenetic manipulation. In combination with a multi-color light source and appropriate emission filters, our approach offers remarkable flexibility in experimental design and facilitates the implication of new molecular tools *in vivo* at minimal cost. The ease of assembly, operation, characterization, and customization of this platform holds the potential to foster the development of experimental strategies for multicolor fiber photometry combined with optogenetics far beyond its current

state.

Anesthetics fragment hippocampal network activity, alter spine dynamics, and affect memory consolidation.
General anesthesia is characterized by reversible loss of consciousness accompanied by transient amnesia. Yet, long-term memory impairment is an undesirable side effect. How different types of general anesthetics (GAs) affect the hippocampus, a brain region central to memory formation and consolidation, is poorly understood. Using extracellular recordings, chronic 2-photon imaging, and behavioral analysis, we monitor the effects of isoflurane (Iso), medetomidine/midazolam/fentanyl (MMF),

and ketamine/xylazine (Keta/Xyl) on network activity and structural spine dynamics in the hippocampal CA1 area of adult mice. GAs robustly reduced spiking activity, decorrelated cellular ensembles, albeit with distinct activity signatures, and altered spine dynamics. CA1 network activity under all 3 anesthetics was different to natural sleep. Iso anesthesia most closely resembled unperturbed activity during wakefulness and sleep, and network alterations recovered more readily than with Keta/Xyl and MMF. Correspondingly, memory consolidation was impaired after exposure to Keta/Xyl and MMF, but not Iso. Thus, different anesthetics distinctly alter hippocampal network dynamics, synaptic connectivity, and memory consolidation, with implications for GA strategy appraisal in animal research and clinical settings.

A neuropeptidergic circuit gates selective escape behavior of Drosophila larvae.
Animals display selective escape behaviors when faced with environmental threats. Selection of the appropriate response by the underlying neuronal network is key to maximizing chances of survival, yet the underlying network mechanisms are so far not fully understood. Using synapse-level reconstruction of the Drosophila larval network paired with physiological and behavioral readouts, we uncovered a circuit that gates selective escape behavior for noxious light through acute and input-specific neuropeptide action. Sensory neurons required for avoidance of noxious light and escape in response to harsh touch, each converge on discrete domains of neuromodulatory hub neurons. We show that acute release of hub neuron-derived insulin-like peptide 7 (Ilp7) and cognate relaxin family receptor (Lgr4) signaling in downstream neurons are required for noxious light avoidance, but not harsh touch responses. Our work highlights a role for compartmentalized circuit organization and neuropeptide release from regulatory hubs, acting as central circuit elements gating escape responses.

[1]Max Planck Institute for Biological Cybernetics, High Field Magnetic Resonance, Tübingen, Germany, [2]University of Tübingen, Institute Of Clinical Anatomy And Cell Analysis, Tübingen, Germany, [3]University of Trieste, Departments Of Physics, Trieste, Italy, [4]Elettra – Sincrotrone Trieste S.C.p.A, ., Basovizza, Italy

Aims Corpora amylacea, which contains polysaccharides, accumulates in human brain throughout aging. We aimed to use multi-modal imaging to locate corpora amylacea and investigate their three-dimensional morphological features. Methods Post mortem human brain stem samples (N=4) were scanned using high field MRI (14.1T, T2*weighted 62µm voxels) and X-ray synchrotron-radiation-based phase-contrast microtomography (PhC-µCT, 1µm voxels). Using an automated segmentation pipeline, corpora amylacea were identified on PhC-µCT images and the diameters was calculated. Finally, the samples were sectioned and stained using Klüver-Barrera and Periodic-acid Schiff reaction. Results In both MRI and PhC-µCT, corpora amylacea rich regions showed signal contrast. Using automated segmentation of the PhC-µCT dataset, we detected over 40,000 corpora amylacea located at the intercollicular region that showed hyperintensity. In T2* weighted MRI, corpora amylacea rich regions had low signal due to T2* shortening. The median diameter of corpora amylacea was 12 µm. Sections stained with Periodic-acid Schiff reaction confirmed that these granular bodies are indeed corpora amylacea. Conclusions Corpora amylacea rich region shows noticeable contrast in T2* weighted MRI. In high resolution phase-contrast microtomography, individual corpora amylacea can be
extracted.

MICROFLUIDIC CHIPS IN A COMPARATIVE STUDY OF MECHANOSENSITIVE PIEZO1 RECEPTORS IN TRIGEMINAL VERSUS DORSAL ROOT GANGLIA NEURONS

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Nikita Mikhailov[1], Lidiia Plotnikova[1], Prateek Singh[2], Rashid Giniatullin[1], Riikka Hämäläinen[1]
[1]University of Eastern Finland, A.i. Virtanen Institute For Molecular Sciences, Kuopio, Finland, [2]Finnadvance, Microfluidics And Microtechnology Solutions, Oulu, Finland

Mechanosensitive Piezo1 receptors involved in sensing of pain and pressure were recently suggested as contributors to migraine pain generation. Indeed, migraine is characterized by pulsatile pain and mechanical hyperalgesia associated with activation of trigeminal ganglia (TG) afferents. Interestingly, anti-migraine medicines are ineffective in other types of pain, suggesting some exclusive nociceptive mechanisms underlying migraine generation. To address potential specific role of Piezo1 receptors in migraine pain, we compared activity and expression of Piezo1 receptors in TG neurons vs. neurons of dorsal root ganglia (DRG) which processes innervate the body. We compared results obtained on a conventional imaging setup equipped with multibarrel application system with results obtained on a microfluidic chip-based setup. Surprisingly, despite the higher expression of Piezo1 gene, TG neurons were less responsive to specific stimulation of Piezo1 receptors than DRG neurons suggesting basic low translation or weak traffic to membrane. Additionally, although both conventional and chip-based setups demonstrated similar difference between TG and DRG neurons, this difference was more prominent on the chip-based setup. This demonstrated that some limitations of the conventional approach, e.g. fluid turbulence, may be overcome by microfluidic devices providing laminar solution flow. This research was published in an Open Access International Journal of Molecular Sciences: Mikhailov, N.; Plotnikova, L.; Singh, P.; Giniatullin, R.; Hämäläinen, R.H. Functional Characterization of Mechanosensitive Piezo1 Channels in Trigeminal and Somatic Nerves in a Neuron-on-Chip Model.
Mechanosensitive ion channels, Piezo1 and 2, are activated by pressure and involved in diverse physiological functions, including senses of touch and pain, proprioception and many more. Understanding their function is important for elucidating the mechanosensitive mechanisms of a range of human diseases. Recently, Piezo channels were suggested to be contributors to migraine pain generation. Migraine is typically characterized by allodynia and mechanical hyperalgesia associated with the activation and sensitization of trigeminal ganglion (TG) nerve fibers. Notably, migraine specific medicines are ineffective for other types of pain, suggesting a distinct underlying mechanism. To address, in a straightforward manner, the specificity of the mechanosensitivity of trigeminal vs. somatic nerves, we compared the activity of Piezo1 channels in mouse TG neurons vs. dorsal root ganglia (DRG) neurons. We assessed the functional expression of Piezo1 receptors using a conventional live calcium imaging setup equipped with a multibarrel application system and utilizing a microfluidic chip-based setup. Surprisingly, the TG neurons, despite higher expression of the gene, were less responsive to Piezo1 agonist Yoda1 than the DRG neurons. This difference was more prominent in the chip-based setup, suggesting that certain limitations of the conventional approach, such as turbulence, can be overcome by utilizing microfluidic devices with laminar solution flow.

Urban air particulate matter induces mitochondrial dysfunction in human olfactory mucosal cells.
The adverse effects of air pollutants including particulate matter (PM) on the central nervous system is increasingly reported by epidemiological, animal and post-mortem studies in the last decade. Oxidative stress and inflammation are key consequences of exposure to PM although little is known of the exact mechanism. The association of PM exposure with

deteriorating brain health is speculated to be driven by PM entry via the olfactory system. How air pollutants affect this key entry site remains elusive. In this study, we investigated effects of urban size-segregated PM on a novel cellular model: primary human olfactory mucosal (hOM) cells.

Modeling a Nociceptive Neuro-Immune Synapse Activated by ATP and 5-HT in Meninges: Novel Clues on Transduction of Chemical Signals Into Persistent or Rhythmic Neuronal Firing.
Extracellular ATP and serotonin (5-HT) are powerful triggers of nociceptive firing in the meninges, a process supporting headache and whose cellular mechanisms are incompletely understood. The current study aimed to develop, with the neurosimulator NEURON, a novel approach to explore in silico the molecular determinants of the long-lasting, pulsatile nature of migraine attacks. The present model included ATP and 5-HT release, ATP diffusion and hydrolysis, 5-HT uptake, differential activation of ATP P2X or 5-HT3 receptors, and receptor subtype-specific desensitization. The model also tested the role of branched meningeal fibers with multiple release sites. Spike generation and propagation were simulated using variable contribution by potassium and sodium channels in a multi-compartment fiber environment. Multiple factors appeared important to ensure prolonged nociceptive firing potentially relevant to long-lasting pain. Crucial roles were observed in: (i) co-expression of ATP P2X2 and P2X3 receptor subunits; (ii) intrinsic activation/inactivation properties of sodium Nav1.8 channels; and (iii) temporal and spatial distribution of ATP/5-HT release sites along the branches of trigeminal nerve fibers. Based on these factors we could obtain either persistent activation of nociceptive firing or its periodic bursting mimicking the pulsating nature of pain. In summary, our model proposes a novel tool for the exploration of peripheral nociception to test the contribution of clinically relevant factors to headache including migraine pain.

The Emerging Role of Mechanosensitive Piezo Channels in Migraine Pain.
Recently discovered mechanosensitive Piezo channels emerged as the main molecular detectors of mechanical forces. The functions of Piezo channels range from detection of touch and pain, to control of the plastic changes in different organs. Recent studies suggested the role of Piezo channels in migraine pain, which is supposed to originate from the trigeminovascular nociceptive system in meninges. Interestingly, migraine pain is associated with such phenomenon as mechanical hypersensitivity, suggesting enhanced mechanotransduction. In the current review, we present the data that propose the implication of Piezo channels in migraine pain, which has a distinctive pulsatile character. These data include: (i) distribution of Piezo channels in the key elements of the trigeminovascular nociceptive system; (ii) the prolonged functional activity of Piezo channels in meningeal afferents providing a mechanistical basis for mechanotransduction in nociceptive nerve terminals; (iii) potential activation of Piezo channels by shear stress and pulsating blood flow; and (iv) modulation of these channels by emerging chemical agonists and modulators, including pro-nociceptive compounds. Achievements in this quickly expanding field should open a new road for efficient control of Piezo-related diseases including migraine and chronic pain.

Mechanosensitive meningeal nociception via Piezo channels: Implications for pulsatile pain in migraine?
Recent discovery of mechanosensitive Piezo receptors in trigeminal ganglia suggested the novel molecular candidate for generation of migraine pain. However, the contribution of Piezo channels in migraine pathology was not tested yet. Therefore, in this study, we explored a potential involvement of Piezo channels in peripheral trigeminal nociception implicated in generation of migraine pain.

Cholinergic Nociceptive Mechanisms in Rat Meninges and Trigeminal Ganglia: Potential Implications for Migraine Pain.
Parasympathetic innervation of meninges and ability of carbachol, acetylcholine (ACh) receptor (AChR) agonist, to induce headaches suggests contribution of cholinergic mechanisms to primary headaches. However, neurochemical mechanisms of cholinergic regulation of peripheral nociception in meninges, origin place for headache, are almost unknown.

Parasympathetic Cholinergic and Neuropeptide Mechanisms of Migraine.
Migraine mechanisms remain largely uncovered for various reasons including a very high complexity of the neurophysiological mechanisms implicated in this disorder and a plethora of endogenous biologically active compounds

involved in the pathological process. The functional role of parasympathetic innervation of meninges and cholinergic mechanisms of migraine are among little explored issues despite multiple evidence indirectly indicating the role of acetylcholine (ACh) and its analogues in migraine and other types of headache. In the current short review, we discuss morphological, functional, and clinical issues related to the role of ACh and its analogues such as carbachol and nicotine in this most common neurological disorder.

INTERMOLECULAR INTERACTIONS IN THE SOLUTIONS OF SERUM ALBUMIN.
The mechanisms of intermolecular protein complex formation were studied by the example of monomers, oligomers and aggregates of bovine serum albumin (BSA) depending on the protein concentration, pH and urea concentration. Using dynamic light scattering (DLS), analytical ultracentrifugation (AUC) and PAG electrophoresis, we have shown that there is dynamic equilibrium between monomers and aggregates in BSA solution. Decreasing pH of the solution (4.0—1.0) resulted in increasing sizes of the aggregates. In the solutions with low urea concentrations (below 2 M), the sizes of aggregates decreased, while higher urea concentrations induced formation of larger aggregates due to the unfolding of the protein.

As a consequence of ischemic stroke, the integrity of the blood-brain barrier (BBB) is affected. Since MSC-EVs improve post ischemic stroke symptoms and can restore the BBB in mice, it was our goal to study the interaction of the BBB with MSC-EVs in more detail. To this end, we have developed a 3D BBB brain model based on a three-dimensional arrangement of three cell types (*i.e.* human astrocytes, pericytes and brain endothelial cells). The uptake of CD63-eGFP labelled mesenchymal stromal cell (MSC)-derived extracellular vesicles (CD63-eGFP$^+$ MSC-EVs) were studied in a two- and three-dimensional co-culture cell model (3D spheroid) by confocal laser scanning microscopy. The spheroid core is composed mainly of astrocytes, covered with pericytes, while brain endothelial cells form the surface layer, establishing the blood-brain barrier that regulates the transport of molecules. In 2D cell co-culture experiments, it was shown that CD63-eGFP$^+$ MSC-EVs readily entered the cells. A similar situation evolved with 3D spheroids, *e.g.* the CD63-eGFP$^+$ MSC-EVs entered the interior of the spheroid. **References:** 1. V. Sokolova, G. Mekky, S.B. van der Meer, M.C. Seeds, A.J. Optical imaging of wide-field cortical areas is limited by the curvature of the brain. To address this issue, we developed a new wide-field optical imaging system adapted to the macaque brain. Our system is composed of a curved detector, an aspherical lens and a ring composed of LEDs providing uniform illumination in four wavelengths relevant for optical imaging, including intrinsic imaging and voltage-sensitive dye (VSD) imaging. The system was fully characterized and compared with the standard optical imaging system currently in use for cortical imaging, and a 3-fold increase of the area with acceptable focus was measured (see figure). Our quantification demonstrated that we could image the visual cortex with a relatively uniform focus over a 16 mm diameter area. This new instrument, by providing good quality imaging over a large field of view, should facilitate the observation of wide-mesoscale phenomena, such as dynamic cortical maps and propagating waves, which are otherwise difficult to observe due to technical limitations of the currently available recording tools.

(a) Original (flat) detector setup (b) Curved detector setup

Figure: Average spot size across the curved field of view at 670 nm. The blue dots represent the positions where the point spread function (PSF) was measured experimentally. The 2D curve is the best power law fit to the data, imposing radial symmetry. White contours indicate the areas where the average spot size reaches 50, 35, 20 and 15 µm. A green rectangle shows the area covered by the flat sensor in the original instrument.

T2 weighted MR imaging at high, isotropic resolution for morphometric studies is hampered at ultra high field small animal scanners. To achieve good T2 contrast, the required long repetition times (TRs) cause prohibitive long scan times for 3D acquisitions unless high turbo factors can be used in combination with Rapid Acquisition with Relaxation Enhancement (RARE) sequences. However, at 9.4T, severe image artifacts can arise from the faster T2 decay at 9.4T, high signal differences can lead to pronounced Gibbs ringing and the magnetic coil's profile (Transmit-receive-CryoProbe) leads to inhomogeneous image intensities. To reduce these unfavorable image artifacts, we employed filters like T2-decay compensation and 3D-unringing together with N4 bias field correction. Therefore, the filtering effects were analyzed on the signal-to-noise ratio (SNR) along with the evaluation of image contrast and edge effects for images acquired from a T2-weighted RARE sequence performed on a 9.4 T MR scanner. The cumulative application of all three filters delivered an overall higher SNR through the whole image by reducing artifacts. The T2 compensation alone enhanced the image contrast at the selected brain tissues, especially at the larger areas like the brain surface and ventricles. The combined filtering with 3D-unringing provides reliable artifact removal and N4-unbias provides a much more homogenous signal across the T2 weighted whole brain image. The application of a single filter by itself is inadequate for artifact removal. Local tissue contrast and edge sharpness do not suffer from the combined filters, so the filtered data sets might be well suited for morphometric studies.

Gut microbiome dysbiosis and correlation with blood biomarkers in active-tuberculosis in endemic setting.
Tuberculosis (TB) is the largest infectious disease with 10 million new active-TB patients and1.7 million deaths per year. Active-TB is an inflammatory disease and is increasingly viewed as an imbalance of immune responses to M. tb. infection. The mechanisms of a switch from latent infection to active disease is not well worked out but a shift in the immune responses is thought to be responsible. Increasingly, the role of gut microbiota has been described as a major influencer of the immune system. And because the gut is the largest immune organ, we aimed to analyze the gut microbiome in active-TB patients in a TB-endemic country, Pakistan. The study revealed that Ruminococcacea, Enetrobactericeae, Erysipelotrichaceae, Bifidobacterium, etc. were the major genera associated with active-TB, also associated with chronic inflammatory disease. Plasma antibody profiles against several M. tb. antigens, as specific biomarkers for active-TB, correlated closely with the patient gut microbial profiles. Besides, bcoA gene copy number, indicative of the level of butyrate production by the gut microbiome was five-fold lower in TB patients compared to healthy individuals. These findings suggest that gut health in TB patients is compromised, with implications for disease morbidity (e.g., severe weight loss) as well as immune impairment. PLoS One, 2021; 16

Development of effective Alzheimer's disease (AD) treatments has been challenging, with limited progression from a lab to clinical setting. Amyloid plaques, a pathological hallmark of AD, have been monitored in humans to determine the success of potential AD treatments. However, only limited technologies are available to monitor amyloid plaques in animal models, in real-time. Here we demonstrate that photometry with a tapered optical fibre allows real-time monitoring of plaque signals with depth resolution, in vivo. We began by performing fibre photometry with a conventional flat fibre, to examine whether plaque signals can be monitored across brain regions of 5xFAD mice, a mouse model of AD. To label plaques, we peripherally administered blood-brain-barrier-permeable plaque marker, Methoxy-x04. We confirmed strong correlation between in vivo fluorescent signals and post-mortem histological plaque signals across depth, indicating that fibre photometry is a feasible approach to assess AD pathology in vivo. To determine if modifications of in vivo fluorescence can be detected, we completed depth-resolved photometry with a tapered fibre to monitor the pharmacokinetic response following Methoxy-x04 administration to 5xFAD mice. We found a steady increase of in vivo fluorescence within 1 hour of Methoxy-x04 injection, indicating that this approach can detect changes in Methoxy-x04 concentration. Our findings advocate this novel approach to be reliable for in vivo, real-time plaque assessment. With changes in Methoxy-x04 concentration being detected, this approach can be used to monitor plaque pathology in response to several pharmaceutical and non-pharmaceutical interventions, helping accelerate prospective treatments from a lab to clinical setting.

Mutual Interactions between Brain States and Alzheimer's Disease Pathology: A Focus on Gamma and Slow Oscillations. Brain state varies from moment to moment. While brain state can be defined by ongoing neuronal population activity, such as neuronal oscillations, this is tightly coupled with certain behavioural or vigilant states. In recent decades, abnormalities in brain state have been recognised as biomarkers of various brain diseases and disorders. Intriguingly, accumulating evidence also demonstrates mutual interactions between brain states and disease pathologies: while abnormalities in brain state arise during disease progression, manipulations of brain state can modify disease pathology, suggesting a therapeutic potential. In this review, by focusing on Alzheimer's disease (AD), the most common form of dementia, we provide an overview of how brain states change in AD patients and mouse models, and how controlling brain states can modify AD pathology. Specifically, we summarise the relationship between AD and changes in gamma and slow oscillations. As pathological changes in these oscillations correlate with AD pathology, manipulations of either gamma or slow oscillations can modify AD pathology in mouse models. We argue that neuromodulation approaches to target brain states are a promising non-pharmacological intervention for neurodegenerative diseases.

[1]King's College London, Brain Centre, Institute Of Psychiatry, Psychology And Neuroscience, London, United Kingdom, [2]King's College London, Sleep And Brain Plasticity Centre, Cns, London, United Kingdom, [3]School of Medicine, University of Zagreb, Croatian Institute For Brain Research, Zagreb, Croatia, [4]School of Medicine, University of Zagreb, Department For Chemistry And Biochemistry, Zagreb, Croatia, [5]Faculty of Medicine, University of Osijek, Department Of Medical Biology And Genetics, Osijek, Croatia

We investigated whether *ex vivo* magnetic resonance imaging (MRI) signal is affected by altered membrane (glycosphingo)lipid composition in GD3 synthase deficient (*St8sia1* knock-out, KO) mice. 19 adult (10 *St8sia1* KO and 9 age-matched wild-type, WT) male mice were perfused with 4% paraformaldehyde, their heads rehydrated in PBS with 0.05% sodium azide for 1 to 3 months and scanned using a 9.4T Bruker Biospec® MR scanner to acquire T2-weighted images, diffusion tensor imaging (DTI) data, and T1 relaxation maps. After imaging, selected histological and immunohistochemical markers were analysed in brain tissue sections. The lack of GD3 synthase caused global and widespread changes in MR signal. Interestingly, *St8sia1* KO brains were larger overall, but there were also distinct regional volume differences, with increases in the hippocampus, brain stem, cerebellum and nucleus accumbens, and decreases in cortical and thalamic regions. T1 relaxation time was decreased in *St8sia1* KO mice in many areas but the overall pattern did not match regional volume changes. Analysis of DTI showed an overall increase in mean, axial and radial diffusivity whereas fractional anisotropy (FA) increased in the corpus callosum and decreased in hypothalamus and inferior colliculi. Preliminary histological analysis indicated morphological differences in the white matter of *St8sia1* KO brains, in the same areas demonstrating changed MRI. Observed changes in MRI signal which accompany altered membrane ganglioside pattern, particularly when DTI components are analysed, suggest that MRI is suitable for detection of structural changes in white matter caused by disruption of membrane lipid composition

CHARACTERIZATION OF NEURONAL CYTO-ARCHITECTURE BY X-RAY PHASE-CONTRAST TOMOGRAPHY

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Marina Eckermann[1], Bernhard Schmitzer[2], Franziska Van Der Meer[3], Jonas Franz[3], Ove Hansen[4], Christine Stadelmann[3], Peter Cloetens[1], Tim Salditt[4]
[1]European Synchrotron Radiation Facility (ESRF), X-ray Nanoprobe, Grenoble, France, [2]Institute of Computer Science, Faculty Of Mathematics And Computer Science, Göttingen, Germany, [3]Institute of Neuropathology, University Medical Center Göttingen, Göttingen, Germany, [4]Institute for X-ray Physics, Faculty Of Physics, Göttingen, Germany

Mappings of the three-dimensional (3d) cyto-architecture are essential for a quantitative understanding of the human brain. The potential of X-ray phase-contrast computed-tomography (PC-CT) for 3d brain imaging has been recently demonstrated [1,2]. Alzheimer's disease (AD) is a case in point where exact disease mechanisms are still unresolved. Here, we present a granular study of the hippocampus in aging and disease [3], including 3d data, sub-nuclear resolution and advanced analysis tools, completed by a subsequent study on the optimization of experimental settings [4]. To study the human hippocampal cyto-architecture in cohorts of 20 (AD patients and controls), we have implemented a multiscale PC-CT workflow to cover mm^3-sized fields-of-view, and subsequently images of target regions with sub-µm resolution. We used machine learning to segment neurons, followed by optimal transport (OT) analysis to unravel pathological alterations. Opposed to standard statistical tools, OT-analysis allows a more detailed comparison of entire neuron populations. Therefore, OT grants insight into the development of a patient cohort, and hence into the pathology. The workflow allows to conclude a pathway from healthy to pathology without prior hypothesis. We found the prototypical transformation between a structure representing healthy dentate gyrus granule cells and the pathological state: a decrease in the volume of granule cell nuclei, as well as an increase in their electron density and its spatial heterogeneity (reflecting heterochromatin). Our experimental and analysis scheme provides a blueprint for studying the cyto-architecture of the human brain and its alterations associated with neurodegenerative diseases. Multi-mode fiber (MMF)-based endoscopes are minimally invasive probes holding big promises for *in vivo* deep-tissue high-resolution imaging [1,2]. By employing wavefront-shaping modulator (DMD) the light propagation through the MMF is controlled resulting in a spot scanned in the focal plane across the fluorescent sample similarly to a scanning microscope. The emitted signal is collected by the same MMF and detected on the photomultiplier tube (PMT). The foci are limited by diffraction as well as the nature of power distribution where a stray optical signal carries typically 20% of input power contaminating the outside of the focal spot. This power is for each position of focal spot distributed in a randomized but reproducible background speckle pattern. We call the focal spots with their speckled background a *muddy modes*. The fluorescence signal generated by excitation with the muddy mode background is incorrectly ascribed to the focal point location and the resulting image suffers from lower contrast and resolution.
Based on the knowledge of the intensity distribution of all muddy modes we present two algorithms for image enhancement. The first reconstruction algorithm of regularized direct pseudo-inversion presumes an intensity independent noise distribution of the detected signal (Gaussian noise), while the approach of regularized iterative algorithm respects the Poisson noise distribution better corresponding to the fluorescent photon signal detection in our experiment. These approaches yield image reconstructions with enhanced contrast and resolution.

DEEP BRAIN STIMULATION OF THE MEDIAL SEPTUM RESTORES BLOOD PERFUSION FOLLOWING PHARMACOLOGIC NMDA ANTAGONISM IN A REGION-DEPENDENT MANNER.

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Lindsey Crown[1], Kofi Agyeman[2], Wooseong Choi[1], Isabella Hoang[1], Steven Siegel[1], Charles Liu[1], Vasileios Christopoulos[2], Darrin Lee[1]
[1]University of Southern California, Keck School Of Medicine, Los Angeles, United States of America, [2]University of California, Riverside, Bioengineering, Riverside, United States of America

Reduced function of the *N*-methyl-D-aspartate (NMDA) receptor is a leading model of schizophrenia. In addition to positive and negative symptoms, schizophrenia is characterized by cognitive impairments, such decreased spatial and working memory, for which there are few effective treatments. It has been demonstrated that MK-801, a highly potent and selective NMDA-antagonist, induces spatial memory impairments in rodents (Lee et al., 2013). These spatial memory deficits can be ameliorated by 5 minutes of theta frequency (7.7Hz) deep brain stimulation (DBS) of the medial septal nucleus (MSN) prior to the start of a task. Intriguingly, while MK-801 alters electrophysiological activity, DBS does not appear to have lasting changes on these measures. This suggest that DBS improves memory function through mechanisms other than direct alterations to electrical brain activity. Using functional ultrasound (fUS) we examine blood perfusion across the septo-hippocampal network including the MSN, hippocampus, thalamus, and medial prefrontal cortex following MK-801 administration and MSN theta- and gamma- frequency DBS. We find that intraperitoneal (i.p) injection of 1mg/kg MK-801 reduces blood perfusion in mice across all regions of interest, but at different rates in different brain regions. We further find that 5 minutes of MSN DBS disrupts MK-801- induced reductions to blood perfusion, even after the cessation of stimulation. Together these results (1) indicate that pharmacologically- induced NMDA hypofunction alters blood perfusion in brain regions associated with spatial memory, and (2) that brief DBS of the MSN can attenuate these changes, suggesting that MSN DBS may improve memory function through vascular mechanisms.

Sleep Spindles and Fragmented Sleep as Prodromal Markers in a Preclinical Model of LRRK2-G2019S Parkinson's Disease.
Sleep disturbances co-occur with and precede the onset of motor symptoms in Parkinson's disease (PD). We evaluated sleep fragmentation and thalamocortical sleep spindles in mice expressing the p.G2019S mutation of the leucine-rich repeat kinase 2 () gene, one of the most common genetic forms of PD. Thalamocortical sleep spindles are oscillatory events that occur during slow-wave sleep that are involved in memory consolidation. We acquired data from electrocorticography, sleep behavioral measures, and a rotarod-based motor enrichment task in 28 -G2019S knock-in mice and 27 wild-type controls (8-10 month-old males). Sleep was more fragmented in -G2019S mice; sleep bouts were shorter and more numerous, even though total sleep time was similar to controls. -G2019S animals expressed more sleep spindles, and individual spindles were longer in duration than in controls. We then chronically administered the LRRK2-inhibitor MLi-2 in-diet to = 12 -G2019S and = 15 wild-type mice for a within-subject analysis of the effects of kinase inhibition on sleep behavior and physiology. Treatment with MLi-2 did not impact these measures. The data indicate that the -G2019S mutation could lead to reduced sleep quality and altered sleep spindle physiology. This suggests that sleep spindles in -G2019S animals could serve as biomarkers for underlying alterations in sleep networks resulting from the -G2019S mutation, and further evaluation in human -G2019S carriers is therefore warranted.

Platform to Enable Combined Measurement of Dopamine and Neural Activity.
Complex behaviors depend on the coordination of the activities of ensembles of neurons and the release of neuromodulators such as dopamine. The mechanisms underlying such coordination are not well-understood due to a lack of instrumentation for combined and real-time monitoring of neuromodulator release and the activities of large ensembles of neurons. Here we describe a measurement platform that allows for the combined monitoring of electrophysiology from a high-density electrode array and dopamine dynamics from a carbon-fiber microelectrode. Integration of these two measurement systems was

achieved through modification of the existing instrumentation. A shared grounded reference electrode was used in both systems to minimize electrical interference. Further, an optional solid-state-relay array positioned between the electrophysiological electrode array and amplifiers was added to provide additional electrical isolation. The capacity of the integrated measurement platform, termed DANA (Dopamine And Neural Activity), to measure action potentials (high frequency) and local-field oscillations (low frequency) was characterized in vitro using an artificial cerebral spinal fluid gelatin. In vivo recordings from the DANA platform in anesthetized rats demonstrated the ability of the system for near-simultaneous measurement of dopamine release and activity from multiple neurons both in distant brain regions (striatum and hippocampus) and within the same brain region (striatum). Furthermore, this system was shown to be sufficiently compact to measure activity in freely moving animals through recording of single-neuron activity, high-frequency local-field oscillations, and dopamine release.

Quantifying inter-individual anatomical variability in the subcortex using 7 T structural MRI.
Functional magnetic resonance imaging (MRI) data are usually registered into standard anatomical space. However, standard atlases, such as LPBA40, the Harvard-Oxford atlas, FreeSurfer, and the Jülich cytoarchitectonic maps all lack important detailed information about small subcortical structures like the substantia nigra and subthalamic nucleus. Here we introduce a new subcortical probabilistic atlas based on ultra-high resolution in-vivo anatomical imaging from 7 T MRI. The atlas includes six important but elusive subcortical nuclei: the striatum, the globus pallidus internal and external segment (GPi/e), the subthalamic nucleus, the substantia nigra, and the red nucleus. With a sample of 30 young subjects and carefully cross-validated delineation protocols, our atlas is able to capture the anatomical variability within healthy populations for each of the included structures at an unprecedented level of detail. All the generated probabilistic atlases are registered to MNI standard space and are publicly available.

Evidence for Distinct Forms of Compulsivity in the SAPAP3 Mutant-Mouse Model for Obsessive-Compulsive Disorder.
The specific mechanisms underlying compulsive behavior in obsessive-compulsive disorder (OCD) are unknown. It has been suggested that such compulsivity may have its origin in cognitive dysfunction such as impaired processing of feedback information, received after the completion of goal-directed actions. The signal attenuation (SA) task models such a processing deficit in animals by attenuating the association strength between food reward and audiovisual feedback (signal) presented after performance of an operant response. The compulsive-like responding resulting from SA is well characterized in rats, but was so far not established in mice, a species for which powerful genetic OCD models exist. Thus, first, we demonstrate that the SA task can be implemented in mice and show that attenuation of reward-associated response feedback produces similar behavior in C57BL/6 mice as previously reported in rats. Second, we tested the hypothesis that knock-out mice (SAPAP3), prone to exhibit several OCD-like abnormalities including excessive grooming, show enhanced compulsive-like behavior in the SA task compared with their wild-type (WT) littermates. However, task-related compulsivity measures in SAPAP3 and WT did not yield significant differences, neither following SA nor during "regular" extinction of operant behavior. Thus, compulsive-like instrumental behavior following feedback distortion was not potentiated in compulsively grooming mice, implicating specifically that (1) a general deficit in feedback processing is not related to excessive grooming in SAPAP3 and (2) different manifestations of compulsivity may be driven by independent mechanisms.

SIMULTANEOUS TWO-PHOTON VOLTAGE OR CALCIUM IMAGING AND MULTI-CHANNEL LOCAL FIELD POTENTIAL RECORDINGS IN THE MOUSE BARREL CORTEX

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Claudia Cecchetto[1], Stefano Vassanelli[1], Bernd Kuhn[2]
[1]University of Padova, Department Of Biomedical Sciences, Padova, Italy, [2]Okinawa institute of science and technology, Optical Neuroimaging Unit, Okinawa, Japan

Neuronal population activity, both spontaneous and sensory-evoked, is known to generate propagating waves in the cortex. However, high spatiotemporal-resolution mapping of these waves is difficult as calcium imaging, the work horse of current imaging, does not reveal subthreshold activity. Here, we present a new platform combining two-photon voltage or calcium imaging with multi-channel local field potential (LFP) recordings from different layers of the barrel cortex in anesthetized and awake mice. A chronic cranial window with access port allows injecting the voltage-sensitive dye (VSD) ANNINE-6plus or a viral vector expressing GCaMP6f, as well as entering the brain with a multi-channel neural probe. We show both average spontaneous activity and average evoked signals in response to multi-whisker airpuff stimulations. Time domain analysis shows the dependence of the evoked responses on the cortical layer and on the state of the animal, here separated into anesthetized, awake but resting, and running. The simultaneous data acquisition allows to compare the average membrane depolarization measured with ANNINE-6plus with the amplitude and shape of the LFP recordings. The calcium imaging data connects these data sets to the large existing database of this important second messenger. Interestingly, in the calcium imaging data, a few cells showed a decrease in calcium concentration in response to vibrissa stimulation in awake mice. This system offers an innovative multimodal technique to study the spatiotemporal dynamics of neuronal signals through a 3D architecture in vivo, providing novel insights on sensory coding and closing the gap between electrical and optical acquisitions.

WHAT CAN TRACTOGRAPHY TELL US ABOUT CORTICAL CONNECTIVITY: A WITHIN-ANIMAL AND ACROSS-VALIDATION COMPARISON WITH TRACT TRACING IN MACAQUE

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Yujie Hou[1], Nathalie Richard[2], Loïc Magrou[3], Pierre Misery[1], Camille Lamy[1], Kenneth Knoblauch[1], Henry Kennedy[1,4], Bassem Hiba[2]
[1]INSERM U1208, Stem Cell And Brain Research Institute, Bron, France, [2]Centre national de la recherche scientifique, Institut Des Sciences Cognitives Marc Jeannerod, Bron, France, [3]New York University, Center Of Neural Science, New York, United States of America, [4]Institute of Neuroscience, Chinese Academy of Sciences, Key Laboratory Of Primate Neurobiology, Shanghai, China

Aims: Diffusion MRI (dMRI) based tractography is widely used for non-invasive investigations of brain connectivity in human, despite lingering doubts about its validity. Here we evaluate inter-areal weighted connectivity revealed by tractography with that of ground truth tract tracing in the same macaque brain. **Methods**: 42 retrograde tracer injections in 41 brains revealed 3780 pathways that were compared to dMRI tractography in 6 brains, of which 3 brains had tracer injections, thereby allowing within-animal and across-animal comparisons. Post-mortem multi-shell dMRI allowed high-spatial resolution (0.3 mm). One animal had an *in-vivo* dMRI scan (0.75 mm). Whole brain tractographies were computed with MRTrix3 based on the Constrained Spherical Deconvolution to model the local diffusion. Streamlines were seeded from the grey-white matter interface and reconstructed using a probabilistic algorithm associated with the Anatomically Constrained Tractography with multiple cut-off, angle and step size, followed by Spherical-deconvolution Informed Filtering of Tractograms. **Results**: Spearman correlation between tract tracing and tractography using the 42x91 connectivity matrix is 0.54 (averaged correlations: 0.65 for connections < 20 mm, 0.26 for connections of 20-40 mm, -0.09 for connections > 40 mm). Within-animal tract tracing tractography correlation is not higher than across animal, contrasting with within-animal tract tracing correlations. Tract tracing tractography correlations showed marked areal variability. Spatial resolution failed to impact on correlations. **Conclusions:** The present results reveal unsuspected limitations in dMRI tractography to capture the inter-areal connectivity of the cortex.

ACTIVITY-DEPENDENT STIMULATION TO ASSESS THE EFFECT OF INFRARED-LASER STIMULATION IN SINGLE NEURONS

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Alicia Garrido-Peña[1], Pablo Sanchez-Martin[1], Rafael Levi[1], Javier Castilla[2], Jesús Tornero[2], Pablo Varona[1]

Near-infrared laser stimulation is becoming popular as a noninvasive stimulation technique and as a promising tool for medical treatments. However, the biophysical basis underlying the neural effect of the laser stimulus is still under study. We have tested the effect of the laser stimulation in neurons of the pond snail *Lymanea stagnalis,* in experimental and in simulation modeling studies. In our experimental protocol, we compared single spike waveforms obtained during control and during laser illumination. The results from that study show that the spike shape is altered during the laser action, with significant changes in the spike duration and the repolarization and depolarization phases. The effect was fully reversible once the laser was off. We used conductance-based models to explain the waveform changes by tuning specific parameters of the equations, effectively replicating the effect. This combination of experimental and modeling study helps us understand with further detail the biophysical effect. In this work we report the results of an activity dependent protocol that selectively turns on and off the laser stimulation during the depolarization or during the hyperpolarization phases of individual action potentials. This protocol allows the detailed characterization of the membrane potential waveform under the laser stimulation in these two phases and the comparison with the biophysical modeling of the neurons. Thus, the effect of the laser on the activation and inactivation of different channels can be assessed. We argue that the protocol can also be generalized for other kinds of activity such as bursts or subthreshold oscillations.

AIMS: Understanding the functional organization of the brain is key to map function and dysfunction. Recent advances in neurotechnologies has enabled neuroscientists to work with a set of implantable tools able to capture neural activity from hundreds of neurons simultaneously, to investigate neural circuits with cell-type specificity and to monitor neurotransmitters release in real time. Here, we describe our efforts in combining high-density electrophysiology and vibrational spectroscopy to map the molecular content of specific brain regions. METHODS: Linear array silicon probes and optrodes were used to obtain laminar local field potential (LFP) recordings in head-fixed mice. Raman spectra from laminar regions were measured using micro-structured tapered optical (TF) fiber implants. A TF was coated with aluminum and an optical sensitive region generated by locally milling the thin layer by Focused Ion Beam. RESULTS: Using laminar LFP recordings across the neocortex and hippocampus of awake head-fixed mice, we first established unambiguous criteria to infer recording depth blindly. Then, we mapped depth-resolved Raman signals using micro-structured tapered optical fibers to obtain spectroscopic profiles of the chemical composition of brain parenchyma. We identified specific Raman signatures of fatty acid and triglycerides, as well as lipid and proteins differentially distributed across brain depth, which can be tracked histologically. The sensitive region can extend from 200µm until 1mm, allowing to tailor the spatial resolution of the spectroscopic investigation. CONCLUSION: Integration of electrophysiological and Raman signals may allow for an unprecedented multimodal evaluation of brain structure and function in health and disease.

The human brain is the most complex organ in biology. This complexity is due to the intricate connections of brain cells and has so far limited the development of in-vitro models for basic and applied neuroscience. We decided to create a new, reliable, and cost-effective in-vitro system of hippocampal neurons and astrocytes co-culture based on the Nichoid, a 3D microscaffold microfabricated by two-photon laser polymerization technology. After 21 days in culture, we morphologically characterized the 3D spatial organization of astrocytes and neurons within the microscaffold and we compared our observations with the classical 2D co-culture. Using confocal microscopy, we found that cells colonized the entire volume of the 3D devices and had well differentiated. This was further elaborated with Drebrin and PSD95 staining, markers for mature dendritic spines, labelling the majority of neurons both in the 2D and in the 3D co-cultures. Using scanning electron microscopy, we found that neurons in the 3D co-culture displayed a significantly larger amount of dendritic protrusions compared to the 2D co-culture, indicating that neurons growing in a 3D environment may be more prone to connections than those in 2D. Our results show that the Nichoid can act as a 3D device and can be used to investigate structure and morphology of neurons and astrocytes in a 3D volume. In the future, this model can be used as a tool for drug screening and to determine the factors at the basis of different human brain diseases plating cells derived directly from patients.

JNK signaling provides a novel therapeutic target for Rett syndrome.
Rett syndrome (RTT) is a monogenic X-linked neurodevelopmental disorder characterized by loss-of-function mutations in the MECP2 gene, which lead to structural and functional changes in synapse communication, and impairments of neural activity at the basis of cognitive deficits that progress from an early age. While the restoration of MECP2 in animal models has been shown to rescue some RTT symptoms, gene therapy intervention presents potential side effects, and with gene- and RNA-editing approaches still far from clinical application, strategies focusing on signaling pathways downstream of MeCP2 may provide alternatives for the development of more effective therapies in vivo. Here, we investigate the role of the c-Jun N-terminal kinase (JNK) stress pathway in the pathogenesis of RTT using different animal and cell models and evaluate JNK inhibition as a potential therapeutic approach.

Common pathways in dementia and diabetic retinopathy: understanding the mechanisms of diabetes-related cognitive decline.
Type 2 diabetes (T2D) is associated with multiple comorbidities, including diabetic retinopathy (DR) and cognitive decline, and T2D patients have a significantly higher risk of developing Alzheimer's disease (AD). Both DR and AD are characterized by a number of pathological mechanisms that coalesce around the neurovascular unit, including neuroinflammation and degeneration, vascular degeneration, and glial activation. Chronic hyperglycemia and insulin resistance also play a significant

role, leading to activation of pathological mechanisms such as increased oxidative stress and the accumulation of advanced glycation end-products (AGEs). Understanding these common pathways and the degree to which they occur simultaneously in the brain and retina during diabetes will provide avenues to identify T2D patients at risk of cognitive decline.

Super-resolution study of PIAS SUMO E3-ligases in hippocampal and cortical neurons.
The SUMOylation machinery is a regulator of neuronal activity and synaptic plasticity. It is composed of SUMO isoforms and specialized enzymes named E1, E2 and E3 SUMO ligases. Recent studies have highlighted how SUMO isoforms and E2 enzymes localize with synaptic markers to support previous functional studies but less information is available on E3 ligases. PIAS proteins - belonging to the protein inhibitor of activated STAT (PIAS) SUMO E3-ligase family - are the best-characterized SUMO E3-ligases and have been linked to the formation of spatial memory in rodents. Whether however they exert their function co-localizing with synaptic markers is still unclear. In this study, we applied for the first time structured illumination microscopy (SIM) to PIAS ligases to investigate the co-localization of PIAS1 and PIAS3 with synaptic markers in hippocampal and cortical murine neurons. The results indicate partial co-localization of PIAS1 and PIAS3 with synaptic markers in hippocampal neurons and much rarer occurrence in cortical neurons. This is in line with previous super-resolution reports describing the co-localization with synaptic markers of other components of the SUMOylation machinery.

Neuronal Localization of SENP Proteins with Super Resolution Microscopy.
SUMOylation of proteins plays a key role in modulating neuronal function. For this reason, the balance between protein SUMOylation and deSUMOylation requires fine regulation to guarantee the homeostasis of neural tissue. While extensive research has been carried out on the localization and function of small ubiquitin-related modifier (SUMO) variants in neurons, less attention has been paid to the SUMO-specific isopeptidases that constitute the human SUMO-specific isopeptidase (SENP)/Ubiquitin-Specific Protease (ULP) cysteine protease family (SENP1-3 and SENP5-7). Here, for the first time, we studied the localization of SENP1, SENP6, and SENP7 in cultured hippocampal primary neurons at a super resolution detail level, with structured illumination microscopy (SIM). We found that the deSUMOylases partially colocalize with pre- and post-synaptic markers such as synaptophysin and drebrin. Thus, further confirming the presence with synaptic markers of the negative regulators of the SUMOylation machinery.

JNK3 as Therapeutic Target and Biomarker in Neurodegenerative and Neurodevelopmental Brain Diseases.
The c-Jun -terminal kinase 3 (JNK3) is the JNK isoform mainly expressed in the brain. It is the most responsive to many stress stimuli in the central nervous system from ischemia to Aβ oligomers toxicity. JNK3 activity is spatial and temporal organized by its scaffold protein, in particular JIP-1 and β-arrestin-2, which play a crucial role in regulating different cellular functions in different cellular districts. Extensive evidence has highlighted the possibility of exploiting these adaptors to interfere with JNK3 signaling in order to block its action. JNK plays a key role in the first neurodegenerative event, the perturbation of physiological synapse structure and function, known as synaptic dysfunction. Importantly, this is a common mechanism in many different brain pathologies. Synaptic dysfunction and spine loss have been reported to be pharmacologically reversible, opening new therapeutic directions in brain diseases. Being JNK3-detectable at the peripheral level, it could be used as a disease biomarker with the ultimate aim of allowing an early diagnosis of neurodegenerative and neurodevelopment diseases in a still prodromal phase.

JNK signaling activation in the Ube3a maternal deficient mouse model: its specific inhibition prevents post-synaptic protein-enriched fraction alterations and cognitive deficits in Angelman Syndrome model.
Deficiency of the E3 ubiquitin ligase UBE3A leads to the neurodevelopmental disorder Angelman syndrome (AS), while higher levels are linked to autism spectrum disorder. The mechanisms underlying the downstream effects of UBE3A loss or gain of function in these disorders are still not well understood, and treatments are still lacking. Here, using the Ube3a maternal loss (Ube3a) mouse model, we report an important JNK signaling activation in the hippocampus, cortex and cerebellum correlating with the onset of behavioral defects and biochemical marker alterations in the post-synaptic element, suggesting important spine pathology. JNK activation occurs at 7 and persists up till 23 weeks in Ube3a mice in two different cellular compartments: the nucleus and the post-synaptic protein-enriched fraction. To study JNK's role in Ube3a pathology we treated mice with the specific JNK inhibitor peptide, D-JNKI1, from 7 to 23 weeks of age. Preventing JNK action in vivo restores the post-synaptic protein-enriched fraction defects and the cognitive impairment in these mice. Our results imply a critical role of UBE3A-JNK signaling in the pathogenesis of UBE3A-related disorders. In particular, it was clear that JNK is a

key player in regulating AS synaptic alterations and the correlated cognitive impairments, in fact, its specific inhibition tackles Ube3a pathology. This study sheds new light on the neuronal functions of UBE3A and offers new prospects for understanding the pathogenesis of UBE3A-related disorders.

30315879: Buccarello L, Musi CA, Turati A, Borsello T
The Stress c-Jun N-terminal Kinase Signaling Pathway Activation Correlates with Synaptic Pathology and Presents A Sex Bias in P301L Mouse Model of Tauopathy.
Pathological Tau (P-Tau) leads to dementia and neurodegeneration in tauopathies, including Alzheimer's disease. The P301L transgenic mice well mimic human tauopathy features; P-Tau localizes also at the dendritic spine level and this correlates with synaptic markers down-regulation. Importantly, tg females present a more severe pathology compared to male mice. We describe JNK activation in P301L-tg mice, characterizing by P-JNK and P-c-Jun, cleaved-Caspase-3, P-PSD95 and P-Tau (direct JNK-targets) increased levels in tg vs control mice. These data indicate that JNK stress pathway is involved in neuronal degenerative mechanisms of this mouse model. In addition, P-JNK level is higher in females compared to male tg mice, underlying a sexual dimorphism in the JNK pathway activation. The behavioral studies highlight that tg females present major cognitive and locomotor defects, strongly correlated with a more severe synaptic injury, in comparison to tg male. Notably, at the dendritic spine level, JNK is powerfully activated and its level reveals a sexual dimorphism that is coherent with behavioral defects and spine pathology. The P301L's synaptic pathology is characterized by a strong increase of P-PSD95/PSD95 and P-JNK/JNK ratios and by an augmented level of cleaved-Caspase-3 and a decrease of Drebrin level in the post-synaptic elements. These results suggest that JNK plays a key role in synaptopathy of P301L mice. Importantly, until now, there are any efficient treatments against synaptic pathology and JNK could represent an interesting target to tackle P-Tau-induced synaptic pathology. It will be important to test specific JNK inhibitors to verify their potential neuroprotective effect.

Genetically encoded optical actuators and indicators of neural activity allowed interfacing with the mammalian brain by means of light, boosting the development of novel implantable multifunctional neural interfaces able to interrogate neural circuits with cell-type specificity. This generated the need of novel methods to multiplex fluorescence signals collected from the scattering brain tissue with spatial resolution, with optical demultiplexing typically based on space and/or time diversity. We have recently demonstrated that exploiting mode-division multiplexing and demultiplexing in tapered fibers allows detecting optical signal with depth-resolution in the living mouse brain in free-moving animals [*Nat. Methods 16, (2019)*]. In this work we describe how this method can be applied in the context of fluorescence lifetime photometry [*Front. Neurosci. 13, (2019)*], introducing the concept of Depth-Resolved Fluorescence Lifetime Photometry (DR-FLiP)[*Biomed. Opt. Express 12, 993 (2021)*], which exploit mode diversity to augment the capabilities of depth-resolution with time-correlated single photon counting detectors. The approach is also combined with an unconventional far-field detection method based on specific orthogonalization of the Fourier space of the optical fiber output plane[*APL Photonics (2022) doi:10.1063/5.0073594*], paving the way for fully exploiting mode-division in optical neural interfaces based on tapered

fibers.

Cerebral metabolic changes in an injured brain can be rapid and dynamic. Therefore, it is imperative that these changes are continuously monitored, thereby enabling timely clinical interventions to treat adverse brain metabolism and consequently improving patients' outcomes. We have integrated cerebral microdialysis (CMD) with a novel mid-infrared (mid-IR) sensor, a system developed by our group, to continuously track dynamic changes in an in-vitro model of brain, and in the brains of TBI patients in the neurocritical care unit. For in vitro studies, CNS perfusion fluid was pumped at 0.3 mL/min, using an M Dialysis 107 pump, through a CMD catheter (M Dialysis 71, 100 kDa cutoff) sited in an external solution composed of CNS perfusion fluid plus human serum albumin (5 mg/mL) and sodium azide (0.05%), to which pure glucose, lactate and pyruvate were added. The microdialysates from this in-vitro brain model were continuously delivered to the mid-IR detector for online analysis. For clinical studies, adult patients with severe TBI (severity evaluated using CT) were assessed for eligibility. Four patients were monitored online using CMD coupled to the mid-IR sensor, for various periods. Following spectral analysis, the findings demonstrate the accuracy and precision of the technology in continuously quantifying cerebral metabolites of a traumatically injured brain. Conclusively, this technology fulfils the clinical need to continuously measure relevant clinical

metabolites albeit more studies are needed to improve its perfomance. Future studies are underway to further refine this technology for enhanced cerebral metabolic change measurements. *Funding:* NIHR HTC, MRC CiC, NIHR i4i

Focused UltraSound (US) is a promising noninvasive technology for stimulating neuronal activity. However, the underlying mechanisms are not well understood. At the cellular scale, US-evoked responses have generally been assessed on transfected cells or on brain slices by recording membrane currents or calcium activity. This study aims to explore the direct stimulation of sensory neurons (dorsal root ganglion DRGs and spiral ganglion SGNs) by combining focused US with live-cell calcium imaging. An experimental set-up based on calcium imaging has been developed to monitor changes in calcium signals in individual DRG neurons subjected to US stimuli. The US transducer was positioned with a tilted angle to reduce interference/standing waves between the transducer and the cell culture dish. The US stimulus consisted of a 20 MHz sinusoidal signal with a peak acoustic pressure of 3.5 MPa, and a pulse duration of 1 ms. Calcium images were recorded before, during and after US stimulation. We found that US activated 39 % of DRG neurons (N=94) and 64 % of SGN neurons (N=108). These results demonstrate that focused ultrasound at 20 MHz is capable of activating a small fraction of DRG neurons. This could be explained by the molecular diversity of the two neuronal types considered: DRGs possessing a greater diversity than SGNs. To test this hypothesis, US-positive DRGs and SGNs, and US-negative DRGs were collected and subjected to single cell RNA sequencing to identify the identity of US sensitive neurons and to perhaps unravel candidate genes encoding proteins responsible for US responses.

ILLUMINATING THE MESOSCALE CONNECTOME: A 100-FIBER INFRARED NEURAL STIMULATION SYSTEM

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Kenneth Schriver[1], Ying Zhang[2], Yipeng Liu[2], Anna Wang Roe[2]

The combination of infrared neural stimulation (INS) with other modalities such as fMRI or optical imaging creates new capabilities for mapping functional mesoscale connectomes in the human and non-human primate brain. To date, most work in this area has been done with one to several optical fibers in contact with cortex or inserting a single fiber into the brain to stimulate regions of interest along the penetration track. To further explore the potential of INS, we have expanded the cortical surface stimulation technique significantly beyond methods using single fibers or linear arrays. We describe here the development and evaluation of a multifiber “bundle” capable of stimulating 100 individual 200 µm diameter sites within a local region of interest (ROI). The fiber bundle is mounted to achieve contact with cortex through a relatively small (5mm diameter) craniotomy. In addition to stimulation of individual sites within the ROI, this multifiber INS system allows exploration of paradigms (such as simultaneous stimulation of multiple sites or programmed sequential stimulation of different sites) to activate different domains in a specific temporal pattern. Preliminary evaluations have been conducted on visual cortex with the fiber bundle mounted in contact with feature-specific functional domains on one hemisphere while monitoring networks of mesoscale BOLD response at brainwide scale. This approach is the first to enable mapping ~100 functionally specified mesoscale networks within a single primate brain.

Selective stimulation of the spinal cord has been in use for decades as treatment for chronic pain. We explored here what implications stimulating single cells might have in network processing by exploiting silicon-based nanoscale photodiodes to optically modulate identified neurons in mammalian spinal cord explants. In order to record activity at a network level, we make use of neuronally expressed genetically encoded Ca^{2+} indicator GCaMP7f. We found that activating single excitatory or inhibitory neurons with near infrared-light stimulation differently affects sensory circuit processing in the dorsal horn: Selective stimulation of a single excitatory neuron can cause potentiation of network activity, reminiscent of 'Central Sensitisation' in chronic pain signaling, the molecular mechanism underlying pain hypersensitivity. Conversely by optically activating single GABAergic interneurons, we could observe a temporary inhibition of resting network activity. Our study introduces nanomaterial-based neural interfaces for optically and selectively stimulating neurons with single cell precision and low invasiveness, a tool with the potential to providing new perspectives in linking brain cell activity to specific behavioral outcome

NEW TOOLS FOR THE REGISTRATION OF SERIAL SECTION-TRACED NEURONAL MORPHOLOGIES TO THE ALLEN MOUSE COMMON COORDINATE FRAMEWORK

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Rembrandt Bakker[1,2], Maria Carla Piastra[3], Maria Garcia-Amado[4], Mario Rubio-Teves[4], Nestor Timonidis[1], Francisco Clascá[4], Paul Tiesinga[1]

The Allen Common Coordinate Framework version 3 (CCF3) is a standard space for sharing mouse brain data. In recent years, large datasets of 3D long-range projection neurons (LRPN) scattered across the brain and acquired with high throughput techniques were shared in CCF3 [1,2]. Our aim is to augment this with LRPNs from labs that study specific brain circuits. In contrast to the 'industrial' approach that works with 3D-scanned data, these labs typically use Neurolucida to trace neurons from mounted and dried serial brain sections. This results in highly accurate morphologies that often come with functionally relevant metadata (numbers/sizes of terminal boutons, relation to specific tissue microdomains, electrophysiological data or response to experimental manipulations, precise location of cortical layers, etc.) that are lacking in the high-throughput data. Registration to CCF3 involves the warping of a 2D slice-stack into a 3D anatomical volume. If tissue sections are damaged, we use manual initial alignment [3] to find corresponding sections in CCF3, followed by deformable 2D-2D registration. When tissue sections are clean, we automatically register them into a volume [4], followed by deformable 3D-3D registration. In both cases, we apply a final step that aligns known cortical layer borders with the corresponding surfaces in CCF3. The tools are shared via the Jupyterlab extension of the EBRAINS platform [5].
