The study of peripheral nerve repair and regeneration is important in the light of the high clinical incidence of nerve lesions. Although peripheral nerve injuries are capable of some degree of regeneration, the clinical outcome and the functional recovery is rarely complete. Therefore, a number of therapeutic models have been investigated, from cell line-based models to in vivo animal models. However, the need to limit the use of animals in biomedical research as much as possible supports the search for other possibilities. Our study describes in vitro model of peripheral nerve regeneration based on organotypic ex vivo-based models that has much lower impact on animal wellbeing in comparison to in vivo models. Spinal cord sections from P3 rats were used to innervate peripheral sciatic nerve segments. Axon growth across nerve segments can be repeatedly imaged by fluorescence microscopy to define the rate of regeneration, and parental neurons can be labelled in a retrograde manner to identify contributing neurons. The whole mount staining was used for the overall visualization of the axon – spinal cord interactions. Its use allows better observation of regeneration processes as a whole than in conventional staining. This model can be modified using any other peripheral nerves or treated with antibodies and growth factors. The regeneration environment is controlled to an extent that is not possible in vivo, and the use of experimental animals is decreased. The flexibility and control that this technique offers should therefore make it a useful tool for studying the biology of regeneration.

Formaldehyde-hardened albumin as a non-penetrating embedding matrix for frozen and vibratome sectioning.
In this paper, we describe a protocol for a non-penetrating embedding matrix that can be used for frozen or vibratome sectioning of various formaldehyde-fixed tissue specimens. In our experiments, we wanted to prepare thin frozen sections from miniature specimens for fluorescent staining. As we could not achieve satisfactory results with any of the previously published methods, we have tried to modify the existing protocols, and systematically evaluated the effect of these modifications on the properties of the embedding matrix. The resulting protocol is simple, the matrix gets firmly attached to the tissues, does not cause autofluorescence and enables preparing extremely thin frozen sections. The matrix can be used for 1, embedding miniature specimens from problematic tissues to enable cutting very thin frozen sections, 2, grouping multiple specimens into one large block for simultaneous processing, and 3, dispersing single cells and preparing cell blocks for frozen sectioning.

Pro-Apoptotic Potential of (L.) Extract and Isolated Physodic Acid in Acute Lymphoblastic Leukemia Model In Vitro.
Acute lymphoblastic leukemia (ALL) is the most frequently diagnosed type of leukemia among children. Although chemotherapy is a common treatment for cancer, it has a wide range of serious side effects, including myelo- and immunosuppression, hepatotoxicity and neurotoxicity. Combination therapies using natural substances are widely recommended to attenuate the adverse effects of chemotherapy. The aim of the present study was to investigate the anti-leukemic potential of extract from the lichen (L.) (PSE) and isolated physodic acid (Phy) in an in vitro ALL model. A screening assay, flow cytometry and Western blotting were used to analyze apoptosis occurrence, oxidative stress, DNA damage and stress/survival/apoptotic pathway modulation induced by the tested substances in Jurkat cells. We demonstrate for the first time that PSE and Phy treatment-induced intrinsic caspase-dependent cell death was associated with increased oxidative stress, DNA damage and cell cycle arrest with the activation of cell cycle checkpoint proteins p53, p21 and p27 and stress/survival kinases p38 MAPK, JNK and PI3K/Akt. Moreover, using peripheral T lymphocytes, we confirmed that PSE and Phy treatment caused minimal cytotoxicity in normal cells, and therefore, these naturally occurring lichen secondary metabolites could be promising substances for ALL therapy.

Overexpression of Galectin-3 in Chronic Lymphocytic Leukemia Is Associated With 17p Deletion: A Short Report.
Galectins belong to the family of galactose-binding proteins known to play an important role in the processes of cell proliferation, differentiation, migration and neoplastic progression. Herein, we studied the expression of galectin-3 (Gal-3) in chronic lymphocytic leukemia (CLL).

The expression of CD73 on pathological B-cells is associated with shorter overall survival of patients with CLL.
CD73 is a membrane-bound enzyme that catalyzes the extracellular conversion of adenosine monophosphate to adenosine. Adenosine is thought to play a role in promoting tumor growth and survival together with suppressing the host immune responses, which contribute to the multistep process of tumorigenesis. Here, we studied the expression of this antigen in chronic lymphocytic leukemia (CLL). The expression of CD73 was analyzed by multiparametric flow cytometry on normal and pathological B-cells from peripheral blood and bone marrow samples from 71 patients with CLL. Pathological B-cells expressed significantly lower levels of CD73 than normal B-cells ($p<0.01$). Patients with splenomegaly showed a higher expression of CD73 on pathological B-cells than patients without splenomegaly ($p<0.05$). The expression of CD73 also correlated with beta-2-microglobulin levels ($p<0.05$). Clinically, patients with higher levels of CD73 versus those with lower expression presented with shorter overall survival (median OS of 65 vs. 113 months, $p<0.05$). Our data indicate that CD73 may play a role in CLL pathophysiology, is correlated with poor clinical and biological prognostic factors and may be of potential value as a prognostic marker and therapeutic target.

Meningeal lymphatic vessels (MLVs) contribute to waste product elimination and immune surveillance in brain tissues. MLVs were identified in the dorsal and caudo-basal regions of the dura mater, where they ensure the clearance of cerebrospinal fluid (CSF). Whether MLVs exist in the complex anterior part of the murine and human skull, and how they connect with the glymphatic system and extracranial lymphatic vasculature remained unclear. Here, we generated three-dimensional (3D) maps of MLV drainage by light-sheet fluorescence microscopy (LSFM) imaging of mouse whole-head preparations following fluorescent OVA-A^{555} tracer injections into the CSF. In humans, we performed real-time magnetic resonance vessel wall imaging (MR-VWI) after systemic gadobutrol injections. We observed a conserved 3D-anatomy of MLVs in mice and humans, and we discovered an extended anterior network around the dural cavernous sinus including multiple capillary beds and exit routes through the foramina of emissary veins. MR-VWI may provide a diagnostic tool for patients with CSF drainage defects and neurological diseases.

Neural circuits are essential for proper animal behavior. Understanding how these circuits are wired is key to deciphering how nervous systems function. Transsynaptic tracing methods, such as *trans*-Tango, are crucial tools in this endeavor. Although a couple of anterograde tracing methods and a targeted retrograde tool have been developed in *Drosophila*, there is still need for a user-friendly retrograde tracing system that is devoid of user bias. Here we describe *retro*-Tango, a modified version of *trans*-Tango that enables retrograde circuit tracing and manipulation in the *Drosophila* nervous system. In this genetically encoded system, a membrane bound ligand, targeted at postsynaptic sites, activates its cognate receptor across the synapse, at the presynaptic site. This, in turn, triggers an intracellular signaling cascade that results in gene expression in the presynaptic neuron. Most importantly, due to the panneuronal expression of its elements, *retro*-Tango does not require the user to make any assumptions regarding connectivity. Therefore, it can be used not only to test hypotheses but also to generate new ones. We validate *retro*-Tango in the olfactory system, in sex-specific circuits, and in the central complex, a brain region responsible for integrating sensory information. For this, we trace connections between the periphery and the central nervous system (CNS) as well as connections within the CNS. Our experiments establish *retro*-Tango as a key method for circuit tracing and manipulation, filling an important gap in *Drosophila* neuroscience research.

DISYNAPTIC PROJECTIONS FROM THE CEREBELLAR NUCLEI TO THE NEUROMODULATORY SYSTEMS

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Marit Lute[1], Willem Van Hoogstraten[1], Su Saka[1], Lieke Kros[1], Arn Van Den Maagdenberg[2,3], Chris De Zeeuw[1,4]

AIMS: The influence of the cerebellum on the neuromodulatory systems has received a surge of interest over the past decade. Nevertheless, detailed descriptions of the anatomy underlying the functional connections of the cerebellum with neuromodudatory centers are sparse at best. Well-known monosynaptic projections suggest the existence of disynaptic projections from the cerebellar nuclei (CN) to these modulatory centers, via midbrain areas like superior colliculus (SC) and ventrolateral periaqueductal grey (vlPAG). METHODS: We employed combinations of classical and viral tracing approaches. We injected in the CN, vlPAG and SC to elucidate disynaptic projections from the CN to a variety of modulatory targets. Using confocal scanning and manual quantification combined with stainings for GAD67 and VGLuT2, we investigated the net effect of the projections of interest. RESULTS: We identified disynaptic projections from the cerebellar nuclei via vlPAG and SC to the ventral tegmental area (VTA), Raphe Magnus (RpMg), and Substantia Nigra pars compacta (SNc). Via vlPAG we also found specific projections to locus coeruleus (LC) and basal forebrain (BF). We found the CN to have both excitatory and inhibitory projections to VTA and SNc, while the other targets (RpMg, LC, BF) seem to receive mostly excitatory projections. CONCLUSIONS: Anatomical investigation of disynaptic projections from cerebellum to the neuromodulatory systems support the hypothesis that the cerebellum exerts bidirectional control over such systems.

Introduction/Aim: Over the last century, neuroscience has struggled to understand how synaptic organization contributes to the functional organization of the brain. In this work, we have used Focused Ion Bean / Scanning Electron Microscopy (FIB/SEM) to study the synaptology of layer V and VI of the human entorhinal cortex (EC, Figure 1). This area, located in the medial temporal lobe, is essential for memory functions and hippocampal connectivity, and it is one of the first regions affected in Alzheimer´s disease. However, very little is known about the synaptic organization of this region. **Methods:** A total of 2502 synapses from 3 human autopsies were three-dimensionally (3D) reconstructed using FIB/SEM and EspINA software to analyze synaptic density, proportions of asymmetric and symmetric synapses, spatial distribution of synapses, synaptic size, synaptic shape and postsynaptic elements (Figure 1). **Results:** Differences between layers were found in synaptic size, being bigger in layer V (Figure 2). The analysis of postsynaptic elements showed that in layer V most synapses were established on dendritic shafts, whereas in layer VI, synapses were predominantly formed on dendritic spine heads (Figure 2). No significant differences were found regarding synaptic density or other morphological characteristics. **Conclusions:** This study represents the first detailed description of the synaptic organization of layers V and VI from the human EC. Our results emphasize that synaptic organization is layer-specific in this region. Further analyses are being performed to include other layers, in order to generate a detailed synaptic map of the human EC. **Figure 1.**

3D Analysis of the Synaptic Organization in the Entorhinal Cortex in Alzheimer's Disease.

The entorhinal cortex (EC) is especially vulnerable in the early stages of Alzheimer's disease (AD). In particular, cognitive deficits have been linked to alterations in the upper layers of EC. In the present report, we examined Layers II and III from eight human brain autopsies (four subjects with no recorded neurologic alterations and four AD cases). We used stereological methods to assess cortical atrophy of the EC and possible changes in the volume occupied by different cortical elements (neuronal and glial cell bodies; blood vessels; and neuropil). We performed 3D ultrastructural analyses of synapses using focused ion beam/scanning electron microscopy (FIB/SEM) to examine possible alterations related to AD. At the light microscope level, we found a significantly lower volume fraction occupied by neuronal bodies in Layer III and a higher volume fraction occupied by glial cell bodies in Layer II in AD cases. At the ultrastructural level, we observed that (1) there was a significantly lower synaptic density in both layers in AD cases; (2) synapses were larger and more complex in Layer II in AD cases; and (3) there was a greater proportion of small and simple synapses in Layer III in AD cases than in control individuals. These structural differences may play a role in the anatomic basis for the impairment of cognitive functions in AD.

SYNAPTIC ORGANIZATION OF THE HUMAN CEREBRAL CORTEX: A 3D-ULTRASTRUCTURAL STUDY OF LAYER III

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Nicolás Cano-Astorga[1,2,3], Sergio Plaza-Alonso[1,2], Javier Defelipe[1,2], Lidia Alonso-Nanclares[1,2]

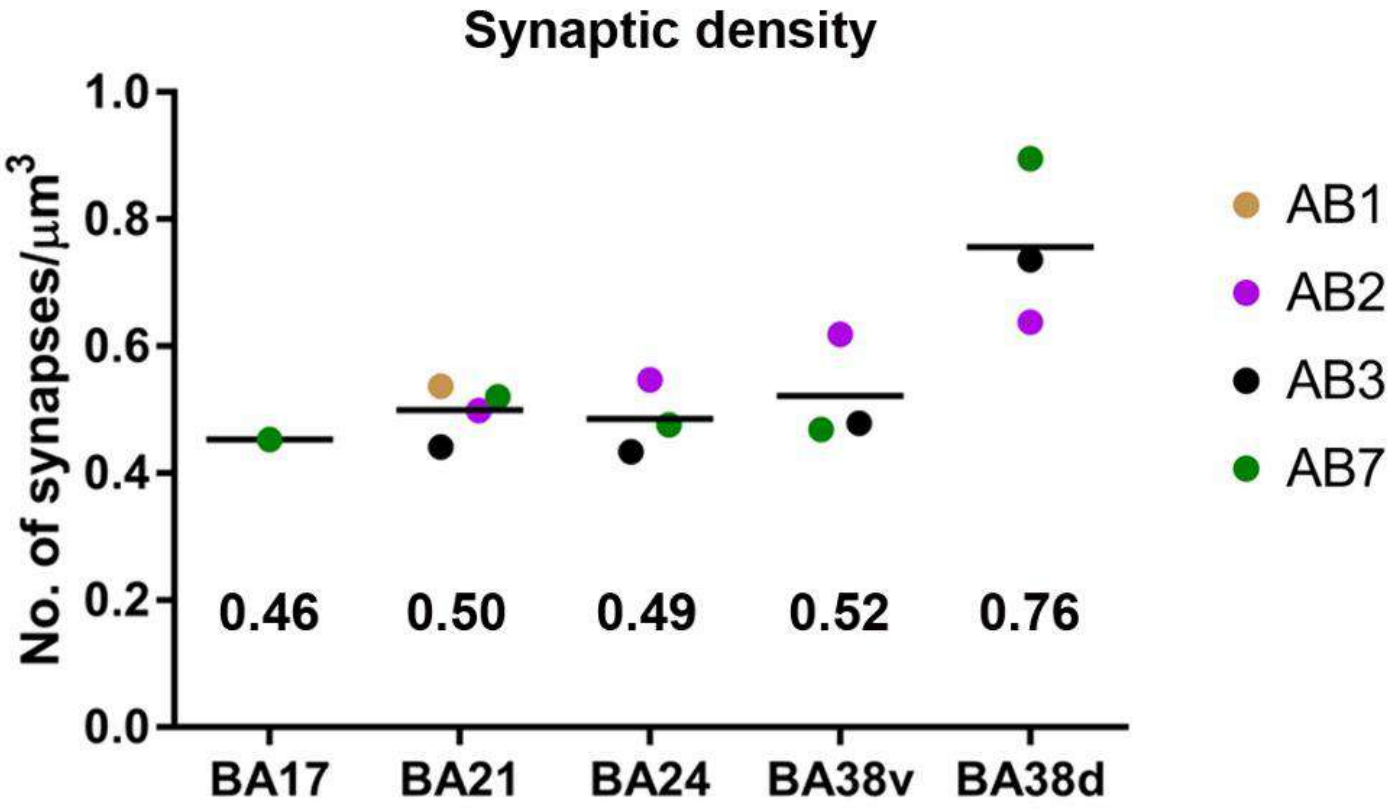
Introduction and aim Layer III pyramidal cell complexity as well as the macroscale connectivity of the human cortex increases from the unimodal primary cortices to the association areas. However, the synaptic organization of these cortical regions are not known. **Methods** We have performed a detailed three-dimensional (3D) ultrastructural analyses in the neuropil of layer III from brain tissue of four human control autopsies, using FIB/SEM technology. Brodmann area (BA) 17, BA21, BA24 and BA38 (ventral and dorsal) were examined. A total of 6877 synapses have been 3D-segmented to analyze the synaptic density, proportions of asymmetric (AS) and symmetric (SS) synapses, spatial distribution of synapses, synaptic size, synaptic shape and postsynaptic elements. **Results** Synaptic densities were similar in all analyzed regions, except in BA38-dorsal which showed a significant higher synaptic density (Figure 1). Besides, in all regions, the ratio of AS:SS synapses was similar (AS 93-95%: SS 7-5%), and the 3D-distribution of synapses fitted to a random distribution. Furthermore, in all regions AS were larger than SS, macular-shaped synapses were smaller than complex-shaped synapses, and they were the most frequent synaptic shape. BA38-dorsal displayed the smallest AS. Most of synapses were found on dendritic spines (range 67-75%), followed by dendritic shafts in all analyzed
regions.



Conclusions The present work suggests that there is not an association between the synaptic characteristics in layer III neuropil and the macroscale connectivity or the complexity of pyramidal cells; and that BA38-dorsal may present a different set of microscale-specific synaptic characteristics.

Three-Dimensional Synaptic Organization of Layer III of the Human Temporal Neocortex.
In the present study, we have used focused ion beam/scanning electron microscopy (FIB/SEM) to perform a study of the synaptic organization of layer III of Brodmann's area 21 in human tissue samples obtained from autopsies and biopsies. We analyzed the synaptic density, 3D spatial distribution, and type (asymmetric/symmetric), as well as the size and shape of each synaptic junction of 4945 synapses that were fully reconstructed in 3D. Significant differences in the mean synaptic density between autopsy and biopsy samples were found (0.49 and 0.66 synapses/µm3, respectively). However, in both types of samples (autopsy and biopsy), the asymmetric:symmetric ratio was similar (93:7) and most asymmetric synapses were established on dendritic spines (75%), while most symmetric synapses were established on dendritic shafts (85%). We also compared several electron microscopy methods and analysis tools to estimate the synaptic density in the same brain tissue. We have shown that FIB/SEM is much more reliable and robust than the majority of the other commonly used EM techniques. The present work constitutes a detailed description of the synaptic organization of cortical layer III. Further studies on the rest of the cortical layers are necessary to better understand the functional organization of this temporal cortical region.

Aim A fluid-clearance pathway in the brain parenchyma, the glymphatic system (GS), was recently re-evaluated in relation to its role in neurodegeneration as controller of the dynamics of neurotoxic proteins. As neuroinflammation is a key feature of neurodegeneration, GS function in this scenario is relevant. We propose a GS on-a-chip-model allowing tunable levels of molecule clearance, to be integrated in a gut-brain axis platform which aims at studying the intestinal microflora impact on brain functionality. Methodology We applied interstitial flows inside our GS model featuring the blood-brain barrier (BBB) and the brain 3D parenchyma and then we coupled the GS to an on-a-chip gut epithelial barrier to simulate the gut-brain connection. The cells used were: intestinal epithelial cells (CaCo2); endothelial cells (bEND.3); astrocytes (C8D1A); neuroglioma cells (H4). We tracked bacteria lipopolysaccharides (LPS) dynamics when administered at gut level and measured downstream H4 inflammatory response under GS clearance. Results The GS model sustained pathophysiological flows and solutes clearance. The on-chip devices allowed long-term culture of all cells. Preliminary results showed inflammatory response inside the 3D brain model, after LPS stimulation, being modulated at different clearance levels suggesting an active role of fluid drainage in controlling neuroinflammatory response. Conclusions Our engineered GS is a suitable tool for modelling *in vitro* pathophysiological drainage of fluids inside the brain parenchyma in the context of microbial neuroinflammation. Intracellular label-free detection of mesenchymal stem cell metabolism within a perivascular niche-on-a-chip.
The stem cell niche at the perivascular space in human tissue plays a pivotal role in dictating the overall fate of stem cells within it. Mesenchymal stem cells (MSCs) in particular, experience influential microenvironmental conditions, which induce specific metabolic profiles that affect processes of cell differentiation and dysregulation of the immunomodulatory function. Reports focusing specifically on the metabolic status of MSCs under the effect of pathophysiological stimuli - in terms of flow velocities, shear stresses or oxygen tension - do not model heterogeneous gradients, highlighting the need for more advanced models reproducing the metabolic niche. Organ-on-a-chip technology offers the most advanced tools for stem cell niche modelling thus allowing for controlled dynamic culture conditions while profiling tuneable oxygen tension gradients. However, current systems for live cell detection of metabolic activity inside microfluidic devices require the integration of microsensors. The presence of such microsensors poses the potential to alter microfluidics and their resolution does not enable intracellular measurements but rather a global representation concerning cellular metabolism. Here, we present a metabolic toolbox coupling a miniaturised in vitro system for human-MSCs dynamic culture, which mimics microenvironmental conditions of the perivascular niche, with high-resolution imaging of cell metabolism. Using fluorescence lifetime imaging microscopy (FLIM) we monitor the spatial metabolic machinery and correlate it with experimentally validated intracellular oxygen concentration after designing the oxygen tension decay along the fluidic chamber by in silico models prediction. Our platform allows the metabolic regulation of MSCs, mimicking the physiological niche in space and time, and its real-time monitoring representing a functional tool for modelling perivascular niches, relevant diseases and metabolic-related uptake of pharmaceuticals.

Microbiota-Host Immunity Communication in Neurodegenerative Disorders: Bioengineering Challenges for In Vitro Modeling.

Human microbiota communicates with its host by secreting signaling metabolites, enzymes, or structural components. Its homeostasis strongly influences the modulation of human tissue barriers and immune system. Dysbiosis-induced peripheral immunity response can propagate bacterial and pro-inflammatory signals to the whole body, including the brain. This immune-mediated communication may contribute to several neurodegenerative disorders, as Alzheimer's disease. In fact, neurodegeneration is associated with dysbiosis and neuroinflammation. The interplay between the microbial communities and the brain is complex and bidirectional, and a great deal of interest is emerging to define the exact mechanisms. This review focuses on microbiota-immunity-central nervous system (CNS) communication and shows how gut and oral microbiota populations trigger immune cells, propagating inflammation from the periphery to the cerebral parenchyma, thus contributing to the onset and progression of neurodegeneration. Moreover, an overview of the technological challenges with in vitro modeling of the microbiota-immunity-CNS axis, offering interesting technological hints about the most advanced solutions and current technologies is provided.

Technological tools and strategies for culturing human gut microbiota in engineered in vitro models.
The gut microbiota directly impacts the pathophysiology of different human body districts. Consequently, microbiota investigation is an hot topic of research and its in vitro culture has gained extreme interest in different fields. However, the high sensitivity of microbiota to external stimuli, such as sampling procedure, and the physicochemical complexity of the gut environment make its in vitro culture a challenging task. New engineered microfluidic gut-on-a-chip devices have the potential to model some important features of the intestinal structure, but they are usually unable to sustain culture of microbiota over an extended period of time. The integration of gut-on-a-chip devices with bioreactors for continuous bacterial culture would lead to fast advances in the study of microbiota-host crosstalk. In this review, we summarize the main technologies for the continuous culture of microbiota as upstream systems to be coupled with microfluidic devices to study bacteria-host cells communication. The engineering of integrated microfluidic platforms, capable of sustaining both anaerobic and aerobic cultures, would be the starting point to unveil complex biological phenomena proper of the microbiota-host crosstalks, paving to way to multiple research and technological applications.

Peripheral nerve injury (PNI) is a significant medical and social problem and is characterized by long-term limb dysfunction and a high level of disability. Treating PNIs represents a major challenge in reconstructive surgery and regenerative medicine. Here, we investigated the efficacy of motor and sensory functional recovery in a rat model of sciatic nerve injury using a novel polyethyleneglycol (PEG)-based 3Dscaffolds featuring tightly packed oriented microchannels. Addition of pentaerythritol triacrylate (PETA) as a crosslinker improved mechanical and cell adhesion properties of the scaffolds. A unilateral 6-mm sciatic nerve defect was repaired using the 3D micro-channelled scaffold, hollow silicon conduit or neurorrhaphy. Recovery of sensory and motor functions in the injured limb during 6 months after the surgery was assessed by mechanical and thermal sensitivity tests as well as by gait analysis. We found that that the rate and degree of functional recovery were significantly higher in the group with the 3D microchannelled scaffolds than in the ones with other treatment choices. The implantation also provided for successful outgrowth of neuronal and vascular tissues in the scaffold microchannels as shown by confocal microscopy and immunochemistry. Thus, the 3D microchannelled scaffold implanted in the site of sciatic nerve injury, may considerably restore motor and sensory function of the rat's posterior paretic leg.

Intro | Axons are neuronal processes specialized for conduction of action-potentials. Mainly due to technical difficulties to monitor axonal conduction, axonal information processing has been neglected, and axons are classically seen as cables that conduct action-potentials in an all-or-none fashion. Later studies have challenged this view and suggested that axons have much more complex roles than previously thought. Advanced high-density microelectrode arrays (HD-MEAs) bear a potential to reveal complex axonal functionalities. These arrays have not yet been fully exploited, arguably due to lack of methods for complex data analysis and visualization. **Aims** | First part of this project aims at developing methods for automatic tracking and visualisation of signal conduction in mammalian axons. Second part aims at using these methods to investigate conduction dynamics in axons. **Methods** | We cultured rat primary cortical and motor neurons directly on HD-MEAs comprising 26,400 densely-packed microelectrodes. Spike-sorting algorithms were used to reconstruct activities of individual neurons. Kalman filter was used to compute trajectories of axonal conduction. **Results** | We developed a method for tracking axonal conduction in cortical and motor neurons. Spatiotemporal features of tracked signals enabled to reconstruct axonal 'functional morphology'. Tracked trajectories revealed information about waveforms of axonal action-potentials, local conduction velocities and times at which action-potentials arrive at axonal terminals. We found that longer axonal paths provide faster signal conduction compared to shorter paths found in the same neuron. **Conclusions** | Axons tune their local conduction velocities to reduce discrepancies among times at which action-potentials arrive at different axonal terminals.

Aims: Chitosan is emerging as a promising FDA-approved, biocompatible biopolymer for tissue engineering. However, its exploitation in regenerative devices can be further improved by blending it with other materials. Also, the critical importance of the nano/micro-structured features of the scaffold surface is overall accepted, impacting the regenerative performance. We have already demonstrated that nano/micro-gratings are capable to direct neuronal and glial cell differentiation, polarization, and migration. Neural cells respond to specific length scales according to the specific cell features. Our study aims to develop microstructured scaffolds for peripheral nerve regeneration, made of biodegradable and soft materials compliant with nerve mechanics. Methods: We develop, by solvent casting, thin, soft films made of chitosan and glycerol, and micro-patterned with directional geometries having different levels of axial symmetry. Their mechanical properties are characterized by scanning probe and light microscopies, and by mechanical and degradation assays. The chitosan-glycerol membranes are tested as in vitro scaffolds with primary cultures of sensitive neurons and Schwann cells, to study cell migration and healing, and as in vivo scaffolds, on a model of Cavernous nerve resection in rats. Results: Overall, we demonstrate that our chitosan-glycerol membranes show optimal physico-mechanical properties, enhancing the neural cell healing response in vitro and also in vivo thanks to their asymmetric directional micropattern. Conclusions: Our results provide information about the production of artificial interfaces for enhancing nerve regeneration, and for the fabrication of novel, bio-compliant neural scaffolds.

Chitosan Micro-Grooved Membranes with Increased Asymmetry for the Improvement of the Schwann Cell Response in Nerve Regeneration.
Peripheral nerve injuries are a common condition in which a nerve is damaged, affecting more than one million people every year. There are still no efficient therapeutic treatments for these injuries. Artificial scaffolds can offer new opportunities for nerve regeneration applications; in this framework, chitosan is emerging as a promising biomaterial. Here, we set up a simple and effective method for the production of micro-structured chitosan films by solvent casting, with high fidelity in the micro-pattern reproducibility. Three types of chitosan directional micro-grooved patterns, presenting different levels of symmetricity, were developed for application in nerve regenerative medicine: gratings (GR), isosceles triangles (ISO) and scalene triangles (SCA). The directional patterns were tested with a Schwann cell line. The most asymmetric topography (SCA), although it polarized the cell shaping less efficiently, promoted higher cell proliferation and a faster cell migration, both individually and collectively, with a higher directional persistence of motion. Overall, the use of micro-structured asymmetrical directional topographies may be exploited to enhance the nerve regeneration process mediated by chitosan scaffolds.

SEGMENTATION OF THE ANTERIOR HUMAN THALAMUS BASED ON ITS EXCITATORY AFFERENTS

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

András Salma[1,2], Csaba Dávid[2,3], László Acsády[2]
[1]Semmelweis University, János Szentágothai Doctoral School Of Neurosciences, Budapest, Hungary, [2]Institute of Experimental Medicine, Laboratory Of Thalamus Research, Budapest, Hungary, [3]Semmelweis University, Department Of Anatomy, Histology And Embryology, Budapest, Hungary

The connectivity between the anterior part of the human thalamus (ATh) and the frontal cortex is crucial for complex cognitive processes. The ATh is also a major target for deep brain neurosurgery in various neurological disorders such as epilepsy, Parkinson's disease, or essential tremor. Functionally relevant nuclear segmentation is essential for understanding both healthy and pathological processes of the brain, however, a comprehensive division of the human ATh, based on morphological and biological properties, is still lacking. Our aim was to create a reliable nuclear segmentation of the ATh based on its excitatory efferents and cell types. To this end, we used vesicular glutamate transporter types 1 and 2 (vGluT1, vGluT2), calbindin, calretinin, and parvalbumin immunostainings in consecutive sections of post-mortem human thalami to label cortical and subcortical excitatory inputs as well as distinct thalamic cell types. The combination of these markers clearly outlined the major nuclear organisation of the human ATh, however showed major differences compared to the accepted schemes. The size and position of the thalamic motor nuclei as defined by its afferentation were not in accordance with other human thalamus atlases. The composition of excitatory inputs in the mediodorsal nucleus also disagreed with non-human primate and rodent data. The results indicate that the nucleus-specific combinations of afferent systems in the human ATh display both evolutionary conserved and highly derived human features and demonstrate that mapping excitatory afferents can indeed lead to a novel understanding of human thalamic functions.

QUANTITATIVE, AUTOMATED DETECTION OF EXCITATORY AFFERENTS IN THE ANTERIOR HUMAN THALAMUS

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Csaba Dávid[1], András Salma[1,2], László Acsády[1]
[1]Institute of Experimental Medicine, Laboratory Of Thalamus Research, Budapest, Hungary, [2]Semmelweis University, János Szentágothai Doctoral School Of Neurosciences, Budapest, Hungary

Nuclear parcellation of human thalamus is largely based on subjective, qualitative criteria which may yield segmentation of functionally related areas. Cortical and subcortical afferents carry the most relevant information concerning thalamic function. Thus, in this project we tested whether quantitative, automated analysis of the excitatory inputs in the anterior part of the human thalamus can yield a functionally relevant nuclear segmentation of ATh and whether it can be used to detect alteration in a postmortem COVID patient. We utilized high quality immunolabeling of serial ATh and visualized cortical and subcortical afferents using vesicular glutamate transporter 1 and 2 (vGluT1 and 2 respectively) in postmortem human samples. Automated, high throughput methods provided reliable quantitative data for morphological analysis of the afferentation. vGluT2 immunostaining yielded more informative dataset for nuclear segmentation than vGluT1. Both vGluT2 terminal size distribution as well as vGluT2 terminal density were nucleus specific and dispalyed large intranuclear heterogenity. Despite large interindividual differences among position and size of thalamic nuclei the nucleus specific quantitative features of vGluT2 afferents were remarkably similar between individuals. However, nuclear boundaries based on its excitatory afferents were not in register with accepted thalamus maps (see accompanying poster). In a postmortem COVID patient vGluT2 immunostaining displayed quantitative, nucleus specific alterations compared to control cases, which can, at least partially, explain some of the post COVID symptoms. Our approach allows large scale quantitative characterization of excitatory afferents and its alteration in pathological cases of human ATh and can lead to a rational segmentation of human thalamus.

FROM SKULL TO BRAIN: 3D DENSITY MAPS OF CORTICAL SULCI AS A POWERFUL TOOL FOR PALEONEUROLOGY

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Edwin De Jager[1], Laurent Risser[2], Muriel Mescam[3], Caroline Fonta[3], Amélie Beaudet[1,4,5]
[1]Cambride, Department Of Archaeology, Cambridge, United Kingdom, [2]Institute de mathématiques de Toulouse, University Of Toulouse, Toulouse, France, [3]CerCo (Brain and Cognition Research Center), Cnrs -university Of Toulouse, Toulouse, France, [4]University of Witwatersrand, School Of Geography, Archaeology And Environmental Studies, Johannesburg, South Africa, [5]Universitat Autònoma de Barcelona, Institut Català De Paleontologia Miquel Crusafont, Barcelona, Spain

The timing and emergence of derived cerebral features in the human linage remains a key question in palaeoneurology. In order to reconstruct a timeline of hominin brain evolution using the fossil record, palaeoneurologists have to rely on endocasts which are replicas of the inner table of the bony braincase. The accurate identification of cerebral sulci imprints in endocasts is critical for assessing the topographic extension and structural organisation of cortical regions. This study aims to provide the first documentation of sulcal pattern imprints from the superolateral surface of the cerebrum using a population based atlas technique on extant human endocasts. Human crania from the Pretoria Bone Collection (South Africa) were scanned using micro-CT. Endocasts were virtually extracted, and sulci were automatically detected and manually labelled. A density map method was applied to project all the labels onto an averaged endocast and to visualise the mean distribution of each identified sulcal imprint. This method allowed for the visualisation of inter-individual variation of sulcal imprints, e.g., frontal lobe sulci, correlating with previous brain-MRI studies, and for the first time the extensive overlapping of imprints in historically debated areas on the endocast (e.g., occipital lobe). In providing an innovative, non-invasive, observer-independent method to investigate human endocranial structural organisation, our analytical protocol introduces a promising perspective for discussing critical hypotheses on the evolution of cognitive abilities among hominins. ***Acknowledgements:*** *We thank the South Africa/France (PROTEA) Joint Research Programme (grant number 129923) and the University of Cambridge Harding Distinguished Postgraduate Scholars Programme for financial support.*

Sulcal pattern variation in extant human endocasts.
Our knowledge of human brain evolution primarily relies on the interpretation of palaeoneurological evidence. In this context, an endocast or replica of the inside of the bony braincase can be used to reconstruct a timeline of cerebral changes that occurred during human evolution, including changes in topographic extension and structural organisation of cortical areas. These changes can be tracked by identifying cerebral imprints, particularly cortical sulci. The description of these crucial landmarks in fossil endocasts is, however, challenging. High-resolution imaging techniques in palaeoneurology offer new opportunities for tracking detailed endocranial neural characteristics. In this study, we use high-resolution imaging techniques to document the variation in extant human endocranial sulcal patterns for subsequent use as a platform for comparison with the fossil record. We selected 20 extant human crania from the Pretoria Bone Collection (University of Pretoria, South Africa), which were detailed using X-ray microtomography at a spatial resolution ranging from 94 to 123 µm (isometric). We used Endex to extract, and Matlab to analyse the cortical imprints on the endocasts. We consistently identified superior, middle and inferior sulci on the frontal lobe; and superior and inferior sulci on the temporal lobe. We were able to label sulci bordering critical functional areas such as Broca's cap. Mapping the sulcal patterns on extant endocasts is a prerequisite for constructing an atlas which can be used for automatic sulci recognition.

Visualization Within the Ventricles of the Brain: A Micro-Focus X-Ray Study.
Conceptualization of the ventricular system of the brain by macroscopic studies is complicated by the lack of physical structure of these interconnected cavities. Dissection procedures designed to display the structures in the walls of the ventricles are destructive and not conducive for the appreciation of the ventricular system in its entirety. The application of Micro-focus X-ray tomography affords the possibility to appreciate hidden structures in a nondestructive manner. The aim of

this study was to explore the possibility of using micro-focus X-ray tomography in the three-dimensional (3D) visualization of the ventricular system as well as the various neuroanatomical structures within its walls for educational purposes. Randomly selected embalmed human cadaver brains were scanned at Necsa (South African Nuclear Energy Corporation) housing the MIXRAD laboratory consisting of a Nikon XTH 225 ST micro-focus X-ray tomography facility. A 3D flythrough video of the ventricular system was reconstructed from these scans using software to view the inner surface of the ventricles. Micro-focus X-ray tomography provides feasible means of delivering high-resolution images in a nondestructive way to design a representation of the ventricular system. In addition, structures in the walls of the ventricular system could be appreciated in a novel way. It is envisaged that this 3D-fly-through video of the ventricular system will be valuable when integrated with standard prosections and atlas pictures in the educational setting. Further studies evaluating the use of this integrative visualization of the ventricular system of the brain for its applicability in the educational setting should be performed. The endocast of StW 573 ("Little Foot") and hominin brain evolution.
One of the most crucial debates in human paleoneurology concerns the timing and mode of the emergence of the derived cerebral features in the hominin fossil record. Given its exceptional degree of preservation and geological age (i.e., 3.67 Ma), StW 573 ('Little Foot') has the potential to shed new light on hominin brain evolution. Here we present the first detailed comparative description of the external neuroanatomy of StW 573. The endocast was virtually reconstructed and compared to ten southern African hominin specimens from Makapansgat, Malapa, Sterkfontein and Swartkrans attributed to Australopithecus and Paranthropus. We apply an automatic method for the detection of sulcal and vascular imprints. The endocranial surface of StW 573 is crushed and plastically deformed in a number of locations. The uncorrected and therefore minimum cranial capacity estimate is 408 cm and plots at the lower end of Australopithecus variation. The endocast of StW 573 approximates the rostrocaudally elongated and dorsoventrally flattened endocranial shape seen in Australopithecus and displays a distinct left occipital petalia. StW 573 and the comparative early hominin specimens share a similar sulcal pattern in the inferior region of the frontal lobes that also resembles the pattern observed in extant chimpanzees. The presumed lunate sulcus in StW 573 is located above the sigmoid sinus, as in extant chimpanzees, while it is more caudally positioned in SK 1585 and StW 505. The middle branch of the middle meningeal vessels derives from the anterior branch, as in MH 1, MLD 37/38, StW 578. Overall, the cortical anatomy of StW 573 displays a less derived condition compared to the late Pliocene/early Pleistocene southern African hominins (e.g., StW 505, SK 1585).

Are endocasts reliable proxies for brains? A 3D quantitative comparison of the extant human brain and endocast.
Endocasts (i.e., replicas of the inner surface of the bony braincase) constitute a critical proxy for qualifying and quantifying variations in brain shape and organization in extinct taxa. In the absence of brain tissues preserved in the fossil record, endocasts provide the only direct evidence of brain evolution. However, debates on whether or not information inferred from the study of endocasts reflects brain shape and organization have polarized discussions in paleoneurology since the earliest descriptions of cerebral imprints in fossil hominin crania. By means of imaging techniques (i.e., MRIs and CT scans) and 3D modelling methods (i.e., surface-based comparisons), we collected consistent morphological (i.e., shape) and structural (i.e., sulci) information on the variation patterns between the brain and the endocast based on a sample of extant human individuals (N = 5) from the 3D clinical image database of the Steve Biko Academic Hospital in Pretoria (South Africa) and the Hôpitaux Universitaires Pitié Salpêtrière in Paris (France). Surfaces of the brain and endocast of the same individual were segmented from the 3D MRIs and CT images, respectively. Sulcal imprints were automatically detected. We performed a deformation-based shape analysis to compare both the shape and the sulcal pattern of the brain and the endocast. We demonstrated that there is close correspondence in terms of morphology and organization between the brain and the corresponding endocast with the exception of the superior region. By comparatively quantifying the shape and organization of the brain and endocast, this work represents an important reference for paleoneurological studies.

Adapted full-face snorkel masks as an alternative for COVID-19 personal protection during aerosol generating procedures in South Africa: A multi-centre, non-blinded simulation study.
SARS-CoV-2 has resulted in increased worldwide demand for personal protective equipment (PPE). With pressure from ongoing epidemic and endemic episodes, we assessed an adapted snorkel mask that provides full-face protection for healthcare workers (HCWs), particularly during aerosol-generating procedures. These masks have a custom-made adaptor

which allows the fitment of standard medical respiratory filters. The aim of this study was to evaluate the fit, seal and clinical usability of these masks.

DETECTION OF CEREBRAL ANEURYSM AND INTRACRANIAL VERTEBRAL DISSECTION USING NON-ENHANCED MAGNETIC RESONANCE IMAGING IN EMERGENCY SETTING: EMPHASIS ON MAGNITUDE IMAGE OF SUSCEPTIBILITY-WEIGHTED IMAGE

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Dae Woong Bae
St. Vincent's Hospital, Neurology, Suwon, Korea, Republic of

Purpose: To evaluate image features and diagnostic performance of susceptibility-weighted image (SWI) in detection of intracranial vertebral artery dissection (VAD) and unruptured intracranial aneurysm (UIA). **Materials and methods**: From January 2015 to December 2021, symptomatic patients who underwent 3.0 T MR SWI were recruited. For study group, transfemoral cerebral angiography-proven lesions were included, while 1:1 matched control group with MR angiography were included. Image features of SWI were evaluated. Diagnostic performance and interobserver agreements were calculated for detecting VAD with stenosis and UIA greater than 7 mm. **Results:** Total of 110 patients (mean age: 60.92 years, female: 60/110) were included. In the study group (N=55), 21 patients (38.2%) had VAD, while 34 patients (61.8%) had UIA. For SWI-detectable VAD, larger parent artery (PA)-dilatation ratio was observed (1.36 vs. 1.84, p = 0.034). For SWI-detectable UIA, larger PA-dome ratio (1.32 vs. 1.90, p = 0.020) and larger PA-height ratio (1.25 vs. 1.77, p = 0.005) were observed. The diagnostic performance and kappa values for VAD with stenosis were as follow: sensitivity: 91.7 (95% CI: 61.5 – 99.8); specificity: 93.9 (95% CI: 87.2 – 97.7); κ: 0.80. The diagnostic performance for UIA larger than 7 mm were as follow: sensitivity: 87.5 (95% CI: 47.4 – 99.7); specificity: 95.1 (95% CI: 88.9 – 98.4); κ: 0.73. **Conclusion**: SWI-detectable lesions were VAD with larger PA-dilatation ratio, and UIA with larger PA-dome ratio, and PA-height ratio. SWI was able to accurately detect VAD with stenosis and UIA larger than 7 mm with substantial interobserver agreements.

Université de Tours, Umr 1253 Inserm, Tours, France

Aims: Ultrasound neurostimulation (USNS) is a promising modality for rewiring brain pathways and treating non-invasively neuropsychological disorders with high spatiotemporal resolution. However, the optimal USNS parameters for successful brain stimulation warrants further investigation. Here, we investigated the influence of the pair ultrasound frequency/focal spot diameter on motor response and neuronal activity in mice. **Methods:** We transcranially administered USNS to the mouse motor cortex (M1) using eight single-element focused transducers operating at 0.2MHz, 0.4MHz, 0.5MHz and 1MHz. For each frequency, two transducers of different diameters/focal lengths were used. For a given pair of frequency/focal spot, mice were exposed to series of progressively increasing peak negative pressures (PNPs) to evaluate visually the motor responses and then the success rate. Next, stimulations at the highest used PNP were applied to further investigate the corresponding neuronal activity using c-Fos immunostaining. **Results:** Our results showed that the success rate increased significantly with PNP regardless of the frequency and the focal spot diameter. Moreover, significant difference in the success rates was observed when changing the focal spot diameter at a given frequency, wide acoustic beams induce higher success rates. In contrast, the analysis of c-Fos expression revealed that USNS significantly enhanced neuronal activation in the M1 when the focal spot diameter decreased. **Conclusions:** Our data demonstrate that the use of larger focal spots evoked motor responses at the lowest PNPs, while smaller focal spots are required to enhance neuronal activation. Further investigation is required to explore USNS-related changes in excitability and functionalities of the brain circuitries.

NANOTAG – A NOVEL ANTIBODY-FREE APPROACH FOR EPIGENOMIC PROFILING

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Maria Dimitriu, Isabelle Mansuy
Laboratory of Neuroepigenetics, Brain Research Institute, University of Zurich and Institute for Neuroscience, ETH Zurich, D-hest, Zurich, Switzerland

The expression of genes is regulated by numerous molecular processes inside the nucleus, including posttranslational modifications of histones, the binding of transcription factors to the DNA, and chromatin accessibility. The ability to obtain genome-wide information about these reversible processes provides great insight into the mechanistic regulation of gene expression. Currently, several methods exist to facilitate the profiling of transcription factor binding sites and histone modifications, including chromatin immunoprecipitation followed by sequencing (ChIP-seq) and more recent alternatives, such as cleavage under targets and release using nuclease (CUT&RUN) and cleavage under targets and tagmentation (CUT&Tag), which can be easily applied to low amounts of cells. However, these methods rely on the use of antibodies to capture target sites in the genome, which has disadvantages such as antibody unspecificity and long processing times. Here, we propose a novel method for epigenomic profiling that allows profiling of transcription factors or histone modifications and chromatin accessibility simultaneously in the same cells without antibodies. This approach called NanoTag relies on a protein fusion between the Tn5 transposase and an antibody mimetic, such as the anti-GFP nanobody, to target fusion Tn5 to sites in the genome where the target is localized. This approach is easy, significantly shortens processing times, and reduces background. It provides an additional level of resolution to chromatin accessibility studies applicable to neurosciences.

SPECIFIC DETECTION AND DELETION OF THE SIGMA-1 RECEPTOR IN NEURONS AND GLIAL CELLS FOR FUNCTIONAL CHARACTERIZATION IN VIVO

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Qing Liu[1], Qilin Guo[1], Li-Pao Fang[1], Honghong Yao[2], Anja Scheller[3], Frank Kirchhoff[4], Wenhui Huang[1]
[1]CIPMM, University of Saarland, Molecular Physiology, Homburg, Germany, [2]Southeast University, 2. department Of Pharmacology, Nanjing, China, [3]University of Saarland, Department Of Molecular Physiology, Cipmm (center For Integrative Physiology And Molecular Medicine), Homburg, Germany, [4]University of Saarland, Center For Integrative Physiology And Molecular Medicine, Homburg, Germany

The chaperon protein sigma-1 receptor (S1R) has been discovered for over forty years. Recent pharmacological studies using S1R exogenous ligands demonstrated a promising therapeutical potential of targeting the S1R for many neurological disorders. Although intensive *in vitro* studies have revealed S1Rs are mainly residing at membranes of the endoplasmic reticulum (ER), the cell-specific in vivo expression pattern of the S1R is still unclear, mainly due to the lack of a reliable detection method which also prevented a comprehensive functional analysis. Here, first, we identified a highly specific antibody using S1R knockout (KO) mice and established an immunohistochemical protocol involving a 1% SDS antigen retrieval step. Second, we characterized the S1R expression in the mouse brain and can demonstrate that the S1R is widely expressed: in principal neurons, interneurons, and all glial cell types. Finally, we generated a novel Cre-dependent S1R conditional KO mouse (S1R flox) to study cell type-specific functions of the S1R. As a proof of concept, we successfully ablated S1R expressions in neurons or microglia employing neuronal and microglial Cre-expressing mice, respectively. In summary, we provide powerful tools to cell-specifically detect, delete and functionally characterize S1Rs *in vivo*.

IMPROVED NEUROCOGNITIVE OUTCOME IN THE SHORT-TERM FOLLOWING PRIMARY GAMMA KNIFE RADIOSURGERY (GKRS) FOR INTRACRANIAL VASCULAR ANOMALIES

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Ruchita Rana, Manju Mohanty, Manjul Tripathi, Sunil Gupta, Kanchan Mukherjee
Postgraduate Institute of Medical Education and Research, Neurosurgery, Chandigarh, India

Objective: To evaluate the effect of GKRS on cognitive functions of patients with vascular anomalies. Methods: A total of 55 patients having vascular anomalies: arteriovenous malformation (AVM) = 37 and cavernous malformation (CM) = 18 without any comorbidities between 2018-2019 were included. Clinical (subjective), radiological (1.5 T MRI), and a multi-domain neuropsychological battery (memory, executive functioning, attention, intelligence) were performed on them pre-GKRS and 6 (n=48) months post-GKRS. Results: Baseline neurocognitive statistical analysis was done on basis of 1. lesion characteristics- hemisphere involved, lesion site, lesion type, lesion volume, and 2: sociodemographic variables- gender, age group, and education group. Before GKRS, it was reported that the CM group performed better than the AVM group in domains of immediate verbal recall (p=0.000*), verbal delayed recall (p=0.012*), and MMSE (p=0.034*). The higher education group performed significantly better in almost all the cognitive domains. No significant difference was seen in the hemisphere involved, lesion site, gender, and age group at pre-GKRS. It was observed that at 6 months, significant improvement was seen in almost all cognitive domains variable except for phonemic fluency, semantic fluency, and psychomotor speed domain variables. At 6 months, 1 patient had subjective complaints of headache and another patient had 2 episodes of seizure. Radiologically the lesion of both patients was static. Rest all patients showed improvement symptomatically. Conclusion: Apart from symptomatic and radiological improvement (resolution of vascular malformations), significant improvement of neurocognitive domains at 6 months ensures a landscape of better neurocognitive outcome and quality of life after GKRS.

DEVELOPMENT OF A VERSATILE AND COST-EFFICIENT AUTOMATED PLATFORM FOR BRAIN TISSUE MICRODISSECTION, SINGLE CELL ACQUISITION AND ADHESION ANALYSIS

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Stanislav Karsten, David Ma, Zhongcai Ma, Lili Kudo
NeuroInDx, Inc., R&d, Torrance, United States of America

Sophisticated approaches such as laser-based microdissection and cell sorting must be used to acquire specific cells or subanatomical regions from heterogeneous brain tissues. Some of their methodological limitations include tissue preprocessing for laser assisted approaches and conversion of tissue to a suspension of cells for sorting technologies. Moreover, none of the existing instruments provide concurrent single cell acquisition and adhesion force measurement. We have developed an automated and cost-efficient platform for brain tissue microdissection, single cell acquisition, measurements of its adhesion strength and deposition of collected samples into single wells for further molecular analysis or clonal expansion. The platform is based on the capillary based on our vacuum pulse assisted technology with incorporated pressure sensor. Collected volumes are compatible with any downstream single cell analyses such as next generation sequencing. Here, we demonstrate its capabilities for microdissection of fresh and fixed brain tissues, including brain organoid cultures, and isolation of individual cells from various adherent cell lines. Furthermore, cell adhesion force measurements were performed for cells grown on eight different substrates including non-treated, poly-L-lysin, laminin, fibronectin, collagen, gelatin, amin and carboxyl surfaces. This cell adhesion measurement function was incorporated into the main instrument’s software permitting automated analysis and collection. In conclusion, a versatile platform for tissue microdissection, single cell acquisition and adhesion strength measurements was developed that allows for further genomics studies to correlate cell’s location and phenotype with underlying molecular program.

AIMS The role of gut microbiota in neurodegeneration is becoming an interesting topic and supports the need of novel in vitro tools for its investigation through the dissection of the biochemical pathways involved in the so-called microbiota-gut-brain axis. The ERC-funded project “MINERVA” aims at developing an innovative multiorgan-on-a-chip platform by connecting ad hoc developed organ-on-a-chip devices. Here, we describe the biological validation of the innovative device we developed through the challenging of the gut epithelium of our featured microbiota-gut-brain final platform. METHODS The gut-on-a-chip device was developed by using gut epithelial Caco-2 cells, and characterized by computational simulations jointly with an experimental set of assays including morphology observation, viability tests, trans epithelial electrical resistance (TEER) measure and immunofluorescence assays. RESULTS The device did not alter Caco-2 cell viability, and suitable TEER values have been detected. Morphological analysis confirmed mature cell layer formation with evident villi structures and proper physiologic expression of tight junctions. CONCLUSION Our results confirmed that our innovative device is a suitable tool to model gut epithelium and pave the way to the serially connection of our devices to build up our ERC project microbiota-gut-brain axis platform. ACKNOWLEDGMENT MINERVA project has received funding from the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation programme (Grant Agreement N° 724734).

GENE EXPRESSION OF THE OXYTOCIN RECEPTOR, C-FOS, AND CGRP IN THE TRIGEMINAL GANGLION IN AN OROFACIAL PAIN MODEL

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Péter Gedei, Heni El Heni, Laura Pálvölgyi, Ivett Kozma-Szeredi, Judit Rosta, Gyöngyi Kis
University of Szeged, Department Of Physiology, Albert Szent-györgyi Medical School, Szeged, Hungary

The most devastating pain conditions include orofacial pain disorders. Binding and activating its receptor in primary sensory neurons of the peripheral sensory system, the hypothalamic nonapeptide, oxytocin is supposed to have an antinociceptive role. The purpose of this work was to investigate the gene expression of the oxytocin receptor (OTR), a marker of neuronal activity, c-Fos, and a characteristic neurotransmitter of a substantial portion of the trigeminal afferents, calcitonin gene-related peptide (CGRP) in the trigeminal ganglion (TG) using an animal model of inflammation-induced orofacial pain. Adult Wistar rats (250-300 g) received unilateral injection of carrageenan (100 µl, of 2% w/v) into their vibrissal pads. OTR, c-Fos, and CGRP mRNA expression levels in the TGs were analysed using RT-qPCR. In TGs ipsilateral to the injection site, both the c-Fos and the CGRP mRNAs exhibited higher expression levels, and a moderate increase was observed regarding the OTR mRNA expression one day after the carrageenan administration, compared to controls. The increase in the c-Fos and the CGRP mRNA expression shows that the inflammatory substance injected into the orofacial area stimulates the peptidergic neurons in the TG. Furthermore, we believe that oxytocin can impact the degree of pain transmitted by inflammation-triggered nociceptive neurons by increasing signalling capability due to the increased OTR expression. Since the effects seen in the animal model are similar to those for people, they may contribute to develop new therapies for orofacial pain relief that target the OTRs.

Brain Organ-on Chips (OoC) is the creation of humanized neural networks culture in relevant microfluidic compartmentalization architecture with the possibility to analyze specific readouts such as functional activity recording. In order to further explore the potential of Brain-on-Chips for preclinical trials and to trigger the adoption by the scientific community, cell culture protocols need to be standardized to achieve a high reproducibility. Here, we present a methodology to control the microfluidic system variability, to optimize culture protocol adapted to specifics of microfluidic technology and to establish analytical methods including validation criteria to quantify axonal outgrowth/ functional activity. We established specific protocols to maintain differentiated neurons derived from hiPSCs (glutamatergic, GABAergic, dopaminergic, motor and sensory neurons) in microfluidic devices. For each cell type, we evaluated the (i) cell morphology and long-term viability, (ii) expression of pluripotency and biological markers by immunofluorescence approach, (iii) growth kinetics and (iv) electrophysiological recordings using multielectrode array (MEA). Reproducibility of cell culture was assessed using semi-automatic image analysis using several cell providers and operators. To conclude, we have applied our methodology to characterize five different neural types, for which Standard Operating Procedures (SOPs) have been developed. We determined and validated specific cell culture renewal media in our devices. We suggest that this validation methodology should be an essential point when using Organ-on-Chip and to facilitate the regulatory acceptance during medicinal product development. Our hope is to open the route to standardize neural cultures for Brain-on-Chip applications.

Alternative methods, such as predictive human-based *in vitro* models are in the spotlight of regulatory bodies. Organs- and Organoids-on-Chips (OoCs) technologies have shown a great potential to reduce the cost and ethical burden of animal studies. Cerebral organoids now appear as a powerful tool to understand complex biological processes with the ability to mimic and recapitulate many features of the human brain. One of the main current challenges is the cell apoptosis described in the center of cerebral organoids leading to a lack of maturation. This is caused by a lack of oxygenation and nutrient supply in the center of this 3D structure. Our objective is to propose an innovative microfluidic system allowing the generation of reproducible cerebral organoids. Here, we develop a microfluidic device with (i) a 3D-Deposition chamber compatible with organoid generation protocol and allowing the developing organoid to expand up to 4 mm in diameter, (ii) a controlled flow to improve exchanges of oxygen, nutrients, and bioactive compounds, and (iii) the compatibility with automation processes to meet the expectations of scientists and pharmaceutical companies. In conclusion, 3D microfluidic *in vitro* models will open the field of multi-OoCs to study toxicology (ADME-tox), as well as the delivery and screening of molecules that target the brain under more physiologically relevant conditions.

CSF-PRODUCING CHOROID PLEXUS ORGANOIDS MODEL PATHOGEN AND DRUG ENTRY TO THE BRAIN

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Laura Pellegrini
MRC-Laboratory of Molecular Biology, Cell Biology, Cambridge, United Kingdom

The choroid plexus (ChP) is a highly conserved secretory tissue in the brain. This tissue displays a number of important functions in the brain such as forming a protective epithelial barrier and secreting the cerebrospinal fluid (CSF). The CSF is important for the maintenance of physiological levels of nutrients in the brain, for transport of signalling molecules and growth factors and for its protective role in the regulation of intracranial pressure. To explore the role of the ChP-CSF system, we recently established a protocol to generate ChP organoids using a combination of signalling molecules that are physiologically present during the stages of development of this tissue. These organoids develop ChP and recapitulate fundamental functions of this tissue, namely secretion and formation of a tight epithelial barrier. Combining single-cell RNA-sequencing with immunohistochemical and EM validation, we detected the presence of ChP specific channels and transporters localised on the apical brush border of the ChP epithelium. By testing different compounds, we were able to demonstrate the selective permeability of the ChP barrier in vitro, using NMR. In addition, we noticed the formation of large fluid-filled cysts protruding from the organoids, the contents of which, analysed by mass spectrometry, highly resembles human CSF. Finally, we used this model to test pathogen entry in the brain and we infected the organoids with live SARS-CoV-2. We found that SARS-CoV-2 infects ChP epithelial cells causing damage of this key brain barrier.

A NOVEL PLATFORM FOR FLUIDIC INTERFACING WITH THE BRAIN

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Simone Marcigaglia, Sebastian Haesler
Neuro-Electronics Research Flanders (NERF), Department Of Neuroscience, Leuven, Belgium

The blood-brain barrier (BBB) is a comprehensive set of adaptations in the brain vasculature that ensure compartmentalisation of the neural environment. Any form of systemic intervention is therefore highly hindered by the intrinsic ability of the injected agent to cross the barrier itself. In most applications where efficacy and targeting are paramount, psychoactive agents are generally infused directly into the structure of interest by means of a technique known as convection-enhanced delivery (CED). However, despite its promise of intraparenchymal delivery, CED can still fail to guarantee consistent results due to the reflux of infusate along the insertion track. Within this project, we explored the use of the latest additive manufacturing techniques (i.e. two-photon polymerization) to design an application-specific catheter for pressure-controlled infusions in different animal models. We then proved an increased likelihood of reflux-free infusions both in a brain surrogate and in a mouse model. The presence of the BBB is an equivalent obstacle in the identification of circulating markers of disease. In this context, we exploited the same microfabrication technique to investigate the possibility of sampling circulating cerebrospinal fluid (CSF) in a longitudinal manner. We demonstrated the ability to obtain intraventricular CSF samples that present no blood contamination and at a frequency of extraction that greatly exceeds the alternative technique (i.e. cisterna magna extraction).

Objective: The advent of ultrasensitive assay technologies has enabled the measurement of very low-abundance blood-based biomarkers of neurodegenerative conditions, reducing the need for invasive cerebrospinal fluid (CSF) collection. Blood-based neurological biomarkers allow for large scale sample acquisition and screening in research, and allows for the early detection of the transition from healthy to diseased status. We have developed an assay for the detection of neurofilament light chain (NfL) in human serum, plasma and CSF samples in healthy and diseased states. NfL is a valuable neurodegenerative biomarker for accessing progression and treatment of Alzheimer's Disease (AD), Multiple Sclerosis (MS) and Huntington's Disease. Methods: Rigorous assay development procedures were undertaken to produce an NfL immunoassay capable of accurately and reproducibly detecting NfL in human serum, plasma, and CSF samples. Results: A robust kit capable of generating consistent and reliable NfL measurements at sub-pg/mL concentrations has been developed and characterized using Single Molecule Counting (SMC™) ultrasensitive immunoassay technology. The developed assay demonstrates excellent performance characteristics for spike/recovery values and dilutional linearity (90-110% for all three matrices). NfL was detected in all sample types tested. Increased NfL sample levels in AD and MS samples as compared to normal serum, plasma and CSF samples was also observed. Additional data is presented to compare SMC™ NfL results to competitor platform results, as well as multi-site consistency of results utilizing matched samples. Conclusions: Our SMC™ NfL immunoassay kit provides a valuable ultrasensitive tool for NfL research in the areas of neurodegenerative disease and neurological injury.

VAS-O-MATIC: A FIJI PLUGIN FOR MICROSCOPY ANALYSIS OF BLOOD-BRAIN BARRIER ORGANIZATION

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Audrey Chagnot, Daniela Garcia, Dorota Stefancova, Conor Mcquaid, Axel Montagne
University of Edinburgh, Uk Dementia Research Institute, Edinburgh, United Kingdom

Background: In brain, the pericytes enwrapping the microvasculature are major contributors of the blood-brain barrier (BBB) homeostasis. Loss of pericyte coverage is observed in aging and the resulting disruption of the BBB might trigger the onset of neurodegenerative diseases. However, measurement of pericyte coverage is often manual, time-consuming and hence restricted to a few regions of interest. Further, controversy in the field arose due to methodology discrepancy between teams. Here, we provide an automated method for fast and accurate pericyte coverage analysis of entire brain regions. **Methods:** We used FIJI to create Vas-o-Matic, a macro for accurate pericyte coverage measurement in relation to vessel diameter. Vas-o-Matic segments the image into portions which are processed independently to quantify structure metrics along the vascular tree. We compared Vas-o-Matic performance to conventional manual analysis by a human expert on brain slices from young and aged mice. **Results:** Vas-o-Matic dramatically reduced the time spent on measures from the images and allowed diameter-wise analysis of pericyte loss. Power of the analysis was also greatly increased due to thousands of individual measures on whole brain structures. Complementary analyses of the degradation of the vascular basement membrane and of the loss of astrocyte endfeet coverage provided the proof of principle that Vas-o-Matic can be used beyond pericyte coverage and for any component of the BBB. **Conclusions:** Vas-o-Matic is a robust and fast method for the analysis of the fine structure of the BBB.

DEEP LEARNING AUTOMATIC DETECTION AND QUANTIFICATION OF ADULT NEURAL PROGENITORS REVEALED BY DOUBLE THYMIDINE ANALOG LABELING AND CONFOCAL MICROSCOPY

POSTER SESSION 05 - SECTION: EMERGING TECHNOLOGIES & METHODS

Ana Carolina Palave[1], Andrés Gomez Caram[2], Waldemar Lopez[2], Maria Castello[1]
[1]Desarrollo y Evaluación Neural, Depto Neurociencias Integrativas y Computacionales, Instituto De Investigaciones Biológicas Clemente Estable, Montevideo, Uruguay, [2]Cogniflow, Ai, Montevideo, Uruguay

Neurogenesis, a complex process central to brain development and plasticity, occurs at the neural stem cell niches (NSCN). To characterize NSCN´s cellular composition using double thymidine analogue labelling technique, it is required the detection and quantification of each type of neural progenitors. As these are “rate-determining steps”, we used Cogniflow to automatically identify and quantify neural progenitors cell types revealed by 5 chlorodeoxiuridine (CldU) and 5 Iododeoxiuridine (IdU) double labelling (separated by short and long chases) in adult *Gymnotus omarurom*. The challenge was approached as an Object Detection (OD) task, using a YOLOv5 architecture: models trained to detect CldU+, IdU+ and double labeled (DL) progenitors. We manually labeled confocal images surrounding each nucleus with a class assigned (CldU+, IdU+ or DL) rectangular bounding box. Images were splitted into training (80’%) and validation (20%) sub-datasets. We analyzed the precision of the model as a function of datasets size: 1) 20 confocal images including 264 objects (59 CldU+, 71 IdU and 134 DL) and 2) 30 images (387 objects: 197 for DL, 99 CldU+ and 91 IdU+). To assess the OD task, we used the MeanAveragePrecision@0.5 (mAP@0.5) that considers how precision and recall perform (Intersection over Union threshold= 0.5). The model achieved mAP@0.5 of 69.0% and 72% for 20 and 30 images, respectively. This encouraging result shows the power of the model to perform well even with a small dataset and indicates the importance of increasing the size of data to train future models.

PAIN-INDUCED ADAPTATIONS IN THE CLAUSTROCINGULATE PATHWAY

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Niels Ntamati, Mario Acuna, Thomas Nevian
University of Bern, Department Of Physiology, Bern, Switzerland

Pain is a common and complex medical concern that poses a major threat to a person's quality of life. In both humans and other animals, chronic pain is associated with increased activity in the anterior cingulate cortex (ACC), a brain region implicated in the control of attentional and emotional processes. The ACC is nested in a broad cortical and subcortical network whose coordinated activity is thought to give rise to the experience of pain. It is largely unknown, however, how many of these structures adapt to persistent pain states. The present study explores for the first time the role of the claustrum – a thin and functionally elusive structure reciprocally connected to the ACC – in pain processing. Using a combination of *ex vivo* electrophysiology, *in vivo* calcium imaging and chemogenetic approaches, we show that nociceptive stimuli are encoded in the claustrum and that its inhibition can reversibly attenuate mechanical allodynia in a mouse model of complete Freund's adjuvant (CFA)-induced inflammatory pain. Additionally, we reveal differential changes in intrinsic and spontaneous activity of ACC-projecting and non-projecting CLA neurons, along with a weakened synaptic efficacy onto layer 5 ACC pyramidal neurons following prolonged pain. Altogether, our results suggest a role for the claustrocingulate pathway in the modulation of pain behaviors, and open up new avenues of research into the contribution of the CLA in sensory and affective processing.

THE NEURAL CORRELATES OF ACUTE AND CHRONIC PAIN IN SLEEP AND WAKE

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Raquel Adaia Sandoval Ortega[1], Margot Renard[1], Mike Cohen[2], Thomas Nevian[1]
[1]University of Bern, Department Of Physiology, Bern, Switzerland, [2]Radboud University, Donders Institute For Brain, Cognition And Behavior, Nijmegen, Netherlands

Mechanical pain is processed by the lateral and the medial pain pathways, which code for the sensory-discriminative and the affective-motivational aspects of the experience of pain, respectively. And while in wake the neural correlates of the pain experience are largely revealed, they remain to be elucidated while in sleep. Here we performed multisite electrophysiological recordings in the hind-limb primary somatosensory cortex (S1HL) and the anterior cingulate cortex (ACC) to evaluate the sensory and the emotional processing of pain during the natural sleep cycle of mice in the light phase. In some sessions, animals received mechanical painful stimuli to the planar surface of the hind paws. Our results show for the first time that acute pain reaches both cortices and is processed during natural sleep in mice. In addition, we have observed that high power in low frequencies (1-16 Hz) protect sleep by either suppressing awakening, motor responses or both response types. Interestingly, analysis of the scale-free properties of the S1HL and ACC local field potentials reveals that chronic pain increases the scaling exponents differntly in wake and sleep. This may be indicative of a deficient modulation in the local network that could affect the excitatory-inhibitory balance. Thus, compromising the sensory and emotional processing of pain and, ultimately, impairing behaviour. In summary, these results indicate that the emotional processing of pain remains intact during sleep and that the changes that chronic pain causes in the local network settle rapidly and are long lasting in sleep.

REAL-TIME DECODING OF SPONTANEOUS PAIN FROM TWO-PHOTON MICROSCOPY IMAGES OF BRAIN CELLULAR CALCIUM USING DEEP LEARNING

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Heera Yoon[1], Myeong Seong Bak[1], Seung Ha Kim[2], Ji Hwan Lee[1], Geehoon Chung[1], Sang Jeong Kim[2], Sun Kwang Kim[1]
[1]Kyung Hee University College of Korean Medicine, Department Of Physiology, Seoul, Korea, Republic of, [2]Seoul National University School of Medicine, Department Of Physiology, Seoul, Korea, Republic of

Chronic pain remains intractable in millions of patients worldwide. Spontaneous ongoing pain is a major clinical problem of chronic pain and extremely challenging to diagnose and treat compared to stimulus-evoked pain. Although extensive efforts have been made in preclinical studies, there still exists a mismatch in focused pain type between animals and human (i.e. evoked vs. spontaneous), which obstructs the translation of knowledge from preclinical animal models into objective diagnosis and effective new treatments. Here, we developed a deep learning algorithm, named AI-bRNN (Average training, Individual test-bidirectional Recurrent Neural Network), to decode spontaneous pain from brain cellular Ca^{2+}signals recorded by two-photon microscopy imaging in awake, head-fixed mice. AI-bRNN robustly determines the intensity and time point of spontaneous pain even in chronic pain models, and evaluates the efficacy of analgesics in real time. Furthermore, AI-bRNN could be applied to various cell types (neurons and glia), brain areas (cerebral cortex and cerebellum) and somatosensations (itch and pain), proving its versatile performance. These results suggest that our approach offer a clinically relevant, quantitative and real-time preclinical evaluation platform for pain medicine, thereby accelerating the development of new methods for diagnosing and treating human chronic pain patients. **Competing interests** Neurogrin Inc. founded by the authors holds the patent applications related to the contents of this poster abstract (10-2019-0173382 in Korea and PCT/KR2020/006221). **Acknowledgements** This work was supported by grants from the National Research Foundation of Korea funded by the Korean government (NRF-2017M3C7A1025604, NRF-2017M3A9E4057926, and NRF-2019R1A2C2086052 to SKK; NRF-2018R1A5A2025964 and NRF-2017M3C7A1029611 to SJK).

SENSORY AND CONTEXTUAL MODULATIONS OF PAIN ARE SERVED BY SPATIALLY AND SPECTRALLY DISTINCT BRAIN NETWORK PATTERNS

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Felix Bott, Moritz Nickel, Laura Tiemann, Vanessa Hohn, Elisabeth May, Cristina Gil Ávila, Markus Ploner
Technical University of Munich, Neurology, School Of Medicine, Munich, Germany

Aims: Pain arises from the integration of sensory information about threats to the body and contextual information such as an individual's expectations. To better understand how this integration process is implemented in the human brain, we analyzed an experiment in which brief painful stimuli were applied to 48 healthy human individuals. Methods: In the experiment, sensory and contextual information were independently varied by varying stimulus intensity and expectations, respectively. Based on EEG data recorded during the experiment, the analysis investigated frequency specific connectivity patterns in a network comprising six brain regions which are known to be crucially involved in the cerebral processing of pain. Results: We found that sensory and contextual modulations of pain were associated with spatially and spectrally distinct network patterns. Specifically, we found that expectation alters connectivity at alpha frequencies (8-13 Hz) from prefrontal cortex to somatosensory cortex. Moreover, discrepancies between sensory and contextual information (prediction errors) were associated with connectivity changes at gamma frequencies (60-100 Hz) between prefrontal, anterior cingulate and parietal opercular cortex. These connectivity changes complement previous observations that have indicated that commonly analyzed evoked and oscillatory EEG responses to painful stimuli are sensitive to sensory modulations but not to expectations and prediction errors. Conclusion: The findings indicate how spatially and spectrally distinct network patterns serve sensory and contextual modulations of pain.

A NEUROIMAGING STUDY OF THE BRAIN CHANGES DUE TO PERIPHERAL NERVE STIMULATION

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Igor Petrušić[1], Giacomo Valle[2], Marko Dakovic[1], Dusan Damjanovic[1], Marko Bumbasirevic[3], Stanisa Raspopovic[2]
[1]University of Belgrade, Faculty of Physical Chemistry, Laboratory For Advanced Analysis Of Neuroimages, Belgrade, Serbia, [2]ETH Zurich, D-hest, Zurich, Switzerland, [3]University of Belgrade, Faculty of Medicine, Orthopaedic Surgery Department, Belgrade, Serbia

Aims: Bionic device connected through peripheral neural implants to the brain of transfemoral amputee could significantly improve quality of life, sensory-motor performance and also reduce phantom limb pain (PLP). However, the effects of the bionic leg on brain re-organization are not explored yet. We aim to present unique neuroimaging data after the neuroprosthesis removal in a patient with transfemoral amputation. Methods: A 37-year-old patient with a left leg amputation underwent a trial with lower limb neuroprosthesis which was removed after 90-days. The brain activations during phantom and healthy leg movements were recorded using task-based fMRI at two-time points (Session-1: 5-days and Session-2: 95-days) after the neuroprosthesis removal. Also, the Neuropathic Pain Symptom Inventory (NPSI) scale was obtained before, during the training period and after removal. Results: Imagined phantom foot movements during Session-2 demonstrated higher activation compared to Session-1 in the right primary somatosensory cortex. During both sessions activation in the motor area restricted to the hemisphere contralateral to the amputation/prosthetic leg was detected. No significant differences were found between Session-1 and Session-2 when the subject performed the task with a healthy leg. No significant differences in the fractional anisotropy of the corticospinal tracts were found between Session-1 and Session-2. PLP was reduced during the trial and partially increased 3 months after neuroprosthesis removal. Conclusions: This study shows the presence of brain neuroplasticity of sensorimotor cortical area induced by 3 months of training and then removal of a bionic leg. Moreover, this neuroplasticity could be also connected to PLP reduction.

TRIGEMINAL NEUROPATHIC PAIN ALTERS ULTRASONIC VOCALIZATIONS IN RATS RESTORED BY ANALGESIC DRUGS

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Erika Araya
Federal University of Parana (UFPR), Pharmacology, Curitiba, Brazil

The emission of ultrasonic vocalizations (USVs) has been found to be a reliable measure of the emotional state of rodents. Rats emit 50-kHz calls in appetitive and social situations, whereas 22-kHz calls may index a negative state. It has been suggested that chronic pain causes a reduction in 50-kHz calls, but such a reduction may also indicate anxiety-like behavior. Thus, the aim of the present study is to determine pharmacologically whether the decrease in 50-kHz USVs is due to persistent hyperalgesia or anxiety. For this end, chronic constriction injury of the infraorbital nerve (CCI-ION) or sham surgery was performed in 60 days-old male Wistar rats. On the fifteenth day after surgery animals were treated with local lidocaine, midazolam or carbamazepine to determine their effect on facial mechanical hyperalgesia using Von frey filaments. Independent groups were subjected to the USV recording test for the assessment of social emissions followed to the elevated plus maze (EPM) test for anxiety-like behavior detection. The results showed that CCI-ION induced hyperalgesia, which was attenuated with lidocaine or carbamazepine but not by midazolam. They also developed anxiety-like behavior, which was significantly reduced only with midazolam, and showed a lower number of 50-kHz calls compared to sham rats. Lidocaine and carbamazepine increased the 50-kHz calls emitted by CCI-ION rats, but midazolam did not modify them. These data suggest that pain and anxiety coexist in CCI-ION rats, but can be dissociated by pharmacological interventions. Furthermore, measurement of USV may reflect the emotional component of pain and increase translational capability.

Trigeminal neuropathic pain causes changes in affective processing of pain in rats.
Trigeminal neuropathic pain has been modeled in rodents through the constriction of the infraorbital nerve (CCI-ION). Sensory alterations, including spontaneous pain, and thermal and mechanical hyperalgesia are well characterized, but there is a notable lack of evidence about the affective pain component in this model. Evaluation of the emotional component of pain in rats has been proposed as a way to optimize potential translational value of non-clinical studies. In rats, 22 and 50 kHz ultrasonic vocalizations (USVs) are considered well-established measures of negative and positive emotional states, respectively. Thus, this study tested the hypothesis that trigeminal neuropathic pain would result, in addition to the sensory alterations, in a decrease of 50 kHz USV, which may be related to altered function of brain areas involved in emotional pain processing. CCI-ION surgery was performed on 60-day-old male Wistar rats. 15 days after surgery, von Frey filaments were applied to detect mechanical hyperalgesia, and USV was recorded. At the same timepoint, systemic treatment with d,l-amphetamine (1 mg/kg) allowed investigation of the involvement of the dopaminergic system in USV emission. Finally, brain tissue was collected to assess the change in tyrosine hydroxylase (TH) expression in the nucleus accumbens (NAc) and c-Fos expression in brain areas involved in emotional pain processing, including the prefrontal cortex (PFC), amygdala, and NAc. The results showed that CCI-ION rats presented mechanical hyperalgesia and a significant reduction of environmental-induced 50 kHz USV. Amphetamine caused a marked increase in 50 kHz USV emission in CCI-ION rats. In addition, TH expression was lower in constricted animals and c-Fos analysis revealed an increase in neuronal activation. Taken together, these data indicate that CCI-ION causes a reduction in the emission of environmental-induced appetitive calls concomitantly with facial mechanical hyperalgesia and that both changes may be related to a reduction in the mesolimbic dopaminergic activity.

Blockade of kappa opioid receptors reduces mechanical hyperalgesia and anxiety-like behavior in a rat model of trigeminal neuropathic pain.
It has been shown that kappa opioid receptor (KOR) antagonists, such as nor-binaltorphimine (nor-BNI), have antinociceptive effects in some pain models that affect the trigeminal system. Also, its anxiolytic-like effect has been extensively

demonstrated in the literature. The present study aimed to investigate the systemic, local, and central effect of nor-BNI on trigeminal neuropathic pain using the infraorbital nerve constriction model (CCI-ION), as well as to evaluate its effect on anxiety-like behavior associated with this model. Animals received nor-BNI systemically; in the trigeminal ganglion (TG); in the subarachnoid space to target the spinal trigeminal nucleus caudalis (Sp5C) or in the central amygdala (CeA) 14 days after CCI-ION surgery. Systemic administration of nor-BNI caused a significant reduction of facial mechanical hyperalgesia and promoted an anxiolytic-like effect, which was detected in the elevated plus-maze and the light-dark transition tests. When administered in the TG or CeA, the KOR antagonist was able to reduce facial mechanical hyperalgesia induced by CCI-ION, but without changing the anxiety-like behavior. Moreover, no change was observed on nociception and anxiety-like behavior after nor-BNI injection into the Sp5C. The present study demonstrated antinociceptive and anxiolytic-like effects of nor-BNI in a model of trigeminal neuropathic pain. The antinociceptive effect seems to be dissociated from the anxiolytic-like effect, at both the sites involved and at the dose need to achieve the effect. In conclusion, the kappa opioid system may represent a promising target to be explored for the control of trigeminal pain and associated anxiety. However, further studies are necessary to better elucidate its functioning and modulatory role in chronic trigeminal pain states.

Toll-like receptor 4 (TLR4) signaling in the trigeminal ganglion mediates facial mechanical and thermal hyperalgesia in rats.
There is increasing evidence that the toll-like receptor 4 (TLR4) signaling pathway contribute to development of hyperalgesia in the trigeminal system. The aim of the present study was to investigate the role of TLR4 in the trigeminal ganglion (TG) in facial hyperalgesia induced by injection of Lipopolysaccharide (LPS) or intraoral mucosal incision, which is an orofacial postoperative pain model, in male Wistar rats. The TLR4 antagonist (LPS-RS, 20 µg/10 µL) was administrated 30 min before LPS injection into the TG (10 µg/10 µL) or oral mucosa (10 µg/50 µL). In the postoperative pain model, rats were treated with LPS-RS (20 µg/10 µL) into the TG for three consecutive days after the incision. Facial heat and mechanical hyperalgesia were assessed hourly after LPS injection or intraoral incision. In addition, expression of NFκB was assessed in the TG on day 3 after intraoral incision. Our results showed that blockade of TLR4 in the TG attenuated facial heat and mechanical hyperalgesia induced by LPS or by mucosal incision, and that both conditions are associated to increase of phosphorylated NFκB in the TG. In conclusion, the present study suggests that activation of TLR4-NFκB signaling pathway in the TG contributes to the development of facial heat and mechanical hyperalgesia and may contribute to pain in inflammatory oral conditions.

Acute orofacial pain leads to prolonged changes in behavioral and affective pain components.
Acute pain that persists for a few days is associated with a reduction in patients' quality of life. Orofacial persistent pain promotes psychological disorders such as anxiety, impairs daily essential activities such as eating, and results in decreased social interaction. Here, we investigated whether rats subjected to orofacial formalin injection or intraoral incision surgery display persistent facial heat hyperalgesia, ongoing pain, anxiety-like behavior, and changes in ultrasonic vocalization. Orofacial formalin injection or intraoral incision caused facial heat hyperalgesia for 3 days compared with saline-injected and sham animals. In addition, both experimental groups showed a reduction in the number of entries and in the time spent in the open arms in the elevated plus maze test on day 3, suggesting that anxiety-like behavior developed as a consequence of persistent pain. At this time point, both groups also displayed a reduction in the number of 50-kHz calls, specifically in the flat subtype, which suggests a decrease in social communication. Moreover, on day 3 after surgery, systemic morphine produced robust conditioned place preference in rats subjected to intraoral incision compared with sham, and the former group also presented increased spontaneous facial grooming, revealing the presence of ongoing pain. Finally, Western blot and immunohistochemistry analysis showed a reduction in tyrosine hydroxylase expression in the nucleus accumbens, which may reflect a decrease in mesolimbic dopaminergic activity. Altogether, the results demonstrate that acute orofacial pain causes prolonged changes in behavioral and affective pain components, which may be related to dopaminergic changes in the nucleus accumbens.

Characterization of rat ultrasonic vocalization in the orofacial formalin test: Influence of the social context.
Rats emit ultrasonic vocalizations (USVs) about 22 kHz and 50 kHz sound frequency to communicate the presence of

negative or positive emotional states, respectively. The calling behavior may be influenced by several factors, including environmental factors. Likewise, pain behavior can be modulated according to the social context, and also can be transferred to conspecifics through direct observation and/or social interaction. Herein we investigated if acute pain induction was related to changes in emission of aversive and appetitive calls and how different social contexts affected the nociceptive behavior and USVs. Our results demonstrated that orofacial formalin injection in rats induced aversive calls in addition to the nociceptive behavior, and both are reduced by systemic treatment with morphine (2.5 mg/kg). Exposure of formalin-injected rats to cagemates had no effect on the nociceptive behavior or calls emitted by the demonstrator, but the observer showed emotional contagion of pain. In contrast, exposure of formalin-injected rats to non-cagemates decreased the nociceptive behavior of the demonstrator, without affecting the calls emission. The emotional contagion was not detected in non-cagemates or in cagemates separated by a visual barrier. In conclusion, we suggest that familiarity and the visual contact contributes to emotional contagion of pain. USV analysis may represent an additional measure in the evaluation of the emotional aspect of orofacial pain, and for the study of pain modulation.

Anxiety- but not depressive-like behaviors are related to facial hyperalgesia in a model of trigeminal neuropathic pain in rats.
Trigeminal neuralgia (TN) is a painful condition characterized by excruciating facial pain, which has a serious impact on quality of life. Depression and anxiety have been commonly associated with TN, but clinical studies report that these comorbidities are frequently underdiagnosed and undertreated in TN patients. Herein it was investigated if rats submitted to the infraorbital nerve constriction (CION), a model of trigeminal neuropathic pain, would display anxiety- and depressive-like behaviors in addition to the facial sensory changes in different time points after the nerve injury. CION rats developed facial heat hyperalgesia on day 5 after the nerve injury, but at this time point the time spent and the number of entries on open arms in the elevated plus maze (EPM) and the time spent on the lit compartment of light-dark transition test (LDT) was not statistically significant between SHAM and CION groups, suggesting that 5 days after CION animals do not display anxiety-like behavior. On the other hand, around 50% of CION rats developed mechanical allodynia on day 15 postsurgery and the analysis of the time spent and the number of entries on open arms on EPM and the time spent on lit compartment of LDT revealed that only CION-allodynic animals displayed anxiety-like behavior when compared to the SHAM group. The depressive-like behavior was assessed by measuring the time of immobility on the forced swim test (FST) and sucrose preference (SP) in rats previously tested for heat (day 5) and mechanical allodynia (days 15, 30 and 45) induced by CION. The evaluation of immobility time on FST and sucrose preference consumption revealed that both CION rats did not displayed depressive- and anhedonic-like behavior at any time point evaluated. Altogether, these results demonstrate that trigeminal neuropathic pain in rats leads to the development of anxiety-, but not depressive-like behavior, suggesting that the CION model represents a methodology that allows the study of drugs targeting both pain and anxiety.

Facial hyperalgesia due to direct action of endothelin-1 in the trigeminal ganglion of mice.
This study assessed the ability of endothelin-1 (ET-1) to evoke heat hyperalgesia when injected directly into the trigeminal ganglia (TG) of mice and determined the receptors implicated in this effect. The effects of TG ET and ET receptor blockade on alleviation of heat hyperalgesia in a model of trigeminal neuropathic pain induced by infraorbital nerve constriction (CION) were also examined.

Role of peripheral and central TRPV1 receptors in facial heat hyperalgesia in streptozotocin-induced diabetic rats.
There is increasing evidence that diabetes may be related to sensory changes in the trigeminal system. Long lasting facial heat hyperalgesia has been described in diabetic rats, but the mechanisms remain to be elucidated. Herein, the contribution of peripheral and central TRPV1 receptors to facial heat hyperalgesia in diabeticrats was investigated. Diabetes was induced in male Wistar rats by streptozotocin (60mg/kg, i.p) and facial heat hyperalgesia was assessed once a week up to four weeks. The role of TRPV1 receptors in the heat hyperalgesia in diabetic rats was evaluated through: 1) the ablation of TRPV1 receptors by resiniferatoxin (RTX) treatment and 2) injection of the TRPV1 antagonist, capsazepine, into the upper lip, trigeminal ganglion or medullary subarachnoid space, at doses that completed prevented the heat hyperalgesia induced by capsaicin in naïve rats. Western blot was used to estimate the changes in TRPV1 expression in diabetic rats. Diabetic rats exhibited facial heat hyperalgesia from the first up to the fourth week after streptozotocin injection, which was prevented by

insulin treatment. Ablation of TRPV1-expressing fibers prevented facial hyperalgesia in diabetic rats. Capsazepine injection in all sites resulted in significant reduction of facial heat hyperalgesia in diabetic rats. Diabetic rats exhibited a significant decrease in TRPV1 expression in the trigeminal nerve, increased expression in the trigeminal ganglion and no changes in subnucleus caudalis when compared to normoglycemic ones. In conclusion, our results suggest that facial heat hyperalgesia in diabetic rats is maintained by peripheral and central TRPV1 receptors activation.

Neuropathic pain (NP) is a common symptom arising as a direct consequence of a lesion or disease affecting the somatosensory system. The traditional approach to managing NP patients is to initiate treatment with conservative pharmacological therapy before interventional strategies. However, first-line drug treatments have shown modest efficacy with less than 50% of pain relief. Since NP is present in ~70% of patients with spinal cord injury (SCI), people with this pathology represent a reliable population to study NP. Interestingly, previous studies have shown a clear correlation between NP and changes in electroencephalography (EEG), which is a good indicator of the state of the central nervous system. We are employing state-of-the-art digital health technology (the Mobsitudy smartphone app and the BitBrain portable EEG) to collect data from SCI patients daily for one month to better understand NP progression. To date, we have recorded EEG and self-reported symptoms from 6 patients, both at home after one-day training and at the hospital, with the assistance of a technician. Early results show that the recordings suffer from low quality and the strong presence of artifacts. We employed the method Artifact Subspace Reconstruction (ASR). for removing artifacts and analysing the power spectral density of the resulting signals. The initial analysis shows that EEG traces recorded at home are of lower quality than those recorded with a technician at the hospital.

Effects of patterned peripheral nerve stimulation on soleus spinal motor neuron excitability.
Spinal plasticity is thought to contribute to sensorimotor recovery of limb function in several neurological disorders and can be experimentally induced in animals and humans using different stimulation protocols. In healthy individuals, electrical continuous Theta Burst Stimulation (TBS) of the median nerve has been shown to change spinal motoneuron excitability in the cervical spinal cord as indexed by a change in mean H-reflex amplitude in the flexor carpi radialis muscle. It is unknown whether continuous TBS of a peripheral nerve can also shift motoneuron excitability in the lower limb. In 26 healthy subjects, we examined the effects of electrical TBS given to the tibial nerve in the popliteal fossa on the excitability of lumbar spinal motoneurons as measured by H-reflex amplitude of the soleus muscle evoked by tibial nerve stimulation. Continuous TBS was given at 110% of H-reflex threshold intensity and compared to non-patterned regular electrical stimulation at 15 Hz. To disclose any pain-induced effects, we also tested the effects of TBS at individual sensory threshold. Moreover, in a subgroup of subjects we evaluated paired-pulse inhibition of H-reflex. Continuous TBS at 110% of H-reflex threshold intensity induced a short-term reduction of H-reflex amplitude. The other stimulation conditions produced no after effects. Paired-pulse H-reflex inhibition was not modulated by continuous TBS or non-patterned repetitive stimulation at 15 Hz. An effect of pain on the results obtained was discarded, since non-patterned 15 Hz stimulation at 110% HT led to pain scores similar to those induced by EcTBS at 110% HT, but was not able to induce any modulation of the H reflex amplitude. Together, the results provide first time evidence that peripheral continuous TBS induces a short-lasting change in the excitability of spinal motoneurons in lower limb circuitries. Future studies need to investigate how the TBS protocol can be optimized to produce a larger and longer

effect on spinal cord physiology and whether this might be a useful intervention in patients with excessive excitability of the spinal motorneurons.

Static Magnetic Field Stimulation over Parietal Cortex Enhances Somatosensory Detection in Humans.
The role of neuronal oscillations in human somatosensory perception is currently unclear. To address this, here we use noninvasive brain stimulation to artificially modulate cortical network dynamics in the context of neurophysiological and behavioral recordings. We demonstrate that transcranial static magnetic field stimulation (tSMS) over the somatosensory parietal cortex increases oscillatory power specifically in the alpha range, without significantly affecting bottom-up thalamocortical inputs indexed by the early cortical component of somatosensory evoked potentials. Critically, we next show that parietal tSMS enhances the detection of near-threshold somatosensory stimuli. Interestingly, this behavioral improvement reflects a decrease of habituation to somatosensation. Our data therefore provide causal evidence that somatosensory perception depends on parietal alpha activity. Artificially increasing alpha power by placing a powerful magnetic field over the somatosensory cortex overcomes the natural decline in detection probability of a repeated near-threshold sensory stimulus.

Dopamine-dependent changes of cortical excitability induced by transcranial static magnetic field stimulation in Parkinson's disease.
Transcranial static magnetic field stimulation (tSMS) is a recent low-cost non-invasive brain stimulation technique that decreases cortical excitability in healthy subjects. The objective of the present study was to test the ability of tSMS to modulate cortical excitability in patients with Parkinson's disease. We performed a randomized double-blind sham-controlled cross-over study to assess cortical excitability before and immediately after tSMS (or sham) applied for 10 min to the more affected motor cortex of patients with Parkinson's disease. Cortical excitability was quantified by the amplitude of motor evoked potentials (MEPs) elicited by single-pulse transcranial magnetic stimulation (TMS). tSMS significantly decreased MEP amplitudes in patients OFF medication (after overnight withdrawal of dopaminergic drugs), but not ON medication (after an acute dose of levodopa). The between-patients variability of tSMS-induced changes was significantly greater ON medication. The variability ON medication could be partly explained by disease progression, i.e. the more advanced the patient, the more likely it was to observe a switch from inhibitory tSMS plasticity OFF medication to paradoxical facilitatory plasticity ON medication. These results suggest that tSMS induces dopamine-dependent changes of cortical excitability in patients with Parkinson's disease.

New Insights from Clinical Assessment of Upper Extremities in Cervical Traumatic Spinal Cord Injury.
Upper extremity function has a strong impact on the quality of life in cervical spinal cord-injured patients. Upper extremity function depends on many factors, such as muscle strength, level of lesion, and extension of the cord damage in its axial axis produced by the injury. These variables can be obtained by the International Standards for Neurological Classification of Spinal Cord Injury, which is the standard for the functional evaluation of traumatic spinal cord injury (SCI) patients. The aim of this study was to describe the relationship between upper limb muscle strength, level of injury, and axial damage with the functionality of upper limb measured using the Jebsen-Taylor Hand Function Test (JTHFT) and the 9 Hole Peg Test (9HPT) in cervical SCI. Twenty-nine patients were included in this study. Our results suggest that both the JTHFT and 9HPT can be similarly used to quantify functional impairment after cervical SCI. Moreover, our data suggest that the upper extremity motor score, JTHFT, and 9HPT strongly correlate with the American Spinal Injury Association (ASIA) impairment scale (graded from A to E), but not with the lesion level. Our findings can be of great importance for the clinician or researchers whose therapeutic interventions have as a main objective to improve upper limb functionality in patients with cervical SCI. We suggest that ASIA impairment scale, ASIA motor score, and functional tests (including JTHFT and/or 9HPT) could be used as outcome measures in cervical SCI clinical trials.

Static Magnetic Field Stimulation over the Visual Cortex Increases Alpha Oscillations and Slows Visual Search in Humans.
Transcranial static magnetic field stimulation (tSMS) was recently introduced as a promising tool to modulate human cerebral excitability in a noninvasive and portable way. However, a demonstration that static magnetic fields can influence human brain activity and behavior is currently lacking, despite evidence that static magnetic fields interfere with neuronal function in animals. Here we show that transcranial application of a static magnetic field (120-200 mT at 2-3 cm from the magnet surface) over the human occiput produces a focal increase in the power of alpha oscillations in underlying cortex. Critically, this neurophysiological effect of tSMS is paralleled by slowed performance in a visual search task, selectively for the most difficult target detection trials. The typical relationship between prestimulus alpha power over posterior cortical areas and reaction time (RT) to targets during tSMS is altered such that tSMS-dependent increases in alpha power are associated with longer RTs for difficult, but not easy, target detection trials. Our results directly demonstrate that a powerful magnet placed on the scalp modulates normal brain activity and induces behavioral changes in humans.

Aims: Chronic pain is the leading cause of disability worldwide. It commonly presents associated with affective and cardiovascular disorders, suggesting common molecular mechanisms. The present study aimed to establish a mouse model with central and peripheral mediated co-morbidities allowing to identify extreme populations to evaluate factors to vulnerability. **Methods**: Diversity Outbred male and female adult mice were intravenously injected with an adeno-associated PCSK9-encoding virus and fed with a high fat 0.25% cholesterol-enriched diet to induce the atherosclerotic phenotype. At day 30, a set of mice were subjected to intra-articular administration of monoiodoacetate (MIA) to induce osteoarthritis while another set was injected with saline (SHAM). Thermal hyperalgesia, mechanical allodynia, glucose blood levels and blood pressure were evaluated every two weeks. At the end of the 60-day protocol, a set of motor coordination, behavioural tests were performed. **Results**: MIA-mice showed significant thermal hyperalgesia and mechanical allodynia up to 4 days' post-osteoarthritis induction when compared with SHAM groups. Male mice experienced an increase in glucose blood levels, whereas only female mice experienced a blood pressure transitory increase. MIA-groups developed affective, cognitive, and motor coordination alterations. Different mice subgroups with the core co-morbidities were identified. **Conclusions**: The repeated exposure to these risk factors generates a mouse model of chronic pain, affective disorders and cardiovascular disease. Using this model, different factors of vulnerability to the development of each component of this co-morbid state can be investigated. **Acknowledgements**: This work was supported by *Generalitat de Catalunya* (FI-2021), ICREA (SAF 2021) and European Commission (Grant Agreement: #848099).

Aims Peripheral nerves are capable of regeneration after damage. However, it remains unclear why pain persists even after the apparent functional recovery in many clinical conditions. We aimed to develop a nerve injury model that reflects both chronic pain and axon regeneration, and further identify histological characteristics of the model. **Methods** We compared the classical sciatic nerve crush model (i.e. complete; full crush) and a novel partial (i.e. incomplete) crush injury in adult mice. The partial nerve injury was performed using a custom-modified hemostat. Assays of thermal and mechanically-evoked pain-like behavior were paralleled by transmission electron microscopy and immunohistochemistry at acute (2-7 days) and chronic (>30 days) time-points. **Results** In both crush models, the sciatic nerve function was recovered approximately 15 days after injury. However, only partial crush developed transient thermal and chronic tactile hypersensitivity. The partial crush resulted in a greater number of surviving axons in the distal nerve beyond the window of Wallerian degeneration, and fewer sensory neurons positive for an axotomy marker, ATF3 at day 2 and 7. The axonal morphology at day 30 revealed thinner myelination after partial crush compared to the full crush and control nerves, and it was consistent with a prolonged expression of a sensory regeneration marker, STMN2. **Conclusion** The partial nerve crush, rather than the full crush with greater nerve damage, produces greater sensory hypersensitivity. We also revealed that long-term myelin-thinning correlates with long-term hypersensitivity. Comparing two similar models with distinctive pain phenotypes may yield insights into the pathophysiology of neuropathic pain.

Aims To assess the impact of early life factors on adolescent chronic pain outcomes at a behavioural and molecular level. **Methods** Sprague Dawley male and female rats were randomly assigned to either a Standard or High Fat-High Sugar (HFHS) Diet, followed by a No Stress or Maternal Stress (MS) paradigm, and lastly a Sham or Injury condition (n=6M:6F/group). In adolescence, all animals were tested for anxiety-like behaviour and mechanical and thermal nociceptive sensitivity through the elevated plus maze, vonFrey, and hot cold plate tasks respectively. Markers of inflammation and microglia were analyzed through a cytokine panel and RT-qPCR from serum and tissue from the limbic region. Four-way ANOVAs with Sex, Diet, Stress, and Injury as factors were run. **Results** Anxiety-like behaviour increased in males (p <.05). Mechanical nociceptive sensitivity was increased in Female, HFHS Diet, MS, and Injured animals (p's <.05). Thermal nociception was altered by Injury on both the hot and cold plates, while also demonstrating multiple interactions (p's <.05). The cytokine panel revealed Sex and Injury effects in IL18, TNFα, and MIP1α, along with a Diet effect in MIP1α, Sex and Stress effects in IL1β, and numerous interactions (p's <.05). Results from the qPCR demonstrated Sex differences in microglial markers IBA1 and P2RY12, along with Diet effects in TNFα, and interactions in GFAP and IL1β (p's <.05). **Conclusions** Results suggest that early life factors prime the neuroimmune system to overrespond to later stressors and increase susceptibility to chronic pain through persistent inflammation and microglia activation.

The Development of Adolescent Chronic Pain following Traumatic Brain Injury and Surgery: The Role of Diet and Early Life Stress.
Pain is evolutionarily necessary for survival in that it reduces tissue damage by signaling the body to respond to a harmful stimulus. However, in many circumstances, acute pain becomes chronic, and this is often dysfunctional. Adolescent chronic pain is a growing epidemic with an unknown etiology and limited effective treatment options. Given that the relationship between acute pain and chronic pain is not straightforward, there is a need to better understand the factors that contribute to the chronification of pain. Since early life factors are critical to a variety of outcomes in the developmental and adolescent periods, they pose promise as potential mechanisms that may underlie the transition from acute to chronic pain. This review examines two early life factors: poor diet and adverse childhood experiences (ACEs); they may increase susceptibility to the development of chronic pain following surgical procedures or traumatic brain injury (TBI). Beyond their high prevalence, surgical procedures and TBI are ideal models to prospectively understand mechanisms underlying the transition from acute to chronic pain. Common themes that emerged from the examination of poor diet and ACEs as mechanisms underlying this transition included: prolonged inflammation and microglia activation leading to sensitization of the pain system, and stress-induced alterations to hypothalamic-pituitary-adrenal axis function, where cortisol is likely playing a role in the development of chronic pain. These areas provide promising targets for interventions, the development of diagnostic biomarkers, and suggest that biological treatment strategies should focus on regulating the neuroinflammatory and stress responses in an effort to modulate and prevent the development of chronic pain.

Pain in the Developing Brain: Early Life Factors Alter Nociception and Neurobiological Function in Adolescent Rats.
Although adverse early experiences prime individuals to be at increased risk for chronic pain, little research has examined the trauma-pain relationship in early life or the underlying mechanisms that drive pathology over time. Given that early experiences can potentiate the nociceptive response, this study aimed to examine the effects of a high-fat, high-sugar (HFHS) diet and early life stress (maternal separation [MS]) on pain outcomes in male and female adolescent rats. Half of the rats also underwent a plantar-incision surgery to investigate how the pain system responded to a mildly painful stimuli in

adolescence. Compared with controls, animals that were on the HFHS diet, experienced MS, or had exposure to both, exhibited increased anxiety-like behavior and altered thermal and mechanical nociception at baseline and following the surgery. Advanced magnetic resonance imaging demonstrated that the HFHS diet and MS altered the maturation of the brain, leading to changes in brain volume and diffusivity within the anterior cingulate, amygdala, corpus callosum, nucleus accumbens, and thalamus, while also modifying the integrity of the corticospinal tracts. The effects of MS and HFHS diet were often cumulative, producing exacerbated pain sensitivity and increased neurobiological change. As early experiences are modifiable, understanding their role in pain may provide targets for early intervention/prevention.

Utilization of a rodent model to examine the neurological effects of early life adversity on adolescent pain sensitivity.
All children experience pain, and although many recover quickly, some go on to develop chronic pain. Adolescent chronic pain is a growing epidemic. It is unknown why some adolescents recover without incident and others experience persistent pain. Although unexplored, early life adversity may contribute to the development and maintenance of chronic pain. This study investigated the effects and underlying neurobiological mechanisms of an early life stressor on nociceptive (pain) sensitivity and emotional function in male and female Sprague-Dawley rats. Using maternal separation (MS) as an established model of early life stress, we addressed two aims: investigation of the effects of MS on behavior (anxiety and pain sensitivity), and investigation of the effects of MS on mRNA and pathophysiological changes associated with an acutely painful stimulus. Our results indicate that MS increased anxiety-like behavior and altered nociceptive responsivity in adolescent rats, with decreased mechanical withdrawal thresholds indicative of heightened and prolonged pain-related behavior. The MS groups also demonstrated increased expression of genes involved in regulating the stress and fight-or-flight response, mood, and neuroplasticity; as well as increased levels of inflammatory markers. We conclude that nociception, both at the behavioral and molecular level, is altered in response to the MS stressor.

The behavioural and pathophysiological effects of the ketogenic diet on mild traumatic brain injury in adolescent rats.
Mild traumatic brain injury (mTBI), caused by an insult to the head, results in a cascade of molecular imbalance that includes altered glucose metabolism, mitochondrial dysfunction, and increases in reactive oxygen species. Although glucose is the primary energy source for the brain, it becomes an inefficient substrate following injury, and the brain is primed to use alternative substrates (such as ketones). The ketogenic diet (KD), a high-fat, low-carbohydrate diet, forces the brain to utilize ketones over glucose for energy. Given that mTBIs are commonly experienced during adolescence, our study sought to examine the effects of the KD on recovery from mTBI in adolescent rats. This was done via two experiments; the first of which animals were fed the KD prior to a mTBI in order to investigate the neuroprotective potential of the diet, and the second the animals were fed the KD following a mTBI to examine the therapeutic potential. Male and female Sprague Dawley rats were assigned to receive a control standard diet or the KD (either pre-injury or post-injury), then further randomized to receive a sham or mTBI. Animals were tested on 6 behavioural measures designed to examine post-concussive symptomology, and mRNA analysis of the brain and small intestine were performed. Pre-injury exposure to the KD offered some neuroprotection, reducing balance and motor impairments while increasing exploratory behaviour and telomere length. Consumption of the KD following the injury also provided some therapeutic benefit, reducing both anxiety- and depressive-like behaviours. The timing of KD administration also differentially modified expression of prefrontal cortex, hippocampus, and intestinal mRNA for our genes of interest (Fgf2, Iba1, Opa1, Sirt1, Claudin3, OCC, and ZO1) This study demonstrates the neuroprotective and therapeutic potential of the KD for mTBI and warrants further investigation.

A Bump on the Head or Late to Bed: Behavioral and Pathophysiological Effects of Sleep Deprivation after Repetitive Mild Traumatic Brain Injury in Adolescent Rats.
An old wives' tale, and strongly held dogma, maintains that one should be kept awake after a mild traumatic brain injury (mTBI) to prevent a coma. This, however, conflicts with the known benefits of sleep: repair and restoration. We therefore sought to examine the effects of sleep deprivation (SD) in the post-traumatic sleep period on post-concussion symptomology (PCS). Adolescent male and female rats were administered repetitive mTBIs (RmTBI) or sham injuries and were then assigned to 5 h of SD or left undisturbed. All animals were then tested using seven behavioral tasks validated to examine PCS, followed by analysis of serum cytokines, and quantitative real-time PCR for messenger RNA (mRNA) expression. Exposure to 3 SD epochs significantly impaired behavior in 4 of 7 of the measures, while RmTBI also produced dysfunction in 5 of 7 tests, but the effects of SD and RmTBI were not cumulative. SD induced long-lasting changes in serum levels of Tnf-α, IL6, and IL-1ß. mRNA expression in the pre-frontal cortex, hippocampus, hypothalamus, and anterior cingulate cortex was modified in response to SD and RmTBI; but similar to the behavioral measures, the mRNA changes were not cumulative.

Consequently, we report that SD often produced impairments similar or worse than RmTBI, and sleep hygiene should become a priority for adolescent health.

Assessment of a nutritional supplement containing resveratrol, prebiotic fiber, and omega-3 fatty acids for the prevention and treatment of mild traumatic brain injury in rats.
Children and adolescents have the highest rates of traumatic brain injury (TBI), with mild TBI (mTBI) accounting for most of these injuries. Adolescents are particularly vulnerable and often suffer from post-injury symptomologies that may persist for months. We hypothesized that the combination of resveratrol (RES), prebiotic fiber (PBF), and omega-3 fatty acids (docosahexaenoic acid (DHA)) would be an effective therapeutic supplement for the mitigation of mTBI outcomes in the developing brain. Adolescent male and female Sprague-Dawley rats were randomly assigned to the supplement (3S) or control condition, which was followed by a mTBI or sham insult. A behavioral test battery designed to examine symptomologies commonly associated with mTBI was administered. Following the test battery, tissue was collected from the prefrontal cortex (PFC) and primary auditory cortex for Golgi-Cox analysis of spine density, and for changes in expression of 6 genes (Aqp4, Gfap, Igf1, Nfl, Sirt1, and Tau). 3S treatment altered the behavioral performance of sham animals indicating that dietary manipulations modify premorbid characteristics. 3S treatment prevented injury-related deficits in the longer-term behavior measures, medial prefrontal cortex (mPFC) spine density, and levels of Aqp4, Gfap, Igf1, Nfl, and Sirt1 expression in the PFC. Although not fully protective, treatment with the supplement significantly improved post-mTBI function and warrants further investigation.

Examining changes in rodent temperament following repetitive mild traumatic brain injury in adolescence.
Mild traumatic brain injuries are known to cause a host of symptoms, including headaches, nausea, and depression, that when persistent, are known as postconcussive syndrome. In addition to these overt symptomologies, individuals may experience changes in day-to-day behavior or temperament, which although not meeting criteria for postconcussive diagnosis, does cause distress to the individual. The aim of this study was to determine whether we could measure temperament in a rat and, if so, determine whether temperament is altered in response to repetitive mild traumatic brain injuries (RmTBI). Forty male and female adolescent Sprague-Dawley rats were same-sex pair housed and subjected to RmTBIs or sham injuries. The rats were recorded at 6 different time points throughout the study for the temperament assessment protocol, a measure of the complex behavioral profile of each rat within its dyadic home cage environment. The temperaments were quantified via a novel behavioral scoring algorithm. The rats were also tested on a battery of tests that were designed to measure symptoms of postconcussion syndrome. We determined that rodent temperament is quantifiable, is sex dependent, changes with age, and is modifiable in response to experiential factors such as RmTBI. Rats that received the RmTBIs were significantly less active and showed decreased levels of social interaction compared with their sham-injury counterparts. Moreover, both task switching and recovery patterns for RmTBI rats were dependent on the injury status of their cage mates. Future studies are now required to determine the mechanisms underlying these important changes in temperament. (PsycInfo Database Record (c) 2020 APA, all rights reserved).

Investigating the cumulative effects of Δ9-tetrahydrocannabinol and repetitive mild traumatic brain injury on adolescent rats.
The prevalence of mild traumatic brain injury is highest amongst the adolescent population and can lead to complications including neuroinflammation and excitotoxicity. Also pervasive in adolescents is recreational cannabis use. Δ9-Tetrahydrocannabinol, the main psychoactive component of cannabis, is known to have anti-inflammatory properties and serves as a neuroprotective agent against excitotoxicity. Thus, we investigated the effects of Δ9-tetrahydrocannabinol on recovery when administered either prior to or following repeated mild brain injuries. Male and female Sprague-Dawley rats were randomly assigned to receive Δ9-tetrahydrocannabinol or vehicle either prior to or following the repeated injuries. Rats were then tested on a behavioural test battery designed to measure post-concussive symptomology. The hippocampus, nucleus accumbens and prefrontal cortex were extracted from all animals to examine mRNA expression changes (, , , , and). We hypothesized that, in both experiments, Δ9-tetrahydrocannabinol administration would provide neuroprotection against mild injury outcomes and confer therapeutic benefit. Δ9-Tetrahydrocannabinol administration following repeated mild traumatic brain injury was beneficial to three of the six behavioural outcomes affected by injury (reducing anxiety and depressive-like behaviours while also mitigating injury-induced deficits in short-term working memory). Δ9-Tetrahydrocannabinol administration following injury also showed beneficial effects on the expression of , and in the hippocampus, nucleus accumbens and prefrontal cortex. There were no notable benefits of Δ9-tetrahydrocannabinol when administered prior to injury, suggesting that Δ9-tetrahydrocannabinol may have potential therapeutic benefit on post-

concussive symptomology when administered post-injury, but not pre-injury.

Examining Parent Adverse Childhood Experiences as a Distal Risk Factor in Pediatric Chronic Pain.
Adverse childhood experiences (ACEs; ie, exposure to abuse, neglect, household dysfunction in childhood) are associated with poor mental and physical health outcomes across the lifespan. Emerging research suggests parent ACEs also confer risk for poor child outcomes. The relation between parent ACEs and child pain in youth with chronic pain has not yet been examined. The aim of the current longitudinal study was to examine the associations among parent ACEs, parent health, and child pain, in a clinical sample of youth with chronic pain.

Adverse childhood experiences in parents of youth with chronic pain: prevalence and comparison with a community-based sample.
Adverse childhood experiences (ACEs) are common occurrences that are related to poor health outcomes, including chronic pain, in youth and adults. Research suggests that children of parents exposed to ACEs are also at risk of poor outcomes. However, little is known about the risk that ACEs confer for chronic pain across generations. Parent ACEs may play an important role in pediatric chronic pain, given their association with key parent factors (eg, mental and physical health).

STUDY OF THE ANTINOCICEPTIVE EFFECT OF MORPHINE EVALUATED BY A NEUROPATHIC PAIN MODEL IN MALE AND FEMALE MICE.

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Virginia Perez, Graciela Balerio
University of Buenos Aires. Facultad de Farmacia y Bioquímica. Cátedra de Farmacología. Instituto de Investigaciones Farmacológicas (ININFA-UBA-CONICET), Pharmacoloy, Buenos Aires, Argentina

Morphine is one of the most widely used analgesics in the treatment of moderate and severe pain. However, its clinical use in chronic pain treatment is limited by the addictive potential. The co-administration of morphine with drugs that enhance the analgesic effect and reduce its reinforcing properties, could be an alternative in pain treatment with opioids. In the present study, we propose to determine the lowest effective dose of morphine to ameliorate the nociceptive threshold by using the partial sciatic nerve ligation (PSNL) in male and female Balb/C mice. Von Frey test (VFT) was performed in order to evaluate mechanical allodynia by calculating the nociceptive threshold. Mice were habituated to the environment for four days, baseline responses were measured, and surgery of the right paw was performed in a group of animals with PSNL (PSNL group), and surgery without PSNL was executed in another group (Sham group). Nine days after surgery, morphine (1, 3, 9 mg / kg, i.p.) or saline were administered and VFT was carried out. Our results showed that morphine (3 and 9 mg/kg) was able to reduce neuropathic pain in both sexes ($p < 0.001$). Although some studies have shown that the antinociceptive effect of morphine is more intense in males than in females, it has been suggested that sex differences depend on the strain of mice. These results will allow us to evaluate potential therapeutic targets to enhance the analgesic effect of opiates using the lowest effective dose of morphine (3 mg/kg) in both sexes.

Chronic pain is due to abnormal, maladaptive neuronal plasticity in the structures known to be involved in pain perception. Our hypothesis is that the aforementioned maladaptive plasticity in these brain areas could be key mechanisms for the development of comorbidities, such as anxiety and depression. Functional ultrasound (fUS) imaging is a sensitive and versatile neuroimaging modality, able to quantify with a large field of view (indirectly) neuronal activation and measure functional connectivity (FC), an indirect measure of the functionality and strength of brain networks. This study aimed at identifying, using fUS imaging, how the functionality of brain networks is changing in link with neuropathic pain and the comorbidity associated to it. We measured the functional connectivity (FC) at rest in awake, head fixed animals, subjected to neuropathic pain (2W cuffing of the sciatic nerve), or anxiety (8W) or depression (12W). Behavioural tests were carried out to follow the various symptoms. Our results show time-specific alterations of the networks. At the emergence of neuropathic pain, FC within regions involved in the sensory aspect of pain are altered and then gradually mutating overtime (8W-12w) into some changes in areas involved in the emotional aspect of pain, as the Anterior part of the Cingulate cortex and the Insular cortex. In agreement with our hypothesis, these findings suggest that alterations in the regions of the '*pain matrix'* are developing along with the stage of the disease and the associated comorbidities.

DESCENDING SEROTONERGIC FACILITATION CONTRIBUTION TO DNIC ANALGESIA IN PROLONGED JOINT INFLAMMATORY PAIN

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Raquel Pereira Da Silva[1,2], Fani Neto[1,2], Isabel Martins[1,2]
[1]Faculty of Medicine - University of Porto, Department Of Biomedicine, Porto, Portugal, [2]i3S - Institute of Health Research and Innovation, Pain Research, Porto, Portugal

Background & Aims: The diffuse noxious inhibitory controls (DNIC) are an analgesic paradigm relying on the descending monoaminergic modulation but the underlying mechanisms remain understudied. We sought to study the descending serotonergic system in monoarthritis (MA). *Methods:* Male Wistar rats received tibiotarsal injections of complete Freund's adjuvant or vehicle. Nociceptive hypersensitivity and DNIC were evaluated weekly until day 42. On day 42, the effects of intrathecal ondansetron (5-hydroxytryptamine 3 receptors (5-HT3R) antagonist) were tested on mechanical hyperalgesia and DNIC (before or after the DNIC conditioning stimulus). Spinal 5-HT3R expression and 5-HT levels were quantified via immunofluorescence and HPLC, respectively. The expression of TPH and its co-localization with the phosphorylated extracellular signal-regulated protein kinases 1 and 2 (pERKs1/2; neuronal activation marker) were evaluated at the rostroventral medulla (RVM). *Results:* DNIC was enhanced at earlier timepoints of MA and attenuated on day 42. Ondansetron reversed mechanical hyperalgesia in MA rats. On controls, this effect was observed with 10mg. MA rats showed increased spinal 5-HT3R and 5-HT. At the RVM, TPH and TPH-pERK1/2 double-labeled neurons were increased. Ondansetron restored DNIC in MA rats and at the dose of 10mg it increased DNIC intensity regardless of being administered before or after the conditioning stimulation in MA and controls. *Conclusion:* Our results suggest an enhancement of descending serotonergic facilitation during prolonged MA. The shift towards an enhancement of descending facilitation is likely involved in the attenuation of DNIC. The descending serotonergic system appears to be involved in the maintenance of DNIC rather than its initiation.

Attenuation of the Diffuse Noxious Inhibitory Controls in Chronic Joint Inflammatory Pain Is Accompanied by Anxiodepressive-Like Behaviors and Impairment of the Descending Noradrenergic Modulation.
The noradrenergic system is paramount for controlling pain and emotions. We aimed at understanding the descending noradrenergic modulatory mechanisms in joint inflammatory pain and its correlation with the diffuse noxious inhibitory controls (DNICs) and with the onset of anxiodepressive behaviours. In the complete Freund's adjuvant rat model of Monoarthritis, nociceptive behaviors, DNICs, and anxiodepressive-like behaviors were evaluated. Spinal alpha2-adrenergic receptors (a2-AR), dopamine beta-hydroxylase (DBH), and noradrenaline were quantified concomitantly with a2-AR pharmacologic studies. The phosphorylated extracellular signal-regulated kinases 1 and 2 (pERK1/2) were quantified in the Locus coeruleus (LC), amygdala, and anterior cingulate cortex (ACC). DNIC was attenuated at 42 days of monoarthritis while present on days 7 and 28. On day 42, in contrast to day 28, noradrenaline was reduced and DBH labelling was increased. Moreover, spinal a2-AR were potentiated and no changes in a2-AR levels were observed. Additionally, at 42 days, the activation of ERKs1/2 was increased in the LC, ACC, and basolateral amygdala. This was accompanied by anxiety- and depressive-like behaviors, while at 28 days, only anxiety-like behaviors were observed. The data suggest DNIC is attenuated in prolonged chronic joint inflammatory pain, and this is accompanied by impairment of the descending noradrenergic modulation and anxiodepressive-like behaviors.

BETAINE AMELIORATES PROVOKED AND ONGOING PAIN IN NERVE-INJURED RATS BY REGULATING KIF17 MEDIATED NR2B ACTIVATION AND NEUROINFLAMMATION

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Vineeta Tiwari, Siva Hemalatha
Indian Institute of Technology (BHU), Pharmaceutical Engineering And Technology, Varanasi, India

Aims: The management of neuropathic pain is still a major challenge because of its unresponsiveness to most common treatments and its elusive mechanisms. Betaine has been reported to play an active role in the treatment of various neurological disorders including inflammatory pain. This study aims to investigate the effect of betaine and elucidate its molecular mechanisms in an animal model of neuropathic pain. **Methods:** We assessed multiple pain parameters including thermal sensitivity, static and dynamic mechanical allodynia and ongoing pain. Further molecular analysis was performed using RT-PCR and western blotting to measure the mRNA and protein expressions of NR2B, KIF17 and important markers of nociception such as TRPV1, substance P, CGRP and other inflammatory mediators. **Results:** We found that betaine treatment showed significant and dose-dependent inhibition of both evoked and chronic ongoing pain in rats with nerve injury. Betaine and gabapentin treatment significantly inhibits spontaneous ongoing pain in nerve-injured rats but did not produce any place preference behavior in healthy naïve rats pointing towards their non-addictive analgesic potential. Molecular findings suggested that enhanced expressions of NR2B and KIF-17 along with increased TRPV1, substance P, CGRP, TNF-α, IL-1β, and IL-6 levels in dorsal root ganglion (DRG) and spinal cord of nerve-injured rats which was significantly attenuated on treatment with different doses of betaine in a dose-dependent manner. **Conclusion:** The current findings suggest that inhibition of the expression of KIF-17 mediated NR2B activation and neuroinflammation further leads to significant inhibition of evoked and chronic ongoing pain in nerve-injured rats.

Unlocking the potential of TRPV1 based siRNA therapeutics for the treatment of chemotherapy-induced neuropathic pain.
Chemotherapy-induced neuropathic pain (CINP) is among the most common clinical complications associated with the use of anti-cancer drugs. CINP occurs in nearly 68.1% of the cancer patients receiving chemotherapeutic drugs. Most of the clinically available analgesics are ineffective in the case of CINP patients as the pathological mechanisms involved with different chemotherapeutic drugs are distinct from each other. CINP triggers the somatosensory nervous system, increases the neuronal firing and activation of nociceptive mediators including transient receptor protein vanilloid 1 (TRPV1). TRPV1 is widely present in the peripheral nociceptive nerve cells and it has been reported that the higher expression of TRPV1 in DRGs serves a critical role in the potentiation of CINP. The therapeutic glory of TRPV1 is well recognized in clinics which gives a promising insight into the treatment of pain. But the adverse effects associated with some of the antagonists directed the scientists towards RNA interference (RNAi), a tool to silence gene expression. Thus, ongoing research is focused on developing small interfering RNA (siRNA)-based therapeutics targeting TRPV1. In this review, we have discussed the involvement of TRPV1 in the nociceptive signaling associated with CINP and targeting this nociceptor, using siRNA will potentially arm us with effective therapeutic interventions for the clinical management of CINP.

Epigallocatechin-3-gallate improves chronic alcohol-induced cognitive dysfunction in rats by interfering with neuro-inflammatory, cell death and oxido-nitrosative cascade.
Alcohol consumption for a longer period of time is linked with neuronal damage and an increase in inflammatory signaling resulting in cell death and dementia. Natural compounds are the focus of research due to their high efficacy and good safety profile. Here we have investigated the effect of chronic epigallocatechin-3-gallate (EGCG) administration against the alcohol-induced cognitive deficit rats. Male Wistar rats were exposed to the 12% ethanol (10 g/kg; oral gavage) for ten weeks and treated with EGCG (25, 50, and 100 mg/kg) for the same duration. Ethanol exposure led to the impaired spatial memory and learning in rats assessed using the Morris water maze and elevated plus-maze test. Further, we assessed the role of EGCG in mitigating the oxidative stress, neuroinflammatory and cell death signaling associated markers. Co-administration with

EGCG significantly prevented all the behavioral, biochemical and molecular alterations in the different brain regions of ethanol-treated rats in a dose-dependent manner. EGCG suppressed the acetylcholinesterase activity, increased oxidative-nitrosative stress, cytokines (TNF-alpha and IL-1beta), NF-kappa β and caspase-3 levels in both the cortex and hippocampus of ethanol-treated rats. Our preliminary study demonstrated that EGCG improves the oxido-nitrosative stress, inflammation, and cell death signaling associated with ethanol-induced cognitive dysfunction. This suggests the potential role of EGCG in mitigating the cognitive deficits associated with chronic alcohol consumption.

Immune-microbiome interplay and its implications in neurodegenerative disorders.
The neurodegeneration and its related CNS pathologies need an urgent toolbox to minimize the global mental health burden. The neuroimmune system critically regulates the brain maturation and survival of neurons across the nervous system. The chronic manipulated immunological drive can accelerate the neuronal pathology hence promoting the burden of neurodegenerative disorders. The gut is home for trillions of microorganisms having a mutual relationship with the host system. The gut-brain axis is a unique biochemical pathway through which the gut residing microbes connects with the brain cells and regulates various physiological and pathological cascades. The gut microbiota and CNS communicate using a common language that synchronizes the tuning of immune cells. The intestinal gut microbial community has a profound role in the maturation of the immune system as well as the development of the nervous system. We have critically summarised the clinical and preclinical reports from the past a decade emphasising that the significant changes in gut microbiota can enhance the host susceptibility towards neurodegenerative disorders. In this review, we have discussed how the gut microbiota-mediated immune response inclines the host physiology towards neurodegeneration and indicated the gut microbiota as a potential future candidate for the management of neurodegenerative disorders.

Kinesin Nanomotors Mediated Trafficking of NMDA-Loaded Cargo as A Novel Target in Chronic Pain.
Chronic pain is among the most prevalent burdensome disorders worldwide. The -methyl-d-aspartate (NMDA) receptor system plays a critical role in central sensitization, a primary feature of chronic pain. Despite the proven efficacy of exogenous ligands to this receptor system in preclinical studies, evidence for the clinical efficacy of NMDA antagonists for the treatment of chronic pain is weak. Researchers are studying alternate approaches, rather than direct inhibition of the NMDA receptors in pain processing neurons. This indirect approach utilizes the modulation of molecular switches that regulates the synthesis, maturation, and transport of receptors from cellular organelles to the synaptic membrane. Kinesins are nanomotors that anterogradely transport the cargo using microtubule tracks across the neurons. Various members of the kinesin family, including KIF17, KIF11, KIF5b, and KIF21a, regulate the intracellular transport of NMDA receptors. Pharmacological targeting of these ATP-driven nanomotors could be a useful tool for manipulating the NMDAR functioning. It could provide the potential for the development of a novel strategy for the management of chronic pain.

Adenosine receptor signalling: Probing the potential pathways for the ministration of neuropathic pain.
Neuropathic pain is a critical burdensome problem due to the complex interplay of several pathological mechanisms and lack of availability of effective therapeutic interventions. The available therapeutic options are associated with a variety of limitations, including severe side effects, and unmet medical needs, warranting further research to identify and validate potential targets. Adenosine receptors system is a widely studied target, which evidently was successful in alleviation of neuropathic pain in several experimental paradigms, and researchers are putting efforts in building its clinical roadmap. The adenosine receptors act by different mechanisms and targeting adenosine receptors for neuropathic pain includes several important pathways such as p38-mitogen-activated protein kinases (MAPK), extracellular signal-regulated kinases (ERK), brain-derived neurotrophic factor (BDNF) signalling, γ-aminobutyric acid (GABA) as well as the ion channel modulations. Various studies have also shown the relevance of targeting adenosine receptors in chemotherapy-induced neuropathic pain and diabetic neuropathy. Several drugs acting on adenosine receptors have undergone clinical trials for management of neuropathic pain, whereas many other drugs are yet to be studied to find a potential anti-nociceptive agent. In this review, we have discussed the roadmap of adenosine receptors as a potential target for the treatment of neuropathic pain.

Activation of μ-δ opioid receptor heteromers inhibits neuropathic pain behavior in rodents.
Several reports support the idea that μ- and δ-opioid receptors (ORs) may exist as heterodimers in brain regions involved in pain signaling. The unique pharmacology of these heteromers may present a novel analgesic target. However, the role of μ-δ heteromers in sensory neurons involved in pain and opioid analgesia remains unclear, particularly during neuropathic pain.

We examined the effects of spinal nerve injury on μ-δ heteromer expression in dorsal root ganglion (DRG) neurons and the effects of a μ-δ heteromer-targeting agonist, CYM51010, on neuropathic pain behavior in rats and mice. An L5 spinal nerve ligation (SNL) in rats significantly decreased μ-δ heteromer expression in L5 DRG but increased heteromer levels in uninjured L4 DRG. Importantly, in SNL rats, subcutaneous injection of CYM51010 inhibited mechanical hypersensitivity in a dose-related manner (EC50: 1.09 mg/kg) and also reversed heat hyperalgesia and attenuated ongoing pain (2 mg/kg, subcutaneously). HEK-293T cell surface-labeled with μ- and δ-ORs internalized both receptors after exposure to CYM51010. By contrast, in cells transfected with μ-OR alone, CYM51010 was significantly less effective at inducing receptor internalization. Electrophysiologic studies showed that CYM51010 inhibited the C-component and windup phenomenon in spinal wide dynamic range neurons of SNL rats. The pain inhibitory effects of CYM51010 persisted in morphine-tolerant rats but was markedly attenuated in μ-OR knockout mice. Our studies show that spinal nerve injury may increase μ-δ heterodimerization in uninjured DRG neurons, and that μ-δ heteromers may be a potential therapeutic target for relieving neuropathic pain, even under conditions of morphine tolerance.

Targeting human Mas-related G protein-coupled receptor X1 to inhibit persistent pain.
Human Mas-related G protein-coupled receptor X1 (MRGPRX1) is a promising target for pain inhibition, mainly because of its restricted expression in nociceptors within the peripheral nervous system. However, constrained by species differences across , drug candidates that activate MRGPRX1 do not activate rodent receptors, leaving no responsive animal model to test the effect on pain in vivo. Here, we generated a transgenic mouse line in which we replaced mouse with human This humanized mouse allowed us to characterize an agonist [bovine adrenal medulla 8-22 (BAM8-22)] and a positive allosteric modulator (PAM), ML382, of MRGPRX1. Cellular studies suggested that ML382 enhances the ability of BAM8-22 to inhibit high-voltage-activated Ca channels and attenuate spinal nociceptive transmission. Importantly, both BAM8-22 and ML382 effectively attenuated evoked, persistent, and spontaneous pain without causing obvious side effects. Notably, ML382 by itself attenuated both evoked pain hypersensitivity and spontaneous pain in mice after nerve injury without acquiring coadministration of an exogenous agonist. Our findings suggest that humanized mice provide a promising preclinical model and that activating MRGPRX1 is an effective way to treat persistent pain.

Mas-Related G Protein-Coupled Receptors Offer Potential New Targets for Pain Therapy.
The founding member of the Mas-related G-protein-coupled receptor (Mrgpr) family was discovered in 1986. Since then, many more members of this receptor family have been identified in multiple species, and their physiologic functions have been investigated widely. Because they are expressed exclusively in small-diameter primary sensory neurons, the roles of Mrgpr proteins in pain and itch have been best studied. This review will focus specifically on the current knowledge of their roles in pathological pain and the potential development of new pharmacotherapies targeted at some Mrgprs for the treatment of chronic pain. We will also discuss the limitations and future scope of this receptor family in pain treatment.

Activation of Peripheral μ-opioid Receptors by Dermorphin [D-Arg2, Lys4] (1-4) Amide Leads to Modality-preferred Inhibition of Neuropathic Pain.
Opioids have long been regarded as the most effective drugs for the treatment of severe acute and chronic pain. Unfortunately, their therapeutic efficacy and clinical utility have been limited because of central and peripheral side effects.

IMPAIRED PAIN TOLERANCE IN AGING: WHAT ROLE FOR LOCAL SKIN BLOOD FLOW?

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Julia Devanne[1], Olivier Despres[1], Thierry Pebayle[2], André Dufour[3], Ségolène Lithfous[1]
[1]Université de Strasbourg, Lnca Umr 7364, Strasbourg, France, [2]Université de Strasbourg, Ci2n Uar 3489, Strasbourg, France, [3]Université de Strasbourg, Lnca Umr 7364, Ci2n Uar 3489, Strasbourg, France

Aim: A decrease in pain tolerance is observed in aging, especially when tested with prolonged hot nociceptive stimuli. This type of stimuli activate Aδ and C fibers, the latter also being involved in the control of cutaneous vasomotricity. However, in the elderly, cutaneous vasodilation in response to local skin heating is impaired. This study therefore aims to test whether an alteration in local skin blood flow may participate in the decrease of pain tolerance with age. Methods: 30 young and 40 old participants performed a pain resistance test, in which they placed their hand in an airtight box with the air temperature regulated at 65°C. Participants continuously estimated the pain intensity using a visual analog scale (VAS). The test was 15 minutes long, but participants could end the test earlier if the pain became intolerable. Local blood flow was continuously recorded using laser Doppler flowmetry. Results: The results showed that the elderly have a decreased blood flow compared to the young. We also observed that pain tolerance is impaired in the elderly as 85% of the young subjects resisted pain until the end of the test compared to 50% in the elderly. In the elderly who did not resist until the end of the test, the results showed that blood flow positively correlated with pain rating, whereas no correlation was observed in the other participants. Conclusion: Our results suggest that altered local skin blood flow may influence thermal pain tolerance in aging.

PRINCIPLES OF NOCICEPTION IN THE ANTERIOR CINGULATE CORTEX

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Mario Acuna[1], Fernando Kasanetz[2], Paolo De Luna[1], Marta Falkowska[3], Thomas Nevian[3]
[1]University of Bern, Department Of Physilogy, Bern, Switzerland, [2]University of Buenos Aires, Grupo De Neurociencias De Sistemas, Buenos Aires, Argentina, [3]University of Bern, Department Of Physiology, Bern, Switzerland

The perception of pain is a multidimensional sensory and emotional/affective experience arising from distributed brain activity. However, the involved brain regions are not specific for pain. Thus, how the cortex distinguishes nociception from other aversive and salient sensory stimuli remains elusive. Using in vivo calcium imaging in mice, we investigated nociceptive in comparison to other sensory coding in the anterior cingulate cortex, a region essential for the emotional processing of pain. The overall population activity, but not single cell responses were required to discriminate nociceptive stimuli and associated behavioral responses. Peripheral nerve injury-induced neuropathic pain led to dysfunctional decoding of sensory events by exacerbation of saliency-detection and impairment of pattern separation and classification, which were reversed by analgesic treatment. These findings provide a novel interpretation for altered nociceptive processing of chronic pain in the brain.

IMPACT OF LONG-TERM AND SHORT-TERM EXPOSURE OF ENVIRONMENTAL ENRICHMENT ON PAIN-RELATED DEPRESSION IN ADOLESCENT MICE.

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Marta Falkowska, Mario Acuna, Thomas Nevian
University of Bern, Department Of Physiology, Bern, Switzerland

Chronic pain significantly impacts well-being of more than 30% of the world's population. Its comorbidities, such as depression, anxiety, cognitive impairments or sleep disturbances may intensify and exacerbate the overall experience of pain, which consists of physiological as well as psychological aspects. Pharmacological treatments are often effective in reversing these changes, yet carry the risk of side-effects and addiction. Moreover, prescription drugs may be costly, therefore inaccessible to number of individuals. This project aims to characterize the impact of environmental manipulation on animal model of chronic pain, and evaluate if this can prevent the development of anxiodepressive symptoms. In a pilot study, we confirmed the presence of depressive-like behaviors in adult mice after Spared Nerve Injury (SNI) causing long-lasting pain in one hind paw. Subsequently, we randomly assigned 64 mice at 21 days of age into one of eight experimental groups, following two different protocols. Each protocol is applied to four groups: SNI (pain) + standard housing, SNI + enriched environment, sham (control) + standard housing, and sham + enriched environment. Protocols differ in the duration of exposure to enrichment: a) enrichment is interrupted after 6 weeks, simultaneously to conducting SNI/sham surgery; or b) all four groups of animals are housed in the enriched environment until the end of the experiment. Six weeks after surgery, we evaluate mechanical hypersensitivity and depression phenotype, using multiple behavioral tests: von Frey, marble burying, novelty suppressed feeding, splash test, and forced swimming task.

TOZASERTIB ATTENUATES EVOKED AND ONGOING PAIN IN NERVE INJURED RATS BY INHIBITING KIF MEDIATED INFLAMMATORY SIGNALLING

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Vinod Tiwari, Ankit Uniyal, Akhilesh K, Anagha Gadepalli

Aims: Kinesins (KIF's) are the motor proteins which are recently reported to be involved in the trafficking of nociceptors leading to chronic pain. Aurora kinases are known to be involved in the regulation of KIF proteins which are associated with the activation of NMDA receptors. Here, we investigated the effect of tozasertib, a pan-Aurora kinase inhibitor, on nerve injury-induced evoked and chronic ongoing pain in rats. **Methods:** In this study we evaluated the effect of tozasertib on nerve injury-induced chronic pain. We assessed various pain parameters such as thermal sensitivity, static and dynamic mechanical allodynia and ongoing pain. Further we performed molecular analysis using RT-PCR and western blotting to measure the mRNA and protein expressions of associated markers. **Results:** Tozasertib produced significant and dose-dependent inhibition of both evoked and chronic ongoing pain in nerve injured rats. Tozasertib and gabapentin treatment significantly attenuates spontaneous ongoing pain in nerve injured rats but did not produce any place preference behaviour in healthy naïve rats pointing towards their non-addictive analgesic potential. Western blotting and RT-PCR studies suggested enhanced expressions of NR2B and KIF-17 along with increased NFkβ, TNF-α, IL-1β, and IL-6 levels in DRG and spinal cord of nerve injured rats which was significantly attenuated on treatment with different doses of tozasertib. **Conclusion:** Findings from the current study suggests that inhibition of pan-aurora kinase attenuates KIF-17- NR2B crosstalk mediated activation of inflammatory signaling which further leads to significant inhibition of both evoked and chronic ongoing pain in nerve-injured rats.

Inhibition of pan-Aurora kinase attenuates evoked and ongoing pain in nerve injured rats via regulating KIF17-NR2B mediated signaling.
Kinesins (KIF's) are the motor proteins which are recently reported to be involved in the trafficking of nociceptors leading to chronic pain. Aurora kinases are known to be involved in the regulation of KIF proteins which are associated with the activation of N-methyl-D-aspartate (NMDA) receptors. Here, we investigated the effect of tozasertib, a pan-Aurora kinase inhibitor, on nerve injury-induced evoked and chronic ongoing pain in rats and the involvement of kinesin family member 17 (KIF17) and NMDA receptor subtype 2B (NR2B) crosstalk in the same. Rats with chronic constriction injury showed a significantly decreased pain threshold in a battery of pain behavioural assays. We found that tozasertib [10, 20, and 40 mg/kg intraperitoneally (i.p.)] treatment showed a significant and dose-dependent inhibition of both evoked and chronic ongoing pain in rats with nerve injury. Tozasertib (40 mg/kg i.p.) and gabapentin (30 mg/kg i.p.) treatment significantly inhibits spontaneous ongoing pain in nerve injured rats but did not produce any place preference behaviour in healthy naïve rats pointing towards their non-addictive analgesic potential. Moreover, tozasertib (10, 20, and 40 mg/kg i.p.) and gabapentin (30 mg/kg i.p.) treatment did not altered the normal pain threshold in healthy naïve rats and didn't produce central nervous system associated side effects as well. Western blotting and reverse transcription polymerase chain reaction studies suggested enhanced expressions of NR2B and KIF-17 along with increased nuclear factor kappa β (NFkβ), tumour necrosis factor-α (TNF-α), interleukin 1β (IL-1β), and interleukin 6 (IL-6) levels in dorsal root ganglion (DRG) and spinal cord of nerve injured rats which was significantly attenuated on treatment with different does of Tozasertib. Findings from the current study suggests that inhibition of pan-Aurora kinase decreased KIF-17 mediated NR2B activation which further leads to significant inhibition of evoked and chronic ongoing pain in nerve-injured rats.

Unlocking the potential of TRPV1 based siRNA therapeutics for the treatment of chemotherapy-induced neuropathic pain.
Chemotherapy-induced neuropathic pain (CINP) is among the most common clinical complications associated with the use of anti-cancer drugs. CINP occurs in nearly 68.1% of the cancer patients receiving chemotherapeutic drugs. Most of the

clinically available analgesics are ineffective in the case of CINP patients as the pathological mechanisms involved with different chemotherapeutic drugs are distinct from each other. CINP triggers the somatosensory nervous system, increases the neuronal firing and activation of nociceptive mediators including transient receptor protein vanilloid 1 (TRPV1). TRPV1 is widely present in the peripheral nociceptive nerve cells and it has been reported that the higher expression of TRPV1 in DRGs serves a critical role in the potentiation of CINP. The therapeutic glory of TRPV1 is well recognized in clinics which gives a promising insight into the treatment of pain. But the adverse effects associated with some of the antagonists directed the scientists towards RNA interference (RNAi), a tool to silence gene expression. Thus, ongoing research is focused on developing small interfering RNA (siRNA)-based therapeutics targeting TRPV1. In this review, we have discussed the involvement of TRPV1 in the nociceptive signaling associated with CINP and targeting this nociceptor, using siRNA will potentially arm us with effective therapeutic interventions for the clinical management of CINP.

Multifarious Targets and Recent Developments in the Therapeutics for the Management of Bone Cancer Pain.
Bone cancer pain (BCP) is a distinct pain state showing characteristics of both neuropathic and inflammatory pain. On average, almost 46% of cancer patients exhibit BCP with numbers flaring up to as high as 76% for terminally ill patients. Patients suffering from BCP experience a compromised quality of life, and the unavailability of effective therapeutics makes this a more devastating condition. In every individual cancer patient, the pain is driven by different mechanisms at different sites. The mechanisms behind the manifestation of BCP are very complex and poorly understood, which creates a substantial barrier to drug development. Nevertheless, some of the key mechanisms involved have been identified and are being explored further to develop targeted molecules. Developing a multitarget approach might be beneficial in this case as the underlying mechanism is not fixed and usually a number of these pathways are simultaneously dysregulated. In this review, we have discussed the role of recently identified novel modulators and mechanisms involved in the development of BCP. They include ion channels and receptors involved in sensing alteration of temperature and acidic microenvironment, immune system activation, sodium channels, endothelins, protease-activated receptors, neurotrophins, motor proteins mediated trafficking of glutamate receptor, and some bone-specific mechanisms. Apart from this, we have also discussed some of the novel approaches under preclinical and clinical development for the treatment of bone cancer pain.

Structure-based virtual screening and molecular dynamics simulation for the identification of sphingosine kinase-2 inhibitors as potential analgesics.
Neuropathic pain is due to an injury or disease of the somatosensory nervous system, which accounts for a significant economical and health burden to society. Due to poor understanding of their underlying mechanisms, the available treatments merely provide symptomatic relief and precipitates a variety of adverse effects. This suggests that there is an unmet medical need that must be addressed with effective strategies for the development of novel therapeutics. Sphingosine kinase 2 (SphK2) is an oncogenic lipid kinase that has emerged as a promising target for chronic pain and other diseases. In the present study, we have explored the structure-based virtual high-throughput screening of the Nuclei of Bioassays, Ecophysiology, and Biosynthesis of Natural Products Database (NuBBE) to identify potent natural products as inhibitors of SphK2. A molecular docking study was performed to calculate binding affinities and specificity to identify potential leads against SphK2. Initially, hits were selected by the implementation of absorption, distribution, metabolism, excretion and toxicity properties, Lipinski rule, and PAINS filters. The top-scoring hits also exhibiting an optimal ADMET profile were subjected to MM/GBSA free binding free energy calculation and molecular dynamics simulation. The results from molecular dynamics simulation revealed a stable ligand -SphK2 complex with protein and ligand RMSD within reasonable limits. Overall, we identified compounds, NuBBE_972 and NuBBE_1107 as potential inhibitors of SphK2 with optimal pharmacokinetic properties which have the potential to be developed as novel therapeutics for the management of chronic pain.Communicated by Ramaswamy H. Sarma.

Epigallocatechin-3-gallate improves chronic alcohol-induced cognitive dysfunction in rats by interfering with neuro-inflammatory, cell death and oxido-nitrosative cascade.
Alcohol consumption for a longer period of time is linked with neuronal damage and an increase in inflammatory signaling resulting in cell death and dementia. Natural compounds are the focus of research due to their high efficacy and good safety profile. Here we have investigated the effect of chronic epigallocatechin-3-gallate (EGCG) administration against the alcohol-induced cognitive deficit rats. Male Wistar rats were exposed to the 12% ethanol (10 g/kg; oral gavage) for ten weeks and treated with EGCG (25, 50, and 100 mg/kg) for the same duration. Ethanol exposure led to the impaired spatial memory and learning in rats assessed using the Morris water maze and elevated plus-maze test. Further, we assessed the role of EGCG

in mitigating the oxidative stress, neuroinflammatory and cell death signaling associated markers. Co-administration with EGCG significantly prevented all the behavioral, biochemical and molecular alterations in the different brain regions of ethanol-treated rats in a dose-dependent manner. EGCG suppressed the acetylcholinesterase activity, increased oxidative-nitrosative stress, cytokines (TNF-alpha and IL-1beta), NF-kappa β and caspase-3 levels in both the cortex and hippocampus of ethanol-treated rats. Our preliminary study demonstrated that EGCG improves the oxido-nitrosative stress, inflammation, and cell death signaling associated with ethanol-induced cognitive dysfunction. This suggests the potential role of EGCG in mitigating the cognitive deficits associated with chronic alcohol consumption.

Immune-microbiome interplay and its implications in neurodegenerative disorders.
The neurodegeneration and its related CNS pathologies need an urgent toolbox to minimize the global mental health burden. The neuroimmune system critically regulates the brain maturation and survival of neurons across the nervous system. The chronic manipulated immunological drive can accelerate the neuronal pathology hence promoting the burden of neurodegenerative disorders. The gut is home for trillions of microorganisms having a mutual relationship with the host system. The gut-brain axis is a unique biochemical pathway through which the gut residing microbes connects with the brain cells and regulates various physiological and pathological cascades. The gut microbiota and CNS communicate using a common language that synchronizes the tuning of immune cells. The intestinal gut microbial community has a profound role in the maturation of the immune system as well as the development of the nervous system. We have critically summarised the clinical and preclinical reports from the past a decade emphasising that the significant changes in gut microbiota can enhance the host susceptibility towards neurodegenerative disorders. In this review, we have discussed how the gut microbiota-mediated immune response inclines the host physiology towards neurodegeneration and indicated the gut microbiota as a potential future candidate for the management of neurodegenerative disorders.

Kinesin Nanomotors Mediated Trafficking of NMDA-Loaded Cargo as A Novel Target in Chronic Pain.
Chronic pain is among the most prevalent burdensome disorders worldwide. The -methyl-d-aspartate (NMDA) receptor system plays a critical role in central sensitization, a primary feature of chronic pain. Despite the proven efficacy of exogenous ligands to this receptor system in preclinical studies, evidence for the clinical efficacy of NMDA antagonists for the treatment of chronic pain is weak. Researchers are studying alternate approaches, rather than direct inhibition of the NMDA receptors in pain processing neurons. This indirect approach utilizes the modulation of molecular switches that regulates the synthesis, maturation, and transport of receptors from cellular organelles to the synaptic membrane. Kinesins are nanomotors that anterogradely transport the cargo using microtubule tracks across the neurons. Various members of the kinesin family, including KIF17, KIF11, KIF5b, and KIF21a, regulate the intracellular transport of NMDA receptors. Pharmacological targeting of these ATP-driven nanomotors could be a useful tool for manipulating the NMDAR functioning. It could provide the potential for the development of a novel strategy for the management of chronic pain.

Tozasertib Attenuates Neuropathic Pain by Interfering with Aurora Kinase and KIF11 Mediated Nociception.
Kinesins are the motor proteins that transport excitatory receptors to the synaptic membrane by forming a complex with receptor cargo leading to central sensitization causing neuropathic pain. Many regulatory proteins govern the transit of receptors by activating kinesin, and Aurora kinases are one of them. In this study, we have performed in silico molecular dynamics simulation to delineate the dynamic interaction of Aurora kinase A with its pharmacological inhibitor, tozasertib. The results from the molecular dynamics study shows that tozasertib-Aurora kinase A complex is stabilized through hydrogen bonding, polar interactions, and water bridges. Findings from the studies suggest that tozasertib treatment significantly attenuates lipopolysaccharide (LPS)-induced increase in oxidonitrosative stress and kif11 overexpression in C6 glial cell lines. Further, we investigated the regulation of kif11 and its modulation by tozasertib in an animal model of neuropathic pain. Two weeks post-CCI surgery we observed a significant increase in pain hypersensitivity and kif11 overexpression in DRG and spinal cord of nerve-injured rats. Tozasertib treatment significantly attenuates enhanced pain hypersensitivity along with the restoration of kif11 expression in DRG and spinal cord and oxidonitrosative stress in the sciatic nerve of injured rats. Our findings demonstrate the potential role of tozasertib for the management of neuropathic pain.

A comprehensive review on pharmacology of efflux pumps and their inhibitors in antibiotic resistance.
The potential for the build-up of resistance to a particular antibiotic endangers its therapeutic application over time. In recent decades, antibiotic resistance has become one of the most severe threats to public health. It can be attributed to the

relentless and unchecked use of antibiotics in healthcare sectors, cell culture, animal husbandry, and agriculture. Some classic examples of resistance mechanisms employed by bacteria include developing antibiotic degrading enzymes, modifying target sites previously targeted by antibiotics, and developing efflux mechanisms. Studies have shown that while some efflux pumps selectively extrude certain antibiotics, others extrude a structurally diverse class of antibiotics. Such extrusion of a structurally diverse class of antibiotics gives rise to multi-drug resistant (MDR) bacteria. These mechanisms are observed in gram-positive and gram-negative bacteria alike. Therefore, efflux pumps find their place in the list of high-priority targets for the treatment of antibiotic-resistance in bacteria mediated by efflux. Studies showed a significant escalation in bacteria's susceptibility to a particular antibiotic drug when tested with an efflux pump inhibitor (EPI) compared to when it was tested with the antibiotic drug alone. This review discusses the pharmacology, current status, and the future of EPIs in antibiotic resistance.

BASOLATERAL AMYGDALA INPUT TO ANTERIOR CINGULATE CORTEX MEDIATES PAIN-AVOIDANCE BEHAVIORS

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Kristina Valentinova, Thomas Nevian
University of Bern, Institute Of Physiology, Bern, Switzerland

Pain is caused by dysfunction of the somatosensory system, often due to injury, although it may appear without any apparent cause. When pain becomes chronic, it manifests both as a sensory and affective condition, giving rise to maladaptive behaviors. One typical consequence is the development of pain-related fear, favoring avoidance behaviors when both rewarding and aversive stimuli are present. Dysfunction of the anterior cingulate cortex (ACC) has been associated to negative states occurring in human neuropathy as well as in rodent pain-models. The ACC integrates sensory and affective information and orchestrates appropriate behavioral responses in a changing environment. It receives excitatory projections from the basolateral amygdala (BLA), a brain area extensively studied in the context of fear and exhibiting plasticity in neuropathic pain states. However, whether BLA-ACC circuit is required for pain-related avoidance behaviors remains unknown. Here we are testing the hypothesis that plasticity at BLA-ACC synapses contributes to pain-related avoidance. We use the spared nerve injury (SNI) mouse model of neuropathic pain, which recapitulates behaviors reminiscent of the condition including mechanical allodynia and avoidance in a conflicting approach-avoidance task. Chemogenetic inhibition of BLA-ACC projections normalizes SNI mice's performance in the conflicting task, but not the allodynia behavior. We further show pain-induced increase of pre- and post-synaptic excitatory transmission at BLA inputs onto ACC layer 2/3 pyramidal neurons, but not onto layer 5 or GABA neurons. Altogether our data suggest a projection- and cell type-specific potentiation in the ACC of neuropathic pain mice, potentially contributing to pain-related avoidance behaviors.

Long-Lasting, Pathway-Specific Impairment of a Novel Form of Spike-Timing-Dependent Long-Term Depression by Neuropathic Pain in the Anterior Cingulate Cortex.
Malfunctioning synaptic plasticity is one of the major mechanisms contributing to the development of chronic pain. We studied spike-timing dependent depression (tLTD) in the anterior cingulate cortex (ACC) of male mice, a brain region involved in processing emotional aspects of pain. tLTD onto layer 5 pyramidal neurons depended on postsynaptic calcium-influx through GluN2B-containing NMDARs and retrograde signaling via nitric oxide to reduce presynaptic release probability. After chronic constriction injury of the sciatic nerve, a model for neuropathic pain, tLTD was rapidly impaired; and this phenotype persisted even beyond the time of recovery from mechanical sensitization. Exclusion of GluN2B-containing NMDARs from the postsynaptic site specifically at projections from the anterior thalamus to the ACC caused the tLTD phenotype, whereas signaling downstream of nitric oxide synthesis remained intact. Thus, transient neuropathic pain can leave a permanent trace manifested in the disturbance of synaptic plasticity in a specific afferent pathway to the cortex. Synaptic plasticity is one of the main mechanisms that contributes to the development of chronic pain. Most studies have focused on potentiation of excitatory synaptic transmission, but very little is known about the reduction in synaptic strength. We have focused on the ACC, a brain region associated with the processing of emotional and affective components of pain. We studied spike-timing dependent LTD, which is a biologically plausible form of synaptic plasticity, that depends on the relative timing of presynaptic and postsynaptic activity. We found a long-lasting and pathway-specific suppression of the induction mechanism for spike-timing dependent LTD from the anterior thalamus to the ACC, suggesting that this pathology might be involved in altered emotional processing in pain.

Morphine withdrawal recruits lateral habenula cytokine signaling to reduce synaptic excitation and sociability.
The lateral habenula encodes aversive stimuli contributing to negative emotional states during drug withdrawal. Here we report that morphine withdrawal in mice leads to microglia adaptations and diminishes glutamatergic transmission onto raphe-projecting lateral habenula neurons. Chemogenetic inhibition of this circuit promotes morphine withdrawal-like social deficits.

Morphine withdrawal-driven synaptic plasticity and reduced sociability require tumor necrosis factor-α (TNF-α) release and neuronal TNF receptor 1 activation. Hence, habenular cytokines control synaptic and behavioral adaptations during drug withdrawal.

Limiting habenular hyperactivity ameliorates maternal separation-driven depressive-like symptoms.
Early-life stress, including maternal separation (MS), increases the vulnerability to develop mood disorders later in life, but the underlying mechanisms remain elusive. We report that MS promotes depressive-like symptoms in mice at a mature stage of life. Along with this behavioral phenotype, MS drives reduction of GABA-GIRK signaling and the subsequent lateral habenula (LHb) hyperexcitability-an anatomical substrate devoted to aversive encoding. Attenuating LHb hyperactivity using chemogenetic tools and deep-brain stimulation ameliorates MS depressive-like symptoms. This provides insights on mechanisms and strategies to alleviate stress-dependent affective behaviors.

Can the Lateral Habenula Crack the Serotonin Code?
The lateral habenula (LHb) and the serotonergic system both contribute to motivational states by encoding rewarding and aversive signals. Converging evidence suggests that perturbation of these systems is critical for the pathophysiology of mood disorders. Anatomical and functional studies indicate that the serotonergic system and the LHb are interconnected in a forward-feedback loop. However, how serotonin release modifies the synaptic and cellular properties of LHb neurons and whether this has any behavioral repercussions remain poorly investigated. In this review article, we discuss insights gained from rodents and humans regarding the implications of the serotonin system and the LHb in aversion encoding and related disorders. We then describe the type, properties and pharmacology of serotonergic receptors expressed throughout the LHb. Finally, we discuss physiological data reporting how serotonergic signaling modifies synaptic transmission and neuronal activity within the LHb. Altogether, we combine a mechanistic- and circuit-level knowledge to provide an overview on how the LHb integrates serotonergic signals, a process potentially contributing to LHb-dependent encoding of valenced external stimuli.

mGluR-LTD at Excitatory and Inhibitory Synapses in the Lateral Habenula Tunes Neuronal Output.
Excitatory and inhibitory transmission onto lateral habenula (LHb) neurons is instrumental for the expression of positive and negative motivational states. However, insights into the molecular mechanisms modulating synaptic transmission and the repercussions for neuronal activity within the LHb remain elusive. Here, we report that, in mice, activation of group I metabotropic glutamate receptors triggers long-term depression at excitatory (eLTD) and inhibitory (iLTD) synapses in the LHb. mGluR-eLTD and iLTD rely on mGluR1 and PKC signaling. However, mGluR-dependent adaptations of excitatory and inhibitory synaptic transmission differ in their expression mechanisms. mGluR-eLTD occurs via an endocannabinoid receptor-dependent decrease in glutamate release. Conversely, mGluR-iLTD occurs postsynaptically through PKC-dependent reduction of β2-containing GABAA-R function. Finally, mGluR-dependent plasticity of excitation or inhibition decides the direction of neuronal firing, providing a synaptic mechanism to bidirectionally control LHb output. We propose mGluR-LTD as a cellular substrate that underlies LHb-dependent encoding of opposing motivational states.

Ventral Subiculum Stimulation Promotes Persistent Hyperactivity of Dopamine Neurons and Facilitates Behavioral Effects of Cocaine.
The ventral subiculum (vSUB) plays a key role in addiction, and identifying the neuronal circuits and synaptic mechanisms by which vSUB alters the excitability of dopamine neurons is a necessary step to understand the motor changes induced by cocaine. Here, we report that high-frequency stimulation of the vSUB (HFSvSUB) over-activates ventral tegmental area (VTA) dopamine neurons in vivo and triggers long-lasting modifications of synaptic transmission measured ex vivo. This potentiation is caused by NMDA-dependent plastic changes occurring in the bed nucleus of the stria terminalis (BNST). Finally, we report that the modification of the BNST-VTA neural circuits induced by HFSvSUB potentiates locomotor activity induced by a sub-threshold dose of cocaine. Our findings unravel a neuronal circuit encoding behavioral effects of cocaine in rats and highlight the importance of adaptive modifications in the BNST, a structure that influences motivated behavior as well as maladaptive

behaviors associated with addiction.

Cocaine-evoked negative symptoms require AMPA receptor trafficking in the lateral habenula.
Addictive substances mediate positive and negative states promoting persistent drug use. However, substrates for aversive effects of drugs remain elusive. We found that, in mouse lateral habenula (LHb) neurons targeting the rostromedial tegmental nucleus, cocaine enhanced glutamatergic transmission, reduced K(+) currents and increased excitability. GluA1 trafficking in LHb was instrumental for these cocaine-evoked modifications and drug-driven aversive behaviors. Altogether, our results suggest that long-lasting adaptations in LHb shape negative symptoms after drug taking.
Nat Neurosci, 2015; 18

Synaptic and cellular profile of neurons in the lateral habenula.
The lateral habenula (LHb) is emerging as a crucial structure capable of conveying rewarding and aversive information. Recent evidence indicates that a rapid increase in the activity of LHb neurons drives negative states and avoidance. Furthermore, the hyperexcitability of neurons in the LHb, especially those projecting to the midbrain, may represent an important cellular correlate for neuropsychiatric disorders like depression and drug addiction. Despite the recent insights regarding the implications of the LHb in the context of reward and aversion, the exact nature of the synaptic and cellular players regulating LHb neuronal functions remains largely unknown. Here we focus on the synaptic and cellular physiology of LHb neurons. First, we discuss the properties of excitatory transmission and the implications of glutamate receptors for long-term synaptic plasticity; second, we review the features of GABAergic transmission onto LHb neurons; and finally, we describe the contribution that neuromodulators such as dopamine (DA) and serotonin may have for LHb neuronal physiology. We relate these findings to the role that the LHb can play in processing aversive and rewarding stimuli, both in health and disease states.

AAV GENE THERAPY DELIVERING RECOMBINANT DIMERIC PEPTIDES TARGETING PICK1 FULLY RELIEVE CHRONIC NEUROPATHIC PAIN

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Gith Noes-Holt[1], Mette Richner[2], Kathrine Jensen[1], Carolyn Goddard[1], Raquel Comaposada Baro[1], Line Sivertsen[1], Nikolaj Christensen[1], Christian Vægter[2], Anke Tappe-Theodor[3], Rohini Kuner[3], Kenneth Madsen[1], Andreas Toft Sørensen[1]

Background / Aim Chronic pain arises from central sensitization in the spinal cord, and AMPA receptors (AMPARs) are believed to play a major role. In an earlier study, we showed that a synthetic bivalent peptide targeting the AMPAR-trafficking protein, Protein Interacting with C-Kinase 1 (PICK1), supplied full and temporary pain relief. We hypothesized that the creation and delivery of recombinant dimeric peptides targeting PICK1 could supply similar but long-term effects. Here, we utilized adeno-associated viral (AAV) vectors encoding recombinant peptides, Di-C5, targeting PICK1 under the control of the human synapsin 1-promoter to provide constitutive and pan-neuronal expression in mouse pain models. **Methods** The binding strength of Di-C5 to PICK1 was tested using fluorescence polarization assays. *In vivo*, Di-C5 was given intrathecally to mice exposed to the spared-nerve injury (SNI) model of neuropathic pain. Mechanical paw withdrawal thresholds were assessed using von Frey filaments. **Results** *In vitro*, Di-C5 displayed high binding-affinity towards PICK1(Ki=119nM). In the SNI model, Di-C5 was able to completely prevent mechanical hypersensitivity when given prior to SNI surgery. Di-C5 was also able to reverse an acutely established hypersensitivity when given 2 days following SNI surgery. And finally, Di-C5 was able to gradually attenuate hypersensitivity when administered 35 days after SNI surgery. **Conclusion** We successfully developed a recombinant peptide, Di-C5 supplying complete and persistent reversal of mechanical allodynia in SNI mouse model of neuropathic pain. Together these results suggest that AAV gene therapy aimed at interfering with AMPAR-trafficking may be of clinical relevance in the treatment of chronic pain.

GREEN LIGHT EXPOSURE ELICITS ANTI-INFLAMMATION, ENDOGENOUS OPIOID RELEASE AND LESSENS SYNAPTIC POTENTIATION TO RELIEVE POST-SURGICAL PAIN IN RATS

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Laurent Martin[1], Kevin Cheng[2], Mohab Ibrahim[3], Amol Patwardhan[3], Stephanie Washington[3]
[1]University of Arizona, Department Of Anesthesiology, Tucson, France, [2]University of Arizona, Department Of Pharmacology, Tucson, United States of America, [3]University of Arizona, Department Of Anesthesiology, Tucson, United States of America

Numerous studies have shown how light exposure could benefits multiple conditions such as seasonal affective disorders, circadian rhythm dysregulations, or even neurodegenerative diseases. However, little is known about its potential benefits in pain management. Postoperative pain severely impacts quality of life and functionality, especially in the elderly. While current pharmacologic methods of pain management are effective in many cases, the associated side effects can limit their use, particularly in elderly population. Non-pharmacological methods would minimize drug reliance, facilitating a reduction of the opioid burden. Green light therapy has been shown to be effective in reducing chronic pain in both humans and rodents; however, the underlying mechanisms of this therapy remain incompletely defined. This study unravels the potential of green light exposure in combination with drugs commonly used in pain management. Through behavioral and pharmacological assays, we have demonstrated that exposure to green light potentiates opioid- and NSAIDS-induced pain relief, minimizing dose requirements to achieve antinociception. Furthermore, these insights gave us directions to delve into the underlying mechanisms of green light in the spinal cord. In a rodent model of postoperative pain, we have shown that green light increased spinal endogenous opioid release, concomitantly to reducing spinal inflammation. Altogether, these results shed light on green exposure mechanisms and provide crucial information about the use of green light in combination with other drug therapies. This evidence is the foundation of future complimentary therapies that will reduce drug prescription and consumption alongside their side effects.

REPETITIVE PREFRONTAL TRANSCRANIAL DIRECT CURRENT STIMULATION ALLEVIATES NEUROPATHIC PAIN VIA NEURAL REMODELLING

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Zheng Gan, Han Li, Paul Naser, Linette Tan, Manfred Oswald, Rohini Kuner
Heidelberg University, Institute Of Pharmacology, Heidelberg, Germany

Non-invasive transcranial direct current stimulation (tDCS) is gaining momentum as a neuromodulation strategy for chronic pain treatment. So far, there are no studies reporting prefrontal cortex (PFC) tDCS in neuropathic pain states in rodents, and neural circuits mediating PFC tDCS remain to be clarified. Therefore, our study aimed to elucidate the effects of PFC tDCS on neuropathic pain in mice and reveal the underlying neural circuitry. We employed repetitive anodal PFC tDCS in a longitudinal manner in mice with spared nerve injury (SNI). Early-stage application post-nerve injury prevented progressive development of mechanical hypersensitivity and dampened pain-related aversion. Chronic stage application alleviated established mechanical hypersensitivity and suppressed aversion as well as anxiety in neuropathic mice. In vivo tetrode recordings and c-Fos-based mapping were undertaken to address neuronal activity changes. While single PFC tDCS led to major excitation in the neocortex, repetitive PFC tDCS was associated with adaptation and even silencing of activity. PFC GABAergic interneurons and excitatory neurons were recruited differently over distinct temporal phases. Both baseline activity and responsivity to tactile stimuli were altered in several cortical and subcortical areas, including rostral anterior cingulate cortex, insular cortex, ventrolateral periaqueductal grey, and spinal dorsal horn, indicating a drastic remodeling of brain circuits. Our study thus identifies repetitive anodal PFC tDCS as a non-invasive neurostimulation paradigm to achieve long-lasting pain relief in neuropathic pain and yields knowledge on underlying circuits and cellular remodeling in rodents, which can be employed to enhance the efficacy of neurostimulation-based therapies in clinical settings.

IS IT POSSIBLE TO REDUCE THE DOSE OF CARBAMAZEPINE BY VERAPAMIL COMBINATION IN TRIGEMINAL NEURALGIA PAIN TREATMENTS?

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Havva Demir[1], Engin Sümer[1], Turgay Çelik[2], Aylin Yaba Uçar[3]
[1]Yeditepe University, Neuroscience, Istanbul, Turkey, [2]Yeditepe University, Pharmacology, Istanbul, Turkey, [3]Yeditepe University, Histology And Embryology, Istanbul, Turkey

Trigeminal neuralgia (TN) is a rare facial pain syndrome that immensely affects patients' life quality. Nowadays, Carbamazepine is used clinically in trigeminal neuralgia pain treatment or until operative treatment, but patients do not tolerate the Carbamazepine treatment for long periods due to its side effects. Therefore, we aimed to increase the tolerability or effectiveness of Carbamazepine with combination treatment. The experiment began after randomly dividing the rats into five groups (n=25); Sham, Control, Carbamazepine, Verapamil, and Carbamazepine-Verapamil combination. First, all animals underwent chronic constriction injury of the infraorbital nerve (CCI-IoN) to constitute the animal model of trigeminal neuralgia. Then, the mechanical stimulation test (MST) as a behavioral experiment is carried out by applying a graded series of von Frey filaments (0.02g, 0.16g, 0.4g, 1g, and 2g). The responses of the animals are tested accordingly. When the responses of the Carbamazepine, Verapamil, or control groups to vFF 0,16g and 0,40g filaments were compared statistically, MST scores of Verapamil (1mg) and Carbamazepine (30mg) were found to be significantly different from the control group ($F=6.763$; $p<0.011$; $F=7.860$; $p<0.023$). There was no significant difference between Carbamazepine or Verapamil and sham groups. However, the mean MST scores (1,8) of CBZ 15mg plus Verapamil 1mg (vFF 0.16g) were decreased significantly than the MST scores (2,6 and 2,8) of Verapamil and CBZ by two-way repeated ANOVA ($F=6,615$, $p<0.048$). These results suggest that Verapamil and Carbamazepine combination may be a novel treatment approach to treat neuropathic pain and reduce the side effects of Carbamazepine in TN disease.

Antiallodynia and antihyperalgesia effects of Cerium oxide nanoparticles in treatment of chronic neuropathic pain in rats Fatemeh Forouzanfar[1,2*], Majid Darroudi[3] 1.Neuroscience Research Center, Mashhad University of Medical Sciences, Mashhad, Iran 2.Department of Neuroscience, Faculty of Medicine, Mashhad University of Medical Sciences, Mashhad, Iran 3.Nuclear Medicine Research Center, Mashhad University of Medical Sciences, Mashhad, Iran Corresponding author: Fatemeh Forouzanfar, Department of Neuroscience, Faculty of Medicine, Mashhad University of Medical Sciences, Mashhad, Iran Tel: +98-5138002538, Fax: +98-5138002477, E-mail: forouzanfarff@gmail.com, forouzanfarf@mums.ac.ir **Aims**: Neuropathic pain is often refractory to pain therapies and thus requires exploration of effective drugs. Nanoparticles are reported to have a potential role in the amelioration of neuropathic pain. The aim of this study was to determine the role of cerium oxide nanoparticles in the chronic constriction injury (CCI)-induced neuropathic pain in rats. **Methods**: Cerium oxide nanoparticles was administered intravenously after the neuropathic pain established. Heat hyperalgesia and allodynia were assessed by hot plate, aceton drop, and von frey filament tests, respectively. **Results:** CCI produced significant development in thermal hyperalgesia, mechanical and cold allodynia, in rats. Treatments with cerium oxide nanoparticles decreased thermal hyperalgesia, cold allodynia and mechanical allodynia. **Conclusions**: It is suggested that cerium oxide nanoparticles would be a promising approach for treatment of chronic neuropathic pain.

The perception of pain is a multidimensional sensory and emotional/affective experience arising from distributed brain activity. Maladaptive changes in the so called pain matrix are thought to play a role in the chronification of pain. However, how the brain encodes the perception of pain is still elusive. In particular, little is known about the neuronal activity patterns associated to the unpleasantness that characterizes the pain experience.
One of the reasons for this caveat is that in preclinical models, pain was traditionally evaluated by means of reflexive responses. Recently, more attention has been devoted to the affective-motivational consequences of pain, which are complex behaviors that reflect the subject's motivation to make the aversive sensation cease and that require processing of nociceptive information in cortico-limbic circuits.
In order to investigate real-time cortical encoding of the unpleasantness of pain, we first characterized the behavioral repertoire in response to noxious stimuli in female and male mice. We observed that naïve females expressed higher self-attending responses to noxious cold than naïve males, whereas neuropathic pain increased affective/motivational behaviors in both sexes.
Then, using in vivo calcium imaging with a miniature microscope, we monitored neuronal activity in cortico-striatal neurons of the Anterior Cingulate Cortex (CS-ACC), a cell population that may converge nociceptive information to the mesolimbic system. Our preliminary results show that while some neurons responded specifically to sensory stimuli, others encoded preferentially the behavioral manifestation of pain. Thus, our data suggest that CS-ACC neurons may encode a broad variety of information associated to noxious stimuli.

MULTIMODAL ANALYSIS OF STRUCTURAL PLASTICITY OF CORTICAL GREY MATTER VOLUME IN CHRONIC PAIN

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Amrita Das Gupta[1], Jennifer John[1], Livia Asan[1], Claudia Falfan-Melgoza[2], Wolfgang Weber-Fahr[2], Thomas Kuner[1], Johannes Knabbe[1,3]

Grey matter volume (GMV) changes due to chronic pain have been extensively studied in humans, yet the underlying neurobiological mechanisms are poorly understood. The goal of the project is to investigate the cellular underpinnings of GMV alterations in chronic pain and possibly provide a basis for novel strategies for prevention and therapy of this debilitating disease. In a longitudinal study design, a MRI-compatible chronic cranial window was implanted in mice expressing eGFP in all cell nuclei. In vivo imaging of nuclei allows inferences on tissue volume (distances between nuclei) and cell type composition (cell type-specific nuclear features) at different stages of chronic pain. Cell types were identified by a novel algorithm that includes PyRadiomics and deep learning. MRI imaging (voxel-based morphometry, diffusion tensor imaging) was performed in parallel to in vivo two-photon imaging of the anterior cingulate cortex (ACC) at different timepoints up to 12 weeks after the induction of chronic neuropathic pain with the spared nerve injury model (SNI). Additionally, behavioral paradigms were employed during acute pain and progression towards chronic pain. Our preliminary data show depressive and anxious behavior phenotypes in SNI mice. Furthermore, the imaging data revealed nuclei properties and tissue volume changes that significantly correlated with changes in behavior of SNI mice. In summary, the study established a novel multi-modal approach suitable to provide a more comprehensive understanding of the cellular mechanisms underlying changes in GMV caused by chronic pain.

ACUPUNCTURE EFFECTS ON THE TOLERANCE OF OPIOID ANALGESICS

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Xiao Zhang, Cong Zhan, Jin Gyeom Lee, Namjun Kim, Bong Hyo Lee
Daegu Haany University, College Of Korean Medicin, Daegu, Korea, Republic of

Introduction:Opioids are widely used world wide as potent pain relievers. Long-term use of opioids can cause a series of side effects, Such as drowsiness,respiratory depression.What's more,tolerance and physical dependence are the most prominent problems. Tolerance will lead to a decrease in the analgesic effect of opioids,and an increase in patient's demand for drugs. The present study examined if acupuncture could prevent opioid tolerance and a possible neuronal mechanism was also investigated. **Methods**:Male Sprague Dawley rats were anesthetized by sodium pentobarbital(50mg/kg), Their right jugular vein was cannulated for intravenous drug-administration and they were placed in a stereotaxic device, An access hole was made by drill through the skull for the RMTg and placd the guide-cannula at the destination.Then we tested the rat's right foot using a VonFrey filament and recorded changes in the rat's pain perception over 16days. In addition,we also investigated possible involvement of the VTA related GABA pathway using Naloxone,picrotoxin,2-hydroxysaclofen at RMTg. **Results**:The results showed that the pain of the rats increased after 7 days,but remained basically unchanged by acupuncture. In addition,We also demonstrate that acupuncture at SI5 inhibits the effect of morphine through the GABAAreceptors of RMTg. And verified that acupuncture at SI5 can affect the protein level of brain-derived neurotrophic factor(BDNF) in VTA. **Conclusion**:The findings suggest that acupuncture at SI5 can be a useful therapy to prevent the tolerance of opioid analgesics. **Key words:**AcupunctureSI5,Morphine,tolerance,RMTg

CENTRAL NOCICEPTIVE TRANSMISSION MODULATED BY P2X7 IN THE THALAMOCINGULATE CIRCUIT

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Bai-Chuang Shyu[1,2], Yunag-Hui Kuan[1]
[1]Institute of Biomedical Sciences, Neuroscience, Taipei, Taiwan, [2]Academia Sinica, Institute Of Biomedical Sciences, Taipei, Taiwan

Among ATP receptor families, P2X7 receptors differ in many respects from the other subtypes of the P2X1-6 family. The short-term stimulation of P2X7 leads to the activation of cationic currents, upon repeated or prolonged ATP application, and the opening of a large membrane pore can be detected. In view of the great significance of P2X7 receptors involved in pain and inflammation, we set out to investigate the possible role of this receptor in the central modulation of pain signaling in the thalamocingulate path. Our study utilized major *in vivo* and *ex vivo* neuropharmacological methods to record the effects of manipulating P2X7 receptors during neuron transmission with electrical stimulations to mimic nociceptive inputs. Our results show that the P2X7 directly participates in nociceptive transmission, which indicates a clear functional existence of P2X7 in the thalamocingulate path. Our *ex vivo* brain slice data reveal that activation of P2X7 may facilitate the transmission velocity along the thalamocingulate projection and facilitate the neuron firings. Synaptic vesicle release in anterior cingulate cortical neurons could occur by simultaneously increasing not only the known calcium influx but also glutamate and ATP secretion during signal transmission in response to electrical stimulation. The *in vivo* and *ex vivo* observations in this study provide evidence that the ATP receptor P2X7 is present along the major ascending pain path, the thalamocingulate circuit, and plays a neuromodulator role involved in acute pain transmission, which could contribute new insights for short-term anti-nociceptive applications.

Aims: Central sensitisation (CS) is characterised by an increase in pain response to noxious stimuli (hyperalgesia). Experimental CS models can elicit hyperalgesia in healthy humans. This study aimed to characterise how CS induced by HFS modulates brain activity as measured by fMRI. ***Methods***: After an initial baseline MRI scan, HFS was applied to the left lower leg of 18 healthy subjects. A second MRI scan was conducted 20 minutes after HFS application. HFS consisted of five 1s trains of 100 Hz electrical pulses separated by 9s intervals. Scans measured blood oxygen level dependent (BOLD) signal changes to 18 punctate mechanical stimuli applied 1cm outside the HFS site (secondary hyperalgesia area). A whole brain, mixed effects analysis with cluster-based correction for multiple comparisons was performed to identify differences in stimulus evoked neural activity post-HFS vs. baseline. ***Results:*** Following HFS, reported mean pain intensity and unpleasentness significantly increased. This was associated with significantly increased activation during the post-HFS scan vs. baseline (mixed effects analysis, $Z > 3.1$, $p < 0.05$) in areas involved in pain perception such as the contralateral posterior insula cortex, mid anterior cingulate cortex, amygdala, hippocampus and nucleus cuneiformis, and bilateral thalamus and secondary somatosensory cortex. ***Conclusions:*** The state of CS induced by HFS consists of increased neural activity in cortical and sub-cortical pain processing areas and key brainstem nuclei such as the nucleus cuneiformis - implicated in both human and animal models of CS. This is consistent with other CS models that have been widely studied using fMRI.

THE STRUCTURES THAT EXCITE THE CENTRAL AMYGDALA NEURONS AND PAIN NETWORK IN OROFACIAL INFLAMMATORY PAIN

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Yukari Takahashi, Takao Okuda, Naoko Sato, Fusao Kato
Jikei University School of Medicine, Neuroscience, Tokyo, Japan

Pain-associated plastic changes have been documented in various brain regions. Of these modules, the central amygdala (CeA) is one of the core regions of the pain network, playing an essential role in the establishment of "nociplastic pain", a mechanism of pain with an altered nociceptive system. We recently demonstrated that suppression of CeA neurons in an inflammatory pain model of rodents mitigates central sensitization (Arimura et al., 2019, Sugimoto et al., 2021). However, various brain sites other than the CeA show elevated c-Fos expression with diverse time courses after an inflammatory injury. To reveal how these activated brain sites give influence each other, particularly to the CeA, we used a cre-reporter mouse line that allows c-Fos-expression-dependent fluorescence with a combination of a retrograde AAV vector for the Cre-dependent expression of green fluorescent protein injected into the right CeA. After a whisker pad injection of formalin followed by 4-hydroxytamoxifen at 5 hr, we removed the brain and visualized the fluorescence in thin slices. Pain-activated cells with projections to the pain-activated CeA were distributed in the ipsilateral paraventricular thalamus, subthalamic nucleus, interstitial nucleus of the posterior limb of the anterior commissure, basolateral amygdala, lateral parabrachial nucleus and bilateral insular cortex. Neurons in the bed nucleus stria terminalis, ventral paraventricular hypothalamic nucleus and supraoptic nucleus were activated by inflammation but not retrogradely labeled from the CeA. These results suggest that, with exception of a few structures, many brain regions project to the CeA, which might contribute to the activation of the CeA neurons.

PAIN MODULATING TOXIN IDENTIFICATION FROM VENOMS BY HIGH CONTENT SCREENING MICROSCOPY

POSTER SESSION 05 - SECTION: NEUROPATHIC PAIN, ANALGESIA, & THERAPEUTICS

Ehsan Alirahimi[1], Jörg Isensee[1], Peter B. Oparin[2], Vanessa O. Zambelli[3], Gisele Picolo[3], Queren Apuque Alcantara[3], André C. Morandini[4,5], Antonio Carlos Marques[4], Juliana Mozer Sciani[6], Alexander Vassilevski[2], Tim Hucho[1]
[1]University of Cologne, Department Of Anesthesiology And Intensive Care Medicine, Translational Pain Research, University Hospital Of Cologne, Cologne, Germany, [2]Shemyakin-Ovchinnikov Institute of Bioorganic Chemistry of the Russian Academy of Sciences, Department Of Molecular Neurobiology, Moscow, Russian Federation, [3]Instituto Butantan, Laboratório De Dor E Sinalização, São Paulo, Brazil, [4]Instituto de Biociências, Departamento De Zoologia, São Paulo, Brazil, [5]Universidade de São Paulo, Centro De Biologia Marinha, São Sebastião, Brazil, [6]São Francisco University (USF), Multidisciplinary Research Laboratory, Bragança Paulista, Brazil

Background and objective In vertebrates, pain-inducing as well as pain-reducing activities of venoms have been observed. We established a unique approach, monitoring intracellular signalling in nociceptive neurons. This allowed identification of pain-inducing toxins from venoms. However, the capability of this approach in identification of toxins that reduce pain-inducing signalling is not known. Methods Venoms were tested on cultured dissociated primary sensory neurons of rats. For this, dorsal root ganglia were prepared, cells dissociated, and neurons cultured. Then, the selected venoms were added one per wells, cells fixed with PFA, and immunocytochemically stained for activation of PKA-II and/or ERK1/2. Immunocytochemical intensities were acquired by high content screening microscopy on a single cell level and statistically analysed with R. Results We tested over 120 venoms Venoms were considered as potentially sensitizing, if they increased phosphorylation of PKA-II and/or ERK1/2. On the other hand, venoms were considered as potentially desensitizing if they reduced activation of PKA-II and/or ERK1/2 in response to a test stimulus. Thirty four percent of the tested venoms showed pain-initiating signalling whereas 13.8% showed signalling-inhibiting, i.e. potentially analgesic activity. Conclusion Our results indicate that our signalling based high content screening microscopy approach may be a potent screening method to identify potentially analgesic toxins. An advantage against other screening methods is that this is independent of the presence of toxins activating the neurons electrically. This approach therefore may help unmasking of novel analgesic toxins, which now will be purified and characterized from the positive hits of this first round of screening.

STABILITY OF HYPOTHALAMIC NEURAL POPULATION ACTIVITY DURING SLEEP STATES

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Yudong Yan, Niccolo Calcini
Insel Gruppe, Department Of Neurology, Bern, Switzerland

Sleep is a primary and essential biological need for most animals. Many brain regions and neural circuits have been implicated in the regulation of sleep and wakefulness, in particular, the lateral hypothalamic area (LH) is central to the orchestration of sleep–wake states, feeding, energy balance, aversion and goal oriented behaviour. This suggested that some of these cells may share both sleep and metabolic functions. In this study, we longitudinally image the activity of VGat, VGlut2, and Orexin neurons in freely behaving mice over a week using in vivo calcium imaging in freely-moving mice, and compute a categorization of their activity across wake, REM and non-REM states and across days. We found that part (±40%) of the cells remained within the same cluster (wake, NREMS or REMS active), however, a significant portion of these 'recluster' into different categories at different times of the day, and over multiple days. Finally, we described the stability of these clusters upon sleep recovery (sleep deprivation). Our findings shed light on the dynamics and plasticity of several neuronal populations in different sleep-wake states and help to better understand multitasking functions of LH circuits.

FROM WAKEFULNESS TO SLEEP, FOCUS ON PATIENTS WITH NARCOLEPSY.

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Arthur Le Coz[1], Pauline Dodet[2], Smaranda Leu-Semenescu[2], Ana Gales[2], Delphine Oudiette[3], Isabelle Arnulf[3], Thomas Andrillon[3]
[1]Paris Brain Institute, Ile De France, Paris, France, [2]AP-HP, Pitié-Salpêtrière Hospital, Sleep Disorder Unit, Paris, France, [3]Paris Brain Institute, Sorbonne Université, Paris, France

Aims: Narcolepsy type 1 (NT1) is a neurological disorder characterised by excessive daytime sleepiness and sleep attacks, as well as symptoms of supposed dissociations between REM sleep and wakefulness (cataplexy, sleep-related hallucinations, sleep paralysis, lucid dreaming). We aimed at testing this hypothesis of dissociated REM sleep states by studying the entanglement of REM and wake activity through new EEG biomarkers. These new EEG biomarkers of NT1 could in turn help understanding the mechanisms associated with sleep attacks, hallucinations, and other dissociated sleep-wake states during wakefulness. **Methods:** We analysed the nocturnal polysomnography (PSG) recordings of 27 NT1 patients and 24 controls. In the PSG signal, we extracted at different time scales: (1) features based on the hypnogram scored by sleep experts across the entire night, (2) spectral features computed on 30s-long epochs, and (3) features related to sleep microstructure based on the automated detection of slow waves, sleep spindles, and rapid eye movements. **Results:** Our results indicate that NT1 is indeed characterised by a waking state that is more REM-sleep-like and, reciprocally, a REM sleep that is more wake-like than in controls (more alpha power in REM sleep and less in wakefulness for example). **Conclusion:** Characterising the neurophysiology of narcolepsy type 1 as a mixing of wake and REM activity further suggests that NT1 daytime (hallucinations) and nighttime (lucid dreaming) symptoms could be explained by intrusions of REM activity during waking and of wake activity during REM sleep.

MICROGLIAL TNFα ORCHESTRATES PROTEIN PHOSPHORYLATION DURING THE SLEEP PERIOD AND CONTROLS HOMEOSTATIC SLEEP

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Maria Joana Pinto[1], Léa Cottin[1], Dingli Florent[2], Victor Laigle[2], Antoine Triller[1], Damarys Loew[3], Véronique Fabre[4], Alain Bessis[1]
[1]École normale supérieure, CNRS, INSERM, Université PSL, Institut De Biologie De L'École Normale Supérieure (ibens), Paris, France, [2]Institut Curie, PSL Research University, Mass Spectrometry And Proteomics Laboratory, Paris, France, [3]Institut Curie, Université PSL, Centre de Recherche, Laboratoire De Spectrométrie De Masse Protéomique, Paris Cedex, France, [4]Neurosciences Paris Seine - Institut de Biologie Paris Seine, Cnrs Inserm Sorbonne Université, Paris, France

A sufficient amount of sleep is ensured by a tight homeostatic control. This relies on factors that build-up in the brain with waking and induce sleep proportionally to the length of the previous wake period. Candidate sleep-promoting factors, including adenosine, TNFα and interleukin-1, have been identified but their molecular mechanisms of action remain elusive. Phosphorylation of synaptic proteins has been described as a fundamental process of sleep control. TNFα is a signaling molecule that controls activation of phosphorylation pathways and its expression is restricted to microglia in the brain parenchyma. We therefore hypothesized that microglia-derived TNFα is involved in phosphorylation-based control of homeostatic sleep. In this study, we performed quantitative phosphoproteomic analysis and polygraphic sleep recordings following sleep deprivation in control and microglia-specific TNFα deleted mice. We demonstrate that in the cortex microglial TNFα massively modulates phosphorylation exquisitely during the sleep period. Phospho-substrates of microglial TNFα comprise sleep-promoting kinases, phosphatases and numerous synaptic proteins. These include proteins whose phosphorylation status has been proposed to encode sleep need and control sleep duration. Consistently, lack of microglial TNFα attenuates accumulation of sleep pressure, as measured by slow wave activity, and prevents sleep rebound following forced wake. Together, we establish microglia as a new cellular component of the sleep homeostat. Microglia control homeostatic sleep by releasing TNFα that acts at the neuronal circuitry through phosphorylation.

ION CONCENTRATIONS IN CEREBROSPINAL FLUID IN WAKEFULNESS, SLEEP AND SLEEP DEPRIVATION IN HEALTHY HUMANS

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

My Forsberg, Eric Hanse
Neuroscience and Physiology, Physiology, Göteborg, Sweden

Sleep is a global state of the brain in which the neurons in the cortex exhibit specific firing patterns. Neuromodulatory transmittors are released into the cortex by projection axons from subcortical nuclei, which presumably regulates and coordinates the transition and stability of sleep and wakefulness across the cortex. It is, however, not known how these neurotransmittors act to change firing patterns in cortical neurons. Pathways including direct modulation of ion channels on neurons as well as modulation via glial cells has been proposed. Recently, a study showed that changes in the extracellular concentration of potassium, as well as of calcium and magnesium, was sufficient to induce transition from sleep to wakefulness in mice. In this study, we investigated if such changes in ion concentrations occur in healthy humans. We collected cerebrospinal fluid from 11 healthy volunteers. Each participant was sampled three times, in randomized order: at 3-5 PM during waking, at 6-7 AM immediately following one night of sleep and at 6-7 AM following one night of sleep deprivation. We could not detect any significant changes in the concentration of calcium or magnesium, but in the concentration of potassium; we saw a small but highly consistent and significant reduction of 0.1 mM (about 3 %) in both sleep and sleep deprivation samples when compared to the samples collected during wakefulness in the afternoon. Our results support a circadian modulation of ion concentrations in the central nervous system which could be involved in sleep regulation in humans.

SPECTRAL POWER AND TEMPORAL COUPLING OF THE EEG DURING REM SLEEP IN PATIENTS WITH FRONTAL BRAIN TUMOR

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Laura Ortega-Leonard, Irma Del Río Portilla
Faculty of Psychology, UNAM, Sleep Laboratory, Mexico City, Mexico

Electrophysiological sleep patterns can be modified because of a brain pathology, such as tumors, which allows us to know in depth what happens when these lesions affect a particular area of the brain, such as the frontal lobes, and which are scant studies about it. Other hand, the cortical brain activity shows electric field oscillations on all temporal and spatial scales. The permanent oscillatory behavior is generated by the intrinsic activity of single neurons and extends to the self-organized motion of large neuronal populations. The aim of this study was to characterize the cerebral electrical activity in patients with frontal brain tumor. Therefore, 10 patients were evaluated by means of polysomnographic recordings. Without comorbid neurological or medical and without surgical treatment, with chemotherapy and radiotherapy. For quantitative EEG (qEEG) analysis, the Fast Fourier Transformation algorithm was used to obtain the spectral power of each participant, channel, and frequency band. Results reveal higher spectral power densities for REM sleep, for all electrodes and for each of the bands; can be observed by patients compared to normative values. Through the analysis of intra and interhemispheric correlation, it is possible to observe the networks that are formed at the level of brain electrical activity. In conclusion, in this study we were able to observe that an alteration in the frontal lobe can generate changes in sleep rhythmogenesis. The presence of this type of pathology, which causes structural and functional changes, allows us to understand the involvement of the frontal lobes during this state.

BRAIN-WIDE RESPONSES TO PROLONGED WAKEFULNESS OUTLINE CRITICAL COMPONENTS OF THE MAMMALIAN SLEEP HOMEOSTAT.

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Vassilis Bitsikas, William Joo, Amelia Hidalgo, Alexander Schier
University of Basel, Biozentrum, Basel, Switzerland

According to the two-process model of sleep regulation, the timing and structure of sleep is regulated by the interaction of circadian and homeostatic processes. The first process influences the probability of sleep over the light-dark cycle and is influenced externally by zeitgebers. The second process manifests through a homeostatic requirement for sleep and can be modeled using prior sleep–wake history. More specifically, prolonged wakefulness causes the feeling of tiredness and leads to sleep episodes marked by increased slow wave activity. Currently we lack a circuit level understanding of how prolonged wakefulness influences the brain and engages homeostatic mechanisms that lead to deep recovery sleep. Here we utilize behavioral manipulations, electrophysiology and whole brain imaging of neuronal activity reporters in order to map brain-wide responses to variable levels of sleep pressure across the circadian cycle. This approach reveals discrete regions in the midbrain and diencephalon that are active during varying homeostatic sleep pressure regiments. Using targeted chemogenetic perturbations and inducible cell ablation, we reveal novel roles these regions have in regulating physiological sleep-wake patterns. Our results can be used to constrain current models for sleep regulation and the interactions between sleep homeostasis and circadian rhythms. Additionally, our experimental approach provides a framework to define functionally important regions in behaviors that unfold across long timescales and are difficult to study in isolation.

REGION-SPECIFIC MODULATION OF ASTROCYTE NETWORK DYNAMICS ACROSS SLEEP-WAKE STATES

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Albert Orero Lopez[1], Christina Gantner[1,2], Christina Czekus[1], Lukas Oesch[1,2], Niccolo Calcini[1], Carolina Gutierrez Herrera[1,3]

Introduction: An increasing body of literature supports the relevance of astrocytes on sleep-wake regulation and sleep homeostasis. However, most of our understanding remains global and regional specificity is lacking. Here, we sought to investigate changes in astrocytic activity in response to different sleep pressure schedules in two different cortical areas related to sensory and non-sensory thalamic networks. **Methodology:** Mini-endoscopy combined with chronically implanted EEG electrodes were employed to measure GCaMP-Ca2+ astrocytic activity in the anterior cingulate cortex (ACC) and Barrel cortex (BrC) across sleep-wake states at different circadian times and during sleep recovery after extended wake periods (SD). Chemogenetics was used to activate or inhibit astrocytes in a spatial-temporal manner. **Results:** Astrocytic activity in the BrC and ACC differ in wake (~50% vs ~27%) and REM (~0.3 % vs ~6.5%) sleep respectively. Interestingly, stable functional astrocytic networks across days underwent a broad reorganization during the sleep recovery following SD. Remarkably, activation of ACC-astrocytes during the light period - when they were mostly inactive - increased NREM sleep, delta power but not spindles. Whereas inhibition failed to have an effect on sleep, the latency to the first NREM episode was longer and delta power during NREM sleep episodes was decreased in the 1 hrs following CNO injections. **Conclusions**: Collectively, our results indicate a region-specificity of astrocyte network dynamics across sleep-wake states. This specificity is further reflected in the response to sleep need by a long-lasting remodelling of their functional networks after SD, suggesting a spatio-temporal specificity of their sleep functions.

The need for sleep or a sleep-like state appears to be universal across the animal kingdom and necessary for survival. Neurodevelopmental alterations found in patients with autism spectrum disorders can disrupt such tightly regulated sleep states. Here, we investigate a highly conserved and neuron-specific splicing program of microexons activated during late neurogenesis and misregulated in autistic individuals. Microexons are believed to fine-tune neurodevelopmental processes such as synaptogenesis and axon guidance, actively contributing to an optimal excitation/inhibition balance in the brain. However, little is known about their impact on behavioral states including sleep/wake patterns. In order to address this, we use a knock-out zebrafish model of the microexon splicing master regulator *srrm3*. Zebrafish show a relatively complex but stereotyped repertoire of movements (bouts) and a diurnal sleep/wake signature. Using high-throughput behavioral tracking of day-night activity and high-resolution recordings of single larvae, we observed a multi-facetted hyperactivity phenotype with sleep loss at night, characterized by a shift in bout type choice as well as increased bout length and frequency. We hypothesize an underlying neuronal activity imbalance caused by early microexon misregulation. To address this hypothesis, we aim to utilize calcium imaging to identify neuronal activity patterns that can explain the sleep disruptions observed as well as neuron-specific bulk RNA sequencing. Our research will not only shed new light into the functional impact of microexons on brain development, but will also contribute to our understanding of brain activity states with a special focus on sleep.

Aims: When awake, we consciously perceive stimuli from the world that surrounds us. When asleep, our brain instead disconnects from the sensory environment. In contrast to these exteroceptive stimuli, little is known about how interoceptive stimuli are processed by the sleeping brain. The vagus nerve is a mixed sensory-motor nerve that interfaces between the autonomic periphery and the central nervous system. We asked whether stimulating specifically vagal sensory afferents modulates sleep. **Methods:** All experiments are based on viral transfection of vGluT2-expressing neurons in the nodose ganglion of the left vagus nerve, in combination with polysomnographic, local field potential (LFP), fiber photometry and brain temperature recordings in freely moving conditions, or patch-clamp physiology. **Results:** Whole-cell patch-clamp recordings confirmed that optogenetic activation of vagal afferents formed functional glutamatergic synaptic contacts in the brainstem nucleus tractus solitarius. We found that chemogenetic activation of the vagal sensory afferents (1.5-2.5 mg/kg CNO) suppressed rapid-eye-movement sleep (REMS) in a dose-dependent manner, as evident by the lack of its characteristic EEG/EMG correlates. To characterize more comprehensively the physiological correlates of sleep during elevated vagal activity, we are currently analyzing breathing rates and the brain temperature of sleeping mice. The mechanisms underlying these alterations are addressed using fiber photometry techniques in combination with LFP recordings. **Conclusions:** Our findings point to a major role for vagal afferent activity in body-brain physiology that regulates the balanced expression of non-REMS and REMS. Moreover, they indicate that vagus nerve stimulation could offer a non-invasive strategy to improve sleep architecture in pathological conditions.

Normal sleep physiology is essential for healthy brain development and aging. Sleep physiology studies rely on the correct classification of brain states within sleep (sleep staging), which is usually constrained by slow scoring methods with fixed rules and definitions of such sleep stages. We hypothesized that unsupervised classification of EEG data would resist the idiosyncrasies of individual recording sessions and unbiasedly identify sleep states within relevant feature spaces. We tested and challenged a workflow for the unsupervised classification of sleep states (WUCSS) that classifies active, REM, and within NREM, deep and light sleep states using head motion and electrophysiological data. We gathered high-quality EEG recordings in mice, combined with accelerometer data in diverse transgenic lines, totaling more than 800 hours. WUCSS works with six feature dimensions, extracted from 4-second epochs and used as inputs for an unsupervised classifier. Features were chosen based on human clinical sleep classification. WUCSS showed high recall, precision, and F1-score compared to manual scoring on active, NREM, and REM sleep states. Within NREM, WUCSS consistently identified two additional clusters that qualify as deep and light sleep states. With just 6 hour long sessions, REM, NREM, deep and light sleep were reliably identified in adult and old mice. The deep and light sleep discrimination allows for a more accurate study of mouse sleep physiology, as evidenced by additional sleep phenotypes identified in CNTNAP2KO mice. We hope that the WUCSS's robustness can be of use to sleep researchers, saving time, resources and ultimately improving sleep staging.

Hallmarks of neural dynamics during different human brain states span spatial scales from neuromodulators acting on microscopic ion channels to macroscopic changes in communication between brain regions. Developing a scale-integrated understanding of neural dynamics has therefore remained challenging. Here, we perform the integration across scales with mean-field modeling of Adaptive Exponential (AdEx) neurons, explicitly incorporating intrinsic properties of excitatory and inhibitory neurons and microscopic parameters, including spike-frequency adaptation, synaptic receptor kinetics, and various membrane conductances. Here, we connect AdEx mean-field neural populations via structural tracts defined by the human connectome, and show that macroscopic, state-dependent dynamics resembling human brain activity emerge that mimic state-dependent signals recorded during both spontaneous and evoked human brain activity. Specifically, modulating microscopic mechanisms enhancing spike-frequency adaptation leads to the emergence of slow-wave dynamics at large scales. Slow waves synchronize across brain areas, shifting the functional connectivity, phase coupling, and power spectral peaks, thus mimicking empirical data describing different brain states. Moreover, evoked activity reproduces observations of more complex spread of stimuli between brain regions during wakefulness compared to slow-wave sleep, analyzed with the perturbational complexity index. The model has been implemented with The Virtual Brain (TVB) simulator, and is open-access in EBRAINS. This approach provides a novel tool to evaluate how changes in microscopic parameters lead to large-scale emergent behavior in the brain, in particular enhanced responsiveness during awake compared to sleeping brain states, and thus offers a more unified, formal understanding of conscious and unconscious states and their associated pathologies.

THE LOCUS COERULEUS IS A GATE FOR NREM-TO-REM SLEEP TRANSITIONS

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Alejandro Osorio-Forero, Romain Cardis, Najma Cherrad, Georgios Foustoukos, Laura Fernandez, Anita Lüthi
University of Lausanne, Department Of Fundamental Neuroscience, Lausanne, Switzerland

Aims: The noradrenergic Locus Coeruleus (LC) system is commonly associated to stress and attention during wakefulness and its activity is highly dependent on behavioral states. However, noradrenaline release is high and fluctuates during non-rapid-eye-movement sleep (NREMS) on a close-to-minute infraslow timescale (Osorio-Forero et al., 2021). These fluctuations generate periods free of sleep spindles, during which evoked or spontaneous awakenings are more probable. Here, we asked whether these moments of increased sleep fragility are also involved the regulation of the NREM-to-REMS transitions and the ultradian sleep cycles. *Methods*: We recorded undisturbed sleep-wake behavior in 6 – 10 week-old dopamine-β-hydroxylase-Cre mice expressing optogenetic actuators, together with hippocampal and somatosensory local field potentials and closed-loop optogenetic modulation of LC neurons. Then, we combined these tools with automatic REMS deprivation to explore LC's role in conditions of high REMS pressure. *Results*: Transitions from NREMS-to-REMS were phase-locked to the infraslow cycles of LC fluctuations. Optogenetic activation of LC neurons during NREMS prevented NREMS-to-REMS transitions, even at moments of high REMS pressure. In contrast, inhibition of these cells precipitated REMS. Moreover, optogenetic manipulations at moments of high or low spindle activity refined these effects. *Conclusions*: These observations position the LC as a gate for the regulation of REMS and of the ultradian sleep cycles during unperturbed sleep. Furthermore, the results suggest that the periodic decline of LC activity during NREMS provides windows of opportunity during which NREM to REMS transitions are facilitated. These findings broaden the scope for future mechanistic models in sleep regulation.

SYSTEMIC INFLAMMATION ALTERS SLEEP STATE DYNAMICS AND POWER SPECTRAL CHARACTERISTICS

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Annu Kala, Athira Nataraj, František Zitrický, Martina Šalomová, Susan Leemburg, Karel Blahna, Karel Jezek
Charles University, Faculty Of Medicine In Pilsen, Pilsen, Czech Republic

Sleep disturbances and cognitive impairment are common in sepsis survivors. We used an LPS-mediated rat model of sepsis to study its effects on 1) sleep architecture and spectral characteristics, and 2) network memory processing. Male Long-Evans rats were implanted with tetrodes in hippocampal CA1. Neuronal activity was recorded during exposure to a familiar and novel linear tracks followed by saline (baseline) or LPS (5mg/kg) injection and a 6-hour rest period. Sleep architecture and oscillatory and non-oscillatory spectrum components were analyzed. LPS injection caused extensive sleep fragmentation by frequent wake episodes. While the total amount of NREM and wake were not affected, cumulative time spent in REM was significantly reduced. Spectral power <40 Hz was reduced in NREM and wake, but not in REM. Delta power (1-4 Hz) in NREM decreased and theta power (5-8 Hz) in REM remained stable. NREM spectrum slopes were steeper after LPS injection, but not after saline. LPS also increased the number of sharp-wave-ripples in NREM sleep. In conclusion, LPS caused sleep fragmentation accompanied by steeper NREM slopes possibly indicating changes in excitation/inhibition (E/I) ratio. The increased number of sharp wave ripples might reflect this E/I imbalance as well. As both sleep quality and the off-line memory processing through sharp-wave ripple activity are essential for memory consolidation, their alterations in sepsis might explain some aspects of post-sepsis cognitive impairment. As such, normalizing sleep-related brain activity may be a therapeutic target for sepsis-associated brain dysfunction.

Contrast enhanced X-ray computed tomography imaging of amyloid plaques in Alzheimer disease rat model on lab based micro CT system.
Amyloid plaques are small (~ 50 μm), highly-dense aggregates of amyloid beta (Aβ) protein in brain tissue, supposed to play a key role in pathogenesis of Alzheimer's disease (AD). Plaques´ in vivo detection, spatial distribution and quantitative characterization could be an essential marker in diagnostics and evaluation of AD progress. However, current imaging methods in clinics possess substantial limits in sensitivity towards Aβ plaques to play a considerable role in AD screening. Contrast enhanced X-ray micro computed tomography (micro CT) is an emerging highly sensitive imaging technique capable of high resolution visualization of rodent brain. In this study we show the absorption based contrast enhanced X-ray micro CT imaging is viable method for detection and 3D analysis of Aβ plaques in transgenic rodent models of Alzheimer's disease. Using iodine contrasted brain tissue isolated from the Tg-F344-AD rat model we show the micro CT imaging is capable of precise imaging of Aβ plaques, making possible to further analyze various aspects of their 3D spatial distribution and other properties.

THE ROLE OF THE MELANIN CONCENTRATING HORMONE (MCH) SYSTEM IN INCREASED REM SLEEP PROPENSITY AND CATAPLEXY IN NARCOLEPSY.

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Bianca Viberti[1], Thomas Rusterholz[1], Antoine Adamantidis[2], Markus H. Schmidt[1]
[1]Centre for Experimental Neurology, Inselspital University Hospital Bern, University of Bern, Department Of Neurology, Bern, Switzerland, [2]University of Bern, Center For Experimental Neurology, Dept Of Neurology, Bern, Switzerland

The melanin-concentrating hormone (MCH) neurons play a regulatory role in REM sleep and they dynamically modulate its expression during thermoneutral ambient temperature (Ta) warming (Komagata et al., 2019). Moreover, Ta warming increases REM sleep but decreases cataplexy in narcoleptic hypocretin knock-out(Hcrt-KO) mice. Given the reciprocal inhibition between the Hcrt and MCH systems, we hypothesize that loss of Hcrt may disinhibit MCH activity resulting in the increased REM sleep propensity characteristic of narcolepsy, whereas MCH hypoactivity may exacerbate boundary state instability and favor cataplexy. We investigated the MCH dynamics across the sleep-wake cycle in MCH:cre mice and then evaluated the role of the MCH system in REM sleep and cataplexy in MCH:cre/HcrtKO mice. Fiber photometry approach revealed that MCH-dependent signal increased in anticipation and during REM sleep but dropped during NREM sleep and wake states in both animal models. Exposure to warm Ta pulsing increased REM sleep expression for MCH:cre mice, whereas the same effect was not detected in narcoleptic mice. Surprisingly, MCH activity in MCH:cre/HcrtKO mice also increased in anticipation of cataplexy and decreased at the transition to the wake state. Moreover, optogenetic inhibition of MCH neurons increased cataplexy, but Ta warming appeared to decrease thi effect. In contrast, narcoleptic mice increased REM sleep during the Ta warming condition, but this ability was blunted by optoslencing MCH neurons. Taken together, these results would suggest that the warming effect on cataplexy reduction is independent of the MCH system, that plays a role in driving the REM sleep propensity seen in narcolepsy.

THE INTEGRATION OF SKIN AND CORE BODY TEMPERATURE IN THE EXPRESSION OF REM SLEEP AND THE ROLE OF THE HYPOTHALAMUS

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Simone Bellini, Bianca Viberti, Markus H. Schmidt
Centre for Experimental Neurology, Inselspital University Hospital Bern, University of Bern, Department Of Neurology, Bern, Switzerland

Rapid eye movement (REM) sleep is preferentially expressed over non-REM sleep during thermoneutral ambient temperature (Ta) warming. The lateral hypothalamus (LH) integrates diverse inputs, including temperature, to modulate sleep-wake expression. Although hypocretin (Hcrt) neurons promote wakefulness, melanin-concentrating hormone (MCH) neurons increase REM sleep during thermoneutral Ta warming. However, how the LH integrates temperature information to modulate REM sleep remains unknown. We hypothesize that skin (TSkin) and core body (TCore) temperature information are integrated in the hypothalamus through the MCH and Hcrt systems. Thermoneutral warm Ta pulsing during the light phase increased wild type (WT) mice's total REM sleep duration and bout number, induced no effect on MCH receptor1 knock-out (MCHR1KO) mice, and increased Hcrt-KO mice's wakefulness while decreasing REM sleep. All groups preserved homeostatic regulation of REM sleep, suggesting that MCH and Hcrt systems are required for the dynamic modulation of Ta-dependent REM sleep, but not for REM sleep homeostasis. We then further investigated brain temperature, TCore and TSkin parameters to investigate whether they may be integrated within the LH to modulate REM sleep. WT and MCHR1KO mice showed clear ultradian TCore cycling and REM sleep nesting at TCore's nadir during the inactive sleep phase, while Hcrt-KO mice showed disrupted ultradian TCore cycling. WT mice dynamically increased REM sleep expression within the TCore cycle as a function of integrated TCore-TSkin, whereas MCHR1KO mice failed to do so. These findings suggest that WT mice integrate TSkin and TCore for dynamic REM sleep expression, where the MCH system plays a critical role.

Complaints of sleep disturbance are prevalent among breast cancer (BC) patients and are predictors of quality of life. Still, electrophysiological measures of sleep are missing in patients, which prevents from understanding the pathophysiological consequences of cancer and its past treatments. Using polysomnography, sleep can be investigated in terms of macro- (e.g. awakenings, sleep stages) and micro- (i.e. cortical activity) structure. We aimed to characterize sleep complaints, and macro- and microstructure in 33 BC survivors untreated by chemotherapy and that had finished radiotherapy since at least 6 months (i.e. out of the acute effects of radiotherapy) compared to 21 healthy controls (HC). Compared to HC, BC patients had a larger number of awakenings (p=0.008); and lower Delta power (p<0.001), related to sleep deepening and homeostasis; greater both Alpha (p=0.002) and Beta power (p<0.001), related to arousal during deep sleep; and lower Theta power (p=0.004), related to emotion regulation during dream sleep. Here we show that patients have increased cortical activity related to arousal and lower activity related to sleep homeostasis compared to controls. These results give additional insights in sleep pathophysiology of BC survivors and suggest sleep homeostasis disruption in non-advanced stages of BC.

Aims: The activity of cortical astrocytes are linked to fluctuations in sleep-wake behaviour. Here we elucidate the role of anterior cingulate cortex astrocytes in sleep homeostasis by assessing how activation of astrocytes contribute to sleep loss and cortical excitability. **Methods:** Using Designer Receptors Exclusively Activated by Designer Drugs (DREADD)-based chemogenetic tools we specifically activated cortical astrocytes in freely behaving female mice. Animals bilaterally injected with GFAP DREADD hM3D(Gq)-mCherry underwent 4h sleep deprivation (SD) starting at ZT0 or left undisturbed. At the end of SD or ZT4, animals were injected with either CNO (0.3 mg/kg, i.p.) or vehicle (saline, i.p.) in a crossover randomised design. In a separate cohort, mice were also stereotaxically injected with AAV1.Camk2a.GCaMP6f and a GRIN lens implanted to observe *in vivo* calcium imaging of cortical neurons. **Results:** We observed a reduction in the fluorescent reporter tag for cortical astrocytes in mice that were sleep deprived. Chemogenetic activation of cingulate/motor cortical astrocytes reduced total sleep time in undisturbed mice for 4hrs post-dose yet had no effect on sleep following SD. **Conclusions:** Our data support a role for cortical astrocytes in sleep-wake states. When sleep-drive is high, such as following sleep loss, supplemental activation of astrocytes are no longer effective in modifying sleep-state.

Impaired K binding to glial glutamate transporter EAAT1 in migraine.
SLC1A3 encodes the glial glutamate transporter hEAAT1, which removes glutamate from the synaptic cleft via stoichiometrically coupled Na-K-H-glutamate transport. In a young man with migraine with aura including hemiplegia, we identified a novel SLC1A3 mutation that predicts the substitution of a conserved threonine by proline at position 387 (T387P) in hEAAT1. To evaluate the functional effects of the novel variant, we expressed the wildtype or mutant hEAAT1 in mammalian cells and performed whole-cell patch clamp, fast substrate application, and biochemical analyses. T387P diminishes hEAAT1 glutamate uptake rates and reduces the number of hEAAT1 in the surface membrane. Whereas hEAAT1 anion currents display normal ligand and voltage dependence in cells internally dialyzed with Na-based solution, no anion currents were observed with internal K. Fast substrate application demonstrated that T387P abolishes K-bound retranslocation. Our finding expands the phenotypic spectrum of genetic variation in SLC1A3 and highlights impaired K binding to hEAAT1 as a novel mechanism of glutamate transport dysfunction in human disease.

Stimulation of 5-HT receptors in anterodorsal BNST guides fear to predictable and unpredictable threat.
Through pharmacological manipulation of the serotonergic (5-Hydroxytryptamin, 5-HT) system, combined with behavioral analysis, we tested the hypothesis that fear responses to predictable and unpredictable threat are regulated through stimulation of 5-HT receptors (5-HT-R) in the anterodorsal section of the bed nucleus of the stria terminalis (adBNST). Local adBNST application of 5-HT1A-R antagonist WAY100635 and 5-HT1B-R antagonist NAS-181 before fear retrieval enhanced freezing, 24 h after predictable fear conditioning. In contrast, increased fear responses to unpredictable threat were blocked by 5-HT1A-R agonist Buspirone (given before conditioning or retrieval) and 5-HT1B-R agonist CP-94253 (applied before training). Prolonged fear responses were also blocked by local application of the 5-HT2A-R antagonist R-96544 before fear retrieval, and conversely, local application of the 5-HT2A-R agonist NBOH-2C-CN hydrochloride before fear retrieval enhanced freezing 24 h after predictable conditioning, indicating augmented fear responses. Activation of inhibitory 5-HT1A- or 5-HT1B-Rs and the blockade of the excitatory 5-HT2A-R before unpredictable fear conditioning significantly reduced freezing during retrieval. The results from this study suggest that modulation of inhibitory 5-HT1A/1B-R and/or excitatory 5-HT2A-R activity in the adBNST may represent potential targets for the development of new treatment strategies in anxiety disorders. In addition, this study supports the validity and reliability of the mouse model of modulated fear to predictable and

unpredictable threats to study mechanisms of fear and anxiety in combination with pharmacological manipulations. Eur Neuropsychopharmacol, 2020; 39

A BENCHMARK FOR SHARP WAVE-RIPPLE DETECTION ALGORITHMS

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Eis Annavini[1,2], Solomiia Korchynska[1,2], Ela Babursah[1,2], Torkel Hafting[1], Charlotte Boccara[1,2]
[1]University of Oslo, Institute Of Basic Medical Sciences, Oslo, Norway, [2]University of Oslo, Ncmm - Norwegian Centre For Molecular Medicine, Oslo, Norway

Sharp Wave Ripples (SWR) are fast oscillatory hippocampal events considered essential for learning, consolidation, and transfer of information. During these events, sequences of neuronal activity underlying previous experiences are replayed in a temporally compressed manner. To better understand the role of SWR, online closed-loop detection and perturbations is needed. To that end, several algorithms for on-line SWR detection have been recently developed. Yet, there is currently no comparison on their performance and no real consensus as to which one to use. Furthermore, algorithms based on Artificial Neural Networks (ANN) are rarely tested outside the controlled conditions they are developed in. Inspired by the seminal role of ImageNet in the development of Deep Learning, we set out to evaluate the performance of two ANN algorithms on a dataset different from the one they were built on, as well as more traditional methods based on ripple power or high synchrony event detection. We observed an overall lower performance with respect to what was stated by the original authors, pointing to a – somehow expected – dependency on the experimental setup and conditions. Specifically, the ANN based algorithms showed the biggest performance drop among the tested methods, suggesting an experimental bias akin to ImageNet's capture bias. This is problematic as it hinders reproducibility and comparison of results between studies. Furthermore, we discuss how specific algorithms may be adapted to different experimental purposes, proposing examples of algorithm tuning to individual data sets, aiming to build a benchmark for adaptive automatic SWR detection.

SLEEP ARCHITECTURE DYNAMICS ACROSS THE LIFESPAN

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Solomiia Korchynska, Eis Annavini, Luca Várhegyi, Charlotte Boccara
The University of Oslo, Institute Of Basic Medical Sciences, Oslo, Norway

Sleep is essential to all animal life. While there are many debates as to why we must sleep, there is no doubt that it is most needed during development. Greater sleep needs in the young are in fact a hallmark of altricial mammals, such as humans and rodents, born in an undeveloped state and whose brain goes through extensive maturation processes postnatally. Rodent models offer a unique opportunity to investigate sleep qualitative and quantitative variations across the lifespan. To that end, we have developed new electrophysiological and computational methods to map sleep architecture in young, adolescent and adult freely-behaving rats. We have designed miniaturised implantable recording probes, that, together with a user-guided sleep scoring program, allow semi-automated classification of sleep stages based on locomotor (camera), EMG (electromyography), ECoG (electrocorticography) and intracerebral (tetrodes) activity. Such methods allowed us to show that rats, like humans, exhibited a steady decrease across the lifespan in sleep duration and marked changes in sleep quality. We specifically observed that while younger animals presented higher amounts of REM (rapid eye movement sleep), older rats showed a significant increase in sleep fragmentation, coinciding with decreased delta power during slow wave sleep. All in all, we present here a novel toolset that allows efficient mapping of sleep architecture across the lifespan while decoding neural dynamics.

Molecular design of hypothalamus development.
A wealth of specialized neuroendocrine command systems intercalated within the hypothalamus control the most fundamental physiological needs in vertebrates. Nevertheless, we lack a developmental blueprint that integrates the molecular determinants of neuronal and glial diversity along temporal and spatial scales of hypothalamus development. Here we combine single-cell RNA sequencing of 51,199 mouse cells of ectodermal origin, gene regulatory network (GRN) screens in conjunction with genome-wide association study-based disease phenotyping, and genetic lineage reconstruction to show that nine glial and thirty-three neuronal subtypes are generated by mid-gestation under the control of distinct GRNs. Combinatorial molecular codes that arise from neurotransmitters, neuropeptides and transcription factors are minimally required to decode the taxonomical hierarchy of hypothalamic neurons. The differentiation of γ-aminobutyric acid (GABA) and dopamine neurons, but not glutamate neurons, relies on quasi-stable intermediate states, with a pool of GABA progenitors giving rise to dopamine cells. We found an unexpected abundance of chemotropic proliferation and guidance cues that are commonly implicated in dorsal (cortical) patterning in the hypothalamus. In particular, loss of SLIT-ROBO signalling impaired both the production and positioning of periventricular dopamine neurons. Overall, we identify molecular principles that shape the developmental architecture of the hypothalamus and show how neuronal heterogeneity is transformed into a multimodal neural unit to provide virtually infinite adaptive potential throughout life.

GPR55 controls functional differentiation of self-renewing epithelial progenitors for salivation.
GPR55, a lipid-sensing receptor, is implicated in cell cycle control, malignant cell mobilization, and tissue invasion in cancer. However, a physiological role for GPR55 is virtually unknown for any tissue type. Here, we localize GPR55 to self-renewing ductal epithelial cells and their terminally differentiated progeny in both human and mouse salivary glands. Moreover, we find GPR55 expression downregulated in salivary gland mucoepidermoid carcinomas and GPR55 reinstatement by antitumor irradiation, suggesting that GPR55 controls renegade proliferation. Indeed, GPR55 antagonism increases cell proliferation and function determination in quasiphysiological systems. In addition, Gpr55-/- mice present ~50% enlarged submandibular glands with many more granulated ducts, as well as disordered endoplasmic reticuli and with glycoprotein content. Next, we

hypothesized that GPR55 could also modulate salivation and glycoprotein content by entraining differentiated excretory progeny. Accordingly, GPR55 activation facilitated glycoprotein release by itself, inducing low-amplitude Ca2+ oscillations, as well as enhancing acetylcholine-induced Ca2+ responses. Topical application of GPR55 agonists, which are ineffective in Gpr55-/- mice, into adult rodent submandibular glands increased salivation and saliva glycoprotein content. Overall, we propose that GPR55 signaling in epithelial cells ensures both the life-long renewal of ductal cells and the continuous availability of saliva and glycoproteins for oral health and food intake.

Hypothalamic CNTF volume transmission shapes cortical noradrenergic excitability upon acute stress.
Stress-induced cortical alertness is maintained by a heightened excitability of noradrenergic neurons innervating, notably, the prefrontal cortex. However, neither the signaling axis linking hypothalamic activation to delayed and lasting noradrenergic excitability nor the molecular cascade gating noradrenaline synthesis is defined. Here, we show that hypothalamic corticotropin-releasing hormone-releasing neurons innervate ependymal cells of the 3 ventricle to induce ciliary neurotrophic factor (CNTF) release for transport through the brain's aqueductal system. CNTF binding to its cognate receptors on norepinephrinergic neurons in the locus coeruleus then initiates sequential phosphorylation of extracellular signal-regulated kinase 1 and tyrosine hydroxylase with the Ca-sensor secretagogin ensuring activity dependence in both rodent and human brains. Both CNTF and secretagogin ablation occlude stress-induced cortical norepinephrine synthesis, ensuing neuronal excitation and behavioral stereotypes. Cumulatively, we identify a multimodal pathway that is rate-limited by CNTF volume transmission and poised to directly convert hypothalamic activation into long-lasting cortical excitability following acute stress.

Life-long impairment of glucose homeostasis upon prenatal exposure to psychostimulants.
Maternal drug abuse during pregnancy is a rapidly escalating societal problem. Psychostimulants, including amphetamine, cocaine, and methamphetamine, are amongst the illicit drugs most commonly consumed by pregnant women. Neuropharmacology concepts posit that psychostimulants affect monoamine signaling in the nervous system by their affinities to neurotransmitter reuptake and vesicular transporters to heighten neurotransmitter availability extracellularly. Exacerbated dopamine signaling is particularly considered as a key determinant of psychostimulant action. Much less is known about possible adverse effects of these drugs on peripheral organs, and if in utero exposure induces lifelong pathologies. Here, we addressed this question by combining human RNA-seq data with cellular and mouse models of neuroendocrine development. We show that episodic maternal exposure to psychostimulants during pregnancy coincident with the intrauterine specification of pancreatic β cells permanently impairs their ability of insulin production, leading to glucose intolerance in adult female but not male offspring. We link psychostimulant action specifically to serotonin signaling and implicate the sex-specific epigenetic reprogramming of serotonin-related gene regulatory networks upstream from the transcription factor Pet1/Fev as determinants of reduced insulin production.

Brain-wide genetic mapping identifies the indusium griseum as a prenatal target of pharmacologically unrelated psychostimulants.
Psychostimulant use is an ever-increasing socioeconomic burden, including a dramatic rise during pregnancy. Nevertheless, brain-wide effects of psychostimulant exposure are incompletely understood. Here, we performed Fos-CreER-based activity mapping, correlated for pregnant mouse dams and their fetuses with amphetamine, nicotine, and caffeine applied acutely during midgestation. While light-sheet microscopy-assisted intact tissue imaging revealed drug- and age-specific neuronal activation, the indusium griseum (IG) appeared indiscriminately affected. By using GAD67 mice we subdivided the IG into a dorsolateral domain populated by γ-aminobutyric acidergic interneurons and a ventromedial segment containing glutamatergic neurons, many showing drug-induced activation and sequentially expressing Pou3f3/Brn1 and secretagogin (Scgn) during differentiation. We then combined Patch-seq and circuit mapping to show that the ventromedial IG is a quasi-continuum of glutamatergic neurons (IG-) reminiscent of dentate granule cells in both rodents and humans, whose dendrites emanate perpendicularly toward while their axons course parallel with the superior longitudinal fissure. IG- neurons receive VGLUT1 and VGLUT2 excitatory afferents that topologically segregate along their somatodendritic axis. In turn, their efferents terminate in the olfactory bulb, thus being integral to a multisynaptic circuit that could feed information antiparallel to

the olfactory-cortical pathway. In IG- neurons, prenatal psychostimulant exposure delayed the onset of Scgn expression. Genetic ablation of was then found to sensitize adult mice toward methamphetamine-induced epilepsy. Overall, our study identifies brain-wide targets of the most common psychostimulants, among which / neurons of the IG link limbic and olfactory circuits.

A ROLE FOR OREXIN IN REM SLEEP REGULATION

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Gianandrea Broglia, Mehdi Tafti, Mojtaba Bandarabadi
University of Lausanne, Department Of Biomedical Sciences, Lausanne, Switzerland

Orexin (hypocretin) neurons are important for sustaining long periods of wakefulness and their activity has been linked to a variety of behaviors including feeding, motivation, and reward processing. However, the role of orexin in the regulation of REM sleep and its components remains elusive as it was hypothesized that these neurons are silent during sleep. We investigated this paradigm using *in vivo* fiber photometry calcium imaging of orexin neurons of the lateral hypothalamus (LH) combined with EEG/EMG recordings in Hcrt-IRES-Cre mice and we found that the activity of orexin neurons correlates with the phasic components of REM sleep, in particular at enhanced power and faster frequency of theta rhythm. Furthermore, we found increased activity of orexin neurons prior to the termination of REM sleep episodes. Our results suggest a strong neuromodulatory role for the orexin system in the regulation of REM sleep theta oscillations and the termination of the state itself.

SLEEP REGULATION BY THE CORTICAL PROJECTIONS TO THE PREOPTIC NUCLEUS

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Mathilde Chouvaeff, Thierry Gallopin, Karim Benchenane
ESPCI, Laboratoire Plasticité Du Cerveau, Paris, France

Sleep is divided into two distinct neurophysiological states : non-rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep. The mechanisms by which these two states alternate remain poorly understood, especially since they can be modulated by learning or stressful situations. To better understand the fine regulation of sleep stages we were interested in the top-down control of high-level cortical structures on sleep-promoting structures. More particularly, we were interested in the projections from the prefrontal cortex (PFC) to the ventrolateral prepotic nucleus (VLPO). This pathway has been anatomically identified but its functionality remains to be determined. In this study, optogenetic tools were used to selectively activate the PFC-VLPO pathway in mouse brain slices as well as in freely moving mice. The sleep scoring was fully performed based on brain signals thanks to electrodes implanted in different structures. Our ex vivo patch-clamp recordings indicate that activation of cortical afferents in the VLPO induces post-synaptic currents in VLPO sleep-promoting neurons, demonstrating the functional nature of this pathway. Our in vivo experiments showed that the PFC-VLPO pathway activation disrupted the theta oscillation during REM sleep but not during wakefulness. Moreover, we found that these optogenetic stimulations induced an increase in ripples density, suggesting that animals went out of REM sleep. Finally, our results indicate that the activation of the PFC-VLPO pathway during REM sleep promotes transitions toward NREM sleep. These results are consistent with the NREM sleep-promoting role of the VLPO.

SLEEP CIRCUITS OBSERVED IN DROSOPHILA OVER MULTIPLE DAYS DURING BEHAVIOR

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Andres Flores-Valle, Johannes Seelig
Max Planck Society, Max Planck Institute For Neurobiology Of Behavior, Bonn, Germany

Neural circuits that control sleep are linked to the function of sleep, but this interaction is only partially understood. In the brain of Drosophila circuits important for sleep control as well as functional circuits important for navigation and memory have been identified in the central complex, an area located in the center of the fly brain. This brain area therefore offers an opportunity to understand the impact of sleep on navigation circuits at the level of small populations of identified cells. Using computational modeling we have started to describe the interaction and dynamics of subsets of these circuits [Flores-Valle et al., Plos. Comp. Biol., 2021]. To experimentally investigate the nature of the interaction between sleep and navigation circuits and to test predictions of our computational model, we have developed an in vivo two-photon imaging method for monitoring behavior and neural activity in head-fixed walking Drosophila for up to one week [Flores-Valle et al., J. Neurosci. Meth., 2021]. We use this method to quantify calcium dynamics in different cell populations important for navigation as well as for sleep over multiple days and nights. We characterize the dynamics of previously described sleep control circuits and identify novel elements of sleep circuits in the fly brain. These experiments provide the first characterization of calcium dynamics of a range of neural populations important for navigation and sleep over extended periods of time during day and night and contribute to an understanding of the interaction of sleep control and function.

PSYCHEDELIC COMPOUND 5-MEO-DMT INDUCES AN ALTERED WAKE STATE IN MICE

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Benjamin Breant[1], José Prius-Mengual[1], Laura Mckillop[1], Trevor Sharp[2], David Bannerman[3], Vladyslav Vyazovskiy[1]
[1]University of Oxford, Department Of Physiology, Anatomy And Genetics, Oxford, United Kingdom, [2]University of Oxford, Dept Of Pharmacology, Oxford, United Kingdom, [3]University of Oxford, Department Of Experimental Psychology, Oxford, United Kingdom

Introduction: The traditional view that the serotonergic system plays an important role in controlling global sleep-wake states is supported by observations that administration of serotonergic psychedelics has a wake-promoting effect. However, the possibility that potentiating the serotonergic system through psychedelics results in an occurrence of altered states of vigilance has received less attention. Here we tested the hypothesis that serotonergic psychedelics alter fundamental characteristics of sleep and waking, rather than merely affecting the time spent in a specific state of vigilance. *Methods:* We performed chronic EEG and EMG recordings in freely-behaving laboratory mice (n = 7) after injection of a short-lasting psychedelic compound, 5-methoxy-N,N-dimethyltryptamine (5 MeO-DMT, 5 mg/kg) at the beginning of the light period. *Results:* We observed that 5-MeO-DMT administration resulted in an awake state characterised by altered EEG patterns as reflected in reduced theta-frequency (-3.82 % to -73.47 %) and increased spectral power in slow frequency range (9.11 % to 48.60 %). The effects were largely dissipated 1 hour after the injection. *Conclusion:* Our data support the notion that the effects of 5-MeO-DMT on EEG recordings are short-lasting. Importantly, this compound did not merely change the amount and distribution of vigilance states but had an observed effect on state-specific brain activity patterns. Reduced theta-activity and increased slow wave activity during waking after administration of 5-MeO-DMT reflect an occurrence of qualitatively different, “hybrid” or “dissociated” state, having features of both waking and sleep. This project was supported by a BBSRC Scholarship. The Compound was provided by Beckley Psytech.

Psilocin acutely alters sleep-wake architecture and cortical brain activity in laboratory mice.
Serotonergic psychedelic drugs, such as psilocin (4-hydroxy-N,N-dimethyltryptamine), profoundly alter the quality of consciousness through mechanisms which are incompletely understood. Growing evidence suggests that a single psychedelic experience can positively impact long-term psychological well-being, with relevance for the treatment of psychiatric disorders, including depression. A prominent factor associated with psychiatric disorders is disturbed sleep, and the sleep-wake cycle is implicated in the homeostatic regulation of neuronal activity and synaptic plasticity. However, it remains largely unknown to what extent psychedelic agents directly affect sleep, in terms of both acute arousal and homeostatic sleep regulation. Here, chronic electrophysiological recordings were obtained in mice to track sleep-wake architecture and cortical activity after psilocin injection. Administration of psilocin led to delayed REM sleep onset and reduced NREM sleep maintenance for up to approximately 3 h after dosing, and the acute EEG response was associated primarily with an enhanced oscillation around 4 Hz. No long-term changes in sleep-wake quantity were found. When combined with sleep deprivation, psilocin did not alter the dynamics of homeostatic sleep rebound during the subsequent recovery period, as reflected in both sleep amount and EEG slow-wave activity. However, psilocin decreased the recovery rate of sleep slow-wave activity following sleep deprivation in the local field potentials of electrodes targeting the medial prefrontal and surrounding cortex. It is concluded that psilocin affects both global vigilance state control and local sleep homeostasis, an effect which may be relevant for its antidepressant efficacy.

SLEEP STRUCTURE IN JUVENILE AND ADULT ZEBRA FINCHES: BROAD DIFFERENCES IN EEG OSCILLATIONS AND FUNCTIONAL CONNECTIVITY

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Hamed Yeganegi[1], Janie Ondracek[2]
[1]LMU Munich, Graduate School Of Neurosciences, Planegg, Germany, [2]Technical University of Munich, Chair Of Zoology, Freising, Germany

Despite their phylogenetic differences and distinct pallial structures, mammals and birds share many features of sleep. However, our current understanding of avian sleep is confined to studies in adult birds. In order to investigate the role of sleep oscillations during brain development, we recorded multi-channel EEG from juvenile and adult zebra finches. We compared the structure of sleep in adults and juveniles by calculating the ratio of slow oscillations to gamma oscillations ("depth of sleep", DOS). We found that the DOS ratio was significantly larger in juveniles compared to adults. Similarly, juveniles underwent state transitions more frequently than adults. A closer look at the multichannel EEG revealed that in addition to global (wide-spread) slow waves, slow oscillations also occurred on a small (local) group of electrode sites. The occurrence of local waves was correlated with the DOS and was higher in frontal sites. Furthermore, we quantified the functional connectivity across adults and juveniles by calculating pair-wise correlations between electrode sites. We observed that the strength of the correlations increased during development and was significantly higher in adults than in juveniles. In addition, we applied graph theory to identify significant spatial networks. The network analysis revealed two main results: 1: The size of highly-correlated subsets of channels was smallest during SWS compared to REM. 2: The highly-correlated networks were smaller in size and more numerous in juveniles compared to adults. Overall, our results suggest that the developing avian brain undergoes significant changes in the oscillatory composition of sleep and connectivity.

AN INTERPLAY BETWEEN PLASTICITY AND STABILITY OF CA1 HIPPOCAMPAL CIRCUITS ACROSS AROUSAL STATES IN BEHAVING MICE

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Ortal Shinikamin[1], Oded Scharf[2], Inna Slutsky[2]
[1]Tel Aviv University, Physiology And Pharmacology, Tel Aviv, Israel, [2]Tel Aviv University, Sagol School Of Neuroscience, Tel Aviv, Israel

(Aims) The ability of hippocampal circuits to maintain the balance between stability and flexibility is critical for normal hippocampal functioning. However, to what extent individual neurons and neuronal populations maintain their firing properties across different arousal states remains elusive. ***(Methods)*** To address this question, we combined Ca^{2+} micro-endoscopy in CA1 pyramidal neurons, local field potential and electromyography recordings in behaving and anesthetized mice. ***(Results)*** We found that physiological vigilance states - active wake, quiet wake and non-rapid eye movement sleep (NREMS) - consist of overlapping populations of active cells. At the population level, CA1 displays a unique activity set point, which is highest for active wake and lowest for NREMS and is stable across days. At the single cell level, 32-52% of individual CA1 neurons change their mean rates over short (1 day) and longer (8 days) time periods. Transitions from active wakefulness to NREMS involves a major decrease in activity of most cells, with a stronger decrease in the mean rate of a sub-population of high-firing neurons. Interestingly, drug-induced general anesthesia reveals a unique population of CA1 active cells and only partial overlap with those activated by natural sleep. The firing rates of the common neurons are only weakly correlated between NREMS and anesthesia. ***(Conclusions)*** Altogether, our results suggest that invariant population dynamics during physiological vigilance states emerge despite intrinsically unstable activity of individual neurons, while general anesthesia reveals a unique hippocampal cell population and activity.

WHOLE BRAIN MAPPING OF ACTIVITY DURING SLEEP AND WAKEFULNESS USING THE TRAP MICE AND IMPROVED DOUBLE FLUORESCENCE METHOD AND AUTOMATIC COUNTING

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Renato Marciano Maciel[1], Sébastien Cabrera[1], Olivier Raineteau[2], Nathalie Mandairon[3], Patrice Fort[1], Pierre-Hervé Luppi[1]
[1]Centre Recherche Neurosciences Lyon (CRNL), CNRS UMR5292, INSERM U1028, Universilté LYON I, Sleep Team, BRON, France, [2]SBRI, Rhône, Bron, France, [3]Centre Recherche Neurosciences Lyon (CRNL), CNRS UMR5292, INSERM U1028, Universilté LYON I, Neuropop Team, BRON, France

Aims Our aim is to identify the populations of neurons activated during paradoxical (REM) sleep and to determine whether introduction of adverse or learning events induce the activation of different populations of neurons than those seen in basal conditions. Methods To this aim, we will use a new genetic TRAP method (2) combining tdtomato expression under Fos promoter with Fos immunohistochemistry. We first examined 3 mice groups: PSR-PSR (2h PS recovery after 48h PS deprivation), PSR-Wake (2h in open field), and Wake-PSR group all receiving 4-OHT 2h after the first condition and perfused 2h after the second condition. We then performed immunofluorescence of cFos and automatic counting of neurons on brain sections of the mice taken every 240um. Results Overall, more cFos and tdtomato labeled neurons were observed in most structures during the W compared to the PSR condition. The dentate gyrus was one of the few structures containing more cFos neurons after PSR than W. As reported recently for the anterior cingulate, retrosplenial and claustrum with DAB staining (Maciel et al., 2021), less double-labeled neurons were observed in the W-PSR and PSR-W conditions than in the PSR-PSR condition in most brain structures examined. Conclusions The development of a new method combining the use of TRAP mice with automatic counting open the path to the study over the whole brain of populations of neurons activated during two different conditions. Further, our results indicate that W and PS are completely different states during which different populations of neurons are activated.

ELECTROPHYSIOLOGICAL CORRELATES OF DISSOCIATIVE EXPERIENCES IN SLEEP DEPRIVED HEALTHY SUBJECTS

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Danilo Menicucci[1], Valentina Cesari[1], Enrico Cipriani[1], Andrea Piarulli[1], Angelo Gemignani[2]
[1]university of pisa, department Of Surgical, Medical And Molecular Pathology And Critical Care Medicine, Pisa, Italy, [2]university of pisa, department Of Surgical, Medical And Molecular Pathology And Critical Care Medicine, pisa, Italy

The fragmented sleep, fragmented mind hypothesis has associated sleep disturbances and dissociative states in subjects with dissociative traits. Resting state EEGs of subjects with dissociative traits show a higher prevalence of slow rhythms albeit with a lower spatial coherence. A labile sleep-wake cycle might support the emergence of dissociative states such derealization, depersonalization, and dissociative amnesia in non-clinical populations even in the absence of background traits. On this basis, we expected that sleep loss could prompt dissociative states, and thus we evaluated dissociative experiences and resting state EEG features (spectral content and phase synchronization) after total sleep deprivation; neuro-phenomenal correlates of dissociative state were identified by correlating changes from baseline to post-deprivation conditions of significant psychometric indices with those of EEG features. We observed a significant increase in perceived altered state of consciousness and in dissociative experiences after sleep deprivation. Correlations between changes in psychometric indices and changes in band spectral contents showed that a higher prefrontal theta was associated with a higher intensity of depersonalization and a lower self-awareness in post sleep deprivation. Correlations between changes in psychometric indices and changes in synchronization showed that a higher intensity of dissociative experiences was paralleled by a higher synchronization increase in alpha, beta, and gamma bands. Acute sleep deprivation might fuel dissociative experiences which in turn might represent a regulatory strategy to face sleep loss, with the establishment of a state of consciousness promoted by a higher synchronization at high frequencies.

PUPIL SIZE DURING SLEEP INDICATES DISTINCT BRAIN STATES IN HUMANS

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Ozge Yuzgec[1], Yesica Gloria[2], Alexandra Novozhilova[1], Laurence Bayer[3], Martina Kropp[4], Gabriele Thumann[4], Sophie Schwartz[5], Daniel Huber[1]
[1]University of Geneva, Basic Neuroscience Department Cmu Huber Lab, Geneva, Switzerland, [2]University of Geneva, Basic Neurosciences, Geneva, Switzerland, [3]University of Geneva Hospital, Sleep Medicine, Geneva, Switzerland, [4]University of Geneva Hospital, Ophthalmology, Geneva, Switzerland, [5]University of Geneva, Basic Neurosciences Department, Sleep And Cognition Lab, Geneva, Switzerland

Brain states, defined by global activity changes across brain regions, are arguably the most important determinant of behavioral output in mammals. Sleep is the longest state that most animals spend their lives in and comprises distinct sub-states crucial for different physiological and behavioral processes. Classification of different sleep stages is therefore essential for understanding and studying processes taking place throughout sleep in health and disease in both mice and humans. Sleep stage classification has typically been done through polysomnographic recordings, which are precise but complex, expensive and tedious to implement. Other auxiliary measures such as heartbeat, breathing and skin conductance indicate neuromodulator levels that can be used to detect sleep stages; however, these signals are relatively low in time resolution. We have taken inspiration from studies involving eye tracking in wakefulness to monitor brain states and translated them into sleep settings by merging them with novel methods for both mice and humans. We discovered robust correlations between fluctuations in pupil size and brain states as well as the activity of the autonomic nervous system. We furthermore showed that pupils might serve a protective function to preserve the stability of deep sleep. Our research revealed a reliable relationship between eye parameters in sleep and brain states, which has so far been hidden behind closed eyelids. It underlines the importance of developing novel methods for physiological tracking in sleep that can be used for assessments in clinical or research settings.

Pupil Size Coupling to Cortical States Protects the Stability of Deep Sleep via Parasympathetic Modulation.
During wakefulness, pupil diameter can reflect changes in attention, vigilance, and cortical states. How pupil size relates to cortical activity during sleep, however, remains unknown. Pupillometry during natural sleep is inherently challenging since the eyelids are usually closed. Here, we present a novel head-fixed sleep paradigm in combination with infrared back-illumination pupillometry (iBip) allowing robust tracking of pupil diameter in sleeping mice. We found that pupil size can be used as a reliable indicator of sleep states and that cortical activity becomes tightly coupled to pupil size fluctuations during non-rapid eye movement (NREM) sleep. Pharmacological blocking experiments indicate that the observed pupil size changes during sleep are mediated via the parasympathetic system. We furthermore found that constrictions of the pupil during NREM episodes might play a protective role for stability of sleep depth. These findings reveal a fundamental relationship between cortical activity and pupil size, which has so far been hidden behind closed eyelids.

Synaptic Mechanisms of Tight Spike Synchrony at Gamma Frequency in Cerebral Cortex.
During the generation of higher-frequency (e.g., gamma) oscillations, cortical neurons can exhibit pairwise tight (<10 ms) spike synchrony. To understand how synaptic currents contribute to rhythmic activity and spike synchrony, we performed dual whole-cell recordings in mouse entorhinal cortical slices generating periodic activity (the slow oscillation). This preparation exhibited a significant amount of gamma-coherent spike synchrony during the active phase of the slow oscillation (Up state), particularly among fast-spiking inhibitory interneurons. IPSCs arriving in pairs of either pyramidal or fast-spiking neurons during the Up state were highly synchronized and exhibited significant coherence at frequencies from 10 to 100 Hz, peaking at ~40 Hz, suggesting both synchronous discharge of, and synaptic divergence from, nearby inhibitory neurons. By inferring synaptic currents related to spike generation in simultaneously recorded pyramidal or fast-spiking neurons, we detected a

decay of inhibition ~20 ms before spiking. In fast-spiking interneurons, this was followed by an even larger excitatory input immediately before spike generation. Consistent with an important role for phasic excitation in driving spiking, we found that the correlation of excitatory inputs was highly predictive of spike synchrony in pairs of fast-spiking interneurons. Interestingly, spike synchrony in fast-spiking interneurons was not related to the strength of gap junctional coupling, and was still prevalent in connexin 36 knock-out animals. Our results support the pyramidal-interneuron gamma model of fast rhythmic oscillation in the cerebral cortex and suggest that spike synchrony and phase preference arises from the precise interaction of excitatory-inhibitory postsynaptic currents.

PALLIDIN FUNCTION IN DROSOPHILA SURFACE GLIA REGULATES SLEEP AND IS DEPENDENT ON AMINO ACID AVAILABILITY

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Hui Li[1], Sami Aboudhiaf[1], Christelle Anaclet[1], Magali Perier[1], Sandrine Parrot[2], Nathalie Strazielle[3], Jean-Francois Ghersi-Egea[3], Jian-Sheng Lin[1], Laurent Seugnet[1]

The Pallidin protein is a component of a multimeric complex named the Biogenesis of Lysosome-related Organelles Complex-1 (BLOC1) that regulates lysosome function. In a gene profiling study we have found *pallidin* mRNA to be strongly upregulated in the cortex of somnolent mice with defective histaminergic transmission, suggesting a link between the cellular and molecular mechanisms controlled by the *pallidin* gene and sleep/wake regulation. To investigate this question, we used a genetic knockdown strategy in *Drosophila* and demonstrated that down-regulation of *pallidin* in the surface glia, the *Drosophila* equivalent of the blood brain barrier, is sufficient to reduce, fragment and delay nighttime sleep at the adult stage and in a circadian clock dependent manner. Other members of the BLOC1 complex appear to be involved in this Pallidin-dependent sleep regulation. In agreement with Pallidin's involvement in amino acid transport, down-regulation of the Large neutral Amino acid Transporter 1 (LAT1)-like transporters JhI-21 and minidiscs, as well as the TOR amino acid signaling, phenocopy the down-regulation of *pallidin*. Supplementing food with essential amino acids normalizes the sleep/wake phenotypes of *pallidin* and *JhI-21* down-regulation. Furthermore, we identify a role for *pallidin* in the subcellular trafficking of JhI-21 in surface glial cells. Finally, we provide evidence that Pallidin function in surface glia is required for GABAergic neurons activation involved in promoting sleep. Taken together, these data identify a novel role for Pallidin that, through LAT1-like transporters subcellular trafficking modulates essential amino acid availability and GABAergic sleep/wake regulation.

TRPM8 AND CIRCADIAN PHYSIOLOGY

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Alfonso Reimúndez Dubra[1], Purificación Ordás[2], Carlos Fernández-Peña[3], Rosalia Gallego[4], Juan Navarro[5], José Pardo-Vázquez[6], Victor Arce[5], Félix Viana[2], Rosa Señarís[5]
[1]Institut De La Vision, Department Of Development, Paris, France, [2]Instituto de Neurociencias de Alicante. CSIC/UMH, -, San Juan de Alicante, Spain, [3]St. Jude Children's Hospital, -, Memphis, United States of America, [4]University of Santiago de Compostela, Morphological Sciences, Santiago de Compostela, Spain, [5]University of Santiago de Compostela, Physiology, Santiago de Compostela, Spain, [6]University of A Coruña, Physiology. Faculty Of Health Sciences, A Coruña, Spain

Most homeostatic functions display circadian oscillations synchronized by light, although ambient and body temperature also regulate the circadian system, especially the peripheral clocks. Because TRPM8 ion channel is a critical cold sensor in mammals and regulates body temperature homeostasis, we investigated its role in circadian regulation. Using TRPM8-deficient mice we studied circadian oscillations of body temperature (Tc) and motor activity in driven and free-running conditions (dark/dark, D/D) and in constant light (L/L). Furthermore, we analyzed the effect of TRPM8 on clockwork in the suprachiasmatic nucleus of the hypothalamus (SCN). Here we show that TRPM8-deficient mice exhibit defective Tc levels and greater oscillations in the absence of external cues, like in constant darkness (D/D). No remarkable changes were observed in the main rhythmic parameters of body temperature. However, in L/L *Trpm8*$^{-/-}$ mice exhibited a Tc with a higher unstable rhythmicity and a significant phase delay in comparison with WT littermates. Interestingly, we found that TRPM8 is expressed in retinal neurons projecting to the SCN, underlining its potential function in the regulation of the master clock. The clock gene Per2 was more expressed in the SCN of *Trpm8*$^{-/-}$ mice, especially during the daytime, accompanied by higher levels of AVP, which regulates many circadian functions, including Tc circadian oscillation. In summary, TRPM8 operates not only as an external thermosensor in skin and mucosae regulating thermal homeostasis, but it might also work as a thermoreceptor in the retina and its projections to the hypothalamus, regulating central circadian clockwork, and consequently influencing Tc circadian oscillations

Cdr1as is a conserved circular RNA (circRNA) enriched in the CNS and important for maintaining brain homeostasis. The loss of Cdr1as results in aberrant synaptic transmission and deregulation of stress response and circadian clock genes. However, it is not known whether the expression of Cdr1as or circRNAs, in general, follows a circadian pattern in different tissues. Here, using newly generated and public RNA-Seq data, we monitor circRNA expression throughout circadian rhythm in various mouse brain regions. We demonstrate that Cdr1as, despite its stable character, has a highly dynamic expression during the circadian cycle in the mouse suprachiasmatic nucleus (SCN). Cdr1as is one of the highest expressed RNAs in a cluster associated with light-induced synaptic transmission and phase shift in the SCN. Further, we identified that another brain enriched circRNA, *mbl*, is also substantially deregulated upon light induction in the fly head. Our study highlights the potential impact of abundant and conserved circRNAs on maintaining a healthy circadian cycle across species.

CIRCADIAN RHYTHM OF NEURONAL ACTIVITY IN VASOPRESSIN NEURONS OF THE SCN IN MALE AND FEMALE RATS.

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Zahra Simone Thirouin[1], Claire Gizowski[1], Charles Bourque[2]
[1]RI-MUHC, Neurology & Neurosurgery, Montreal, Canada, [2]McGill University, Dept Neurology-Neurosurgery, Brain Repair And Integrative Neuroscience Program, Research Institute Mcgill University Health Centre, Montreal, Canada

The hypothalamic suprachiasmatic nucleus (SCN) orchestrates mammalian behavioural and physiological rhythm following the daily light and dark cycle. Assuming that 90 to 95% of the neuronal population are GABAergic, 30% of them co-express the neuropeptide arginine-vasopressin (AVP), also known as anti-diuretic hormone or ADH. AVP neurons contribute to the overall circadian rhythm of SCN neuronal population. They display a pronounced fluctuation of AVP gene as well as cyclic peptide release into the cerebrospinal fluid. These may result of a possible day and night firing activity of these neurons as it was reported a higher frequency of firing during mid-day compared to the mid of the night. A complete activity profile of AVP-expressing neurons has not been shown yet. In this study, we recorded SCN-AVP positive neurons from AVP-eGFP Wistar rats (A kind gift from Dr. Ueta, Japan). Our results show a clear daily oscillation of AVP neuronal firing pattern which is similar in both gender male and female rats. However, females display a lower firing frequency pattern than males which is independent of their oestrus cycle.

Mechanism and function of phasic firing in vasopressin-releasing magnocellular neurosecretory cells.
Magnocellular neurosecretory cells that release vasopressin (MNC) from axon terminals in the neurohypophysis display a unique pattern of action potential firing termed phasic firing. Under basal conditions, only a small proportion of MNC display spontaneous phasic firing. However, acute and chronic conditions that stimulate vasopressin release, such as hemorrhage and dehydration, greatly enhance the number of MNC that fire phasically. Phasic firing optimizes VP neurosecretion at axon terminals by allowing action potential broadening to promote calcium-dependent frequency-facilitation, at the same time as preventing the secretory fatigue caused by spike inactivation that occurs during prolonged continuous stimulation. This review provides an update on our mechanistic understanding of these processes and highlights important gaps in our knowledge that must be addressed in future experiments.

Trpv4 Mediates Hypotonic Inhibition of Central Osmosensory Neurons via Taurine Gliotransmission.
The maintenance of hydromineral homeostasis requires bidirectional detection of changes in extracellular fluid osmolality by primary osmosensory neurons (ONs) in the organum vasculosum laminae terminalis (OVLT). Hypertonicity excites ONs in part through the mechanical activation of a variant transient receptor potential vanilloid-1 channel (dn-Trpv1). However, the mechanism by which local hypotonicity inhibits ONs in the OVLT remains unknown. Here, we show that hypotonicity can reduce the basal activity of dn-Trpv1 channels and hyperpolarize acutely isolated ONs. Surprisingly, we found that mice lacking dn-Trpv1 maintain normal inhibitory responses to hypotonicity when tested in situ. In the intact setting, hypotonicity inhibits ONs through a non-cell-autonomous mechanism that involves glial release of the glycine receptor agonist taurine through hypotonicity activated anion channels (HAAC) that are activated subsequent to Ca influx through Trpv4 channels. Our study clarifies how Trpv4 channels contribute to the inhibition of OVLT ONs during hypotonicity in situ.

Several posttranslational modifications act in concert to regulate gephyrin scaffolding and GABAergic transmission.
GABA receptors (GABARs) mediate the majority of fast inhibitory neurotransmission in the brain via synergistic association with the postsynaptic scaffolding protein gephyrin and its interaction partners. However, unlike their counterparts at glutamatergic synapses, gephyrin and its binding partners lack canonical protein interaction motifs; hence, the molecular

basis for gephyrin scaffolding has remained unclear. In this study, we identify and characterize two new posttranslational modifications of gephyrin, SUMOylation and acetylation. We demonstrate that crosstalk between SUMOylation, acetylation and phosphorylation pathways regulates gephyrin scaffolding. Pharmacological intervention of SUMO pathway or transgenic expression of SUMOylation-deficient gephyrin variants rescued gephyrin clustering in CA1 or neocortical neurons of Gabra2-null mice, which otherwise lack gephyrin clusters, indicating that gephyrin SUMO modification is an essential determinant for scaffolding at GABAergic synapses. Together, our results demonstrate that concerted modifications on a protein scaffold by evolutionarily conserved yet functionally diverse signalling pathways facilitate GABAergic transmission.

WHOLE-BRAIN SIMULATIONS OF WAKEFULNESS, SLOW-WAVE SLEEP, AND ANESTHETIZED STATES IN THE MACAQUE MONKEY

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Rodrigo Cofre, Jennifer Goldman, Alain Destexhe
CNRS, Neuropsi, Saclay, France

Recent advances in invasive electrophysiological recordings and non-invasive brain-imaging technology provide a fertile ground to investigate how the anatomical structure of the brain shapes complex brain dynamics in different states of consciousness and in different species. The anatomical connectivity between brain areas is known for macaque monkey with an excellent level of accuracy and is openly available in the COCOMAC database. Here, we have simulated the activity of the whole brain of macaque based on the COCOMAC connectome, using The Virtual Brain simulation platform. We have integrated a biologically-realistic population model based on mean-field models of Adaptive Exponential (AdEx) integrate-and-fire neurons displaying two cell types, Regular Spiking (RS) cells, representing cortical pyramidal neurons, and Fast Spiking (FS) cells, representing inhibitory interneurons. The AdEx mean-field can simulate asynchronous activity states, or Up/Down states and the associated slow-wave activity. We report that from changing the level of adaptation one can switch the entire brain behavior from an asynchronous mode similar to wakefulness to slow-wave activity similar to sleep or anesthesia. We also show that the model can be used to simulate brain signals such as the electrocorticogram or the BOLD signal of functional magnetic resonance imaging. Our TVB-AdEx macaque model replicates functional properties of the macaque brain seen in fMRI in different states of anesthesia. Our bottom-up approach opens the way for mechanistic explanations of data obtained from different sources of experimental data.

TACKLING THE ELECTROTOPOGRAPHY OF SELF THROUGH THE SPHERE MODEL OF CONSCIOUSNESS

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Michele Pellegrino[1], Patrizio Paoletti[1], Rotem Leshem[2], Tal Dotan Ben-Soussan[1]
[1]Patrizio Paoletti Foundation, Research Institute Of Neuroscience, Education And Didactics (rined), Assisi, Italy, [2]Bar-Ilan University, Criminology Department, Ramat Gan, Israel

Different models of the Self focused on alpha activity, yet cognitive and contemplative studies emphasized the role of additional frequencies bands. We hypothesized that the hierarchy of Self, within the framework of the Sphere Model of Consciousness (SMC), can be electrophysiologically represented by faster-to-slower frequency bands. SMC posits three types of Self: Narrative Self, involving self-referential processes; Minimal Self, the consciousness of oneself as an immediate and embodied experience in the “here-and-now”; and Overcoming of the Self, in which the sense of Self disappears. Our hypotheses: Gamma (30-100 Hz) and Beta (13-30 Hz) are associated with Narrative Self. Alpha (8-12 Hz) and Theta (4-7 Hz) are associated with Minimal Self. Delta (1-3 Hz) is associated with Overcoming of the Self. We performed a mini-review of the literature regarding states of Self in association with meditation and electrophysiological findings. 257 papers were identified through database search, 222 papers were excluded according to exclusion criteria (Behavioural/fMRI results without EEG; EEG analyses outside of frequency domain). 35 papers were examined. In line with our hypotheses, Narrative Self is related to Gamma and Beta, Minimal Self is associated with Alpha and Theta and Overcoming of the Self is linked to Delta. To our knowledge, this is the first attempt to formulate a topographic map combining Self and electrophysiological results across frequency bands. SMC and proposed electrotopography can contribute to open issues in cognitive and contemplative neuroscience, including the differentiation between higher/altered states of consciousness and their relationship with executive functions.

FIBER PHOTOMETRY IMAGING OF LOCUS COERULEUS NOREPINEPHRINE ACTIVITIES FOR STUDYING NEUROMODULATORY SPATIOTEMPORAL DYNAMICS ACROSS SLEEP AND WAKEFULNESS

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Noa Matosevich[1], Noa Regev[2], Yuval Nir[1,2,3]
[1]Tel Aviv University, Sagol School Of Neuroscience, Tel-Aviv, Israel, [2]Tel Aviv University, Department Of Physiology And Pharmacology, Sackler Faculty Of Medicine, Tel-Aviv, Israel, [3]Tel Aviv University, Department Of Biomedical Engineering, Faculty Of Engineering, Tel-Aviv, Israel

Aims The locus coeruleus (LC) is the main source of norepinephrine (NE) to the forebrain and is involved in multiple functions including regulation of vigilance states. New evidence points to modularity within the LC-NE system, suggesting that distinct efferent pathways may have distinct dynamics. To test this possibility our aim was to validate, in freely sleeping animals, methods to capture dynamics of (i) activities of LC cell bodies and LC subpopulations projecting to forebrain and brainstem regions, and (ii) NE levels in target regions. **Methods** Adult mice were monitored with EEG, EMG, and video during 24-hours of wakefulness and sleep with fiber photometry. Additional experiments combining optogenetics, pupillometry, and noxious stimulation were conducted under moderate isoflurane anesthesia. Fiber photometry was used to either record calcium population activity in LC cell bodies or in LC subpopulations using GCaMP, or to measure levels of free extracellular NE in forebrain regions using $GRAB_{NE}$. **Results** We first validated that under anesthesia LC calcium activity induced by noxious stimulation coincides with pupil dilation. Next, in behaving mice, calcium activities in LC and its subpopulations displayed higher activation in wakefulness compared to sleep, in line with established electrophysiology patterns. In forebrain regions, NE levels are parametrically elevated by LC optogenetic stimulation along with pupil dilation. Finally, NE measurements are possible across 24h recordings, and are modulated by vigilance states. **Conclusions** Fiber photometry allows robust measurements of LC population calcium activities, in LC subpopulations, and extracellular NE levels in forebrain regions, across wakefulness and sleep.

CYCLICITY OF CEREBRAL GLUTAMATE AND GLUTAMINE LEVELS ACROSS SLEEP-WAKE STATES IN HUMANS

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Suji Lee, Haejin Hong, Eunji Ha, Rye Young Kim, Hyeonji Lee, Youngeun Shim, Sujung Yoon, In Kyoon Lyoo
Ewha W. University, Ewha Brain Institute, Seoul, Korea, Republic of

Glutamatergic signaling is critically involved in several brain functions including information processing and neuronal plasticity. However, a sequential pattern of changes in cerebral glutamate and glutamine levels across the sleep-wake cycle has not yet been documented in the living human brain. In this study, we explored whether brain glutamatergic signaling changes during the sleep-wake cycle and how the sleep-wake pattern of glutamate and glutamine levels is perturbed by sleep deprivation. In the current study, healthy participants with a regular sleep-wake cycle schedule were recruited. Using ^{1}H-magnetic resonance spectroscopy, a continuous around-the-clock monitoring approach was implemented to evaluate brain glutamate and glutamine levels during the normal sleep-wake cycle and sleep deprivation period. Continuous monitoring of the metabolites in the prefrontal cortex of the brain indicated that glutamate levels increased and glutamine levels decreased during normal wakefulness. During the night sleep, the opposite direction for metabolite changes was observed such as decreased glutamate levels and increased glutamine levels. Sleep deprivation clearly perturbed the sleep-wake pattern of these cerebral metabolites. Specifically, sustained elevation in glutamate levels was observed during forced wakefulness. Similar to the changes observed in naturalistic wakefulness state, low levels of glutamine persisted throughout forced wakefulness. Our study first documents the distinct sleep-wake pattern of cerebral glutamate and glutamine levels in humans. These findings strongly suggest that sleep plays a central role in brain function through maintaining glutamatergic metabolic homeostasis.

"CONTROLLING THE GATES" OF REM SLEEP: DUAL MUSCARINIC-NICOTINIC MODULATION OF GABAERGIC TRANSMISSION AT THE REM-S EXECUTIVE AREA

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Esteban Pino Rodriguez[1,2], Héctor Kunizawa[1], Michel Borde[1]
[1]Facultad de Medicina, Universidad de la República, Departamento De Fisiología, Montevideo, Uruguay, [2]UNIVERSITY OF REGENSBURG, Neurophysiology, Institute Of Zoology, Regensburg, Germany

Intense research in the past decades led to the identification of a relatively well-conserved mesopontine network critically involved in REM sleep (REM-S) and wakefulness (W) control. This network includes a population of 'REM-on' glutamatergic reticular neurons in the *nucleus pontis oralis* (PnO), considered to as the executive area for REM-S onset and maintenance. Based on evidence obtained *in vivo*, a gating mechanism relying on the mutual inhibitory interactions between W-promoting GABAergic and REM-S-promoting cholinergic processes at this area has been proposed as playing a major role in REM-S control. Notwithstanding its probable physiological relevance, this gating mechanism has not been studied in sufficient detail to determine its cellular and synaptic basis. We hypothesised that cholinergic inputs locally inhibit GABAergic synaptic transmission at the PnO. This was evaluated by employing a recently developed *in vitro* model of REM-S motor suppression using electrophysiological and pharmacological approaches. The local micro-application of carbachol elicited either presynaptic depression or facilitation of single evoked GABAergic IPSCs recorded from PnO neurons. Presynaptic depression was replicated by juxtacellular application of muscarine and presynaptic facilitation by nicotine. Using presumed physiological patterns of presynaptic activation (15 Hz stimulation trains) we found that, despite of their opposing effects on short-term plasticity of GABAergic inputs, both muscarine and nicotine reduced the total inhibitory charge transferred to PnO neurons, an effect that was also evoked by carbachol. Our results suggest that a muscarinic-nicotinic cooperation underlies the cholinergic-mediated relief of GABAergic inhibition of PnO neurons responsible for the GABAergic gating mechanism of REM-S.

Sleep in all species is universally defined as a reversible, homeostatically-regulated state of a reduced behavioral responsiveness, with a high arousal threshold in response to external sensory stimulation. However, it remains unclear whether sleep mainly gates motor output or affects responses along sensory pathways, and whether sleep primarily modulates specific aspects of the sensory response such as feedforward vs. feedback signaling. Here, we presented auditory stimuli (e.g. click-trains, words, music) during wakefulness and sleep in epilepsy patients (8 nights / 6 naps from 13 patients), while recording neuronal spiking, microwire LFPs, iEEG, and polysomnography. Auditory stimuli induced robust and selective spiking and high-gamma (80-200 Hz) power responses across the lateral temporal lobe during both NREM and REM sleep. Sleep only moderately attenuated response magnitudes, mainly affecting late responses beyond early auditory cortex and entrainment to rapid click-trains in NREM sleep. By contrast, auditory-induced alpha-beta (10-30Hz) desynchronization (i.e. decreased power) prevalent in wakefulness was strongly reduced in sleep. Thus, extensive auditory responses persist during sleep whereas alpha-beta power decrease, likely reflecting neural feedback processes, is deficient. More broadly, our findings suggest that feedback signalling is key to conscious sensory processing.

THE ROLE OF SLEEP IN GLYMPHATIC SYSTEM REGULATION

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Natalie Hauglund[1], Maiken Nedergaard[2]
[1]University of Copenhagen, Center For Translational Neuromedicine, København, Denmark, [2]University of Rochester Medical Center, Center For Translational Neuromedicine, Rochester, United States of America

The brain parenchyma is devoid of lymphatic vessels. To remove waste products, the brain instead relies on clearance of waste products from the brain to the periphery via the glymphatic system. Strikingly, glymphatic flow of cerebrospinal fluid (CSF) into the brain is limited in wakefulness but triggered during sleep. What drives the enhanced glymphatic activity in sleep is still largely unknown. The aim of this study was to correlate different characteristics of sleep with glymphatic inflow to the brain. A fluorescent tracer was injected into the CSF of mice while electroencephalographic recordings were continuously acquired to monitor the behavioral state. Half of the mice were sleep deprived for 4 hours prior to the experiment, and all mice were either allowed to sleep or were kept awake following the tracer infusion. More tracer was present in the brains of mice that were allowed to sleep after the tracer infusion than mice that were kept awake. The amount of tracer in the brain was positively correlated with the total time spent in sleep, but not delta power. Surprisingly, we found a strong correlation between the amount of tracer in the brain and the number of sleep and wake transitions across experimental groups. These results indicate that entrance of CSF to the brain parenchyma is not merely low in wakefulness and high in sleep, but is also triggered by state transitions and effected by sleep pressure. The exact mechanism behind state transition-induced CSF influx and how it may benefit waste removal requires further investigation.

Sleep microarchitecture is complex and includes short increases in vigilance, known as micro-arousals, as well as restorative processes related to memory consolidation such as sleep spindles. Near-silence of the arousal-promoting nucleus, locus coeruleus (LC), is considered a requirement for sleep, yet LC activity continues during distinct sleep stages suggesting a more complex role. LC releases norepinephrine (NE), but poor temporal resolution of NE measurements has previously limited our insight into the relationship between LC, NE, and sleep structures related to memory performance. Therefore, we set out to study NE during sleep and its connection to micro-arousals and memory-related sleep processes. Combining fiber photometry with EEG and EMG recordings in freely moving mice, we measured LC activity and NE levels across the sleep wake cycle. We found NE levels to oscillate at an infraslow rate during NREM sleep, generating a recurring pattern of micro-arousals alternating with periods of increased sleep spindle activity during NE peak and trough levels, respectively. Optogenetic manipulations of LC revealed that the amplitude of NE oscillations during sleep play a crucial part in memory-related sleep structures: longer NE descents induces spindle-enriched intermediate state and REM sleep, but paradoxically, also increase the likelihood of awakening; shorter NE descents support NREM sleep and micro-arousals. In conclusion NE oscillatory amplitude represents a key target for shaping sleep stages and improving the quality of sleep.

DOSE-RESPONSE ANALYSIS BETWEEN SMARTPHONE ADDICTION AND SLEEP QUALITY: A SYSTEMATIC REVIEW AND META-ANALYSIS OF OBSERVATIONAL STUDIES

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Hyunwoo Kim[1], Yoora Chu[2], Da Jung Jung[1], Hye Min Lee[1], Yun Hak Kim[3]
[1]Pusan National University of Yangsan Hospital, Neurology, Yangsan, Korea, Republic of, [2]Pusan National University, School Of Medicine, Busan, Korea, Republic of, [3]Pusan National University, Biomedical Informatics, Yangsan, Korea, Republic of

Study Objective: Several studies have recently been published on the association between smartphone addiction and sleep quality. However, no systematic review or meta-analysis has yet been performed. We aimed to analyse the association between smartphone usage time and sleep quality.
Methods: We searched for articles published up to 13 January 2022 using the Embase and Medline databases. All observational studies were eligible for inclusion. The Newcastle–Ottawa scale was used to evaluate the risk of bias within the studies. We used restricted cubic spline analysis to perform a dose-response analysis.
Results: Seventeen studies with 36,485 participants were included. The pooled odds ratio was 2.28 (confidence interval [CI]: 1.81-2.89, $p<0.00001$), and the heterogeneity was 80%. In the dose-response analysis drawn from five studies, the regression coefficient between daily smartphone usage time (h/day) and poor sleep quality was 1.058 (1.011-1.106), which confirmed a significant association.
Conclusion: This study shows that smartphone addiction is closely associated with sleep quality, such as insomnia, sleep deprivation, and sleep latency. Further studies with a more structured method and high-quality evidence (cohort or case-control) should be conducted.

PHYSIOLOGICALLY RELEVANT LIGHT STIMULATION LEADS TO LOCAL SIGNATURES OF SLEEP PRESSURE IN THE CONTRALATERAL VISUAL CORTEX IN FREELY MOVING MICE

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

José Prius-Mengual[1], Matthew Unwin[2], Atreyi Chakrabarty[1], Lukas Krone[1], Colin Akerman[3], Vladyslav Vyazovskiy[1]

Aims: Extended wakefulness leads to a global increase in electroencephalogram (EEG) slow-wave activity (SWA: power density between 0.5-4Hz) during subsequent sleep. SWA is regulated at the local level, which led to the hypothesis that sleep is a use dependent process. There is a scarcity of experimental models that afford the manipulation of sleep locally and physiologically in the neocortex. We present a model for investigating the neurobiological mechanisms of local sleep based on a selective local stimulation during waking. **Methods:** To induce sustained synaptic activity in the mice visual system, we position light-emitting diodes in front of the animal's eyes. EEG and/or 16-channel laminar electrodes were used to record cortical activity. The mice were kept awake for 4 hours starting at light onset under monocular light stimulation (8 Hz, train duration 2 s every 30 s, pulse duration 10 ms) and allowed to sleep undisturbed after the period of visual stimulation. **Results:** During the first hour after sleep deprivation combined with visual stimulation, the occipital EEG spectral power density in part of the SWA frequency range (0.25-2 Hz) was consistently higher in the stimulated visual cortex than the non-stimulated hemisphere [CA1] (mean ± SEM: 50±5.2% vs. 33±5.2%, n=8). A second stimulation generated a bigger difference (63±7% vs. 42±5%, n=8). **Conclusions:** These preliminary results establish a new model for local manipulations of neural activity in freely behaving mice, using peripheral sensory stimulation delivered at physiologically relevant (theta) frequency. This paradigm will be useful for investigating the neurobiological mechanisms of homeostatic sleep need.

THE EFFECT OF ALTERED NORMOBARIC OXYGEN MANIPULATION ON TMS INDUCED CORTICOSPINAL EXCITABILITY

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Daniel Graham[1,2,3], Gary Smerdon[2], Hannah Windmill[1,3], Alastair Smith[1,3], Jonathan Marsden[1,4], Stephen Hall[1,3]
[1]University of Plymouth, Brain Research And Imaging Centre, Plymouth, United Kingdom, [2]DDRC Healthcare, Hyperbaric Medical Centre, Plymouth, United Kingdom, [3]University of Plymouth, School Of Psychology, Plymouth, United Kingdom, [4]University of Plymouth, School Of Health Professions, Plymouth, United Kingdom

Aim: The human brain relies on oxygen for cellular respiration, with a reduction of this supply having profound negative effects on brain function and cognition. Conversely, increased levels of oxygen are proposed to have beneficial and possible therapeutic effects. However, the associated effects of oxygen concentration on cortical excitability (CE) are not well understood. Here we explore how altered levels of oxygen affect CE, using a TMS recruitment curve paradigm. **Methods:** The motor hotspot of the first dorsal interosseous (FDI) was identified using a neuronavigation guided TMS–EMG approach. Resting motor threshold (RMT) was calculated using an adaptive threshold-hunting method based on maximum–likelihood parameter estimation by sequential testing. We applied a repeated measures TMS paradigm, in which participants breathed three different oxygen concentrations (10.5, 21, or 100%), provided in a randomised order, while TMS pulses were delivered between 70–140% of the RMT. **Results**: Motor evoked potentials (MEP's) were calculated by the root mean square of the FDI–EMG response and fitted to a Boltzmann Sigmoid curve. Parameters, including the MEP saturation threshold, curve slope and latency were considered. These results show the changes in CE as a function of oxygen concentration. **Discussion**: These findings have implications for our understanding of the potential importance of cerebral oxygen concentration on neural network activity and related performance. Moreover, it highlights the value of brain stimulation approaches for evaluating the efficacy of hyperbaric oxygen therapy as a treatment for central nervous system related disorders.

Aim: Many neurological disorders present cognitive dysfunction along with high levels of fatigue. However, our understanding of the neurological effects of fatigue on cognition is poor. Generally, research informs of a disconnect between reported measures of objective and subjective sleep, such that individuals are not commonly capable of accurately predicting their own sleep quality and quantities. Here we explore the role of sleep using objective and subjective measures alongside fMRI investigation of cognitive functions. **Method:** Participants (n=25) wore a wrist accelerometer device (GENEActiv) for 7-days to obtain objective measures of sleep and completed the Pittsburgh Sleep Quality Index as a subjective measure of sleep. An MRI protocol consisting of a T1 anatomical scan and task-based fMRI consisting of an n-back and go/no-go task was acquired. A general linear model analysis was used to determine the relationship between fMRI haemodynamic responses, cognitive performance, and sleep measures. **Results:** Here we demonstrate the relationship between objective and subjective measures of sleep quality and quantity, and functional performance in the n-back and go/no-go tasks (accuracy and reaction times). Furthermore, we highlight the corresponding neural network changes associated with perceived and actual sleep quality and subsequent impact on cognitive and behavioural measures. **Conclusion:** Demonstrating the relationship between objective and subjective sleep measures, functional performance and subsequent neural correlates evidences the role of differing sleep measures on cognition in a healthy population. Through this understanding, we can expand further into the role that fatigue plays in cognitive symptoms of neurological disease.

IS IT POSSIBLE TO DIALOGUE WITH SLEEPWALKERS IN THE MIDST OF AN EPISODE?

POSTER SESSION 05 - SECTION: SLEEP HOMEOSTASIS, REGULATION MECHANISMS & WAKEFULNESS

Yannis Idir[1,2], Sony Saint-Auret[1,2], Emmanuel Morain[1,2], Isabelle Arnulf[1,2], Delphine Oudiette[1,2]
[1]Sorbonne University, Brain Institute, Paris, France, [2]AP-HP, Pitié-Salpêtrière Hospital, Sleep Disorder Unit, Paris, France

We have recently shown that lucid dreamers can behaviorally respond to stimuli while in the midst of a dream during REM sleep. Here, we tested if this ability to communicate with the outside world extends to sleepwalkers (SW), who exhibit complex behaviors (including speech) during slow-wave sleep. Method: 62 SWs filled a questionnaire investigating their memory of their nocturnal episodes, the type and frequency of behaviors exhibited during an episode (e.g., fighting, laughing, opening doors), as well as the relationship between these behaviors, their mental activity, and the environment. Results: 82% of SWs experienced a conversation with a loved one during an episode at least once in their life. While SWs perceived the interlocutor's words accurately in 81.3% of the cases, they often misperceived the speaker as a dream character (47.9%). Similarly, SWs' verbal responses were more frequently (72.9%) related to the dream scenario (e.g., 'there is a monster') than to reality. The dream scenery was mostly distressing (91.1%). SWs could remember having these nightly discussions (66.5%), but their memory was mostly fragmentary (39.5%) or without content (52.6%). Our results suggest that SWs can perceive stimuli from their environment and converse with a real person during an episode. We are planning to confirm this promising finding by sending verbal stimuli during episodes while SWs' sleep/wake states are monitored with video-polysomnography. If validated, our findings would open the possibility to "interview" sleepers in real-time about the content of their dreams, potentially unlocking the mystery of dreams and their functions.

EVOKED AND INTRINSIC NEURAL SIGNATURES OF HUMAN RECOVERY-OF-CONSCIOUSNESS

POSTER SESSION 04 - SECTION: MENTAL HEALTH, ADDICTION AND OBSESSIVE-COMPULSIVE DISORDER

Georgios Michalareas[1], Christina Weismantel[2], Johannes Gehrig[2], Bertram Scheller[3], Christian Kell[2]
[1]Max Planck Institute for Empirical Aesthetics, Department Of Neuroscience, Frankfurt am Main, Germany, [2]Goethe University Frankfurt, Department Of Neurology, Frankfurt am Main, Germany, [3]Goethe University Frankfurt, Department Of Anaesthesiology, Frankfurt am Main, Germany

AIMS In this work we aimed to investigate two novel neural markers of Recovery-of-Consciousness (ROC), one based on externally evoked and one based on intrinsic brain processes. First, we examined whether the human brain has different excitability and response to external electrical somatosensory stimulation during anesthesia and after recovery of consciousness. Second, we investigated whether band-limited permutation entropy in various frequency bands of intrinsic brain activity can identify the transition from coma to consciousness. METHODS We recorded brain activity with electrocorticography (ECoG) in 11 patients who underwent awake brain tumor surgery in interleaved blocks of steady state somatosensory electric stimulation and resting state between aesthesia-induced unconsciousness to full wakefulness. RESULTS/CONLUSIONS ERP magnitudes from external stimulation were reduced after ROC. This reduced response is likely attributed to the modulation of bottom-up processing by the more prominent top-down processing in wakefulness. The intrinsic activity showed a sharp increase in peak frequency of ongoing alpha oscillations right at the moment of the patients' first behavioral response independent of eye opening. The presence of this effect in various brain areas, even in ones without a prominent power alpha peak in the spectrum, offers supporting evidence for previously posed hypotheses on the functional role of alpha oscillations as a canonical mechanism for information sampling and sensory integration in the brain, with faster sampling in the awake state. Our findings constitute novel and significant contributions to the understanding of the brain mechanisms that underlie recovery of consciousness.

PRE-TRAUMA BEHAVIOURAL RISK FACTORS OF POSTTRAUMATIC STRESS DISORDER

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

László Szente[1,2], Mano Aliczki[1], Christina Miskolczi[1,2], Gyula Balla[1], Zsolt Borhegyi[1], László Biró[1], Zoltán Balogh[1], Anett Szilvásy-Szabó[3], Róbert Maróthy[1], Huba Szebik[1,2], Zoltan K Varga[1], Máté Tóth[1], Eva Mikics[1]

Experiencing a traumatic life event results in Posttraumatic Stress Disorder (PTSD) in vulnerable individuals (10-20% of trauma-exposed populations). PTSD can be characterized by extinction-resistant fear memories and generalization of fear to safe contexts. For better treatment options, it is essential to identify risk factors contributing to vulnerability for PTSD. To identify specific predisposing emotional and cognitive domains of fear generalization and impaired fear extinction, we exposed rats to a wide behavioural test battery prior to the trauma. Then subjects were exposed to a traumatic experience utilizing inescapable footshocks. Four weeks later, freezing responses were quantified in an altered/safe context to assess generalization and extinction to differentiate vulnerable and resilient subpopulations (quartiles). Subsequently, we conducted immunohistochemical or gene expression analysis (q-RT PCR of 96 candidate genes) on medial prefrontal cortical (mPFC) samples, respectively. Finally, we virally knocked down CRH gene expression in the mPFC after fear memory consolidation. We found that specific anxiety-like traits and operant learning-like characteristics are predictive factors of PTSD-like symptoms. Furthermore expression of interneuron markers such as CRH, VIP showed major differences with an additional decrease of neuronal activity in the vulnerable population. Immunohistochemical staining confirmed this finding, which is particularly apparent in VIP/CRF-expressing interneurons. Interestingly, CRH knockdown in mPFC decreased fear expression and generalization, thereby recapitulating the resilient phenotype. In conclusion, lower pre-trauma cognitive abilities are vulnerability factors in the development of fear generalization symptoms of PTSD. Moreover, mPFC CRH signaling seems to play a mediatory role in this process.

Endocannabinoid interactions in the regulation of acquisition of contextual conditioned fear.
Endocannabinoids (eCBs) anandamide (AEA) and 2-arachidonoylglycerol (2-AG) were shown to be involved in the basis of trauma-induced behavioral changes, particularly contextual conditioned fear, however, their ligand-specific effects and possible interactions are poorly understood. Here we assessed specific eCB effects and interactions on acquisition of contextual conditioned fear employing electric footshocks in a rat model. We selectively increased eCB levels by pharmacological blockade of the degrading enzymes of AEA by URB597 and 2-AG by JZL184 before traumatization either systemically or locally in relevant brain areas, the prelimbic cortex (PrL), ventral hippocampus (vHC) and basolateral amygdala (BLA). Following traumatization, a series of contextual reminders were conducted during which conditioned fear was assessed. While systemic URB597-treatment during traumatization only slightly enhanced the acquisition of contextual conditioned fear, administration of the compound in the PrL and vHC led to the acquisition of stable, lasting conditioned fear, resistant to extinction. These effects of URB597 were blocked by simultaneous administration of JZL184. Similar treatment effects did not occur in the BLA. Treatment effects were not secondary to alterations in locomotor activity or nociception. Our findings suggest that AEA and 2-AG functionally interact in the regulation of acquisition of contextual conditioned fear. AEA signaling in the PrL and vHC is a crucial promoter of fear acquisition while 2-AG potentially modulates this effect. The lack of eCB effects in the BLA suggests functional specificity of eCBs at distinct brain sites.

BRAINSTEM SOMATOSTATIN-EXPRESSING CELLS CONTROL THE EMOTIONAL REGULATION OF PAIN BEHAVIOR

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Nanci Winke[1], Daniel Jercog[1], Franck Aby[2], Delphine Girard[1], Marc Landry[2], Emmanuel Valjent[3], Stephane Valerio[1], Pascal Fossat[4], Cyril Herry[1]
[1]University of Bordeaux, Inserm U1215, Neurocentre Magendie, Bordeaux, France, [2]3Interdisciplinary Institute for Neuroscience, Cnrs Umr 5297, Bordeaux, France, [3]IGF, Université Montpellier, CNRS, Inserm, Molecular And Neural Coding Of Behavior (mncb)lab, Montpellier, France, [4]Institut des Maladies Neurodégénératives, Neuroscience, Bordeaux, France

In mammals, threat-related behavior is typically induced by a noxious physical stressor and is associated with a broad range of behavioral responses such as freezing and avoidance. These behavioral responses are associated with the regulation of pain responses allowing individuals to cope with noxious stimuli. Whereas the structures and mechanisms involved in pain behavior are well documented, little is known about the precise neuronal circuits mediating the emotional regulation of pain behavior. Here we used a combination of behavioral, anatomical, optogenetic, and electrophysiological approaches to show that somatostatin-expressing neurons in the ventrolateral periaqueductal gray matter (vlPAG SST cells) promote antinociceptive responses during the presentation of conditioned stimuli (CS) predicting footshocks. Whereas the optogenetic inhibition of vlPAG SST cells during CS presentation promoted analgesia, their optogenetic activation reduced analgesia by potentiating pain responses in the spinal cord through a relay in the rostral ventromedial medulla (RVM). Together these results identify a brainstem circuit composed of vlPAG SST cells specifically projecting to the RVM and mediating FCA to regulate pain responses during threatful situations.

Fear is known to serve essential purposes in protecting individuals from dangerous situations and threats. Dysfunctionnal fear biology is implicated in neuropsychiatric disorders such as pathological anxiety and post-traumatic stress disorder. The understanding of the neuropathophysiology of those disorders is still limited, and therapeutic options (psychotherapy or medication) remain too often ineffective. Works investigating the function of neuronal networks helped highlight the implication of the dorsomedial prefrontal cortex (dmPFC) in fear response. Mice studies, using fear conditioning and dmPFC optogenetic stimulation, have proven that fear behavior can be precisely manipulated. Hence, neuromodulation could be an innovative therapeutic option for fear-linked psychiatric disorders. However, the use of brain stimulation in clinical practice is limited by the unvaforable risk-benefit balance of their use : techniques allowing a precise stimulation are highly invasive, and current non-invasive techniques lack in efficacy and precision. This project aims to develop innovative transcranial optogenetic stimulation techniques, using infrared light that can travel through living tissue, before being converted into visible light at the site of interest by UpConversion NanoParticles (UCNP) (spatial focus). The attached figures rolls out different scales of the project, from the whole animal with its brain implants, to the dmPFC and its neurons, modulated via the light emitted by UCNPs. Moreover this stimulation is conditional, triggered by electrophysiological and behavioral real-time analysis in a closed-loop system (temporal focus).

PREFRONTAL NEURONAL CIRCUITS OF PASSIVE AND ACTIVE FEAR BEHAVIOURS

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Juliette Viellard[1], Suzana Khoder[1], Ha-Rang Kim[2], Newton Canteras[3], Yann Humeau[2], Daniel Jercog[1], Cyril Herry[1]
[1]Institut Magendie, Inserm U1215, Bordeaux, France, [2]IINS, Umr 5297, Bordeaux, France, [3]University of Sao Paulo, Institute Of Biomedical Sciences, Sao Paulo, Brazil

When facing danger, mammals display a broad range of defensive behaviours including freezing and avoidance behaviors. Several studies emphasized the role of the dorsal medial prefrontal cortex (dmPFC) in encoding the acquisition as well as the expression of freezing behavior. However the role of this structure in processing avoidance behavior and the contribution of distinct prefrontal circuits to both freezing and avoidance responses are largely unknown. To further investigate the role of dmPFC circuits in encoding passive and active fear-coping strategies, we developed in the laboratory a novel behavioural paradigm in which a mouse has the possibility to choose either to passively freeze to an aversive stimulus or to actively avoid it as a function of contextual contingencies. Using this behavioural paradigm where both passive and active behaviors were present, we performed single unit recordings in the dmPFC. We observed large populations of dmPFC neurons encoding either freezing or avoidance behavior. Importantly, avoidance-encoding dmPFC neurons project to the dorsal periaquedecutal gray matter and their optogenetic activation and inhibition, promoted or disrupted avoidance learning, respectively. Likewise, an in-vitro patch-clamp recording analysis after optogenetic activation at dmPFC inputs onto dl/lPAG cells resulted in the development of synaptic potentiation. Our data identify a dmPFC-dPAG circuit involved in the acquisition of avoidance behavior.

ROLE OF HIPPOCAMPO-PREFRONTAL CIRCUITS IN FEAR MEMORY CONSOLIDATION.

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Pierre Feugas[1], Yohan Wards[2], Clement Hazet[3], Jeremy Lesas[3], Delphine Girard[1], Cyril Herry[1], Cyril Dejean[2]
[1]Inserm U1215, Neurocentre Magendie, Bordeaux, France, [2]Neurocentre Magendie, Inserm U1215, Bordeaux, France, [3]Neurocampus, Neurocentre Magendie, Bordeaux, France

Fear and anxiety-related disorders are among the most frequent psychiatric conditions with a lifetime prevalence of about 28% in the population worldwide and are therefore a major public health concern. Fear can be modelled in mice with pavlovian fear conditioning (FC) during which mice learn to associate a sound with an electric shock. Concurrent with this learning we observed a subset of prefrontal cortex (PFC) neurons that show synchronous activation during fear expression. We hypothesize that this synchronous activation is the cortical representation of the consolidated associative memory. The ventral part of the hippocampus (vHPC) appears as a likely candidate to orchestrate this consolidation. Hebbian theory posits that memory formation starts in hippocampus before being transferred to cortical regions for long term retention. The ventral region is specifically implicated in emotional memory and send a monosynaptic connection to the PFC. The CA1-field of the vHPC display high frequency oscillations called Sharp-wave-ripples that are crucial for memory consolidation, synchronously activating neurons and strengthening their synaptic weights. To test our hypothesis we used *in vivo* extracellular recordings in the PFC and vHPC during sleep and awake behavior. To investigate the causal role of ripples on fear memory consolidation we used optogenetics to inhibit the pathway from vHPC to PFC during ripples using a closed-loop system. We found that PFC neurons participating in the memory trace display increasing and specific co-activity around SWRs following conditionning, thus highlighting the role of sharp wave ripples in the consolidation of fear neuronal representation and fear memory.

PHYSIOLOGICAL, NEURONAL AND PHARMACOLOGICAL IDENTIFICATION OF PANIC AND ANXIETY-LIKE STATES DURING FREEZING

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Baptiste Maheo[1], Sophie Bagur[2], Karim Benchenane[3]
[1]ESPCI Paris, Brain Plasticity Laboratory, Paris, France, [2]Institut Pasteur, Institut De L'audition, Paris, France, [3]ESPCI, Laboratoire Plasticité Du Cerveau, Paris, France

Ethological studies show fear to be a complex, flexible strategy to manage diverse threats. This approach often focuses on behaviour alone despite the important adaptive value of the underexplored neural and somatic states accompanying them. In particular, identifying brain states through their oscillatory markers should shed light on the cognitive strategies implemented to respond to danger. In this context, we designed a U-shaped maze with one arm associated with aversive shocks while the opposite arm was a clear safe zone. Depending on the distance to threat, we observed the full spectrum of fear behaviours. Surprisingly, we observed in both arms behaviourally identical freezing that differed by a host of physiological and neurophysiological characteristics. Shock side freezing is a more aroused state with higher heart rate, breathing, gamma frequency and power and theta oscillation in the hippocampus. On the contrary, safe side freezing is a less aroused state characterized by hippocampal ripples. The difference between these two states is reliably reflected in prefrontal cortex population firing. Moreover during safe-side ripples, these neurons reactivate shock activity suggesting that this state supports offline processing of threat.
We hypothesized that shock side freezing is a panic-like state while safe side freezing anxiety-like and tested this pharmacologically. Panicolytic administration (chronic fluoxetine) specifically modified shock-side freezing whereas anxiolytic (diazepam) had more widespread effects but crucially inhibits ripples, a hallmark of safe side freezing.
These findings allow a clear distinction of panic and anxiety like states based on physiological, neurophysiological, neuronal and pharmacological markers without motor bias.

SEX-DEPENDENT EFFECTS OF OXR1 BLOCKADE ON ACQUISITION, RETENTION AND EXTINCTION OF ACTIVE AVOIDANCE

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Laia Vila, Soleil García-Brito, Laura Aldavert-Vera, Pilar Segura-Torres
Universitat Autònoma de Barcelona, Psychobiology, Bellaterra, Spain

Orexins are a type of neuropeptide which neurons are located in the lateral hypothalamus and project widely across the brain. Orexin A and its receptor orexin-1-receptor (OX1R) are specifically involved in reward, feeding, and emotional memories. Fear is an emotion that helps the arise of adaptative behaviors when a threatening stimulus or context is detected. A maladaptive response during fear learning or its extinction can lead to anxiety or fear-based disorders, such as posttraumatic stress disorder, which are known to affect men and women differently. It has been shown that the selective OX1R blockade enhances the extinction of fear/emotional memories as well as the activation of pro-extinction circuits. The aim of this study is to assess the effects of OX1R blockade on the acquisition and subsequent retention and extinction of an active avoidance task, which involves both classical conditioning of fear and the production of an instrumental response to avoid it. Forty-eight male and female rats were chronically implanted with a canula to icv administer the OX1R blocker (SB334867) or vehicle after each acquisition session. OX1R blockade was found to detriment the acquisition of male rats, while it did not affect female performance. The affectation on acquisition on males did affect further learning sessions, such as the retention, extinction and, the spontaneous recovery. These results suggest that OX1R could be positively involved in the acquisition of conditioning in males but not in females, and support the idea that there might be differences between sexes regarding circuit activity.

PREFRONTAL CORTEX NEURONAL NETWORK PROCESSES RISK ASSESSMENT BEHAVIORS IN MICE.

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Jose Casanova, Clément Pouget, Ishaant Agarwal, Gisella Vetere
ESPCI, Plasticité Du Cerveau, Paris, France

Anxiety and fear are distinct but overlapping emotions that are expressed as different behaviours depending on the risk the situation entails. Here we visualized the activity of medial prefrontal cortex (mPFC) cells with a miniaturized microscope while mice are tested in tasks with increasing anxiety and fear behavioural outcomes. Different ensembles of mPFC cells convey information about the anxiety-like behaviour (identified as mice spend time in the corners) or fear (when mice engage in freezing behaviour) in a dynamic, behaviour- and task-specific, fashion. We also analysed mPFC neural activity at a population level. We show that, at low-risk tasks, anxiety-like behaviour predominates, and its accompanying neural state can fully predict the fear-related neuronal configuration. However, in high-risk tasks, where a potential or a real threat is present, fear behaviour predominates, and its related neuronal representation is able to predict the anxiety configuration. Finally, we show evidence of fear memory retention in the mPFC neuronal network as early as 1 day after contextual fear conditioning training. These data suggest that the mPFC engages partially overlapping neural states during anxiety- or fear-like behaviours, that can be regulated by present or past threatening experiences.

SEX DIFFERENCES IN A MOUSE SENSORY PRECONDITIONING TASK

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Júlia Pinho, Arnau Garcia
Instituto de investigaciones médicas Hospital del Mar, Neuroscience, Barcelona, Spain

Our daily choices are not always dictated by stimuli that have been directly associated with a potent reinforcer. Indeed, they are often triggered by stimuli that have not been explicitly associated with a reinforcer. These processes are called higher-order conditioning or mediated learning and can be assessed by sensory preconditioning. This task involves repeated simultaneous presentations of two *low-salience* stimuli (e.g. light&tone) and, after, the devaluation of one of the stimuli with an unconditioned stimulus (e.g. foot-shock). These associative processes result in a conditioned response (e.g. fear response) to both the conditioned (direct_learning) and the non-conditioned stimulus (mediated_learning). In our study, male and female mice underwent a protocol of sensory preconditioning divided into 4 different stages: habituation, preconditioning, conditioning, and tests. In habituation, mice freely explore the context where the behavioral paradigm will be performed. In preconditioning, mice were exposed to simultaneous presentation of light and tone. In conditioning, the light was devaluated by pairing a mild foot-shock. Finally, animals performed two tests where we exposed the mice to tone (mediated_cue) and to light (direct_cue) in a different context to avoid fear response elicited by the context where they received the stressor. Our results indicated that females showed a higher sensory-preconditioning performance than males exhibiting a higher percentage of freezing in the presence of mediated cue. No differences were observed in habituation and preconditioning between both sexes. Overall, we implemented a new protocol of light-tone mouse sensory preconditioning and, importantly, we observed sex-dependent behavioral effect in mediated learning.

Enhanced LTP in aged rats: Detrimental or compensatory?
Age-dependent memory deterioration has been well documented and yet an increase in rat hippocampal LTP upon aging has been reported. This poses the question of whether the enhanced LTP is a cause or an attempt to compensate the memory deficits described in aged rats. Hippocampal slices from young, adult and aged Wistar rats were pre-incubated, with an NMDA receptor (NMDAR) antagonist, memantine (1 μM, 4 h), and hippocampal LTP was evaluated. The results show that memantine significantly decreases the larger LTP magnitude recorded in hippocampal slices from aged rats without compromising LTP recorded in slices from young and adult animals. To unveil the impact of in vivo administration of memantine, different doses (1, 5 and 10 mg/kg/day) or saline vehicle solution were intraperitoneally administered, for 15-20 days, to both young and aged animals. Memantine did not significantly affect neither the place learning of young animals, evaluated by Morris Water Maze, nor LTP recorded from hippocampal slices from the same group of animals. However, memantine (5 and 10 mg/kg/day) significantly decreased the large LTP recorded in hippocampal slices from aged animals. Moreover, aged animals treated with memantine (10 mg/kg/day) showed a significantly compromised place learning when compared to aged control animals. Overall, these results suggest that the larger LTP observed in aged animals is a compensatory phenomenon, rather than pathological. The finding that age-dependent blockade of LTP by a NMDAR antagonist leads to learning deficits, implies that the increased LTP observed upon aging may be playing an important role in the learning process.

Innate chemical, but not visual, threat cues have been co-opted as unconditioned stimulus for social fear learning in zebrafish.
Animals can use social information to detect threat in the environment. In particular, social learning allows animals to learn about dangers without incurring in the costs of trial-and-error learning. In zebrafish, both chemical and visual social cues elicit an innate alarm response, which consists of erratic movement followed by freezing behavior. Injured zebrafish release an alarm substance from their skin that elicits the alarm response. Similarly, the sight of conspecifics displaying the alarm response can also elicit the expression of this response in observers. In this study, we investigated if these social cues of

danger can also be used by zebrafish as unconditioned stimulus (US) in learning. We found that only the chemical cue was effective in the social fear conditioning. We suggest that this differential efficacy of social cues results from the fact that the alarm cue is a more reliable indicator of threat, than the sight of an alarmed conspecific. Therefore, although multiple social cues may elicit innate responses not all have been evolutionarily co-opted to act as US in associative learning. Furthermore, the use of the expression of the immediate early genes as markers of neuronal activity showed that chemical social fear conditioning is paralleled by a differential activation of the olfactory bulbs and by a different pattern of functional connectivity across brain regions involved in olfactory processing.

Actin remodeling, the synaptic tag and the maintenance of synaptic plasticity.
Activity-dependent plasticity of synaptic connections is a hallmark of the mammalian brain and represents a key mechanism for rewiring neural circuits during development, experience-dependent plasticity, and brain disorders. Cellular models of memory, such as long-term potentiation and long-term depression, share common principles to memory consolidation. As for memory, the maintenance of synaptic plasticity is dependent on the synthesis of de novo protein synthesis. The synaptic-tagging and capture hypothesis states that the maintenance of synaptic plasticity is dependent on the interplay between input-specific synaptic tags and the allocation or capture of plasticity-related proteins (PRPs) at activated synapses. The setting of the synaptic tag and the capture of PRPs are independent processes that can occur separated in time and different groups of activated synapses. How are these two processes orchestrated in time and space? Here, we discuss the synaptic-tagging and capture hypothesis in the light of neuronal compartmentalization models and address the role of actin as a putative synaptic tag. If different groups of synapses interact by synaptic-tagging and capture mechanisms, understanding the spatial rules of such interaction is key to define the relevant neuronal compartment. We also discuss how actin modulation can allow an input-specific capture of PRPs and try to conciliate the temporal dynamics of synaptic actin with the maintenance of plasticity. Understanding how multiple synapses interact in time and space is fundamental to predict how neurons integrate information and ultimately how memory is acquired.

FEAR LEARNING CONDITIONS INFLUENCE HIPPOCAMPAL-DEPENDENT MEMORY AND CONTEXT DISCRIMINATION

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Nuria Cano-Adamuz[1], Íñigo Azcoitia[2], Clara Ulloa-García[1], César Redondo-Alañón[1], Pablo Mendéz[1]
[1]Cajal Institute (CSIC), Dept. Functional And Systems Neurobiology, Madrid, Spain, [2]Universidad Complutense de Madrid, Dept. Cellular Biology, Madrid, Spain

In contextual fear conditioning, learning occurs when an aversive foot-shock is presented within a context. Hippocampal CA1 neurons integrate sensory and spatial information to form neuronal representations of contexts. Fear learning is expressed in the form of a conditioned response (freezing), which can be restricted to the conditioning context (discrimination) or extended to a similar neutral context (generalization). This capacity to perceive and respond to differences among stimuli has a critical role in learning adapting our behaviour according to past experiences. This work aims to: 1) Identify learning conditions that influence discrimination and 2) elucidate the impact of those conditions on the activity of CA1 neurons using fibre photometry, optogenetics and c-fos expression. Although mice discriminate contexts efficiently before and after conditioning, shock modifies how mice behaviourally express context discrimination. Inter-individual variability suggests that experience-related factors influence discrimination. Correlation analysis showed multiple significant associations of behavioural traits (freezing, locomotion, centre/periphery exploration, shock reactivity) and learning conditions with discrimination. Manipulations of learning conditions (shock reception zone –centre/periphery– and shock intensity) resulted in differences in mice discrimination, in line with the previous correlations. Fibre photometry revealed different levels of activity in CA1 excitatory and inhibitory neurons (Somatostatin and Parvalbumin) depending on mice speed and position (centre/periphery) during exploration. We are now using cell type-specific optogenetics and c-fos tagging of neuronal ensembles to address how CA1 circuitry regulates context discrimination. In conclusion, our results show that discrimination relies on learning conditions that affect the hippocampal circuits involved in memory encoding.

A FRONTOPARIETAL CIRCUIT REGULATES FEAR RENEWAL IN A NOVEL CONTEXT

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Bitna Joo[1,2], Ja Wook Koo[1,2]
[1]Korea Brain Research Institute, Emotion, Cognitive, & Behavior Research Group, Daegu, Korea, Republic of, [2]Daegu Gyeongbuk Institute of Science and Technology, Department Of Brain And Cognitive Sciences, Daegu, Korea, Republic of

Fear renewal following extinction therapy is a critical issue associated with the treatment of many fear-related disorders. After extinction learning, the contextual effect becomes important to evoke a fear response, and an extinguished fear response can easily return outside of the extinction context (fear renewal). However, brain regions associated with context-dependent retrieval of fear remains poorly understood. Posterior parietal cortex (PPC) receives diverse sensory and cognitive inputs and integrates multisensory signals for making decisions. To study its role in the contextual modulation of fear relapse, pharmacological and optogenetic inhibition were conducted in various contextual situation. Here, we found that the PPC mediates fear renewal in a novel context. Fear relapses were selectively blocked during inhibition of the PPC, only when animals were placed in a novel context, but not in a familiar context. The suppression of the PPC-driven input to the anterior cingulate cortex (ACC) also attenuated fear response. However, fear responses were increased by inhibition of the activity of PPC-ACC neurons innervating to the amygdala. Further study of neural population switching the fear state is needed to understand the fundamental mechanisms underlying relapse of traumatic response even in safe context, and can provide insight into pathologies of traumatic disorder.

NEURAL CIRCUIT AND MECHANISMS FOR LEARNING RELATIVE AVERSIVE VALUE IN MICE

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Magdalena Miranda[1], Amaury François[2], Christina-Anna Vallianatou[1], Emmanuel Valjent[2], Emmanuel Perisse[1], Stephanie Trouche[1]
[1]IGF, Univ Montpellier, CNRS, INSERM, Montpellier, France, Neuroscience, Montpellier, France, [2]IGF, Univ Montpellier, CNRS, Inserm, Montpellier, France, Neuroscience, Montpellier, France

Throughout our lifetime, we are constantly approaching or avoiding situations such as places associated with positive (e.g. where food is present) or negative (e.g. where a danger may occur) outcomes, respectively. Surprisingly, very little is known about the neural processes underlying relative aversive value-based learning and choice. Indeed, individual are often confronted to two situations both holding negative outcomes, but each of different intensities, forcing them to choose the less worse option. To understand how such complex decision-making process is selected, it is crucial to identify the brain circuits and mechanisms involved in learning relative (better or worse) aversive value. In a newly-developed conditioned place aversive task, we combined behavioral analysis, c-fos quantification, manipulation and recording of neuronal activity to dissect the neural circuits for learning relative aversive value. We found that while mice can perform both relative and absolute value-based choices, yet they exhibit distinct behavioral strategies. The manipulation and monitoring of identified neurons at the time of the conditioning revealed differential involvement of discrete brain circuits for relative versus absolute value-based learning.

An action-concept processing advantage in a patient with a double motor cortex.
Patients with atrophy in motor brain regions exhibit selective deficits in processing action-related meanings, suggesting a link between movement conceptualization and the amount of regional tissue. Here we examine such a relation in a unique opposite model: a rare patient with a double cortex (due to subcortical band heterotopia) in primary/supplementary motor regions, and no double cortex in multimodal semantic regions. We measured behavioral performance in action- and object-concept processing as well and resting-state functional connectivity. Both dimensions involved comparisons with healthy controls. Results revealed preserved accuracy in action and object categories for the patient. However, unlike controls, the patient exhibited faster performance for action than object concepts, a difference that was uninfluenced by general cognitive abilities. Moreover, this pattern was accompanied by heightened functional connectivity between the bilateral primary motor cortices. This suggests that a functionally active double motor cortex may entail action-processing advantages. Our findings offer new constraints for models of action semantics and motor-region function at large.

Functional connectivity of anterior retrosplenial cortex in object recognition memory.
Recognition memory can rely on three components: "what", "where" and "when". Recently we demonstrated that the anterior retrosplenial cortex (aRSC), like the perirhinal cortex (PRH) and unlike the hippocampus (HP), is required for consolidation of the "what" component. Here, we aimed at studying which brain structures interact with the aRSC to process object recognition (OR) memory in rats. We studied the interaction of six brain structures that are connected to the aRSC during OR memory processing: PRH, medial prefrontal cortex (mPFC), anteromedial thalamic nuclei (AM), medial entorhinal cortex (MEC), anterior cingulate cortex (ACC) and the dorsal HP (dHP). We previously described the role of the PRH and dHP, so we first studied the participation of the mPFC, AM, MEC and ACC in OR memory consolidation by bilateral microinfusions of the GABA receptor agonist muscimol. We observed an impairment in OR long-term memory (LTM) when inactivating the mPFC, the AM and the MEC, but not the ACC. Then, we studied the functional connections by unilateral inactivation of the aRSC and each one of the six structures in the same (ipsilateral) or the opposite (contralateral) hemisphere. Our results showed an amnesic LTM effect in rats with ipsilateral inactivations of aRSC-PRH, aRSC-mPFC, aRSC-AM, or aRSC-MEC. On the other hand, we observed memory impairment when aRSC-ACC were inactivated in opposite hemispheres, and no effect when the aRSC-dHP connection was inactivated. Thus, our ipsilateral inactivation findings reveal that the aRSC and, at

least one brain region required in OR LTM processing are essential to consolidate OR memory. In conclusion, our results show that several cortico-cortical and cortico-thalamic pathways are important for OR memory consolidation.

Molecular mechanisms within the dentate gyrus and the perirhinal cortex interact during discrimination of similar nonspatial memories.
Differentiating between similar memories is a crucial cognitive function that enables correct episodic memory formation. The ability to separate the components of memories into distinct representations is thought to rely on a computational process known as pattern separation, by which differences are amplified to disambiguate similar events. Although pattern separation has been localized to the dentate gyrus (DG) of the hippocampus and shown to occur in a spatial domain, this cognitive function takes place also during processing of other types of information. In particular, there is some debate on whether the DG participates in pattern separation of nonspatial representations. Considering the classic role of the Prh in the acquisition and storage of object memories in general and tasks with similar features in particular, this cognitive function could rely more heavily on perirhinal regions when object-related information is processed. Here we show that two plasticity-related proteins, BDNF, and Arc, are required in the DG for nonspatial mnemonic differentiation. Moreover, we found that the crucial role of the DG is transient since activity of AMPAR is only required in the Prh but not the DG during differentiated object memory retrieval. Additionally, this memory is not modifiable by postacquisition rhBDNF infusions in the DG that are known to improve memory when given in the Prh. This highlights a differential role of Prh and DG during differentiated object memory consolidation. Additionally, we found that these molecular mechanisms actively interact in the DG and Prh for the formation of distinguishable memories, with infusions of rhBDNF in the Prh being able to rescue mnemonic deficits caused by reduced Arc expression in the DG. These results reveal a complex interaction between plasticity mechanisms in the Prh and DG for nonspatial pattern separation and posit the Prh as the key structure where unique object representations are stored.

Neurophotonics Approaches for the Study of Pattern Separation.
Successful memory involves not only remembering over time but also keeping memories distinct. Computational models suggest that pattern separation appears as a highly efficient process to discriminate between overlapping memories. Furthermore, lesion studies have shown that the dentate gyrus (DG) participates in pattern separation. However, these manipulations did not allow identifying the neuronal mechanism underlying pattern separation. The development of different neurophotonics techniques, together with other genetic tools, has been useful for the study of the microcircuit involved in this process. It has been shown that less-overlapped information would generate distinct neuronal representations within the granule cells (GCs). However, because glutamatergic or GABAergic cells in the DG are not functionally or structurally homogeneous, identifying the specific role of the different subpopulations remains elusive. Then, understanding pattern separation requires the ability to manipulate a temporal and spatially specific subset of cells in the DG and ideally to analyze DG cells activity in individuals performing a pattern separation dependent behavioral task. Thus, neurophotonics and calcium imaging techniques in conjunction with activity-dependent promoters and high-resolution microscopy appear as important tools for this endeavor. In this work, we review how different neurophotonics techniques have been implemented in the elucidation of a neuronal network that supports pattern separation alone or in combination with traditional techniques. We discuss the limitation of these techniques and how other neurophotonic techniques could be used to complement the advances presented up to this date.

The "Use It or Lose It" Dogma in the Retina: Visual Stimulation Promotes Protection Against Retinal Ischemia.
Enriched environment (EE) protects the retina from adult rats against ischemia/reperfusion (I/R) injury; however, how the components of EE contribute to the recovery after retinal ischemic damage remains unclear. We analyzed the contribution of social, cognitive, and visual stimulation on functional and histological alterations induced by I/R. Male Wistar rats were submitted to unilateral ischemia by increasing intraocular pressure to 120 mmHg for 40 min. After ischemia, animals were housed in the following conditions: standard environment (SE), enriched environment (EE), novelty environment (NE), standard social environment (SoE), standard visual environment (SVE), or visual environment (VE). In another set of experiments, rats were submitted to bilateral ischemia and housed in SE or EE. At 2 weeks post-ischemia, rats were subjected to electroretinography and histological analysis. EE (but not SoE or NE) afforded functional and histological protection against unilateral ischemia. EE did not induce protection in animals submitted to bilateral ischemia. VE protected retinal function and histology and increased retinal BDNF levels, while a TrkB receptor antagonist prevented the protective effect of VE against I/R damage. In animals submitted to unilateral ischemia, EE and VE induced an increase in c-fos immunoreactivity in the ipsi and contralateral superior colliculus, whereas in animals submitted to bilateral ischemia, no

changes in c-fos-immunoreactivity were observed in either superior colliculus from EE-housed animals. These results support that visual stimulation could be a potent stimulus for driving retinal protection in adult rats through a BDNF/TrkB-dependent mechanism, likely involving the superior colliculus.

Brain-Derived Neurotrophic Factor: A Key Molecule for Memory in the Healthy and the Pathological Brain.
Brain Derived Neurotrophic Factor (BDNF) is a key molecule involved in plastic changes related to learning and memory. The expression of BDNF is highly regulated, and can lead to great variability in BDNF levels in healthy subjects. Changes in BDNF expression are associated with both normal and pathological aging and also psychiatric disease, in particular in structures important for memory processes such as the hippocampus and parahippocampal areas. Some interventions like exercise or antidepressant administration enhance the expression of BDNF in normal and pathological conditions. In this review, we will describe studies from rodents and humans to bring together research on how BDNF expression is regulated, how this expression changes in the pathological brain and also exciting work on how interventions known to enhance this neurotrophin could have clinical relevance. We propose that, although BDNF may not be a valid biomarker for neurodegenerative/neuropsychiatric diseases because of its disregulation common to many pathological conditions, it could be thought of as a marker that specifically relates to the occurrence and/or progression of the mnemonic symptoms that are common to many pathological conditions.

NMDA receptors and BDNF are necessary for discrimination of overlapping spatial and non-spatial memories in perirhinal cortex and hippocampus.
Successful memory involves not only remembering information over time but also keeping memories distinct and less confusable. Discrimination of overlapping representations has been investigated in the dentate gyrus (DG) of the hippocampus and largely in the perirhinal cortex (Prh). In particular, the DG was shown to be important for discrimination of overlapping spatial memories and Prh was shown to be important for discrimination of overlapping object memories. In the present study, we used both a DG-dependent and a Prh-dependent task and manipulated the load of similarity between either spatial or object stimuli during information encoding. We showed that N-methyl-D-aspartate-type glutamate receptors (NMDAr) and BDNF participate of the same cellular network during consolidation of both overlapping object and spatial memories in the Prh and DG, respectively. This argues in favor of conserved cellular mechanisms across regions despite anatomical differences.

29717980: Morici JF, Miranda M, Gallo FT, Zanoni B, Bekinschtein P, Weisstaub NV
5-HT2a receptor in mPFC influences context-guided reconsolidation of object memory in perirhinal cortex.
Context-dependent memories may guide adaptive behavior relaying in previous experience while updating stored information through reconsolidation. Retrieval can be triggered by partial and shared cues. When the cue is presented, the most relevant memory should be updated. In a contextual version of the object recognition task, we examined the effect of medial PFC (mPFC) serotonin 2a receptor (5-HT2aR) blockade during retrieval in reconsolidation of competing objects memories. We found that mPFC 5-HT2aR controls retrieval and reconsolidation of object memories in the perirhinal cortex (PRH), but not in the dorsal hippocampus in rats. Also, reconsolidation of objects memories in PRH required a functional interaction between the ventral hippocampus and the mPFC. Our results indicate that in the presence of conflicting information at retrieval, mPFC 5-HT2aR may facilitate top-down context-guided control over PRH to control the behavioral response and object memory reconsolidation.

Molecular Mechanisms in Perirhinal Cortex Selectively Necessary for Discrimination of Overlapping Memories, but Independent of Memory Persistence.
Successful memory involves not only remembering over time but also keeping memories distinct. The ability to separate similar experiences into distinct memories is a main feature of episodic memory. Discrimination of overlapping representations has been investigated in the dentate gyrus of the hippocampus (DG), but little is known about this process in other regions such as the perirhinal cortex (Prh). We found in male rats that perirhinal brain-derived neurotrophic factor (BDNF) is required for separable storage of overlapping, but not distinct, object representations, which is identical to its role in the DG for spatial representations. Also, activity-regulated cytoskeletal-associated protein (Arc) is required for disambiguation of object memories, as measured by infusion of antisense oligonucleotides. This is the first time Arc has been implicated in the discrimination of objects with overlapping features. Although molecular mechanisms for object memory have been shown previously in Prh, these have been dependent on delay, suggesting a role specifically in memory duration. BDNF and Arc

involvement were independent of delay-the same demand for memory persistence was present in all conditions-but only when discrimination of similar objects was required were these mechanisms recruited and necessary. Finally, we show that BDNF and Arc participate in the same pathway during consolidation of overlapping object memories. We provide novel evidence regarding the proteins involved in disambiguation of object memories outside the DG and suggest that, despite the anatomical differences, similar mechanisms underlie this process in the DG and Prh that are engaged depending on the similarity of the stimuli.
eNeuro, 2017 Sep-Oct; 4
28603027: Miranda M, Bekinschtein P
Plasticity Mechanisms of Memory Consolidation and Reconsolidation in the Perirhinal Cortex.
In this review we explore the role of the perirhinal cortex (Prh) in memory, focusing on the cellular and molecular mechanisms that have been described to happen in this structure. The Prh is part of the medial temporal lobe, but the evidences show that it has a different function than that of the hippocampus. In particular, the Prh is known to be important for object recognition memory, although it could have a role in other types of memory. However, despite the fact that object recognition tasks are widely used, information regarding the molecular and cellular mechanisms underlying this type of memory in Prh is lacking. We discuss a series of studies of memory and plasticity in this region and how they might relate. In addition, we propose that Prh could play a role as a "pattern separator" for object memories, similar to the function of the dentate gyrus of the hippocampus in the spatial domain.

SYNCHRONIZATION OF A CEREBELLO-THALAMO-PREFRONTAL PATHWAY REGULATES FEAR EXTINCTION LEARNING

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Jimena Frontera, Romain Sala, Ioana Georgescu, Hind Baba Aissa, Daniela Popa, Clement Lena
Institut de Biologie de l'Ecole Normale Superieure (IBENS), Biologie, Paris, France

Failure to suppress aversive memories is a landmark feature of several severe psychiatric conditions, and it is studied using fear extinction paradigms. While it is now well accepted that the cerebellum participates in emotion processing, whether and how the cerebellum affects extinction learning is poorly understood. Here, we establish a cerebello-thalamo-cortical pathway that connects the cerebellar fastigial nucleus (FN) to the lateral subregion of the thalamic mediodorsal nucleus (MD), which sends and receives inputs from the dorsomedial prefrontal cortex (dmPFC). Inhibition or activation of FN input to MD impairs extinction learning. Consistent with this, manipulations of the FN input to the MD increase the bursting of MD neurons, known to prevent extinction learning. Moreover, disrupting FN-MD during extinction of fear memory leads to an enhanced cortico-thalamic coherence of 4Hz oscillations associated with the fear response (freezing). Combined recordings across the FN-MD-dmPFC pathway further indicate that the cerebellum regulates the maintenance of these fear-related dmPFC 4Hz oscillations by providing a destructive interference in the MD. Overall, our results show that, under physiological conditions, the cerebellar activity regulates the fear-related thalamo-cortical patterns of activity and promotes extinction learning.

QUANTITATIVE MOLECULAR PROFILING OF BASOLATERAL AMYGDALA NEURONS WITH IDENTIFIED FEAR-RELATED PLASTICITY PHENOTYPES

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Andras Szonyi[1], Julian Hinz[1,2], Zoltan Nusser[3], Andreas Lüthi[1,2]
[1]Friedrich Miescher Institute for Biomedical Research, Neurobiology, Basel, Switzerland, [2]University of Basel, Biozentrum, Basel, Switzerland, [3]Institute of Experimental Medicine, Laboratory Of Cellular Neurophysiology, Budapest, Hungary

Using *in vivo* imaging methods, a previous study from our laboratory showed that during associative learning of tone-shock associations, apparently homogenous principal cells of the mouse basolateral amygdala (BLA) show opposing plasticity of sensory responses. Correlational and decoding analysis revealed that BLA neurons that potentiated or de-potentiated their neural responses for the auditory stimulus paired with a foot shock both contributed to fear memory formation. The molecular mechanisms behind the heterogeneity of the observed plasticity are not understood, therefore we developed a pipeline for quantitative immunostaining of candidate plasticity molecules on functionally characterized BLA cells. First, using sparse, adeno-associated virus-mediated expression of the Ca^{2+}-indicator GCaMP6s and two-photon imaging of neuronal Ca^{2+}-activity in multiple planes through a GRIN lens, we functionally characterized BLA principal neurons before and after auditory fear conditioning. This was followed by perfusion fixation, post-hoc identification of the imaged cells, postprocessing of the tissue and immunostaining. Our pipeline allows for reliably comparing the sensory-evoked Ca^{2+}-responses of individual BLA principal neurons before and after fear learning and for performing multiple rounds of quantitative immunostaining of membrane-associated proteins, postsynaptic receptors, or calcium-binding proteins on the same, functionally identified neurons. These experiments will further broaden our understanding of the molecular mechanisms underlying distinct forms of plasticity during associative learning and fear memory formation.

Median raphe controls acquisition of negative experience in the mouse.
Adverse events need to be quickly evaluated and memorized, yet how these processes are coordinated is poorly understood. We discovered a large population of excitatory neurons in mouse median raphe region (MRR) expressing vesicular glutamate transporter 2 (vGluT2) that received inputs from several negative experience-related brain centers, projected to the main aversion centers, and activated the septohippocampal system pivotal for learning of adverse events. These neurons were selectively activated by aversive but not rewarding stimuli. Their stimulation induced place aversion, aggression, depression-related anhedonia, and suppression of reward-seeking behavior and memory acquisition-promoting hippocampal theta oscillations. By contrast, their suppression impaired both contextual and cued fear memory formation. These results suggest that MRR vGluT2 neurons are crucial for the acquisition of negative experiences and may play a central role in depression-related mood disorders.

Brainstem nucleus incertus controls contextual memory formation.
Hippocampal pyramidal cells encode memory engrams, which guide adaptive behavior. Selection of engram-forming cells is regulated by somatostatin-positive dendrite-targeting interneurons, which inhibit pyramidal cells that are not required for memory formation. Here, we found that γ-aminobutyric acid (GABA)-releasing neurons of the mouse nucleus incertus (NI) selectively inhibit somatostatin-positive interneurons in the hippocampus, both monosynaptically and indirectly through the inhibition of their subcortical excitatory inputs. We demonstrated that NI GABAergic neurons receive monosynaptic inputs from brain areas processing important environmental information, and their hippocampal projections are strongly activated by

salient environmental inputs in vivo. Optogenetic manipulations of NI GABAergic neurons can shift hippocampal network state and bidirectionally modify the strength of contextual fear memory formation. Our results indicate that brainstem NI GABAergic cells are essential for controlling contextual memories.

Co-transmission of acetylcholine and GABA regulates hippocampal states.
The basal forebrain cholinergic system is widely assumed to control cortical functions via non-synaptic transmission of a single neurotransmitter. Yet, we find that mouse hippocampal cholinergic terminals invariably establish GABAergic synapses, and their cholinergic vesicles dock at those synapses only. We demonstrate that these synapses do not co-release but co-transmit GABA and acetylcholine via different vesicles, whose release is triggered by distinct calcium channels. This co-transmission evokes composite postsynaptic potentials, which are mutually cross-regulated by presynaptic autoreceptors. Although postsynaptic cholinergic receptor distribution cannot be investigated, their response latencies suggest a focal, intra- and/or peri-synaptic localisation, while GABA receptors are detected intra-synaptically. The GABAergic component alone effectively suppresses hippocampal sharp wave-ripples and epileptiform activity. Therefore, the differentially regulated GABAergic and cholinergic co-transmission suggests a hitherto unrecognised level of control over cortical states. This novel model of hippocampal cholinergic neurotransmission may lead to alternative pharmacotherapies after cholinergic deinnervation seen in neurodegenerative disorders.

Cellular architecture and transmitter phenotypes of neurons of the mouse median raphe region.
The median raphe region (MRR, which consist of MR and paramedian raphe regions) plays a crucial role in regulating cortical as well as subcortical network activity and behavior, while its malfunctioning may lead to disorders, such as schizophrenia, major depression, or anxiety. Mouse MRR neurons are classically identified on the basis of their serotonin (5-HT), vesicular glutamate transporter type 3 (VGLUT3), and gamma-aminobutyric acid (GABA) contents; however, the exact cellular composition of MRR regarding transmitter phenotypes is still unknown. Using an unbiased stereological method, we found that in the MR, 8.5 % of the neurons were 5-HT, 26 % were VGLUT3, and 12.8 % were 5-HT and VGLUT3 positive; whereas 37.2 % of the neurons were GABAergic, and 14.4 % were triple negative. In the whole MRR, 2.1 % of the neurons were 5-HT, 7 % were VGLUT3, and 3.6 % were 5-HT and VGLUT3 positive; whereas 61 % of the neurons were GABAergic. Surprisingly, 25.4 % of the neurons were triple negative and were only positive for the neuronal marker NeuN. PET-1/ePET-Cre transgenic mouse lines are widely used to specifically manipulate only 5-HT containing neurons. Interestingly, however, using the ePET-Cre transgenic mice, we found that far more VGLUT3 positive cells expressed ePET than 5-HT positive cells, and about 38 % of the ePET cells contained only VGLUT3, while more than 30 % of 5-HT cells were ePET negative. These data should facilitate the reinterpretation of PET-1/ePET related data in the literature and the identification of the functional role of a putatively new type of triple-negative neuron in the MRR.

The ascending median raphe projections are mainly glutamatergic in the mouse forebrain.
The median raphe region (MRR) is thought to be serotonergic and plays an important role in the regulation of many cognitive functions. In the hippocampus (HIPP), the MRR exerts a fast excitatory control, partially through glutamatergic transmission, on a subpopulation of GABAergic interneurons that are key regulators of local network activity. However, not all receptors of this connection in the HIPP and in synapses established by MRR in other brain areas are known. Using combined anterograde tracing and immunogold methods, we show that the GluN2A subunit of the NMDA receptor is present in the synapses established by MRR not only in the HIPP, but also in the medial septum (MS) and in the medial prefrontal cortex (mPFC) of the mouse. We estimated similar amounts of NMDA receptors in these synapses established by the MRR and in local adjacent excitatory synapses. Using retrograde tracing and confocal laser scanning microscopy, we found that the majority of the projecting cells of the mouse MRR contain the vesicular glutamate transporter type 3 (vGluT3). Furthermore, using double retrograde tracing, we found that single cells of the MRR can innervate the HIPP and mPFC or the MS and mPFC simultaneously, and these double-projecting cells are also predominantly vGluT3-positive. Our results indicate that the majority of the output of the MRR is glutamatergic and acts through NMDA receptor-containing synapses. This suggests that key forebrain areas receive precisely targeted excitatory input from the MRR, which is able to synchronously modify activity in those regions via individual MRR cells with dual projections.

Quantitative ultrastructural analysis of basket and axo-axonic cell terminals in the mouse hippocampus.

Three functionally different populations of perisomatic interneurons establish GABAergic synapses on hippocampal pyramidal cells: parvalbumin (PV)-containing basket cells, type 1 cannabinoid receptor (CB1)-positive basket cells both of which target somata, and PV-positive axo-axonic cells that innervate axon initial segments. Using electron microscopic reconstructions, we estimated that a pyramidal cell body receives synapses from about 60 and 140 synaptic terminals in the CA1 and CA3 area, respectively. About 60 % of these terminals were PV positive, whereas 35-40 % of them were CB1 positive. Only about 1 % (CA1) and 4 % (CA3) of the somatic boutons were negative for both markers. Using fluorescent labeling, we showed that most of the CB1-positive terminals expressed vesicular glutamate transporter 3. Reconstruction of somatic boutons revealed that although their volumes are similar, CB1-positive boutons are more flat and the total volume of their mitochondria was smaller than that of PV-positive boutons. Both types of boutons contain dense-core vesicles and frequently formed multiple release sites on their targets and innervated an additional soma or dendrite as well. PV-positive boutons possessed small, macular synapses; whereas the total synaptic area of CB1-positive boutons was larger and formed multiple irregular-shaped synapses. Axo-axonic boutons were smaller than somatic boutons, had only one synapse and their ultrastructural parameters were closer to those of PV-positive somatic boutons. Our results represent the first quantitative measurement-using a highly reliable method-of the contribution of different cell types to the perisomatic innervation of pyramidal neurons, and may help to explain functional differences in their output properties.

NMDA receptors in GABAergic synapses during postnatal development.
GABA (gamma-aminobutyric-acid), the main inhibitory neurotransmitter in the adult brain, exerts depolarizing (excitatory) actions during development and this GABAergic depolarization cooperates with NMDARs (N-methyl-D-aspartate receptors) to drive spontaneous synchronous activity (SSA) that is fundamentally important for developing neuronal networks. Although GABAergic depolarization is known to assist in the activation of NMDARs during development, the subcellular localization of NMDARs relative to GABAergic synapses is still unknown. Here, we investigated the subcellular distribution of NMDARs in association with GABAergic synapses at the developmental stage when SSA is most prominent in mice. Using multiple immunofluorescent labeling and confocal laser-scanning microscopy in the developing mouse hippocampus, we found that NMDARs were associated with both glutamatergic and GABAergic synapses at postnatal day 6-7 and we observed a direct colocalization of GABA(A)- and NMDA-receptor labeling in GABAergic synapses. Electron microscopy of pre-embedding immunogold-immunoperoxidase reactions confirmed that GluN1, GluN2A and GluN2B NMDAR subunits were all expressed in glutamatergic and GABAergic synapses postsynaptically. Finally, quantitative post-embedding immunogold labeling revealed that the density of NMDARs was 3 times higher in glutamatergic than in GABAergic synapses. Since GABAergic synapses were larger, there was little difference in the total number of NMDA receptors in the two types of synapses. In addition, receptor density in synapses was substantially higher than extrasynaptically. These data can provide the neuroanatomical basis of a new interpretation of previous physiological data regarding the GABA(A)R-NMDAR cooperation during early development. We suggest that during SSA, synaptic GABA(A)R-mediated depolarization assists NMDAR activation right inside GABAergic synapses and this effective spatial cooperation of receptors and local change of membrane potential will reach developing glutamatergic synapses with a higher probability and efficiency even further away on the dendrites. This additional level of cooperation that operates within the depolarizing GABAergic synapse, may also allow its own modification triggered by Ca(2+)-influx through the NMDA receptors.

Nitric oxide signaling modulates synaptic transmission during early postnatal development.
Early γ-aminobutyric acid mediated (GABAergic) synaptic transmission and correlated neuronal activity are fundamental to network formation; however, their regulation during early postnatal development is poorly understood. Nitric oxide (NO) is an important retrograde messenger at glutamatergic synapses, and it was recently shown to play an important role also at GABAergic synapses in the adult brain. The subcellular localization and network effect of this signaling pathway during early development are so far unexplored, but its disruption at this early age is known to lead to profound morphological and functional alterations. Here, we provide functional evidence--using whole-cell recording--that NO signaling modulates not only glutamatergic but also GABAergic synaptic transmission in the mouse hippocampus during the early postnatal period. We identified the precise subcellular localization of key elements of the underlying molecular cascade using immunohistochemistry at the light--and electron microscopic levels. As predicted by these morpho-functional data, multineuron calcium imaging in acute slices revealed that this NO-signaling machinery is involved also in the control of synchronous network activity patterns. We suggest that the retrograde NO-signaling system is ideally suited to fulfill a general presynaptic regulatory role and may effectively fine-tune network activity during early postnatal development, while GABAergic transmission is still depolarizing.

Neuroprotective effects of a novel kynurenic acid analogue in a transgenic mouse model of Huntington's disease.
Huntington's disease (HD) is a progressive neurodegenerative disorder, the pathomechanism of which is not yet fully understood. Excitotoxicity is known to be involved in the development of HD and antiglutamatergic agents may, therefore, have beneficial neuroprotective effects. One of these agents is the tryptophan metabolite kynurenic acid (KYNA), which is an endogenous NMDA receptor antagonist. However, its pharmacological properties rule out its systemic administration in CNS disorders. We have tested a novel KYNA analogue, N-(2-N,N-dimethylaminoethyl)-4-oxo-1H-quinoline-2-carboxamide hydrochloride, in the N171-82Q transgenic mouse model of HD. The analogue exhibited several significant effects: it prolonged the survival of the transgenic mice, ameliorated their hypolocomotion, prevented the loss of weight and completely prevented the atrophy of the striatal neurons. The beneficial effects of this KYNA analogue are probably explained by its complex anti-excitotoxic activity. As it did not induce any appreciable side-effect at the protective dose applied in a chronic dosing regime in this mouse model, it appears worthy of further thorough investigations with a view to eventual clinical trials.

TITLE: ROLE OF MICROGLIA IN RECONSOLIDATION-RESISTANT FEAR MEMORIES

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Azka Khan[1,2]
[1]Sapienza University of Rome, Department Of Physiology, Rome, Italy, [2]Sapienza University of Rome, Department Of Psychology, Rome, Italy

Background: Memory reconsolidation is a transient process which after retrieval stabilizes the labile state of consolidated memory. However, some experimental conditions (boundary conditions) can inhibit reconsolidation to occur that model persistent maladaptive memories observed in post-traumatic stress disorder (PTSD). Studies suggest that alterations in immune status in the central nervous system (CNS) may contribute to PTSD. Together with the emerging role of CNS immune cells, microglia, in regulating synaptic plasticity and memory, this study aims to investigate the role of microglia in the underlying mechanisms of reconsolidation-resistant memories. **Methods:** Mice were trained with auditory fear conditioning with one tone-shock pairing (1P) and ten tone-shock pairings (10P) to develop weak and strong (reconsolidation-resistant) memories respectively and treated for 7 days with PLX5622, a specific antagonist of colony-stimulating factor-1 receptor, for microglia depletion. Then mice were presented with one conditioned stimulus (CS) in a different context to reactivate the fear memory and 24-hours later, reconsolidated memory was tested by presenting one CS. **Results:** We found that 10P group created extinction-resistant memories compared to 1P group and PLX treatment did not alter the freezing behavior of 10P group. Interesting,1P group with PLX treatment showed higher freezing compared to the control and 10P group suggesting microglial association with increased fear memory at recall. **Conclusion:** Our preliminary results demonstrated role of microglia in regulating the maintenance of fear memories. An understanding of the processes determining memory persistence or inhibition could be relevant for the development of new therapeutic interventions for the post-traumatic stress disorder (PTSD).

A DELAY AND TRACE CONDITIONING PARADIGM FOR HEAD-FIXED LARVAL ZEBRAFISH

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Joaquim António Contradanças, Raquel Jacinto, Edite Figueiras, Alexandre Laborde, Joe Paton, Michael Orger
Champalimaud Foundation, Champalimaud Research, Lisboa, Portugal

Learning causal relationships is a major step to survive in a dynamic environment. Animals from flies to humans can learn that a conditioned stimulus (CS) predicts an unconditioned stimulus (US) either when the US overlaps with the CS or when a temporal gap (trace period) separates the two stimuli. These two forms of associative learning are known as delay and trace conditioning, respectively. Although in mammals both require brain regions including the cerebellum and amygdala, trace conditioning additionally involves the hippocampus to keep an internal representation of the CS in the trace period. Here we describe a delay and trace conditioning assay for head-fixed larval zebrafish, a small and transparent model organism amenable to whole-brain imaging with cellular resolution. In this conditioning assay, the fish are conditioned to associate a visual stimulus (CS) with an aversive optochemical stimulus (US). A reduction in tail movement during the CS indicated that larvae successfully learned to anticipate the US in both the delay and trace conditions. This reduction was not observed when the CS and US were presented in an unpaired protocol. This is in contrast to previously described delay conditioning tasks in zebrafish larvae using different US, where an increase in swimming was observed. We are now simultaneously recording behavior and neural activity in pan-neural calcium indicator lines, employing a custom light-sheet microscope that allows whole-brain imaging with cellular resolution, with the aim of comparing the neural mechanisms of delay and trace conditioning at the level of the entire brain.

The serotonin 2A (5-HT2A) receptor is a key target underlying the effects of psychedelics on emotional arousal but its role in anxiety and fear processing remains controversial. Using the psychedelic 5-HT2A/5-HT2C receptor agonist 2,5-dimethoxy-4-iodoamphetamine (DOI) and 5-HT2A receptor knockout (KO) mice we investigated the effect of 5-HT2A receptor activation on emotional processing. We show that DOI administration increased exploratory behavior and reduced anxiety-like avoidance in mice through activation of 5-HT2A receptors. Moreover, we found that DOI did not block memory recall but diminished anxiety-like behavior and conditioned freezing in a passive avoidance task. Likewise, DOI administration reduced conditioned freezing in an auditory fear conditioning paradigm, while it did not affect fear extinction learning in wild type (WT) mice. The effect of DOI on conditioned freezing was abolished in 5-HT2A receptor KO mice. Administration of DOI induced a significant increase of c-Fos expression in specific amygdalar nuclei. Moreover, local infusion of the 5-HT2A receptor antagonist M100907 into the amygdala reversed the effect of systemic administration of DOI on conditioned freezing while local administration of DOI into the amygdala was sufficient to suppress conditioned freezing. Our data indicate that activation 5-HT2A receptors in the amygdala suppresses conditioned freezing behavior but we found no no evidence for an effect of DOI on fear extinction.

AVERSIVE CONTEXTS: HOW TO REMEMBER, DISCRIMINATE AND ADAPT

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Ha-Rang Kim[1], Mario Martin-Fernadez[2], Juliette Viellard[2], Cyril Herry[2], Yann Humeau[1]

In mammals, survival critically depends on the ability to detect threatening situations and in selecting appropriate defensive behavior. This crucial mechanism is contributed by contextual fear discrimination that largely depends on continuous evaluation of surrounding cues defining specific contexts. Although it is known that contextual discrimination based on specific sensory cues induces efficient defensive strategies, the precise neurobiological substrates governing such mechanism are yet poorly understood. In the laboratory, we previously identified a neuronal projection from the dorsal medial prefrontal cortex (dmPFC) to the periaqueductal gray (PAG), that is selectively activated during contextual fear discrimination. We now aim at the identification of neuronal determinants allowing the building and consolidation of this dmPFC-PAG population, by characterizing how threat-predicting context is associated with specific dmPFC, amygdala (AMG) and hippocampus (HPC) networks to successfully drive adaptive responses. We first developed a novel behavioral paradigm that enables gradual transition of the context, which induced significant changes in the freezing behavior. We next used extracellular recording simultaneously targeting aforementioned brain regions (dmPFC, AMG and HPC) in freely moving and sleeping mice all along the contextual fear paradigm. This allowed us to characterize the physiological determinants of this behavioral adaptation at the cellular and population-level, with the identification of distinct neuronal representation and population coding in discriminative and generalizing mice, both during awake and sleeping periods. These results reveal that, in mice, the cognitive control of emotion related to a context relies on a dynamic encoding of information within the tripartite networks.

BASOLATERAL AMYGDALA PLASTICITY DURING AUDITORY SECOND-ORDER ASSOCIATIVE LEARNING

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Nigel Whittle[1], Julian Hinz[1,2], Mathias Mahn[1], Kenta Hagihara[1,2], Christian Müller[1], Yael Bitterman[1], Andreas Lüthi[1,2]

Pavlovian first-order conditioning is an associative learning paradigm characterized by the acquisition of a conditioned response to an initially neutral stimulus which becomes a conditioned stimulus (CS1) by virtue of its association with an unconditioned stimulus (US). Recent data showing that conditioning drives the neuronal population representation of the CS1 in the basal and lateral amygdala (BLA) to align with the US following conditioning supports learning models in which the US representation guides the transformation of the CS1 representation. Although most learning of organisms is arguably higher-order learning, it is currently unknown whether the neuronal mechanism that governs higher-order learning is similar to that of first-order learning (i.e., does the CS1 representation guide the transformation of the CS2-representation during higher-order learning?). We addressed this question by combining second-order conditioning, a form of associative learning wherein the previously conditioned stimulus (CS1) can associate with a second naïve conditioned stimulus (CS2) to elicit a conditioned response, with calcium imaging of principle BLA neurons in freely behaving mice. Longitudinal imaging along the entire paradigm uncovered similarities and differences in the transformation of the CS2 representation during the different stages of the second-order conditioning paradigm (from conditioning through extinction and extinction-retrieval sessions). Optogenetic manipulation confirmed that these CS1-CS2 mediated transformations in the BLA are necessary for second-order learning. These data may provide novel insight into the mechanisms underlying anxiety disorders in humans, which has been proposed to be maintained by higher-order conditioning mechanisms.

BRAIN-WIDE EPIGENETICS MAPPING OF FEAR MEMORY ENGRAM CELLS

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Kwok Yui (Tony) Yip, Johannes Graff
EPFL, Brain Mind Institute Of The School Of Life Sciences, Lausanne, Switzerland

A memory engram is thought to be the physical substrate of the memory trace within the brain, which is generally depicted as a neuronal ensemble activated by learning to fire together during encoding and retrieval. Nowadays, emerging evidence supports the postulation that memory engram exhibits a multiscale organization both at a brain network level and at an epigenetic state. However, as engram cells have thus far been visualized in a limited number of brain regions, it remains unclear if engram cell ensembles are broadly distributed across the entire brain to construct the functional connectivity of a memory. Furthermore, as epigenetic mechanisms underlying memory formation and storage have mainly been studied at heterogeneous whole tissue level, engram cell-specific epigenetic modifications have only started to be elucidated. To fill these loopholes, our project aims to generate a composite image of whole brain fear memory engram epigenetics (aka epi-engram) during memory consolidation. By applying iDISCO+ optical clearing, light sheet microscopy and semi-automated 3D colocalization analysis, we overcome the technical bottleneck of whole mount multiple immunostaining to visualize activity-tagged neurons in the TRAP2-tdTomato mouse line, concomitantly with the neuronal activation marker *cfos* and histone modifications. Our data reveal that contextual fear memory formation triggers an increase in recruitment of *cfos*+ *H3S10pK9me3*+ epi-engram cells, which indicates a change from close to open chromatin state for transcriptional activation, in basolateral amygdala, lateral septum, medial septum and anterior cingulate cortex. Ultimately, we hope that such brain-wide epi-engram mapping will illustrate how memory consoliation is orchestrated by chromatin states within engram cells.

EXPLORING THE ROLE OF CALCINEURIN IN THE EXTINCTION OF AVERSION

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Salma Reyes-Garcia, Martha Escobar
UNAM, Faculty Of Psychology, Mexico City, Mexico

Nowadays, it is widely accepted that memory extinction involves the formation of a new associative rather than unlearning of conditioning. Nevertheless, the cellular and molecular mechanisms that underlie this process are still unclear. In this regard, it has been suggested that kinases and phosphatases modulate the processes of conditioning and extinction, respectively. A body of evidence suggests that protein phosphatase calcineurin (CaN) is involved in the extinction of some behavioral tasks. Indeed, our previous studies showed that conditioned taste aversion (CTA) extinction increases the CaN expression in the insular cortex (IC). CTA is a well-established learning and memory paradigm in which an animal associates a novel taste with nausea. Meanwhile, the IC is a region of the brain that lies in the temporal neocortex and is known for its role in processing aversively motivated learning tasks, like CTA. The present study aimed to evaluate the participation of CaN in the extinction of CTA. To do so, we pharmacologically inhibited calcineurin in the IC of adult male Wistar rats during CTA-extinction. Our results show that CaN inhibition elicits an impairment of CTA extinction, thus revealing that this phosphatase plays an important role in extinction learning. These findings led us to explore the synaptic plasticity associated with the effects of CaN on CTA extinction. In this sense, our preliminary results show that CaN plays an important role in the maintenance of long-term depression in the IC, suggesting that both processes are associated at a molecular level.

Calcineurin Participation in Hebbian and Homeostatic Plasticity Associated With Extinction.
In nature, animals need to adapt to constant changes in their environment. Learning and memory are cognitive capabilities that allow this to happen. Extinction, the reduction of a certain behavior or learning previously established, refers to a very particular and interesting type of learning that has been the basis of a series of therapies to diminish non-adaptive behaviors. In recent years, the exploration of the cellular and molecular mechanisms underlying this type of learning has received increasing attention. Hebbian plasticity (the activity-dependent modification of the strength or efficacy of synaptic transmission), and homeostatic plasticity (the homeostatic regulation of plasticity) constitute processes intimately associated with memory formation and maintenance. Particularly, long-term depression (LTD) has been proposed as the underlying mechanism of extinction, while the protein phosphatase calcineurin (CaN) has been widely related to both the extinction process and LTD. In this review, we focus on the available evidence that sustains CaN modulation of LTD and its association with extinction. Beyond the classic view, we also examine the interconnection among extinction, Hebbian and homeostatic plasticity, as well as emergent evidence of the participation of kinases and long-term potentiation (LTP) on extinction learning, highlighting the importance of the balance between kinases and phosphatases in the expression of extinction. Finally, we also integrate data that shows the association between extinction and less-studied phenomena, such as synaptic silencing and engram formation that open new perspectives in the field.

MULTISENSORY INTEGRATION AND TONE PLASTICITY IN THE POSTERIOR INSULAR CORTEX DURING AUDITORY FEAR LEARNING

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Denys Osypenko, Shriya Palchaudhuri, Olexiy Kochubey, Ralf Schneggenburger
Ecole Polytechnique Federale de Lausanne, Brain Mind Institute, Laboratory For Synaptic Mechanisms, Lausanne, Switzerland

Aversively-motivated associative learning allows the organism to avoid or reduce harm and thus ensure its survival. Canonically, associative plasticity in the amygdala is thought to underly the process of fear learning (LeDoux, 2000). Interestingly, brain areas upstream to the amygdala like the posterior insular cortex (pInsCx), are known to process auditory, somatosensory and other sensory modalities. Here we used in-vivo optrode recordings in awake behaving mice to study the activity of pInsCx neurons during and following auditory cued fear learning. Significant subpopulations of neurons responded to the footshock and acquired a response to the CS following fear conditioning ("tone learners"). Furthermore, a population that partially overlapped with the tone learners showed a response to the onset of movements following freezing. We next investigated the origin and putative plasticity of the auditory input(s) to the pInsCx. Retrograde tracer experiments showed input neurons to the pInsCx both in the thalamic MGm and in the primary auditory cortex (A1), amongst other areas. Expression of Chronos in either of these presynaptic areas led to robust optogenetically- evoked EPSCs (oEPSCs) in the pInsCx. Interestingly, oEPSCs originating from the A1 showed robust signs of postsynaptic plasticity after fear learning, whereas the ones from the MGm did not. Thus, pInsCx integrates auditory- , footshock- and movement information, and shows plasticity of auditory responses during aversive learning; the latter might be caused by plasticity at a novel A1 to pInsCx connection. These findings suggest an important role for the multisensory pInsCx in fear learning.

Most individuals experience traumatic events throughout their lifetime, however, only a subpopulation (10-20%) develop a persistent set of biological symptoms referred to as post-traumatic stress disorder (PTSD). Key features of PTSD are the impaired fear extinction and generalisation of fear to safe contexts. Extinction is orchestrated by coordinated operations of several brain regions. Major candidates (i.e. prefrontal cortex, amygdala) have been implicated, however, unbiased large-scale assessments are needed to discover complex networks regulating fear extinction. Pre-trauma differences in behaviour may be a predisposing factor for developing PTSD. To differentiate individuals that are prone or resistant to PTSD, we performed a wide behavioural test battery on adult male Long-Evans rats before a footshock-induced traumatic experience. We discerned subjects based on their freezing response in a safe/altered context four weeks later (i.e. their fear generalisation and extinction). Upper and lower quartiles were identified based on safe context performances as vulnerable and resilient groups and their whole-brain activity patterns were compared and contrasted using complex statistical methods. We compared the two groups based on immunohistochemical labelling with the neuronal activity marker c-Fos. Whole-brain mapping using delineations from the Waxholm Space Atlas identified numerous cortical and subcortical regions distinguishing the investigated groups. The presented model may help understand complex network alterations underlying PTSD and imply new therapeutic targets in the future.

Cell-specific STORM super-resolution imaging reveals nanoscale organization of cannabinoid signaling.
A major challenge in neuroscience is to determine the nanoscale position and quantity of signaling molecules in a cell type- and subcellular compartment-specific manner. We developed a new approach to this problem by combining cell-specific physiological and anatomical characterization with super-resolution imaging and studied the molecular and structural parameters shaping the physiological properties of synaptic endocannabinoid signaling in the mouse hippocampus. We found that axon terminals of perisomatically projecting GABAergic interneurons possessed increased CB1 receptor number, active-zone complexity and receptor/effector ratio compared with dendritically projecting interneurons, consistent with higher efficiency of cannabinoid signaling at somatic versus dendritic synapses. Furthermore, chronic Δ(9)-tetrahydrocannabinol administration, which reduces cannabinoid efficacy on GABA release, evoked marked CB1 downregulation in a dose-dependent manner. Full receptor recovery required several weeks after the cessation of Δ(9)-tetrahydrocannabinol treatment. These findings indicate that cell type-specific nanoscale analysis of endogenous protein distribution is possible in brain circuits and identify previously unknown molecular properties controlling endocannabinoid signaling and cannabis-induced cognitive dysfunction.

SECOND-ORDER FEAR CONDITIONING ENGAGES EPIGENETIC MECHANISMS IN THE AMYGDALA AND PRIMARY SENSORY CORTICES

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Tayebeh Sepahvand, Tian Qin, Samantha Carew, Lauren Macgowan, Qi Yuan
Memorial University, Faculty Of Medicine, St. John's, Canada

AIMS: A characteristic of post-traumatic stress disorder (PTSD) is fear generalization beyond the initial association between a conditioned stimulus (CS) and an aversive stimulus, which we model using a 2nd order fear conditioning (SOC) paradigm. SOC forms when a 2nd CS (CS2) becomes aversive by association with a CS1 that has been previously associated with an aversive stimulus (1st order conditioning). Here we sought to determine the brain areas and mechanisms underlying SOC. METHODS: Rats underwent SOC using a tone as CS1 and an odor as CS2. We then conducted mapping of cFos and epigenetic marks of histone acetylation (H3Ac, H4ac) and DNA methylation (5MC) expression in multiple brains regions upon encoding and retrieval of SOC using immunohistochemistry. A CS1/CS2 unpaired group was used as a control. RESULTS: Following SOC encoding, cFos expression was elevated in the lateral amygdala (LA). However, upon retrieval of SOC, cFos was elevated in multiple structures including LA, basolateral amygdala (BLA), dorsal and ventral CA1 and CA3, as well as the olfactory piriform cortex (PC) and primary auditory cortex (AuD1). Upon retrieval, higher expressions of 5MC, H3Ac and H4Ac marks were observed in the BLA and AuD1. Moreover, higher expression of H3Ac and H4Ac in the LA and aPC was observed. CONCLUSION: Our preliminary data highlights the role of sensory cortices in SOC memory formation. We suggest a role for epigenetics in the storage of these memories. Epigenetic-mediated plasticity in SOC may have important implications for fear-related disorders such as PTSD.

NEURAL SIGNATURE OF FEAR RECALL ASSOCIATED WITH STRESS SUSCEPTIBILITY

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Ana Carolina Temporão[1], Bart Dirven[1], Judith Homberg[1], Tamas Kozicz[2], Marloes Henckens[1]
[1]Donders Institute for Brain, Cognition and Behaviour - Radboudumc, Department Of Cognitive Neuroscience, Nijmegen, Netherlands, [2]Donders Institute for Brain, Cognition and Behaviour - Radboudumc, Department Of Anatomy, Nijmegen, Netherlands

Exposure to a severely stressful event can haunt one for life. Flashbacks, spontaneous recollections, and recurrent nightmares of the trauma are amongst the most devastating symptoms of post-traumatic stress disorder (PTSD). Aberrant trauma memory processing seems to lie at the root of these symptoms and is targeted in current PTSD treatment, but the success rate is low as insight into the nature of the memory deviations is lacking. Here we investigated neural activity patterns supporting fear memory recall in a well-established mouse model for PTSD. The model is based on the phenomenon of stress-enhanced fear learning, which builds on the clinical observation that prior stress exposure precipitates PTSD by altering future fear learning. Hence, mice were first exposed to a stressor (intense, unpredictable foot shocks) followed by mild contextual fear conditioning the next day. Since most individuals recover adequately from trauma exposure and stay healthy, we specifically investigated the differences between resilient mice and those susceptible to the long-term behavioral consequences of trauma exposure, which were assessed starting from 1-week post-stress. Recall-induced brain activity was analyzed in response to re-exposure to a) the initial stress context, b) the subsequent conditioned context and c) a similar, yet novel context and compared between resilient and susceptible mice. Since memories are distributed across the entire brain, we assessed whole-brain responses by iDISCO+ (immunolabeling and brain clearing) and subsequent light-sheet microscopy. Moreover, we approximated functional connectivity across memory-related brain regions by calculating within-group inter-subject correlations in activity patterns. Results will be discussed.

NEUROTROPHIN-3/TRKC CONTRIBUTION TO FEAR EXTINCTION AND REGULATION OF GLUTAMATERGIC SYNAPSES

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Gianluca Masella[1], Francisca Silva[1], Miranda Mele[1], Carlos Duarte[2], Mónica Santos[1]
[1]University of Coimbra, Centre For Neuroscience And Cell Biology, Coimbra, Portugal, [2]University of Coimbra, Center For Neuroscience And Cell Biology, Coimbra, Portugal

Excessive fear that is resistant to extinction is a prominent feature to many anxiety disorders. Fear extinction, mediated by a brain network comprising the amygdala, hippocampus and medial prefrontal cortex, is a learning process that relies on synaptic plasticity events. The regulation of NMDAR and AMPAR in glutamatergic synapses contributes to this. Neurotrophins regulate synaptic plasticity and have been associated with anxiety disorders and the formation of fear memories. Here, we investigate the role of neurotrophin-3 (NT3)/TrkC receptor signaling in fear extinction and dissect their involvement in the regulation of synaptic NMDAR and AMPAR. We trained C57Bl/6J mice in a contextual fear conditioning and extinction paradigm and studied TrkC activation in the brain fear network, by Western Blot. Moreover, we stimulated cultured hippocampal neurons with NT3 and performed live staining of surface NMDAR and AMPAR subunits, confirming synaptic localization by co-staining with pre- and post-synaptic markers. In our behavioral model, a subset of animals extinguishes fear (>30% reduction in freezing levels) while the remaining fail to do so. Successful extinction was correlated positively with increased TrkC activation in the amygdala at extinction consolidation, and inversely with TrkC activation in the hippocampus at extinction reconsolidation. *In vitro,* NT3 administration increased the synaptic expression of GluN2A, GluN2B and GluA1 but decreased GluA2. Our results suggest that modulation of NT3/TrkC signaling in the brain fear network may contribute to extinction performance. Moreover, NT3 regulates the synaptic expression of glutamate receptors, posing as a putative molecular mechanism underlying NT3/TrkC role in fear extinction.

SEX DIFFERENCES IN NEURAL REPRESENTATION OF THREAT IN VENTRAL HIPPOCAMPAL AND PREFRONTAL CORTICAL PROJECTIONS TO NUCLEUS ACCUMBENS

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Jessie Muir[1], Eshaan Iyer[1], Karen Wassef[2], Sarah Gostlin[3], Rosemary Bagot[3,4]

BACKGROUND: Although fear is essential for survival, excessive fear characterizes many neuropsychiatric disorders. The nucleus accumbens (NAc) plays a role in encoding and responding to aversive stimuli by integrating input from brain regions including the ventral hippocampus (vHIP) and prefrontal cortex (PFC). Here we investigate how neural activity in these projections is shaped by aversive experiences. METHODS: Using frame-projected independent fiber photometry (FIP) to image *in vivo* calcium activity in male and female mice, we recorded PFC and vHIP NAc-projecting neurons during a Pavlovian fear conditioning paradigm in which mice encounter both threat cues (CS+) predicting shock and neutral cues (CS-) with no outcome. RESULTS: Neural activity in both the vHIP-NAc and PFC-NAc encode aversive experiences. Both pathways show elevated activity to foot-shock with an augmented PFC-NAc response in females compared to males. vHIP-NAc neural activity is significantly elevated at CS+ cue onset, compared to CS-, in males but not females, while the PFC-NAc showed elevated activity at CS+ cue onset in female alone. Furthermore, both pathways exhibited suppression prior to shock. Despite differentiating between cues, this activity did not predict freezing behavior. Consistent with this, pathway-specific chemogenetic inhibition did not impair cue-induced freezing but did lead to attenuation of reward seeking during aversive cues in a conditioned suppression task. CONCLUSIONS: Our findings suggest that both the vHIP and PFC convey information about threat prediction to the NAc medial shell with pathway-specific sex differences that may relate to sex differences in threat processing and stress vulnerability.

POPULATION LEVEL ENCODING OF THREAT MEMORY IN TEMPORAL NEOCORTEX

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Delin Pu[1], Julian Hinz[2], Andreas Lüthi[2], Benjamin Grewe[3], Johannes Letzkus[1]
[1]University of Freiburg, Institute For Physiology, Dept. I, Freiburg, Germany, [2]Friedrich Miescher Institute for Biomedical Research, Neurobiology, Basel, Switzerland, [3]University of Zurich, Institute Of Neuroinformatics, Zürich, Switzerland

Memory for cues associated with threat is critical for survival, and a leading model for elucidating how sensory information is linked to adaptive behavior by learning. While classical work focused on the contribution of limbic structures, we recently identified the temporal neocortex as an essential site for threat memory to complex, naturalistic auditory stimuli. However, how discriminative threat memory is encoded in this area at the single neuron and population level remains elusive. Here we perform deep brain miniscope calcium imaging in freely moving mice during acquisition and extinction of threat memory to reveal the response dynamics of large populations of neurons in both ventral auditory cortex (AuV) and temporal association cortex (TeA). Our data indicate pronounced dynamics of conditioned stimulus (CS) representation at the single neuron level but stable population responses in both areas before learning. During threat conditioning, mice that form a discriminative memory selectively develop a form of population plasticity that is not observed in generalization and tracks the temporal profile of discrimination learning. Moreover, threat learning increases the signal correlation of CS responses, which remains stable during subsequent extinction learning. At the population level, discriminator and generalizer mice show selective enhancement and reduction of stimulus discrimination during acquisition and extinction, and distinct responses during extinction recall. Moreover, our results reveal that threat learning switches CS encoding from bottom-up sensory responses to a top-down dominated memory representation. These data indicate that temporal neocortex dynamically encodes threat and extinction memory at the level of individual neurons and populations.

ENCODING OF SPATIAL LONG TERM MEMORIES IN A NEURAL NETWORK: UNDERSTANDING FEAR GENERALIZATION WITH MINISCOPE CALCIUM IMAGING

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Clément Pouget[1], Jose Casanova[1], Gisella Vetere[2]
[1]ESPCI, Plasticité Du Cerveau, Paris, France, [2]ESPCI, Brain Plasticity Unit, Paris, France

Fear memories are highly resistant to forgetting, but environmental details are often lost during consolidation, through a process called fear generalization. I aim to understand the role that the anterodorsal thalamic nucleus (ADn) and the laterodorsal thalamic nucleus (LDn) play during memory consolidation, and how it relates to reduced spatial specificity. Both regions contain a high number of head direction cells (HDc), and they are differently engaged in the recall of recently (1day after) versus remotely (4weeks after) acquired memories. We visualized the real time activity of ADn and LDn neurons at different time points by monitoring calcium activity via a miniaturized microscope implanted in mice brains. Doing so, we identified different population of cells responding to head direction (HDc), as well as shock-responsive cells. We were able to study the overlaps between those populations of cells, as well as their changes in activity over time, from fear conditioning (CFC) to recent and remote recalls. We also identified changes in neuronal activity when mice are in context A (associated to the CFC) and context B (similar, but different to context A) to study ADn and LDn role in memory generalization for recent and remote memory traces. This study aims to directly observe single-cell and population-level mechanics that may explain fear generalization of long-lasting memories.

DYSREGULATED MIDBRAIN DOPAMINE PREDICTION ERROR SIGNALING MAY UNDERLIE IMPAIRED FEAR EXTINCTION

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Eva Maria Fritz[1], Ozge Gunduz-Cinar[2], Maya Xia[2], Elise Van Leer[2], Andrew Holmes[2], Nicolas Singewald[1]
[1]University of Innsbruck, Pharmacology & Toxicology, Innsbruck, Austria, [2]NIH/NIAAA, Laboratory Of Behavioral And Genomic Neuroscience, Rockville, United States of America

Aims: The core mechanism underlying cognitive behavioral therapy, fear extinction, is deficient in many patients suffering from anxiety- and trauma related disorders, resulting in treatment resistance or relapse. This endophenotype is well-modeled in the extinction-impaired 129S1/SvImJ (S1) mouse strain and our groups previously reported that dopamine (DA) precursor L-DOPA facilitated fear extinction in these mice, although the exact mechanism remained unclear. Interestingly, recent studies demonstrate that upon omission of the aversive, unconditioned stimulus during extinction training, DA neurons in the ventral tegmental area (VTA) signal a reward-like prediction error (PE), which is necessary to initiate fear extinction before it dissipates. We hypothesized that PE signaling in S1 mice may be insufficient, while its enhancement would rescue their extinction-deficient phenotype. **Methods & Results:** As opposed to published studies in extinction-competent C57BL/6 mice, optogenetic activation of VTA DA neurons did not facilitate fear extinction in S1 animals. We analyzed VTA DA neuron activity using GCaMP fiber photometry and found that PE signals in S1 mice increased throughout extinction training and retrieval but were reduced in C57BL/6 mice, which was correlated with extinction performance. **Conclusions:** We propose that in S1 mice, VTA PE signals are not properly conveyed to relevant target structures, resulting in deficient extinction acquisition and, due to missing negative feedback, no attenuation of VTA activity. Consequently, dysregulations downstream of the VTA (e.g. insufficient DA release) will have to be investigated as possible neurobiological correlates and novel targets in impaired fear extinction. Supported by FWF (I2433-B26).

Altered sleep behavior in a genetic mouse model of impaired fear extinction.
Sleep disturbances are a common complaint of anxiety patients and constitute a hallmark feature of post-traumatic stress disorder (PTSD). Emerging evidence suggests that poor sleep is not only a secondary symptom of anxiety- and trauma-related disorders but represents a risk factor in their development, for example by interfering with emotional memory processing. Fear extinction is a critical mechanism for the attenuation of fearful and traumatic memories and multiple studies suggest that healthy sleep is crucial for the formation of extinction memories. However, fear extinction is often impaired in anxiety- and trauma-related disorders-an endophenotype that is perfectly modelled in the 129S1/SvImJ inbred mouse strain. To investigate whether these mice exhibit altered sleep at baseline that could predispose them towards maladaptive fear processing, we compared their circadian sleep/wake patterns to those of typically extinction-competent C57BL/6 mice. We found significant differences regarding diurnal distribution of sleep and wakefulness, but also sleep architecture, spectral features and sleep spindle events. With regard to sleep disturbances reported by anxiety- and PTSD patients, our findings strengthen the 129S1/SvImJ mouse models' face validity and highlight it as a platform to investigate novel, sleep-focused diagnostic and therapeutic strategies. Whether the identified alterations causally contribute to its pathological anxiety/PTSD-like phenotype will, however, have to be addressed in future studies.

Stabilization of negative activation voltages of Cav1.3 L-Type Ca-channels by alternative splicing.
-->Low voltage-activated Cav1.3 L-type Ca-channels are key regulators of neuronal excitability controlling neuronal development and different types of learning and memory. Their physiological functions are enabled by their negative activation voltage-range, which allows Cav1.3 to be active at subthreshold voltages. Alternative splicing in the C-terminus of their pore-forming α1-subunits gives rise to C-terminal long (Cav1.3) and short (Cav1.3) splice variants allowing Cav1.3 to activate at even more negative voltages than Cav1.3. We discovered that inclusion of exons 8b, 11, and 32 in Cav1.3 further shifts activation (-3 to -4 mV) and inactivation (-4 to -6 mV) to more negative voltages as revealed by functional

characterization in tsA-201 cells. We found transcripts of these exons in mouse chromaffin cells, the cochlea, and the brain. Our data further suggest that Cav1.3-containing exons 11 and 32 constitute a significant part of native channels in the brain. We therefore investigated the effect of these splice variants on human disease variants. Splicing did not prevent the gating defects of the previously reported human pathogenic variant S652L, which further shifted the voltage-dependence of activation of exon 11-containing channels by more than -12 mV. In contrast, we found no evidence for gating changes of the missense variant R498L, located in exon 11, which has recently been identified in a patient with an epileptic syndrome. Our data demonstrate that alternative splicing outside the C-terminus involving exons 11 and 32 contributes to channel fine-tuning by stabilizing negative activation and inactivation gating properties of wild-type and mutant Cav1.3 channels.

The Good, the Bad and the Unknown Aspects of Ghrelin in Stress Coping and Stress-Related Psychiatric Disorders.
Ghrelin is a peptide hormone released by specialized X/A cells in the stomach and activated by acylation. Following its secretion, it binds to ghrelin receptors in the periphery to regulate energy balance, but it also acts on the central nervous system where it induces a potent orexigenic effect. Several types of stressors have been shown to stimulate ghrelin release in rodents, including nutritional stressors like food deprivation, but also physical and psychological stressors such as foot shocks, social defeat, forced immobilization or chronic unpredictable mild stress. The mechanism through which these stressors drive ghrelin release from the stomach lining remains unknown and, to date, the resulting consequences of ghrelin release for stress coping remain poorly understood. Indeed, ghrelin has been proposed to act as a stress hormone that reduces fear, anxiety- and depression-like behaviors in rodents but some studies suggest that ghrelin may - in contrast - promote such behaviors. In this review, we aim to provide a comprehensive overview of the literature on the role of the ghrelin system in stress coping. We discuss whether ghrelin release is more than a byproduct of disrupted energy homeostasis following stress exposure. Furthermore, we explore the notion that ghrelin receptor signaling in the brain may have effects independent of circulating ghrelin and in what way this might influence stress coping in rodents. Finally, we examine how the ghrelin system could be utilized as a therapeutic avenue in stress-related psychiatric disorders (with a focus on anxiety- and trauma-related disorders), for example to develop novel biomarkers for a better diagnosis or new interventions to tackle relapse or treatment resistance in patients.

Effects of disrupted ghrelin receptor function on fear processing, anxiety and saccharin preference in mice.
Obesity is a risk factor for stress-related mental disorders such as post-traumatic stress disorder. The underlying mechanism through which obesity affects mental health remains poorly understood but dysregulation of the ghrelin system may be involved. Stress increases plasma ghrelin levels, which stimulates food intake as a potential stress-coping mechanism. However, diet-induced obesity induces ghrelin resistance which in turn may have deleterious effects on stress-coping. In our study, we explored whether disruption of ghrelin receptor function though high-fat diet or genetic ablation affects fear processing, anxiety-like behavior and saccharin preference in mice.

Distinct Parameters in the EEG of the PLP α-SYN Mouse Model for Multiple System Atrophy Reinforce Face Validity.
Multiple system atrophy (MSA) is a neurodegenerative movement disorder characterized by parkinsonian symptoms and cerebellar symptoms. Sleep disturbances also play a crucial role in MSA. One of the most convincing animal models in MSA research is the PLP α-SYN model, but to date no studies on sleep disturbances in this mouse model, frequently found in MSA patients are available. We identified spectral shifts within the EEG of the model, strikingly resembling results of clinical studies. We also characterized muscle activity during REM sleep, which is one of the key symptoms in REM sleep behavioral disorder. Spectral shifts and REM sleep-linked muscle activity were age dependent, supporting Face Validity of the PLP α-SYN model. We also strongly suggest our findings to be critically evaluated for Predictive Validity in future studies. Currently, research on MSA lacks potential compounds attenuating or curing MSA. Future drugs must prove its potential in animal models, for this our study provides potential biomarkers.

In response to specific threats, mammals select a response among a repertoire of different defensive behaviors. The selection and the rapid execution of this response are crucial for animal survival and are determined not only by the nature of the threat but also by the contextual contingencies. Therefore, in order to survive a dangerous situation mammals have to integrate multimodal information regarding the threat, the context and its internal state to rapidly elicit the most adaptive fear response. The neuronal circuits and mechanisms allowing this rapid selection of appropriate defensive fear responses are still largely unknown. To address this question, we used a multi-level approach combining simultaneous electrophysiological recordings and optogenetic manipulations in a novel and unique behavioral paradigm allowing mice to select different defensive behaviors when facing different threats. Using this combination of techniques, we monitored the neuronal activity of dmPFC neurons of mice presented with different threats to demonstrate that at the population level, dmPFC neuronal activity encodes both a general fear state and more specific information about the identity of the threats.

CRISPR-BASED EPIGENETIC EDITING OF ENGRAM CELLS IN FEAR MEMORIES

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Davide Martino Coda, Lisa Watt, Lilliane Glauser, Johannes Graff
EPFL, Brain And Mind Institute, Lausanne, Switzerland

The experience of traumatic, life-threatening events gives rise to some of the most enduring forms of fear memories, which can degenerate into a devastating pathological state known as post-traumatic stress disorder (PTSD). Nevertheless, surprisingly little is known about how long-lasting memories are formed and stored. By being at the same time dynamic and stable, epigenetic mechanisms have long been proposed as the molecular substrates for memory, but a cell type, locus-restricted and temporally controlled demonstration thereof has thus far been lacking. Here, we combine *in vivo*epigenetic editing approaches with c-Fos driven engram tagging technologies. First, we show that in transgenic c-Fos::tTA mice, overexpressing the histone acetyl transferase CREB binding protein (CBP) in the dentate gyrus of engram cells increases whole-genome H3K27ac levels and the ability to recall recent fear memories, while overexpressing of HDAC8 has the opposite effects. Then, we go on to show that epigenetic editing of a single site on the genome – using CRISPR-dCas9 coupled to transcriptional activators or repressors – might be sufficient to alter memory performances. Engram-specific, dCas9-VPR mediated upregulation of *Arc*, a master regulator of synaptic plasticity,improves recent fear memory, whilst expression of dCas9-KRAB-MeCP2 in the same cells decreases *Arc* mRNA levelsandimpairs fear memory recall. Overall, these findings show how the modulation of epigenetic marks in a cell type and locus-specific manner can impact neuronal function and memory capacity; at the same time, they deepen our understanding of the molecular mechanisms of traumatic memory storage.

Neurogenetic and Neuroepigenetic Mechanisms in Cognitive Health and Disease.
Over the last two decades, the explosion of experimental, computational, and high-throughput technologies has led to critical insights into how the brain functions in health and disease. It has become increasingly clear that the vast majority of brain activities result from the complex entanglement of genetic factors, epigenetic changes, and environmental stimuli, which, when altered, can lead to neurodegenerative and neuropsychiatric disorders. Nevertheless, a complete understanding of the molecular mechanisms underlying neuronal activities and higher-order cognitive processes continues to elude neuroscientists. Here, we provide a concise overview of how the interaction between the environment and genetic as well as epigenetic mechanisms shapes complex neuronal processes such as learning, memory, and synaptic plasticity. We then consider how this interaction contributes to the development of neurodegenerative and psychiatric disorders, and how it can be modeled to predict phenotypic variability and disease risk. Finally, we outline new frontiers in neurogenetic and neuroepigenetic research and highlight the challenges these fields will face in their quest to decipher the molecular mechanisms governing brain functioning.

Distinct modes of SMAD2 chromatin binding and remodeling shape the transcriptional response to NODAL/Activin signaling.
NODAL/Activin signaling orchestrates key processes during embryonic development via SMAD2. How SMAD2 activates programs of gene expression that are modulated over time however, is not known. Here we delineate the sequence of events that occur from SMAD2 binding to transcriptional activation, and the mechanisms underlying them. NODAL/Activin signaling induces dramatic chromatin landscape changes, and a dynamic transcriptional network regulated by SMAD2, acting via multiple mechanisms. Crucially we have discovered two modes of SMAD2 binding. SMAD2 can bind pre-acetylated nucleosome-depleted sites. However, it also binds to unacetylated, closed chromatin, independently of pioneer factors, where it induces nucleosome displacement and histone acetylation. For a subset of genes, this requires SMARCA4. We find that long term modulation of the transcriptional responses requires continued NODAL/Activin signaling. Thus SMAD2 binding does not linearly equate with transcriptional kinetics, and our data suggest that SMAD2 recruits multiple co-factors during sustained signaling to shape the downstream transcriptional program.

SMYD1 and G6PD modulation are critical events for miR-206-mediated differentiation of rhabdomyosarcoma.
Rhadomyosarcoma (RMS) is the most common soft tissue sarcoma of childhood. RMS cells resemble fetal myoblasts but are unable to complete myogenic differentiation. In previous work we showed that miR-206, which is low in RMS, when induced in RMS cells promotes the resumption of differentiation by modulating more than 700 genes. To better define the pathways involved in the conversion of RMS cells into their differentiated counterpart, we focused on 2 miR-206 effectors emerged from the microarray analysis, SMYD1 and G6PD. SMYD1, one of the most highly upregulated genes, is a H3K4 histone methyltransferase. Here we show that SMYD1 silencing does not interfere with the proliferative block or with the loss anchorage independence imposed by miR-206, but severely impairs differentiation of ERMS, ARMS, and myogenic cells. Thus SMYD1 is essential for the activation of muscle genes. Conversely, among the downregulated genes, we found G6PD, the enzyme catalyzing the rate-limiting step of the pentose phosphate shunt. In this work, we confirmed that G6PD is a direct target of miR-206. Moreover, we showed that G6PD silencing in ERMS cells impairs proliferation and soft agar growth. However, G6PD overexpression does not interfere with the pro-differentiating effect of miR-206, suggesting that G6PD downmodulation contributes to - but is not an absolute requirement for - the tumor suppressive potential of miR-206. Targeting cancer metabolism may enhance differentiation. However, therapeutic inhibition of G6PD is encumbered by side effects. As an alternative, we used DCA in combination with miR-206 to increase the flux of pyruvate into the mitochondrion by reactivating PDH. DCA enhanced the inhibition of RMS cell growth induced by miR-206, and sustained it upon miR-206 de-induction. Altogether these results link miR-206 to epigenetic and metabolic reprogramming, and suggest that it may be worth combining differentiation-inducing with metabolism-directed approaches.

Failure to downregulate the BAF53a subunit of the SWI/SNF chromatin remodeling complex contributes to the differentiation block in rhabdomyosarcoma.
Rhabdomyosarcoma (RMS), the most common soft tissue sarcoma in children and young adults, is characterized by a partially differentiated myogenic phenotype. We have previously shown that the blocking of tumor growth and resumption of differentiation can be achieved by re-expression of miR-206, a muscle-enriched microRNA missing in RMS. In this work, we focused on BAF53a, one of the genes downregulated in miR-206-expressing RMS cells, which codes for a subunit of the SWI/SNF chromatin remodeling complex. Here we show that the BAF53a transcript is significantly higher in primary RMS tumors than in normal muscle, and is a direct target of miR-206. Sustained expression of BAF53a interferes with differentiation in myogenic cells, whereas its silencing in RMS cells increases expression of myogenic markers and inhibits proliferation and anchorage-independent growth. Accordingly, BAF53a silencing also impairs embryonal RMS and alveolar RMS tumor growth, inducing their morphological and biochemical differentiation. These results indicate that failure to downregulate the BAF53a subunit may contribute to the pathogenesis of RMS, and suggest that BAF53a may represent a novel therapeutic target for this tumor.

EPIGENETIC PLASTICITY CONTRIBUTES TO NEURONAL COMPETITION DURING MEMORY ALLOCATION

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Giulia Santoni[1], Lilliane Glauser[1], Simone Astori[2], Simon Zamora[1], Ana Marques[1,3], Carmen Sandi[2], Johannes Graff[1]
[1]EPFL, Laboratory Of Neuroepigenetics, Bmi, Lausanne, Switzerland, [2]EPFL, Laboratory Of Behavioural Genetics, Brain Mind Institute, Lausanne, Switzerland, [3]Faculdade de Ciências Médicas, Nova Medical School, Lisboa, Portugal

Long-lasting memories are thought to be stored in a small set of neurons, so-called engram cells. To define a stable engram each region of the brain involved in memory storage recruits between 5 and 20 percent of excitatory neurons. In parallel, recent studies have revealed that the neuronal allocation to participate in the memory engram is not random; rather, post-synaptic neurons with higher excitability than their neighbors are more likely to be selected into the memory trace. However, the precise mechanism that enables neurons to acquire such profile has not yet been investigated. With this project we further explore the process of memory allocation by studying how histone acetylation contributes to neuronal competition during memory formation. To this end, we virally manipulated the histone acetyltransferase (HAT) content of a sparse population of excitatory cells in the lateral amygdala (LA) of wild-type mice. Using patch-clamp recordings, we found that HAT overexpressing neurons are intrinsically more excitable. Furthermore, a higher histone acetylation content increased the probability of individual LA neurons to be selected as part of the engram. Interestingly, mice overexpressing HAT in the LA show a strengthened fear memory response, and, importantly, this fear potentiation is absent when neurons carrying the HAT construct are optogenetically silenced. These findings highlight that epigenetic plasticity is an integral process that co-determined memory allocation.

A neuronal basis for fear discrimination in the lateral amygdala.
In the presence of new stimuli, it is crucial for survival to react with defensive responses in the presence of stimuli that resemble threats but also to not react with defensive behavior in response to new harmless stimuli. Here, we show that in the presence of new uncertain stimuli with sensory features that produce an ambiguous interpretation, discriminative processes engage a subset of excitatory and inhibitory neurons within the lateral amygdala (LA) that are partially different from those engaged by fear processes. Inducing the pharmacogenetic deletion of this neuronal ensemble caused fear generalization but left anxiety-like response, fear memory and extinction processes intact. These data reveal that two opposite neuronal processes account for fear discrimination and generalization within the LA and suggest a potential pathophysiological mechanism for the impaired discrimination that characterizes fear-related disorders.

A thalamo-amygdalar circuit underlying the extinction of remote fear memories.
Fear and trauma generate some of the longest-lived memories. Despite the corresponding need to understand how such memories can be attenuated, the underlying brain circuits remain unknown. Here, combining viral tracing, neuronal activity mapping, fiber photometry, chemogenetic and closed-loop optogenetic manipulations in mice, we show that the extinction of remote (30-day-old) fear memories depends on thalamic nucleus reuniens (NRe) inputs to the basolateral amygdala (BLA). We found that remote, but not recent (1-day-old), fear extinction activates NRe-to-BLA inputs, which become potentiated upon fear reduction. Furthermore, both monosynaptic NRe-to-BLA and total NRe activity increase shortly before freezing cessation, suggesting that the NRe registers and transmits safety signals to the BLA. Accordingly, pan-NRe and pathway-specific NRe-to-BLA inhibition impairs, whereas their activation facilitates, remote fear extinction. These findings identify the NRe as a crucial BLA regulator for extinction and provide the first functional description of the circuits underlying the attenuation of consolidated fear memories.

Anxiety disorders are often characterized by an inability to extinguish learned fear responses. Hypocretins/orexins are involved in the regulation of aversive memories, and dysregulation of this system may contribute to the aetiology of fear and anxiety disorders. The aim of this study is to describe the neurobiological mechanisms by which the orexin system modulates fear extinction. Experiments were performed using adult male C57BL/6J and eGFP-CB2R mice. The selective inhibitor of 2-arachidonoylglycerol (2-AG) biosynthesis O7460 abolished the fear extinction deficits induced by orexin-A (OXA). Increased levels of 2-AG were observed in the amygdala of mice treated with OXA which do not extinguish fear. Indeed, a correlation between fear (percentage of freezing) and 2-AG levels was found in this brain region, suggesting that high levels of this endocannabinoid are related to poor extinction. Impairment of fear extinction induced by OXA was associated with increased expression of CB2 cannabinoid receptors (CB2R) in microglial cells of the basolateral amygdala. Consistently, intra-amygdalar administration of the CB2R antagonist AM630 blocked the OXA-induced impairment of fear extinction, whereas the CB1 cannabinoid receptor antagonist rimonabant increased the fear response. Microglial and CB2R expression depletion in the amygdala with PLX5622 chow also prevented these extinction deficits. These results reveal a key role for 2-AG and CB2R probably located in microglial cells of the amygdala in impaired extinction of aversive memories promoted by overactivation of the orexin system.

RECENT TO REMOTE MEMORY ACTIVITY AND CONNECTIVITY

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Ron Refaeli, Tirzah Kreisel, Inbal Goshen
The Hebrew University, Elsc, Jerusalem, Israel

Recent memory involves relatively fast processes that take place during the first hours following learning. Remote memories, however, are not yet well-defined. In this research we targeted the transition of a memory from recent to remote recall, to find missing links between these memory stages. For that purpose, we tagged cFos positive cells using genetic manipulation, and using immunohistochemistry within the same mouse, thus allowing comparison of the two populations in each animal. First, we show that neuronal activation throughout different stages in memory consolidation and reconsolidation is consistent in the hippocampus, but not in other memory related brain areas. Secondly, during the transition from recent to remote, several brain structures maintain fixed ensembles, not necessarily similar to the acquisition. In order to define whether the ensembles supporting remote memory are selected based on their connectivity and if they differ from the ensembles supporting recent memory, we marked cells in the CA1 based on their projection target. Recent to remote transition does include recruitment of projection based sub-population; CA1 to ACC projecting cells are more likely to be activated during remote than during recent recall or acquisition. Additionally, hyper activation of hippocampal astrocytes during an acquisition of a memory, increases the activation of the CA1 to ACC projecting cells during recent but not remote recall. Lastly, analyzing projections of active cells from the CA1 during different stages of memory consolidation, using full brain reconstruction, revealed that as time progresses, the CA1 to ACC projections ratio increases, compared to other areas.

Features of hippocampal astrocytic domains and their spatial relation to excitatory and inhibitory neurons.
The mounting evidence for the involvement of astrocytes in neuronal circuits function and behavior stands in stark contrast to the lack of detailed anatomical description of these cells and the neurons in their domains. To fill this void, we imaged >30,000 astrocytes in hippocampi made transparent by CLARITY, and determined the elaborate structure, distribution, and neuronal content of astrocytic domains. First, we characterized the spatial distribution of >19,000 astrocytes across CA1 lamina, and analyzed the morphology of thousands of reconstructed domains. We then determined the excitatory somatic content of CA1 astrocytes, and measured the distance between inhibitory neuronal somata to the nearest astrocyte soma. We find that on average, there are almost 14 pyramidal neurons per domain in the CA1, increasing toward the pyramidal layer midline, compared to only five excitatory neurons per domain in the amygdala. Finally, we discovered that somatostatin neurons are found in close proximity to astrocytes, compared to parvalbumin and VIP inhibitory neurons. This work provides a comprehensive large-scale quantitative foundation for studying neuron-astrocyte interactions.

Astrocytic Activation Generates De Novo Neuronal Potentiation and Memory Enhancement.
Astrocytes respond to neuronal activity and were shown to be necessary for plasticity and memory. To test whether astrocytic activity is also sufficient to generate synaptic potentiation and enhance memory, we expressed the Gq-coupled receptor hM3Dq in CA1 astrocytes, allowing their activation by a designer drug. We discovered that astrocytic activation is not only necessary for synaptic plasticity, but also sufficient to induce NMDA-dependent de novo long-term potentiation in the hippocampus that persisted after astrocytic activation ceased. In vivo, astrocytic activation enhanced memory allocation; i.e., it increased neuronal activity in a task-specific way only when coupled with learning, but not in home-caged mice. Furthermore, astrocytic activation using either a chemogenetic or an optogenetic tool during acquisition resulted in memory recall enhancement on the following day. Conversely, directly increasing neuronal activity resulted in dramatic memory impairment. Our findings that astrocytes induce plasticity and enhance memory may have important clinical implications for cognitive augmentation treatments.

The Claustrum Supports Resilience to Distraction.
A barrage of information constantly assaults our senses, of which only a fraction is relevant at any given point in time. However, the neural circuitry supporting the suppression of irrelevant sensory distractors is not completely understood. The claustrum, a circuit hub with vast cortical connectivity, is an intriguing brain structure, whose restrictive anatomy, thin and elongated, has precluded functional investigation. Here, we describe the use of Egr2-CRE mice to access genetically defined claustral neurons. Utilizing conditional viruses for anterograde axonal labeling and retrograde trans-synaptic tracing, we validated this transgenic model for accessing the claustrum and extended the known repertoire of claustral input/output connectivity. Addressing the function of the claustrum, we inactivated CL neurons, chronically as well as acutely, in mice performing an automated two-alternative forced-choice behavioral task. Strikingly, inhibition of CL neurons did not significantly impact task performance under varying delay times and cue durations, but revealed a selective role for the claustrum in supporting performance in the presence of an irrelevant auditory distractor. Further investigation of behavior, in the naturalistic maternal pup-retrieval task, replicated the result of sensitization to an auditory distractor following inhibition of CL neurons. Initiating investigation into the underlying mechanism, we found that activation of CL neurons modulated cortical sensory processing, suppressing tone representation in the auditory cortex. This functional study, utilizing selective genetic access, implicates the claustrum in supporting resilience to distraction, a fundamental aspect of attention.

Microglia and their LAG3 checkpoint underlie the antidepressant and neurogenesis-enhancing effects of electroconvulsive stimulation.
Despite evidence implicating microglia in the etiology and pathophysiology of major depression, there is paucity of information regarding the contribution of microglia-dependent molecular pathways to antidepressant procedures. In this study, we investigated the role of microglia in a mouse model of depression (chronic unpredictable stress-CUS) and its reversal by electroconvulsive stimulation (ECS), by examining the effects of microglia depletion with the colony stimulating factor-1 antagonist PLX5622. Microglia depletion did not change basal behavioral measures or the responsiveness to CUS, but it completely abrogated the therapeutic effects of ECS on depressive-like behavior and neurogenesis impairment. Treatment with the microglia inhibitor minocycline concurrently with ECS also diminished the antidepressant and pro-neurogenesis effects of ECS. Hippocampal RNA-Seq analysis revealed that ECS significantly increased the expression of genes related to neurogenesis and dopamine signaling, while reducing the expression of several immune checkpoint genes, particularly lymphocyte-activating gene-3 (Lag3), which was the only microglial transcript significantly altered by ECS. None of these molecular changes occurred in microglia-depleted mice. Immunohistochemical analyses showed that ECS reversed the CUS-induced changes in microglial morphology and elevation in microglial LAG3 receptor expression. Consistently, either acute or chronic systemic administration of a LAG3 monoclonal antibody, which readily penetrated into the brain parenchyma and was found to serve as a direct checkpoint blocker in BV2 microglia cultures, rapidly rescued the CUS-induced microglial alterations, depressive-like symptoms, and neurogenesis impairment. These findings suggest that brain microglial LAG3 represents a promising target for novel antidepressant therapeutics.

FEAR CIRCUIT-BASED NEUROBEHAVIORAL SIGNATURES AND TRANSCRIPTIONAL NETWORKS PROMOTING RESILIENCE TO CHRONIC SOCIAL STRESS

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Sarah Ayash[1], Thomas Lingner[2], Soojin Ryu[3], Raffael Kalisch[4], Ulrich Schmitt[5], Marianne Müller[1]
[1]Leibniz Institute for Resilience Research, Molecular And Cellular Mechanisms Of Resilience, Mainz, Germany, [2]Genevention GmbH, Genevention Gmbh, Göttingen, Germany, [3]University of Exeter, Living Systems Institute, Exeter, United Kingdom, [4]Leibniz Institute for Resilience Research, Systemic Mechanisms Of Resilience, Mainz, Germany, [5]Leibniz Institute for Resilience Research, Molecular And Cellular Mechanisms Of Resilience, mainz, Germany

Consistent evidence from human data points to successful threat-safety discrimination and responsiveness to extinction training of aversive memories as key characteristics of resilient individuals. In contrast, susceptible individuals are characterised by generalisation of aversive responses and resistance to extinction. To promote valid cross-species approaches for the identification of resilience mechanisms, we established a translationally informed mouse model enabling the stratification of mice into three phenotypic subgroups following chronic social defeat stress based on their individual ability for threat-safety discrimination and conditioned learning: the *Discriminating-avoiders*, characterised by successful social threat-safety discrimination and successful extinction of social aversive memories; the *Indiscriminate-avoiders*, showing social aversive response generalisation and resistance to extinction of social aversive memories, and the *Non-avoiders* displaying impaired aversive conditioned learning. Employing inter-regional transcriptional analysis revealed distinct functional alternations of the fear circuitry associated with stress resilience and susceptibility. Transcriptional analysis across and between brain regions of the fear circuitry revealed subgroup-specific gene networks and differentially expressed genes, respectively. By modelling translationally relevant phenotypic characteristics, our approach holds the potential to serve as a blueprint for multiple approaches to identifying valid neurobiological mechanisms of resilience in the future.

THE β-ADRENERGIC RECEPTOR ANTAGONIST PROPRANOLOL ATTENUATES THE ESTABLISHMENT OF CONDITIONED CONTEXT AVERSION IN LABORATORY MICE

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Çınar Furkan Ilhan[1], Esra Ülke[1], Gonzalo Urcelay[2], Sezen Kışlal[1]

Introduction: Anticipatory nausea is a type of classical conditioning in which chemotherapy-induced illness is associated with environmental cues in the hospital. Although antiemetic drugs can reduce anticipatory nausea, 30% of patients still suffer from it. We investigated whether β-adrenergic receptor antagonist propranolol impairs the consolidation of conditioned context aversion (CCA), the preclinical model of anticipatory nausea. **Method**: Twelve-week-old CD1 outbred male mice were assigned to the LiCl–Propranolol (n = 11), LiCl–NaCl (n = 9), or NaCl–NaCl (n = 12) group. Five minutes into a 20-minute conditioning trial, the LiCl–Propranolol and LiCl–NaCl groups received an intraperitoneal injection of illness-inducing LiCl (6 mEq/kg); the NaCl–NaCl group received NaCl (0.9%) in a novel context. Immediately after, the LiCl–Propranolol group was injected with propranolol (10mg/kg) and the LiCl–NaCl and NaCl–NaCl groups were injected with NaCl. A retention test (20 minutes) was conducted 72 hours later. Water intake was measured during the conditioning and retention trials. One-way ANOVAs and t-tests were used as statistical tools. **Results:** There were no differences in water intake between groups in the conditioning trial (Figure 1). In the retention test, there was a statistically significant difference between LiCl–NaCl and LiCl–Propranolol ($p = .006$) and LiCl–NaCl and NaCl–NaCl ($p = .01$) but not LiCl–Propranolol and NaCl–NaCl ($p = .83$) (Figure 2). **Conclusion:** Propranolol, an amnestic agent, attenuates the consolidation of CCA, and thereby shows promise to mitigate the stress and discomfort associated with chemotherapy.

BLA-MPFC-DMS CIRCUITRY: THE GATEWAY TO THE EFFECT OF FEAR ON ACTION CONTROL

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Shlomi Habusha, Oded Klavir
Haifa University, School Of Psychological Scienses, Haifa, Israel

When an action is carried out to achieve a desired goal, we operate through the "Goal directed" system. Conversely, behaviors less driven by outcome expectancy are often carried out by the "habitual" system. The same behavior can be executed by either of the systems. The connection and information transfer between them, as well as the ability to switch control when needed, is crucial for adaptive behavior. Dysfunctions in this mechanism are suggested to underlie psychopathologies such as OCD and addiction. Symptoms are known to be affected by stress, possibly through stress-induced changes in action-control neural circuits, involving the cortico-striatal loops. These loops are anatomically similar, yet parallel and functionally different. Habit control involves the sensorimotor cortico-striatal loop going through the dorsolateral striatum (DLS) and sensorimotor cortex. Goal-directed control require cognitive-emotional integration involving the BLA-mPFC pathway and the associative loop going through the dorsomedial striatum (DMS) and the medial prefrontal cortex (mPFC). The latter is an important cortical hub in fear-related behaviors. Here, we use fear conditioning and two distinct behavioral models (Forced alteration delta maze, lever pressing task) allowing mice to produce completely different behaviors theoretically under the same action control. Combined with reward devaluation process, we test the effects of stress on action control in mice. Results from our lab work indicate that behavior can be controlled by both goal-directed and habitual control, and that stressful stimulus promotes habitual control. We use optogenetic manipulations and electrophysiological recordings to examine the effect of fear on the BLA-mPFC-DMS circuit action control.

EXPLORING THE GUT-MICROBIOTA-BRAIN AXIS IN A SPANISH POPULATION IN THE AFTERMATH OF THE COVID-19 PANDEMIC

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Stefanie Malan-Müller[1], Mireia Valles-Colomer[2], Juan Carlos Leza[1], Tomas Palomo[3]
[1]Universidad Complutense de Madrid, Departamento De Farmacología Y Toxicología, Facultad De Medicina, Madrid, Spain, [2]University of Trento, Department Of Cellular, Computational And Integrative Biology, Trento, Italy, [3]Complutense University of Madrid, Psychiatry Department, Madrid, Spain

Introduction: The prevalence of anxiety and depression significantly increased in the aftermath of the COVID-19 pandemic. To develop novel treatment strategies, we need to identify all potential role players in these complex disorders. Aim: This study will identify gut microbial features associated with mental health outcomes in individuals with anxiety and depressive symptoms in a Spanish cohort. Methods: Microbial communities from stool samples were profiled in 197 individuals who completed self-reported online questionnaires (March 2021 - Jan 2022). Based on the Centre for Epidemiologic Studies Depression scale, 64 individuals had depressive symptoms, 104 reported state anxiety, and 131 trait anxiety symptoms (based on State-trait anxiety and depression inventory for state anxiety). Furthermore, data about trauma exposure (PTSD Checklist for DSM-5 with Life Events Checklist for DSM-5 and Childhood Trauma Questionnaire-Short Form), quality of life (World Health Organization Quality Of Life questionnaire), health, and lifestyle were also collected. Currently, 16S ribosomal RNA gene V3-4 amplicon sequencing is being performed. Microbial diversity and community structure will be analyzed, together with relative taxonomic abundance at the genus and phylum levels, to identify associations with variables of interest relating to anxiety and depressive symptoms. Results and Conclusion: Gut microbiota data will be analyzed in conjunction with self-report data to identify associations between mental health outcomes and the gut microbiota. Associations with particular taxa will be presented and discussed in the context of novel adjunctive therapies that could alleviate symptoms of anxiety and depression (through the use of prebiotics, probiotics, and synbiotics).

ALTERED CORTISOL AWAKENING RESPONSE IN RELATIONSHIP WITH TRAUMA IN FUNCTIONAL NEUROLOGICAL DISORDERS

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Samantha Weber[1], Janine Bühler[1], Giorgio Vanini[1], Rupert Bruckmaier[2], Selma Aybek[1]
[1]Psychosomatic Medicine, Department Of Neurology, Inselspital, Bern University Hospital, University Of Bern, Bern, Switzerland, [2]Veterinary Physiology, Vetsuisse Faculty, University Of Bern, Bern, Switzerland

Psychological stress is a well-known risk factor to develop a functional neurological disorder (FND), a neuropsychiatric condition in which patients experience neurological symptoms in the absence of classical neurological disease. However, only little is known about the biological stress regulation in FND and its role in the aetiology of FND. Investigating the relationship between psychological stressors and a potential dysregulation of the Hypothalamic-Pituitary-Adrenal (HPA) axis in FND could shed a light on the underlying neurobiological mechanisms. We examined potential alterations in the HPA axis in a broad range of cortisol indices, including the cortisol awakening response (CAR), post-awakening cortisol concentration (PACC, AUC_G), and overall hormonal secretion (OHS, AUC_G) of 86 FND patients and 75 healthy controls. Salivary cortisol was collected nine times throughout one day. In parallel presence and severity of traumatic life events were compared in FND patients and controls. Overall, FND patients reported 46% more emotional neglect as compared to healthy controls ($p < 0.001$). Moreover, FND patients had a significantly flatter CAR ($p < 0.001$), and lower AUC_G measures as compared to healthy controls ($p < 0.008$). Using a partial least squares correlation, we found that particularly in FND patients with a history of sexual abuse, trauma might play an important role in the multivariate pattern between trauma history and HPA axis dysfunction. This study supports a stress-diathesis model of FND and showed an association between different attributes of trauma history and potential biological vulnerability in patients with FND.

TRANSCRANIAL MAGNETIC STIMULATION (TMS) AND SENSE OF AGENCY (SOA) IN FUNCTIONAL NEUROLOGICAL DISORDER (FND); PRELIMINARY DATA

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Janine Bühler[1,2], Samantha Weber[1,3], Serafeim Loukas[1,4], Sebastian Walther[5], Selma Aybek[1]
[1]Psychosomatic Medicine, Department Of Neurology, Inselspital, Bern University Hospital, University Of Bern, Bern, Switzerland, [2]Graduate School for Health Sciences (GHS), University Of Bern, Bern, Switzerland, [3]Graduate School for Cellular and Biomedical Sciences (GCB), University Of Bern, Bern, Switzerland, [4]Institute of Bioengineering, Ecole Polytechnique Fédérale De Lausanne (epfl), Lausanne, Switzerland, [5]University Hospital of Psychiatry and Psychotherapy (UPD), University Of Bern, Bern, Switzerland

Patients suffering from functional neurological disorder (FND) present with neurological symptoms not related to an underlying classical neurological disorder. A disrupted sense of agency (SOA) is assumed to be involved in sensorimotor symptom development. The right temporoparietal junction (rTPJ) is a key node of the agency network and has been shown to be a suitable target for neuromodulation of the SOA. The goal of the study is to investigate the effect of a transcranial magnetic stimulation (TMS) over the rTPJ on the SOA in FND patients compared to healthy controls. In a randomized, cross-over, single-blinded trial with active control condition, 23 FND patients and 19 healthy controls were included. In three sessions, every participant underwent excitatory, inhibitory or sham TMS over the rTPJ. Before and after stimulation, participants played a game targeting the SOA during functional magnetic resonance imaging. The game consists of two phases: one with normal SoA (baseline) and one with decreased SoA (turbulence). Preliminary results of whole brain analysis demonstrated that FND patients showed decreased activity in temporoparietal regions compared to healthy controls when contrasting manipulated game-phases versus baseline (p = 0.292, [56 -50 40]). Further, a region-of-interest (ROI) surrounding the subjects' peak activation within a sphere around the rTPJ [62 -34 30] was defined and revealed a lower activation in FND patients compared to controls during turbulence compared to baseline. Further ongoing analyses will determine whether TMS (inhibitory or excitatory) has an effect on these hypoactivation found in patients as well as on behavioural data.

CORRELATIONS BETWEEN THE WHITE MATTER ANISOTROPY AT THE WHOLE-BRAIN SCALE AND ANXIETY RATINGS

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Sergey Kartashov[1], Dina Mitiureva[2,3], Olga Martynova[2,4]
[1]National Research Centre "Kurchatov Institute", Complex Of Nbics Technologies, Moscow, Russian Federation, [2]Institute of Higher Nervous Activity and Neurophysiology of the Russian Academy of Sciences, Laboratory Of Human Higher Nervous Activity, Moscow, Russian Federation, [3]Lomonosov Moscow State University, Department Of Psychology, Moscow, Russian Federation, [4]Higher School of Economics, Centre For Cognition & Decision Making, Moscow, Russian Federation

Diffusion tensor imaging studies of trait anxiety often report that trait anxiety predicts white matter integrity of fiber tracts between frontal regions and the limbic system, e.g. the uncinate fasciculus. However, the whole-brain structural connectivity has been rarely investigated in non-clinical populations despite its particular importance for developing preventive diagnostic markers of pathological anxiety. The aim of the present study was to explore correlations between white matter tracts characteristics and state and trait anxiety inventory (STAI) scores at the whole-brain scale. In addition, we conducted psychological testing twice in order to examine the within-study reproducibility of correlations. The study sample included 25 participants without prior complaints of excess anxiety and clinical history of anxiety disorders. They filled in the STAI twice: one day before and several minutes before the scanning procedure. The 64-direction protocol was applied to obtain diffusion-weighted images. We used the connectometry approach to investigate correlations between the generalized fractional anisotropy (GFA) and STAI scores. Among the reproduced correlations, there were significant associations of both trait and state anxiety self-report ratings with GFA in the corpus callosum and association fibers predominantly in the right hemisphere, including the inferior, superior, and inferior fronto-occipital fasciculus and cingulum bundle. Our findings point to the role of the integrity of these white matter tracts in susceptibility to high trait and state anxiety. The defined local connectome correlations with anxiety ratings could serve as targets for anxiety disorders preventive diagnostics.

A PRECLINICAL MODEL OF COMORBID ANXIETY AND DEPRESSION

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Diána Pejtsik[1], Zoltan K Varga[1], Olga Wronikowska[2], Mano Aliczki[1], Máté Tóth[1], Eva Mikics[1]
[1]Institute of Experimental Medicine, Laboratory Of Translational Behavioral Neuroscience, Budapest, Hungary, [2]Medical University of Lublin, Chair Of Biomedical Sciences, Lublin, Poland

Approximately half of patients diagnosed with major depressive disorder also suffer from co-occurring anxiety. Comorbid patients have more severe symptoms, are more likely to seek pharmacotherapy, which is less effective in their case. The underlying neurobiological factors behind this phenomenon are not well-known, and currently there are no established animal models to support better understanding. Consequently, we aimed to establish a simple, reliable rodent model of comorbidity with high clinical translational validity. Previously, we developed a behavioral sampling protocol to measure trait-anxiety (rather than commonly measured anxious states) involving repeated testing using the most common anxiety tests. Here, we extended this method to preclinical tests of passive coping, a core symptom of major depression. After examining the correlation of anxiety- and depression-related traits, we observed a subpopulation consistently showing high anxiety and passive coping. By increasing test-repetitions and test-types used, we were able to detect stronger associations between anxiety- and depression-like behavior. Next, the animals underwent the Learned Helplessness (LH) model, which induces a depression-like phenotype in vulnerable subpopulations, while also measuring passive coping. Animals showing high anxiety and passive coping prior to LH were more susceptible to developing learned helplessness in the model. Through a semi-supervised machine learning method we have greatly simplified the testing protocol into two tests that reliably predict an animal's coping style in the LH model. In summary, we developed a simple, reliable model of comorbid anxiety and depression, which will help us understand the underlying neurobiological factors, and improve the efficiency of pharmacotherapy treatment.

Conserved Serotonergic Background of Experience-Dependent Behavioral Responsiveness in Zebrafish ().
Forming effective responses to threatening stimuli requires the adequate and coordinated emergence of stress-related internal states. Such ability depends on early-life experiences and, in connection, the adequate formation of neuromodulatory systems, particularly serotonergic signaling. Here, we assess the serotonergic background of experience-dependent behavioral responsiveness using male and female zebrafish (). For the first time, we have characterized a period during behavioral metamorphosis in which zebrafish are highly reactive to their environment. Absence of social stimuli during this phase established by isolated rearing fundamentally altered the behavioral phenotype of postmetamorphic zebrafish in a challenge-specific manner, partially due to reduced responsiveness and an inability to develop stress-associated arousal state. In line with this, isolation differentially affected whole-brain serotonergic signaling in resting and stress-induced conditions, an effect that was localized in the dorsal pallium and was negatively associated with responsiveness. Administration of the serotonin receptor 1A partial agonist buspirone prevented the isolation-induced serotonin response to novelty in the level of the whole brain and the forebrain as well, without affecting catecholamine levels, and rescued stress-induced arousal along with challenge-induced behaviors, which together indicates functional connection between these changes. In summary, there is a consistent negative association between behavioral responsiveness and serotonergic signaling in zebrafish, which is well recognizable through the modifying effects of developmental perturbation and pharmacological manipulations as well. Our results imply a conserved serotonergic mechanism that context-dependently modulates environmental reactivity and is highly sensitive to experiences acquired during a specific early-life time window, a phenomenon that was previously only suggested in mammals. The ability to respond to challenges is a fundamental factor in survival. We show that zebrafish that lack appropriate social stimuli in a sensitive developmental period show exacerbated alertness in nonstressful conditions while failing to react adequately to stressors. This shift is reflected inversely by central serotonergic signaling, a system that is implicated in numerous mental disorders in humans. Serotonergic changes in brain regions modulating responsivity and behavioral impairment were both prevented by the pharmacological blockade of serotonergic function. These results imply a serotonergic mechanism in zebrafish that transmits early-life experiences to the

later phenotype by shaping stress-dependent behavioral reactivity, a phenomenon that was previously only suggested in mammals. Zebrafish provide new insights into early-life-dependent neuromodulation of behavioral stress-responses.

The swimming plus-maze test: a novel high-throughput model for assessment of anxiety-related behaviour in larval and juvenile zebrafish (Danio rerio).
Larval zebrafish (Danio rerio) has the potential to supplement rodent models due to the availability of resource-efficient, high-throughput screening and high-resolution imaging techniques. Although behavioural models are available in larvae, only a few can be employed to assess anxiety. Here we present the swimming plus-maze (SPM) test paradigm, a tool to assess anxiety-related avoidance of shallow water bodies in early developmental stages. The "+" shaped apparatus consists of arms of different depth, representing different levels of aversiveness similarly to the rodent elevated plus-maze. The paradigm was validated (i) in larval and juvenile zebrafish, (ii) after administration of compounds affecting anxiety and (iii) in differentially aversive experimental conditions. Furthermore, we compared the SPM with conventional "anxiety tests" of zebrafish to identify their shared characteristics. We have clarified that the preference of deeper arms is ontogenetically conserved and can be abolished by anxiolytic or enhanced by anxiogenic agents, respectively. The behavioural readout is insensitive to environmental aversiveness and is unrelated to behaviours assessed by conventional tests involving young zebrafish. Taken together, we have developed a sensitive high-throughput test allowing the assessment of anxiety-related responses of zebrafish regardless of developmental stage, granting the opportunity to combine larva-based state-of-the-art methods with detailed behavioral analysis.

INVOLVEMENT OF METHYL-CPG BINDING PROTEIN 2 IN VULNERABILITY TO POST-TRAUMATIC STRESS DISORDER: FROM MICE TO (WO)MEN

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Livia Cosentino[1,2], Herta Flor[2], Bianca De Filippis[1]
[1]Istituto Superiore di Sanità, Center Of Reference For Behavioral Sciences And Mental Health, Roma, Italy, [2]Central Institute of Mental Health, Institute Of Cognitive And Clinical Neuroscience, Mannheim, Germany

Aims: post-traumatic stress disorder (PTSD) is a mental disorder characterized by symptoms of persistent anxiety arising after trauma exposure in vulnerable individuals. Considering the emerging functions of epigenetics in establishing interindividual differences in PTSD risk, we aimed at translationally addressing the contribution of the X-linked epigenetic regulator Methyl-CpG binding protein 2 (MECP2) in shaping susceptibility to traumatic stress. **Methods:** predisposition to the onset of PTSD-like symptomatology was evaluated in mice carrying hypofunctional MeCP2; the association between peripheral *MECP2* expression and psychometric measures of vulnerability to stress and traumas was assessed in human cohorts. **Results:** after footshock delivery, mutant males displayed lasting cognitive, avoidance and arousal symptoms, mimicking PTSD psychopathology; sex-dependent modulations in stress responsivity were evident, with mutant females releasing lower and males higher glucocorticoids levels compared to controls. In non-traumatized healthy participants *MECP2* underexpression was accompanied by the maladaptive outcomes of childhood adversities, a well-known PTSD risk factor; similarly, in participants exposed to childhood stress and traumatized in adulthood, *MECP2* underexpression paralleled increased PTSD symptom severity. In both cohorts, the association was stronger in women than in men. **Conclusion:** the present results support the relevance of MECP2 hypofunctionality in boosting PTSD risk, suggesting that MECP2-related epigenetic pathways are involved in disease etiology. Gender and exposure to childhood adversities emerge as important factors involved in the association between MECP2 and PTSD susceptibility. Chronic treatment with the phytocannabinoid Cannabidivarin (CBDV) rescues behavioural alterations and brain atrophy in a mouse model of Rett syndrome.
Rett syndrome (RTT) is a rare neurodevelopmental disorder, characterized by severe behavioural and physiological symptoms. RTT is caused by mutations in the MECP2 gene in about 95% of cases and to date no cure is available. The endocannabinoid system modulates several physiological processes and behavioural responses that are impaired in RTT and its deregulation has been associated with neuropsychiatric disorders which have symptoms in common with RTT. The present study evaluated the potential therapeutic efficacy for RTT of cannabidivarin (CBDV), a non-psychotropic phytocannabinoid from Cannabis sativa that presents antagonistic properties on the G protein-coupled receptor 55 (GPR55), the most recently identified cannabinoid receptor. Present results demonstrate that systemic treatment with CBDV (2, 20, 100 mg/Kg ip for 14 days) rescues behavioural and brain alterations in MeCP2-308 male mice, a validated RTT model. The CBDV treatment restored the compromised general health status, the sociability and the brain weight in RTT mice. A partial restoration of motor coordination was also observed. Moreover, increased levels of GPR55 were found in RTT mouse hippocampus, suggesting this G protein-coupled receptor as new potential target for the treatment of this disorder. Present findings highlight for the first time for RTT the translational relevance of CBDV, an innovative therapeutic agent that is under active investigation in the clinical setting.

Rescue of prepulse inhibition deficit and brain mitochondrial dysfunction by pharmacological stimulation of the central serotonin receptor 7 in a mouse model of CDKL5 Deficiency Disorder.
Mutations in the X-linked cyclin-dependent kinase-like 5 (CDKL5) gene cause CDKL5 Deficiency Disorder (CDD), a rare

neurodevelopmental syndrome characterized by severe behavioural and physiological symptoms. No cure is available for CDD. CDKL5 is a kinase that is abundantly expressed in the brain and plays a critical role in neurodevelopmental processes, such as neuronal morphogenesis and plasticity. This study provides the first characterization of the neurobehavioural phenotype of 1 year old Cdkl5-null mice and demonstrates that stimulation of the serotonin receptor 7 (5-HTR) with the agonist molecule LP-211 (0.25 mg/kg once/day for 7 days) partially rescues the abnormal phenotype and brain molecular alterations in Cdkl5-null male mice. In particular, LP-211 treatment completely normalizes the prepulse inhibition defects observed in Cdkl5-null mice and, at a molecular level, restores the abnormal cortical phosphorylation of rpS6, a downstream target of mTOR and S6 kinase, which plays a direct role in regulating protein synthesis. Moreover, we demonstrate for the first time that mitochondria show prominent functional abnormalities in Cdkl5-null mouse brains that can be restored by pharmacological stimulation of brain 5-HTR.

Rett syndrome before regression: A time window of overlooked opportunities for diagnosis and intervention.
Rett syndrome (RTT) is a rare neurological disorder primarily affecting females, causing severe cognitive, social, motor and physiological impairments for which no cure currently exists. RTT clinical diagnosis is based on the peculiar progression of the disease, since patients show an apparently normal initial development with a subsequent sudden regression at around 2 years of age. Accumulating evidences are rising doubts regarding the absence of early impairments, hence questioning the concept of regression. We reviewed the published literature addressing the pre-symptomatic stage of the disease in both patients and animal models with a particular focus on behavioral, physiological and brain abnormalities. The emerging picture delineates subtle, but reliable impairments that precede the onset of overt symptoms whose bases are likely set up already during embryogenesis. Some of the outlined alterations appear transient, suggesting compensatory mechanisms to occur in the course of development. There is urgent need for more systematic developmental analyses able to detect early pathological markers to be used as diagnostic tools and precocious targets of time-specific interventions.

Methyl-CpG binding protein 2 functional alterations provide vulnerability to develop behavioral and molecular features of post-traumatic stress disorder in male mice.
Post-traumatic stress disorder (PTSD) is a mental disorder characterized by symptoms of persistent anxiety arising after exposure to traumatic events. Stress susceptibility due to a complex interplay between genetic and environmental factors plays a major role in the disease etiology, although biological underpinnings have not been clarified. We hypothesized that aberrant functionality of the methyl-CpG binding protein 2 (MECP2), a master regulator of experience-dependent epigenetic programming, confers susceptibility to develop PTSD-like symptomatology in the aftermath of traumatic events. Transgenic male mice expressing a truncated form of MeCP2 protein (MeCP2-308) were exposed at adulthood to a trauma in the form of high-intensity footshocks. The presence and duration of PTSD-like symptoms were assessed and compared to those of trauma-exposed wild type littermates and MeCP2-308 mice subjected to a mild stressor. The effects of fluoxetine, a prime pharmacological PTSD treatment, on PTSD-like symptomatology were also explored. Trauma-exposed MeCP2-308 mice showed long-lasting hyperresponsiveness to both correct and incorrect predictors of the trauma and persistent increased avoidance of trauma-related cues. Traumatized MeCP2-308 mice also displayed abnormal post-traumatic plasma levels of the stress hormone corticosterone and altered peripheral gene expression mirroring that of PTSD patients. Fluoxetine improved PTSD-like symptoms in trauma-exposed MeCP2-308 mice. These findings provide evidence that MeCP2 dysfunction results in increased susceptibility to develop PTSD-like symptoms after trauma exposure, and identify trauma-exposed MeCP2-308 mice as a new tool to investigate the underpinnings of PTSD vulnerability.

Chronic Treatment with Cannabidiolic Acid (CBDA) Reduces Thermal Pain Sensitivity in Male Mice and Rescues the Hyperalgesia in a Mouse Model of Rett Syndrome.
Rett syndrome (RTT) is a rare neurologic disorder, characterized by severe behavioural and physiological symptoms. RTT is caused by mutations in the MECP2 gene in about 95% of cases and to date no cure is available. Recent evidence suggests that non-euphoric phytocannabinoids (pCBs) extracted from Cannabis sativa may represent innovative therapeutic molecules for RTT, with the cannabinoid cannabidivarin having beneficial effects on behavioural and brain molecular alterations in RTT mouse models. The present study evaluated the potential therapeutic efficacy for RTT of cannabidiolic acid (CBDA; 0.2, 2, 20 mg/kg through intraperitoneal injections for 14 days), a pCB that has proved to be effective for the treatment of nausea and anxiety in rodents. This study demonstrates that systemic treatment with the low dose of CBDA has anti-nociceptive effects and reduces the thermal hyperalgesia in 8 month-old MeCP2-308 male mice, a validated RTT mouse model. CBDA did not affect other behavioural or molecular parameters. These results provide support to the antinociceptive effects of CBDA and

stress the need for further studies aimed at clarifying the mechanisms underlying the abnormal pain perception in RTT. Neuroscience, 2021; 453

The Anti-Diabetic Drug Metformin Rescues Aberrant Mitochondrial Activity and Restrains Oxidative Stress in a Female Mouse Model of Rett Syndrome.

Metformin is the first-line therapy for diabetes, even in children, and a promising attractive candidate for drug repurposing. Mitochondria are emerging as crucial targets of metformin action both in the periphery and in the brain. The present study evaluated whether treatment with metformin may rescue brain mitochondrial alterations and contrast the increased oxidative stress in a validated mouse model of Rett syndrome (RTT), a rare neurologic disorder of monogenic origin characterized by severe behavioral and physiological symptoms. No cure for RTT is available. In fully symptomatic RTT mice (12 months old MeCP2-308 heterozygous female mice), systemic treatment with metformin (100 mg/kg ip for 10 days) normalized the reduced mitochondrial ATP production and ATP levels in the whole-brain, reduced brain oxidative damage, and rescued the increased production of reactive oxidizing species in blood. A 10-day long treatment with metformin also boosted pathways related to mitochondrial biogenesis and antioxidant defense in the brain of metformin-treated RTT mice. This treatment regimen did not improve general health status and motor dysfunction in RTT mice at an advanced stage of the disease. Present results provide evidence that systemic treatment with metformin may represent a novel, repurposable therapeutic strategy for RTT.

Stimulation of the Serotonin Receptor 7 Restores Brain Histone H3 Acetylation and MeCP2 Corepressor Protein Levels in a Female Mouse Model of Rett Syndrome.

Rett syndrome (RTT) is a rare neurological disorder caused by mutations in the X-linked MECP2 gene, characterized by severe behavioral and physiological impairments for which no cure is available. The stimulation of serotonin receptor 7 (5-HT7R) with its selective agonist LP-211 (0.25 mg/kg/day for 7 days) was proved to rescue neurobehavioral alterations in a mouse model of RTT. In the present study, we aimed at gaining insight into the mechanisms underpinning the efficacy of 5-HT7R pharmacological stimulation by investigating its epigenetic outcomes in the brain of RTT female mice bearing a truncating MeCP2 mutation. Treatment with LP-211 normalized the reduced histone H3 acetylation and HDAC3/NCoR levels, and increased HDAC1/Sin3a expression in RTT mouse cortex. Repeated 5-HT7R stimulation also appeared to strengthen the association between NCoR and MeCP2 in the same brain region. A different profile was found in RTT hippocampus, where LP-211 rescued H3 hyperacetylation and increased HDAC3 levels. Overall, the present data highlight a new scenario on the relationship between histone acetylation and serotoninergic pathways. 5-HT7R is confirmed as a pivotal therapeutic target for the recovery of neuronal function supporting the translational value of this promising pharmacological approach for RTT.

Methyl-CpG binding protein 2 dysfunction provides stress vulnerability with sex- and zygosity-dependent outcomes.

Stress vulnerability is a critical factor for the development of trauma-related disorders; however, its biological underpinnings are not clear. We demonstrated that dysfunctions in the X-linked epigenetic factor methyl-CpG binding protein 2 (MeCP2) provide trauma vulnerability in male mice. Given the prominent role of sex in stress outcomes, we explored the effects of MeCP2 hypofunctionality in females. Female mice carrying truncated MeCP2 (heterozygous and homozygous) and wild type controls (wt) were tested for fear memory. Stress-induced corticosterone release and brain expression of hypothalamic-pituitary-adrenal (HPA) axis regulatory genes were also evaluated in wt and mutant mice of both sexes. Although heterozygous females displayed a normal stress-related behavioural profile, homozygous mice showed enhanced memory recall for the threatening context compared to wt, thus recapitulating the phenotype previously evidenced in hemizygous males. Interestingly, MeCP2 truncation abolished the sex differences in stress-induced corticosterone release, which was found increased in mutant males, whereas blunted in mutant females in a zygosity-independent manner. Although heterozygous mice did not differ from controls, homozygous females and hemizygous males showed increased hypotalamic Crh and Avp mRNAs and a differentially altered expression of Fkbp5 in cortical areas. Present results demonstrate that in female mice carrying truncated MeCP2, altered stress responsivity is driven by homozygosity, whereas heterozygosity does not lead to maladaptive stress outcomes. MeCP2 dysfunctions thus provide stress vulnerability in mice with sex- and zygosity-dependent outcomes.

Treatment with the Bacterial Toxin CNF1 Selectively Rescues Cognitive and Brain Mitochondrial Deficits in a Female Mouse Model of Rett Syndrome Carrying a MeCP2-Null Mutation.
Rett syndrome (RTT) is a rare neurological disorder caused by mutations in the X-linked gene and a major cause of intellectual disability in females. No cure exists for RTT. We previously reported that the behavioural phenotype and brain mitochondria dysfunction are widely rescued by a single intracerebroventricular injection of the bacterial toxin CNF1 in a RTT mouse model carrying a truncating mutation of the gene (MeCP2-308 mice). Given the heterogeneity of mutations in RTT patients, we tested the CNF1 therapeutic efficacy in a mouse model carrying a null mutation (MeCP2-Bird mice). CNF1 selectively rescued cognitive defects, without improving other RTT-related behavioural alterations, and restored brain mitochondrial respiratory chain complex activity in MeCP2-Bird mice. To shed light on the molecular mechanisms underlying the differential CNF1 effects on the behavioural phenotype, we compared treatment effects on relevant signalling cascades in the brain of the two RTT models. CNF1 provided a significant boost of the mTOR activation in MeCP2-308 hippocampus, which was not observed in the MeCP2-Bird model, possibly explaining the differential effects of CNF1. These results demonstrate that CNF1 efficacy depends on the mutation beared by MeCP2-mutated mice, stressing the need of testing potential therapeutic approaches across RTT models.

Genes and sex hormones interaction in neurodevelopmental disorders.
The prevalence, age of onset and symptomatology of many neurodevelopmental disorders strongly differ between genders. This review examines sex biases in human neurodevelopmental disorders and in validated animal models. A focus is made on disorders of well-established genetic origin, such as Rett syndrome, CDKL5-associated disorders, Fragile X and Down syndrome. Autism is also addressed, given its paradigmatic role as a sex-biased neurodevelopmental disorder. Reviewed literature confirms that a complex interaction between genetic factors and sex hormones may underlie the differential susceptibility of genders and may impact the severity of symptoms in most of the analyzed neurodevelopmental disorders. Even though further studies addressing the advantages and disadvantages conferred by biological sex in this class of disorders are needed to disentangle the underlying mechanisms, present findings suggest that modulation of sex steroid-related pathways may represent an innovative approach for these diseases. Much effort is now expected to unravel the potential therapeutic efficacy of drugs targeting sex hormones-related signaling pathways in neurodevelopmental disorders of well-established genetic origin.

USING THE HEART RATE AS A SENSOR TO DETECT EVOKED RESPONSES OF THE AUTONOMOUS NERVOUS SYSTEM IN BRAIN-HEART COMMUNICATIONS

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Harish Kambampati
Tor Vergata University of Rome, Department Of Industrial Engineering, Room No:3158, Roma, Italy

Abstract: Observing the instantaneous heart rate variability (HRV) under the sympathetic nervous system while watching scary, thrill, suspense and action videos that influence cardiac muscle activities that trigger automatic physiological reactions. We took males and females aged between 20-60 as subjects, we attached one lead IOT based wireless-enabled ECG to subjects V1 and V2 positions(**V1 is placed to the right of the sternal border, and V2 is placed at the left of the sternal border)** on the chest and recorded the ECG signal data, while they are watching videos which have scary and action scenes at different time intervals and the data were analyzed and observed in MATLAB. Every subject shows a normal heart rate While watching the pleasant and sudden high Heart rate appears at the scary scenes. After detecting the evoked responses at the particular time interval, It matches the scary clip or stressful or action scenes appears, we can understand that Vagus nerve stimulation occurs under the sympathetic nervous system when this subject is in stress or fear conditions. Results are surprisingly reliable and this method can be extended to many other signals whose frequency is changing over time. We used one lead ECG inbuilt with Bluetooth attached to a strap containing two electrodes. “MOVESENSE” IOS Application to record the data from subjects. MATLAB R2021b for analyzing ECG data and Microsoft Excel, IOS Device and Laptop **Keywords:** Heart rate variability (HRV), Autonomous nervous system (ANS) Sympathetic nervous system (SNS), Parasympathetic nervous system (PNS) ECG, Vagus nerve, MATLAB.

CONSEQUENCES OF THE LACK OF ONE OR MULTIPLE DYSTROPHIN ISOFORMS ON COGNITION AND BEHAVIOUR IN PREDNISOLONE TREATED MOUSE MODELS OF DUCHENNE MUSCULAR DYSTROPHY

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Minou Verhaeg, Davy Van De Vijver, Christa Tanganyika-De Winter, Tiberiu Stan, Annemieke Aartsma-Rus, Maaike Van Putten
Leiden University Medical Centre, Human Genetics, Leiden, Netherlands

Duchenne muscular dystrophy (DMD) is a recessive X-linked neuromuscular disorder. Next to severe muscle wasting, patients present with cognitive impairments. Several dystrophin isoforms are expressed in the brain. A correlation between the amount of missing isoforms and cognitive problems has been found in DMD patients, however knowledge about this correlation in mouse models is limited. Standards of care of patients includes corticosteroid treatment, prednisolone (PDN). PDN influences cognition in healthy individuals. The effects of chronic PDN treatment on cognition has not been investigated yet in DMD patients or mouse models. To investigate this, C57BL/6J (WT), *mdx* (lacking Dp427) and *mdx*^{4cv}(lacking Dp427+Dp140) males aged 7 weeks were treated with PDN or placebo and subjected to behavioural tests to analyse anxiety, fear and learning for a duration of 9 weeks. *Mdx*^{4cv} mice showed a more severe anxiety phenotype compared to *mdx* in the open field and dark light box. Both *mdx* and *mdx*^{4cv} males showed an increased fear response in the restraint unconditioned fear test compared to WTs, however no differences were observed between the DMD strains. Chronic PDN treatment did not seem to affect anxiety or fear response in de DMD strains. Results of the memory tasks are still being analysed. These results confirm that also in mice, the amount of missing isoform correlates with the severity of cognitive problems. PDN treatment does not seem to increase anxiety or the fear response. Further analyses will show whether or not the missing isoforms or PDN affect other cognitive processes.

KG, Cns Diseases, ngelheim am Rhein, Germany, [4]Boehringer Ingelheim Pharma GmbH & Co. KG, Cns Diseases, Biberach an der Riss, Germany

Commonly used tasks for studying behaviour akin to fear and anxiety in rodent models are pavlovian threat conditioning and the elevated plus maze (EPM) respectively. These two tasks have been used extensively, yet research into whether they interact is scarce. AIMS: We investigated whether recall of an aversive memory, across contextual, odour or auditory modalities, would potentiate anxiety-like behaviour in the elevated plus maze. METHODS: To better characterize potential impacts of prior aversive experience on EPM performance a series of experiments were carried out that systematically varied the time since stimulus presentation and the modality of the conditioning stimulus. Furthermore, we examined whether the EPM measurements taken days before or after threat conditioning measurements held any relationship to conditioned freezing or production of ultrasonic alarm calls. RESULTS: The data did not support that memory recall, even over a series of timepoints, could influence EPM behaviour. Furthermore, there was no correlation between EPM behaviour and conditioned freezing in independent cohorts tested in the EPM before or after auditory threat conditioning. Further analysis found the production of 22kHz ultrasonic vocalisations revealed the strongest responders to a conditioned threat cue. CONCLUSIONS: These results are of particular importance for consideration when using the EPM and threat conditioning to identify individual differences, and the possibility to use the tasks in batteries of tests without cross-task interference. These presented findings call for caution in generalisation of interpretations from the typical range of behaviour in the EPM across other aversively motivated tasks.

THE EFFECT OF THE SOCIAL ISOLATION STRESS ON FEAR EXTINCTION – THE ROLE OF THE DOPAMINERGIC AND ENDOGENOUS OPIOID NEUROTRANSMISSION

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Aleksandra Wisłowska-Stanek[1], Małgorzata Lehner[2], Anna Skórzewska[2], Filip Tomczuk[3], Anna Sułek[3], Adriana Wawer[1], Karolina Kołosowska[2]
[1]Medical University of Warsaw, Department Of Experimental And Clinical Pharmacology, Warsaw, Poland, [2]Institute of Psychiatry and Neurology, Department Of Neurochemistry, Warsaw, Poland, [3]Institute of Psychiatry and Neurology, Department Of Genetics, Warsaw, Poland

Aims: The aim of the study was to assess the influence of the recurrent social isolation stress on the aversive memory extinction as well as dopaminergic, endogenous opioid neurotransmission in the amygdala. Methods: Male Wistar rats were aversively conditioned and then exposed to three extinction sessions. The control group was only exposed to experimental cage. The conditioned animals were divided into two groups – extinguished group and socially isolated extinguished group. The stressed animals were socially isolated for 48 h before each extinction. After the last exposition to the aversive context, expression of dopamine type 2 (D2) receptors in the subnuclei of the amygdala (immunocytochemistry), KOR expression and D2 (mRNA) and epigenetic factors (miRNA-128 and miRNA-142) in the amygdala were analyzed. Moreover, the levels of beta-endorphin and corticosterone were evaluated in the plasma (ELISA). Results: Social isolation stress decreased the fear extinction rate. After third exposition to aversive context socially isolated animals were characterized by higher expression of D_2 receptors in the basal amygdala compared to controls. Socially isolated extinguished rats were characterized by lower KOR expression in amygdala and plasma beta-endorphins level compared to control group. Moreover, extinguished rats presented lower levels of miRNA-128 and miRNA-142 in the amygdala compared to control and isolated extinguished animals. Conclusions: Observed changes suggest that social isolation stress is an important factor that impairs aversive memory extinction via affecting dopaminergic neurotransmission, endogenous opioid system and epigenetic mechanisms in the amygdala. The study was supported by Grant No 2018/28/C/NZ7/00240, National Science Centre, Krakow, Poland.

INVESTIGATING THE ROLE OF CEREBELLAR ENDOCANNABINOIDS IN CONDITIONED FEAR EXTINCTION

POSTER SESSION 06 - SECTION: NEUROBIOLOGY OF FEAR AND ANXIETY

Fernando Senovilla Sanz[1], Vasiliki Spatharioti[1], Bridget Lump[1], Richard Apps[2], Charlotte Lawrenson[1]
[1]University of Bristol, School Of Physiology, Pharmacology & Neuroscience, Bristol, United Kingdom, [2]University of Bristol, School Of Physiology, Pharmacology And Neuroscience, Bristol, United Kingdom

Anxiety disorders can be associated with an individual's inability to extinguish the memory of a conditioned fear response. Endocannabinoids are known to be involved in fear extinction. The cerebellum has also been implicated in fear extinction and its cortex contains the highest density of CB1 receptors. However, the role of endocannabinoids in the cerebellum in relation to fear extinction has not been fully investigated. To assess heterogeneity of behavioural responses during fear extinction, male Sprague Dawley rats (n=12), were tested in an auditory cued fear conditioning paradigm over three days consisting of conditioning, extinction and extinction retention testing. Consistent with previous studies we found that individual animals extinguish their freezing response on different time scales indicating behavioural heterogeneity in fear responses. To investigate the contribution of the endocannabinoid system in the cerebellar cortex the synthesis of the 2 major endocannabinoids, anandamide and 2-AG, were decreased by inhibiting the enzymes NAPE-PLD and DAGL using combined LEI-401 and DO34 respectively, prior to extinction. Animals (n = 16) were implanted with single cannula targeting lobules V/VI of the midline cerebellar vermal cortex to deliver the drugs or vehicle control. Here we present preliminary findings comparing drugs vs vehicle control on the effect of freezing and ultrasonic vocalisations in extinction and extinction retention.

DIVERSE ROLES OF THE VARIOUS NEURONAL CLASSES IN THE PRELIMBIC CORTEX IN SOCIAL BONDING

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Anna Bryksa[1], Maciej Winiarski[1], Joanna Borowska[2], Szymon Łęski[3], Joanna Jędrzejewska-Szmek[3], Ewelina Knapska[1], Alicja Puścian[1]
[1]Nencki Institute, Polish Academy of Sciences, Center Of Excellence For Neural Plasticity And Brain Disorders: Braincity, A Nencki-embl Partnership, Warsaw, Poland, [2]Nencki Institute of Experimental Biology Polish Academy of Sciences, Laboratory Of Emotions Neurobiology, Warsaw, Poland, [3]Nencki Institute of Experimental Biology PAS, Laboratory Of Neuroinformatics, Warsaw, Poland

Although many studies indicate a crucial role of the prefrontal cortex (PFC) in social attachment, the involvement of various neuronal classes in that process remains unexplored. Thus, we investigated the effects of the chemogenetic manipulation of the pyramidal neurons (PNs), as well as inhibitory interneurons expressing parvalbumin (PV+), somatostatin (SOM+) and vasoactive intestinal peptide (VIP+) in the prelimbic part (PL) of the PFC, on the spontaneous social interactions with familiar conspecifics. Animals were tested in Eco-HAB, an ecologically relevant, RFID-based system for assessment of spontaneous social behavior in group-housed mice. Using genetically modified mice combined with the PSAM/PSEM-based chemogenetic approach, we performed a time-constrained, cell-specific manipulations in the PL. We tested subjects' social behavior after the systemic administration of the drug (PSEM) activating virally introduced artificial ligand-gated ion channels (PSAM) on the specific cell class. We show that PL-constrained inhibition of the PNs, as well as activation of the PV+ interneurons attenuates sociability by decreasing the time voluntarily spend together. Notably, activating SOM+ and VIP+ cells has no impact on social bonding. Further, alongside the loss of interest in interacting with familiar conspecifics inhibition of the PNs leads to hiper interest in novel social stimuli. Notably, such behavior upon activation of the PV+ and VIP+ interneurons, while the opposite effect, loss of interest in social novelty, is observed when SOM+ cells are activated. Presented data illustrates the diverse roles various neuronal classes play in social bonding and points to the distinct neural underpinnings of processing familiar and novel social stimuli.

Ability to share emotions of others as a foundation of social learning.
The natural habitats of most species are far from static, forcing animals to adapt to continuously changing conditions. Perhaps the most efficient strategy addressing this challenge consists of obtaining and acting upon pertinent information from others through social learning. We discuss how animals transfer information via social channels and what are the benefits of such exchanges, playing out on different levels, from theperception of socially delivered information to emotional sharing, manifesting themselves across different taxa of increasing biological complexity. We also discuss how social learning is influenced by different factors including pertinence of information for survival, the complexity of the environment, sex, genetic relatedness, and most notably, the relationship between interacting partners. The results appear to form a consistent picture once we shift our focus from emotional contagion as a prerequisite for empathy onto the role of shared emotions in providing vital information about the environment. From this point of view, we can propose approaches that are the most promising for further investigation of complex social phenomena, including learning from others.

Loss of mu and delta opioid receptors on neurons expressing dopamine receptor D1 has no effect on reward sensitivity.
Opioid signaling controls the activity of the brain's reward system. It is involved in signaling the hedonic effects of rewards and has essential roles in reinforcement and motivational processes. Here, we focused on opioid signaling through mu and delta receptors on dopaminoceptive neurons and evaluated the role these receptors play in reward-driven behaviors. We generated a genetically modified mouse with selective double knockdown of mu and delta opioid receptors in neurons expressing dopamine receptor D1. Selective expression of the transgene was confirmed using immunostaining. Knockdown was validated by measuring the effects of selective opioid receptor agonists on neuronal membrane currents using whole-cell

patch clamp recordings. We found that in the nucleus accumbens of control mice, the majority of dopamine receptor D1-expressing neurons were sensitive to a mu or delta opioid agonist. In mutant mice, the response to the delta receptor agonist was blocked, while the effects of the mu agonist were strongly attenuated. Behaviorally, the mice had no obvious impairments. The mutation did not affect the sensitivity to the rewarding effects of morphine injections or social contact and had no effect on preference for sweet taste. Knockdown had a moderate effect on motor activity in some of the tests performed, but this effect did not reach statistical significance. Thus, we found that knocking down mu and delta receptors on dopamine receptor D1-expressing cells does not appreciably affect some of the reward-driven behaviors previously attributed to opioid signaling.

AN EXTENDED AMYGDALA-HABENULA CIRCUIT FOR PARENTAL BEHAVIOURS

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Salvatorre Lecca[1], Mauro Congiu[1], Léa Royon[1], Leonardo Restivo[1], Benoît Girard[2], Noémie Mazaré[1], Camilla Bellone[3], Ludovic Telley[1], Manuel Mameli[1]

Parental behaviours are vital for the optimal development of newborns. Importantly, these behaviours are preserved across species and their correct execution requires the wiring of highly-conserved neuronal circuits. Accordingly, published studies depicted the lateral habenula (LHb) as a region embedded in the parental neuronal network and contributing to parental behaviours, although the functional understanding of its participation in parenting remains unknown. Here, we monitored virgin female mice exposed to foreign pups while employing single-cell calcium imaging, viral-based circuit mapping and genetic approaches. Virgin females display stereotypical parental behaviours including grooming, nest building and retrieval of the pup to a nest. Single-cell microendoscopic calcium imaging shows that a territorially-segregated cluster of LHb cells increased their activity during pup retrieval. We further demonstrate that this population is defined by its excitatory input from the bed nucleus of the stria terminalis (^{BNST}LHb), a central node in the parental circuit. Accordingly, optogenetic activation and inhibition of BNST axons in the LHb promoted and impaired pup retrieval, respectively. Merging imaging of BNST-recipient LHb neurons with decoding analysis highlights specific processing of pup retrieval. Finally, we interrogated the transcriptome of ^{BNST}LHb cells in virgin female mice to reveal i. genetic signatures consistent with a role in parental behaviours and ii. a gene expression similar to mothers but divergent from non-parental virgin male mice. Altogether this study uncovers a neuronal circuit element fundamental for specific parental behaviours.

BRAIN CODING OF MATERNAL BEHAVIOUR: ROLE OF THE TAIL OF THE VENTRAL TEGMENTAL AREA

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Clara Pérez-Gozalbo, Manuela Barneo-Muñoz, Fernando Martínez-García, María José Sánchez-Catalán
Universitat Jaume I, Unitat Predepartamental De Medicina, Facultat De Ciències De La Salut, Castellón de la Plana, Spain

Maternal behaviour entails an increased motivation for pups, which is reflected in a reward-related response occurring in females when pups are present. Motivated behaviours are critically dependent on brain dopamine systems. Thus, understanding its functioning is necessary to elucidate how motivation and reinforcement occur in the brain in response to drugs of abuse or natural rewards, such as social/maternal rewards. The activity of dopaminergic pathways mainly depends on the excitatory and inhibitory balance exerted by glutamatergic and GABAergic afferents to dopamine cells, respectively. The tail of the ventral tegmental area (tVTA) or rostromedial tegmental nucleus (RMTg), is a major inhibitory control center of dopamine midbrain cells, whose integration in reward and aversion brain circuits has been accepted, however there is no evidence of its involvement in social or maternal reward. Thus, in the present study, we explored the role of the activity of the tVTA/RMTg in maternal behaviour in rats. To this end, pregnant Sprague-Dawley female rats underwent stereotaxic implantation of a guide cannula through the tVTA/RMTg (E15-E18). During the first week after delivery, female rats underwent intra-tVTA/RMTg microinjections of vehicle and/or several pharmacological agents (glutamate, DAMGO or muscimol) in a cross-design, in order to explore the impact of the tVTA/RMTg activity (activation and/or inhibition) on maternal behaviour in rats. Our results revealed an involvement of the tVTA/RMTg in maternal reward processing and suggest a possible role of this brain region in the development of maternal behaviour. Multiple system atrophy-associated oligodendroglial protein p25α stimulates formation of novel α-synuclein strain with enhanced neurodegenerative potential.
Pathology consisting of intracellular aggregates of alpha-Synuclein (α-Syn) spread through the nervous system in a variety of neurodegenerative disorders including Parkinson's disease, dementia with Lewy bodies, and multiple system atrophy. The discovery of structurally distinct α-Syn polymorphs, so-called strains, supports a hypothesis where strain-specific structures are templated into aggregates formed by native α-Syn. These distinct strains are hypothesised to dictate the spreading of pathology in the tissue and the cellular impact of the aggregates, thereby contributing to the variety of clinical phenotypes. Here, we present evidence of a novel α-Syn strain induced by the multiple system atrophy-associated oligodendroglial protein p25α. Using an array of biophysical, biochemical, cellular, and in vivo analyses, we demonstrate that compared to α-Syn alone, a substoichiometric concentration of p25α redirects α-Syn aggregation into a unique α-Syn/p25α strain with a different structure and enhanced in vivo prodegenerative properties. The α-Syn/p25α strain induced larger inclusions in human dopaminergic neurons. In vivo, intramuscular injection of preformed fibrils (PFF) of the α-Syn/p25α strain compared to α-Syn PFF resulted in a shortened life span and a distinct anatomical distribution of inclusion pathology in the brain of a human A53T transgenic (line M83) mouse. Investigation of α-Syn aggregates in brain stem extracts of end-stage mice demonstrated that the more aggressive phenotype of the α-Syn/p25α strain was associated with an increased load of α-Syn aggregates based on a Förster resonance energy transfer immunoassay and a reduced α-Syn aggregate seeding activity based on a protein misfolding cyclic amplification assay. When injected unilaterally into the striata of wild-type mice, the α-Syn/p25α strain resulted in a more-pronounced motoric phenotype than α-Syn PFF and exhibited a "tropism" for nigro-striatal neurons compared to α-Syn PFF. Overall, our data support a hypothesis whereby oligodendroglial p25α is responsible for generating a highly prodegenerative α-Syn strain in multiple system atrophy.

INVESTIGATING THE ROLE OF THE DORSAL AND VENTRAL HIPPOCAMPUS IN MICE EMPATHY AND HELPING BEHAVIOUR

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Ada Braun[1], Charitha Omprakash[1], Endre Marosi[2], Pavol Bauer[2], Sanja Mikulovic[1]
[1]Leibniz Institute for Neurobiology Magdeburg, Cognition And Emtion Research Group, Magdeburg, Germany, [2]Leibniz Institute für Neurobiologie, Cognition And Emotion Research Group, MAGDEBURG, Germany

Empathy and helping behaviour are century-old psychological concepts, traditionally attributed solely to humans, but the underlying cognitive and emotional brain mechanisms are poorly understood. Increasing research evidence shows rodents also being capable of displaying empathy and helping each other. While the majority of the rodent studies were performed in rats, it has been more debatable whether mice display helping to a similar extent and which brain regions are governing this type of behaviour. We here show that helping behaviour is prominent in mice too and discuss the effect of stress, familiarity, gender and social hierarchy on the willingness to help. We further sought to understand the role of the dorsal and ventral hippocampal subregions, known to be involved in cognitive and emotional information processing respectively, in innate and learned helping. Using microendoscopic Calcium imaging, we recorded activity in the “helpers” while liberating a “victim”, over multiple days and additional control conditions. We found a subpopulation of cells that was robustly tuned for a heading angle that was facing towards the victim (+/- 10 degrees) throughout the recording, as well as during active attempts to help. We analysed how the cells activity changes during the course of learning, and compared the coding in the dorsal and ventral hippocampal subregions. These results indicate that hippocampal subregions play an important role in innate and learned helping behaviour in mice. Ongoing work investigating the causal relationship between the dorsoventral hippocampal axis and helping behaviour will be discussed.

MOTIVATION STATES THAT PROMOTE MATERNAL BEHAVIORS IN MICE

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Habon Issa[1], Silvana Valtcheva[2], Robert Froemke[1]
[1]NYU Grossman School of Medicine, Skirball/Neuroscience Institutes, Departments Of Otolaryngology/neuroscience And Physiology, New York, United States of America, [2]University of Cologne, Faculty Of Medicine, Cologne, Germany

Maternal motivation enables heightened responsivity of mothers towards offspring. While this motivational state is critical to infant survival, little is known about its regulation. Previous work in maternal rodents demonstrates that lesioning ventral tegmental area (VTA) dopamine neurons disrupts maternal motivated behaviors; and these behaviors are restored by manipulating pup sensory salience (i.e., by increasing pup cries) and maternal states (Hansen 1994 Physiol Behav). Additionally, the neurohormone oxytocin is known to convey pup sensory information to VTA (Valtcheva et al., 2021, bioRxiv) and promote VTA-mediated maternal behaviors. We aim to elucidate how infant sensory information and motivation states of the mother are integrated in VTA dopamine neurons to determine the overall levels of maternal motivation that drive context-specific offspring care. We manipulated maternal states by separating mothers (dams) from their litters for several hours. We observed that following separation, dams exhibit a short latency to approach returned pups and prolonged, continuous bouts of crouching over and nursing pups, indicating heightened levels of maternal motivation. Using this behavioral protocol, we observed a significant ($p=0.003$) increase in the density of cFOS+ neurons in the VTA of dams that were separated from their litters ($n=4$) compared to unseparated controls ($n=4$). This is consistent with our electrophysiological recordings in brain slices demonstrating that VTA dopamine neurons of separated dams are differentially modulated by oxytocin compared to unseparated control dams. Our findings suggest that VTA activity is positively associated with maternal motivation and may lower the sensory threshold for maternal behaviors.

Astroglial Calcium Signaling Encodes Sleep Need in Drosophila.
Sleep is under homeostatic control, whereby increasing wakefulness generates sleep need and triggers sleep drive. However, the molecular and cellular pathways by which sleep need is encoded are poorly understood. In addition, the mechanisms underlying both how and when sleep need is transformed to sleep drive are unknown. Here, using ex vivo and in vivo imaging, we show in Drosophila that astroglial Ca signaling increases with sleep need. We demonstrate that this signaling is dependent on a specific L-type Ca channel and is necessary for homeostatic sleep rebound. Thermogenetically increasing Ca in astrocytes induces persistent sleep behavior, and we exploit this phenotype to conduct a genetic screen for genes required for the homeostatic regulation of sleep. From this large-scale screen, we identify TyrRII, a monoaminergic receptor required in astrocytes for sleep homeostasis. TyrRII levels rise following sleep deprivation in a Ca-dependent manner, promoting further increases in astrocytic Ca and resulting in a positive-feedback loop. Moreover, our findings suggest that astrocytes then transmit this sleep need to a sleep drive circuit by upregulating and releasing the interleukin-1 analog Spätzle, which then acts on Toll receptors on R5 neurons. These findings define astroglial Ca signaling mechanisms encoding sleep need and reveal dynamic properties of the sleep homeostatic control system.

Comparison of bonobo and chimpanzee brain microstructure reveals differences in socio-emotional circuits.
Despite being closely related, bonobos and chimpanzees exhibit several behavioral differences. For instance, studies indicate that chimpanzees are more aggressive, territorial, and risk-taking, while bonobos exhibit greater social tolerance and higher rates of socio-sexual interactions. To elucidate the potential neuroanatomical variation that accompanies these differences, we examined the microstructure of selected brain areas by quantifying the neuropil fraction, a measure of the relative tissue area occupied by structural elements of connectivity (e.g., dendrites, axons, and synapses) versus cell bodies. In bonobos and chimpanzees, we compared neuropil fractions in the nucleus accumbens (NAc; core and shell), amygdala (whole, accessory basal, basal, central and lateral nuclei), anterior cingulate cortex (ACC; dorsal and subgenual), anterior

insular cortex (AIC), and primary motor cortex (M1). In the dorsal ACC and frontoinsular cortex (FI) we also quantified numbers of von Economo neurons (VENs), a unique subset of neurons thought to be involved in rapid information processing during social interactions. We predicted that the neuropil fraction and number of VENs in brain regions associated with socio-emotional processing would be higher in bonobos. In support of this hypothesis, we found that bonobos had significantly greater neuropil in the central and accessory basal nuclei of the amygdala, as well as layers V-VI of the subgenual ACC. However, we did not find a difference in the numbers of VENs between the two species. These findings support the conclusion that bonobo and chimpanzee brains differ in the anatomical organization of socio-emotional systems that may reflect species-specific variation in behavior.

Structure of the polyisoprenyl-phosphate glycosyltransferase GtrB and insights into the mechanism of catalysis.
The attachment of a sugar to a hydrophobic polyisoprenyl carrier is the first step for all extracellular glycosylation processes. The enzymes that perform these reactions, polyisoprenyl-glycosyltransferases (PI-GTs) include dolichol phosphate mannose synthase (DPMS), which generates the mannose donor for glycosylation in the endoplasmic reticulum. Here we report the 3.0 Å resolution crystal structure of GtrB, a glucose-specific PI-GT from Synechocystis, showing a tetramer in which each protomer contributes two helices to a membrane-spanning bundle. The active site is 15 Å from the membrane, raising the question of how water-soluble and membrane-embedded substrates are brought into apposition for catalysis. A conserved juxtamembrane domain harbours disease mutations, which compromised activity in GtrB in vitro and in human DPM1 tested in zebrafish. We hypothesize a role of this domain in shielding the polyisoprenyl-phosphate for transport to the active site. Our results reveal the basis of PI-GT function, and provide a potential molecular explanation for DPM1-related disease.

EFFECTS OF CHEMOGENETIC MANIPULATIONS OF CRF+ NEURONS IN THE CENTRAL AMYGDALA ON SOCIABILITY IN MICE

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Mariia Dorofeikova[1,2], Chandrashekhar Borkar[1], Katherine Weissmuller[3], Lydia Smith-Osborne[1], Samhita Basavanhalli[3], Erin Bean[3], Anh Duong[3], Alexis Resendez[1], Jonathan Fadok[1]
[1]Tulane University, Department Of Psychology, New Orleans, United States of America, [2]University Medical Center Hamburg-Eppendorf, Institute Of Developmental Neurophysiology, Center For Molecular Neurobiology, Hamburg, Germany, [3]Tulane University, Neuroscience Program, New Orleans, United States of America

Aims Multiple brain regions are involved in social cognition, including the amygdala, but the mechanisms underlying differences in social approach or avoidance are still poorly understood. Since it has been shown that neurons expressing corticotropin-releasing factor (CRF) regulate sociability in a sex-dependent manner, and that the CeA plays a key role in emotion discrimination, we decided to manipulate CRF-expressing CeA neurons during social interaction using a chemogenetic approach. **Methods** Heterozygous 2-4 month-old CRF-IRES-Cre mice (Jackson Laboratory) were bilaterally injected into the CeA with AAV5-hSyn-DIO-hM4D(Gi)-mCherry, AAV5-hSyn-DIO-hM3D(Gq)-mCherry or AAV5-hSyn-DIO-mCherry vectors. Clozapine N-oxide or vehicle was injected intraperitoneally 30 min before the start of social interaction and appetitive tests. **Results** Manipulation of CRF+ CeA neurons' activity led to a change in social investigation ($F(2,23)=4.887$, $P=0.0170$) but did not change the preference of social novelty or exploration time during social interaction test. At the same time, appetite was reduced as a result of CeA CRF+ neuronal activation ($F(2,35)=4.239$, $P=0.0225$; post hoc tests, $P=0.0030$ in the excitation group). Progressive ratio 4 test showed no changes in motivation of mice. **Conclusions** The role of CRF+ neurons of the CeA in social investigation but not social novelty preference was demonstrated using a chemogenetic approach. Sociability was increased as a result of CeA CRF+ excitation and decreased due to inhibition, while appetite was changed in an opposite manner . These findings together with previous studies indicate that CeA CRF+ neurons modulate not just aversive and appetitive responses, but also play a separate distinct role in social investigation.

DELINEATING IQ MOTIF AND SEC7 DOMAIN ARFGEF2, IQSEC2 IN RELEVANCE TO SOCIAL DEFICITS: FROM PHYSIOLOGY TO SYNAPSE.

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Anuradha Mehta[1], Yoshinori Shirai[1], Emi Suzuki[1], Zhou Mengyun[1], Takuma Mori[1,2], Toru Yanagawa[3], Takahiro Yoshizawa[4], Katsuhiko Tabuchi[1,2]
[1]Shinshu University, School of Medicine, Department Of Molecular And Cellular Physiology, Matsumoto, Japan, [2]Shinshu University, Department Of Neurohealth Innovation, Institute For Biomedical Sciences, Interdisciplinary Cluster For Cutting Edge Research, Matsumoto, Japan, [3]University of Tsukuba, Department Of Oral And Maxillofacial Surgery, Faculty Of Medicine, Tsukuba, Japan, [4]Shinshu University, Research Center For Advanced Science And Technology, Shinshu University, Matsumoto, Japan

A potential candidate associated with the etiology of a wide variety of developmental psychiatric disorders is the PSD-95 binding excitatory post-synaptic molecule, IQ Motif and Sec7 Domain ArfGEF2 (IQSEC2). We seek to elucidate the role of this molecule in physiology at the level of synaptic crosstalk in *Mus musculus*. We used a global and local approach to justify our hypothesis by generating a CRISPR/Cas9-mediated knockout (KO) mouse model and shRNA knockdown of IQSEC2, respectively. Technical details include in-utero electroporation and stereotactic viral injection for selective knockdown and rescue of the target molecule in brain. We have shown the involvement of this molecule in social behavior. Moreover, the excitatory and inhibitory synaptic functions were also found to be altered in Medial Prefrontal Cortex (mPFC) pyramidal neurons in the absence of this molecule. The social deficits and synaptic defects were successfully abolished when we reconstituted the longest isoform of IQSEC2 to the mPFC, a region known to be involved in social decision making, by an adeno-associated viruses (AAV)-mediated gene delivery system. We also studied the early neuron activity marker c-fos, through selected brain regions relevant to social behavior in mice. The mPFC showed an extensive reduction of neuronal activity in our IQSEC2 KO model. Our current findings involve characterization of the type of neurons that are more precisely associated with the physiological deficits observed in the lack of IQSEC2. Disrupted activity pattern as observed from the Excitatory/Inhibitory neuron specific c-fos expression in the mPFC has imparted considerable insight into our preliminary characterization.

A pilot Indian family-based association study between dyslexia and Reelin pathway genes, DCDC2 and ROBO1, identifies modest association with a triallelic unit TAT in the gene RELN.
Dyslexia is a neurodevelopmental disorder that manifests as a reading disability despite normal intelligence and adequate educational opportunity. Twin and family studies have indicated a genetic component, while genome-wide studies have implicated a number of susceptibility genes, most of which have direct or indirect roles in neuronal migration. Reelin (RELN) has important biological functions facilitating migration of neurons. Polymorphisms in RELN have been implicated in related disorders like autism and schizophrenia but have not been examined in dyslexia. We hypothesized that not only RELN, but its interactors in the neuronal migration pathway may play roles in the etiology of dyslexia. Twenty two functional variants across six RELN signalling genes (RELN, VLDLR, APOER2, DAB1, LIS1 and NDEL1) and two dyslexia candidate genes (DCDC2 and ROBO1) were analyzed for association in twenty six nuclear and three extended families with individuals affected with dyslexia. Univariate association analysis was suggestive of association (p = 0.01) with rs362746 in RELN which however did not withstand Bonferroni corrections (p = 0.21). Multimarker tests indicated significant association (p = 0.037), based on which we tested for haplotype associations. Although there were no significant haplotypic associations, we found that a three marker unit with rs3808039 and rs2072403 flanking and independently in linkage disequilibrium with rs362746 was significantly overtransmitted (risk allelic combination - TAT) to dyslexia affected individuals in the sample (p = 0.002). Our results suggest preliminary evidence for a new potential risk variant in the RELN locus for dyslexia.

Role of EphrinA3 in HIV-1 Neuropathogenesis.

Glial cells perform important supporting functions for neurons through a dynamic crosstalk. Neuron-glia communication is the major phenomenon to sustain homeostatic functioning of the brain. Several interactive pathways between neurons and astrocytes are critical for the optimal functioning of neurons, and one such pathway is the ephrinA3-ephA4 signaling. The role of this pathway is essential in maintaining the levels of extracellular glutamate by regulating the excitatory amino acid transporters, EAAT1 and EAAT2 on astrocytes. Human immunodeficiency virus-1 (HIV-1) and its proteins cause glutamate excitotoxicity due to excess glutamate levels at sites of high synaptic activity. This study unravels the effects of HIV-1 transactivator of transcription (Tat) from clade B on ephrinA3 and its role in regulating glutamate levels in astrocyte-neuron co-cultures of human origin. It was observed that the expression of ephrinA3 increases in the presence of HIV-1 Tat B, while the expression of EAAT1 and EAAT2 was attenuated. This led to reduced glutamate uptake and therefore high neuronal death due to glutamate excitotoxicity. Knockdown of ephrinA3 using small interfering RNA, in the presence of HIV-1 Tat B reversed the neurotoxic effects of HIV-1 Tat B via increased expression of glutamate transporters that reduced the levels of extracellular glutamate. The in vitro findings were validated in autopsy brain sections from acquired immunodeficiency syndrome patients and we found ephrinA3 to be upregulated in the case of HIV-1-infected patients. This study offers valuable insights into astrocyte-mediated neuronal damage in HIV-1 neuropathogenesis.

IQSEC2 Deficiency Results in Abnormal Social Behaviors Relevant to Autism by Affecting Functions of Neural Circuits in the Medial Prefrontal Cortex.
IQSEC2 is a guanine nucleotide exchange factor (GEF) for ADP-ribosylation factor 6 (Arf6), of which protein is exclusively localized to the postsynaptic density of the excitatory synapse. Human genome studies have revealed that the IQSEC2 gene is associated with X-linked neurodevelopmental disorders, such as intellectual disability (ID), epilepsy, and autism. In this study, we examined the behavior and synapse function in IQSEC2 knockout (KO) mice that we generated using CRIPSR/Cas9-mediated genome editing to solve the relevance between IQSEC2 deficiency and the pathophysiology of neurodevelopmental disorders. IQSEC2 KO mice exhibited autistic behaviors, such as overgrooming and social deficits. We identified that up-regulation of c-Fos expression in the medial prefrontal cortex (mPFC) induced by social stimulation was significantly attenuated in IQSEC2 KO mice. Whole cell electrophysiological recording identified that synaptic transmissions mediated by α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPAR), N-methyl-D-aspartate receptor (NMDAR), and γ-aminobutyric acid receptor (GABAR) were significantly decreased in pyramidal neurons in layer 5 of the mPFC in IQSEC2 KO mice. Reexpression of IQSEC2 isoform 1 in the mPFC of IQSEC2 KO mice using adeno-associated virus (AAV) rescued both synaptic and social deficits, suggesting that impaired synaptic function in the mPFC is responsible for social deficits in IQSEC2 KO mice.

Social interaction and connection are crucial factors in shaping mental statements, and positive and negative social experiences would have different impacts on mental status, emotions and behaviors, but the neural circuitry mechanisms of how brain integrates previous social stimuli to mediate behaviors are still unclear. Studies have shown that the paraventricular nucleus of the thalamus (PVT) plays a role in mice's social behaviors, and medial prefrontal cortex (mPFC)-innervated PVT neurons are recruited by social interaction. PVT is also known to be an integrator in processing positive and negative valence, and it modulates mice's motivational behaviors through distinct efferent outputs. It remains elusive whether PVT regulates sociability and motivation through distinct or common neural circuits. Therefore, we set up to investigate the functional connections involving the PVT in social interaction as well as motivational behaviors. To understand the functional roles of PVT-centered connections, we first employed anterograde and retrograde viral tracing and activity-dependent targeting techniques to identify selective afferents and efferents of PVT involved in social interaction in mice. Furthermore, we also found that the anterior and posterior parts of PVT were involved in distinct anatomy connections in processing social stimuli. Causal optogenetic manipulation will be employed to examine the regulatory roles of PVT-involved circuits in sociability and motivational behaviors of the mice.

Individual choices favoring self-interest or the interest of others depend on context and the relationships between individuals. These social behaviors are conserved in evolution as they greatly influence the survival and everyday life of all mammals. However, the neurobiological bases of choices that benefit others at a personal cost are not understood. *Aims*. To investigate decision-making in a social environment and understand the factors and the underlying neurobiology determining prosocial or selfish decisions. *Methods*. We developed a two-choice social decision-making task in which mice could decide whether to share a positive reinforcement with their conspecifics. We then used fiber photometry recordings and chemogenetic silencing to demonstrate that BLA neurons are involved in the establishment of prosocial decisions. *Results*. Preference for altruistic choices was more evident between familiar males with the highest hierarchical distance, and if the recipient was in direct social contact and in a hungry state. Furthermore, individual variability in the preference for altruistic choices correlated with affective state matching. BLA neurons projecting to the prelimbic region (PL) of the PFC are involved in the development of a preference for altruistic choices. Conversely, PL projections to the BLA modulated self-interest motives on decision-making. *Conclusions*. Here, we reveal the role of the basolateral amygdala (BLA) and its connections with the prefrontal cortex (PFC) in altruistic and selfish choices. This provides a neurobiological comparative model of altruistic and selfish choices with relevance to pathologies associated with dysfunctions in social decision-making

LESIONS OF NUCLEUS ACCUMBENS SHELL ABOLISH SOCIALLY TRANSMITTED FOOD PREFERENCES

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Irina Noguer Calabus[1], Sandra Schäble[2], Tobias Kalenscher[2]
[1]Heinrich-Heine-Universität Düsseldorf, Experimental Psychology, Düsseldorf, Germany, [2]Heinrich Heine University, Comparative Psychology, Düsseldorf, Germany

Aims: The Socially Transmitted Food Preference (STFP) task is a well-established paradigm in rodent research consisting of overwriting the endogenous food preference by the preference of the conspecific. The Nucleus accumbens shell (NAcSh) is an important area in the reward system for adaptative responses, however, its role in this task remained unknown. Therefore, we hypothesized that the integrity of the NAcSh is necessary to show socially transmitted food preferences. Methodology: 36 male Long-Evans rats (observers) received either bilateral NAcSh lesion or sham surgery. In the STFP task, two food options were provided to observer rats and their consumption patterns were measured to determine their individual food preference. Then, they were exposed to a demonstrator rat who was fed with the observer's originally non-preferred food. Afterward, the observer's consumption patterns were assessed again. Two control tasks were performed to rule out potential confounds: anxiety and odor discrimination deficits. Moreover, the histological analysis verified lesions' accuracy. Results: Sham lesioned observer rats changed their food preferences following interaction with the demonstrator, specifically by increasing the intake of their originally non-preferred food. This interaction-related change in preference was not found after NAcSh lesions. The lesion-effects on choice were not the consequence of anxiety or impaired motivation, cognitive flexibility, or sensory or motor function. Conclusion: This experiment suggests that NAcSh lesions result in a deficit in socially transmitted reward reevaluation. These results provide new information about the areas underpinning social learning and contribute to the understanding of social influence on choice and preference.

Distinct Profiles of 50 kHz Vocalizations Differentiate Between Social Versus Non-social Reward Approach and Consumption. Social animals tend to possess an elaborate vocal communication repertoire, and rats are no exception. Rats utilize ultrasonic vocalizations (USVs) to communicate information about a wide range of socially relevant cues, as well as information regarding the valence of the behavior and/or surrounding environment. Both quantitative and qualitative acoustic properties of these USVs are thought to communicate context-specific information to conspecifics. Rat USVs have been broadly categorized into 22 and 50 kHz call categories, which can be further classified into subtypes based on their sonographic features. Recent research indicates that the 50 kHz calls and their various subtype profiles may be related to the processing of social and non-social rewards. However, only a handful of studies have investigated USV elicitation in the context of both social and non-social rewards. Here, we employ a novel behavioral paradigm, the social-sucrose preference test, that allowed us to measure rats' vocal responses to both non-social (i.e., 2, 5, and 10% sucrose) and social reward (interact with a Juvenile rat), presented concurrently. We analyzed adult male Long-Evans rats' vocal responses toward social and non-social rewards, with a specific focus on 50 kHz calls and their 14 subtypes. We demonstrate that rats' preference and their vocal responses toward a social reward were both influenced by the concentration of the non-social reward in the maze. In other words, rats showed a trade-off between time spent with non-social or social stimuli along with increasing concentrations of sucrose, and also, we found a clear difference in the emission of flat and frequency-modulated calls in the social and non-social reward zones. Furthermore, we report that the proportion of individual subtypes of 50 kHz calls, as well as the total USV counts, showed variation across different types of rewards as well. Our findings provide a thorough overview of rat vocal responses toward non-social and social rewards and are a clear depiction of the variability in the rat vocalization repertoire, establishing the role of call subtypes as key players driving context-specific vocal responses of rats.

CORTICAL ASTROCYTES MODULATE EMOTION DISCRIMINATION THROUGH CANNABINOID SYSTEM

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Giada Pacinelli[1], Francesca Managò[1], Gabriella Contarini[2], Francesco Papaleo[1]
[1]Istituto Italiano di Tecnologia, Department Of Neuroscience, Genova, Italy, [2]University of Catania, Department Of Biomedical And Biotechnological Sciences (biomed), Catania, Italy

Within the "*social brain*", the prefrontal cortex (PFC) orchestrate a top-down control of social cognitive processes, including the ability to understand others' emotional states. Accumulating evidence are proving a pivotal role of astrocytes in brain functions and behavior. However, how these glial cells mediate socio-cognitive processes is still unexplored. The endocannabinoid system has been implicated as major modulator of astrocytic activity. Yet, the specific involvement of astrocytic cannabinoid signaling in distinct social behaviors is scarcely addressed. Here, combining *in vivo* chemogenetics and genetics manipulations with a behavioral task designed to study in mice the ability to discriminate conspecifics based on their affective state, we assessed the role of PFC astrocytes in social behavior. Furthermore, we investigated the influence of PFC astrocytic cannabinoid receptor 1 in social behaviors. Our data revealed that activation of cortical astrocytes increase the preference towards emotionally altered mice compared to those in a neutral state. Notably, this ability is abolished following acute and chronic treatment with a cannabinoid agonist (THC). Furthermore, we observed that chemogenetics activation of PFC astrocytes might rescue emotion discrimination deficits induced by systemic THC administration. Lastly, we demonstrated that removing astroglial CB1 within PFC abolish emotion discrimination. Our findings indicate a prominent role of PFC astrocytes and cannabinoid system in emotion recognition abilities.

To survive animals have to finely regulate their approach and defensive behaviors towards threats. In mice, the brainstem dorsal periaqueductal gray (dPAG) generates innate defensive behaviors towards a multitude of threats, like predators, prey and aggressive conspecifics. Glutamatergic neurons in the anterior cingulate cortex (ACC) project to dPAG and have an inhibitory effect on the structure, promoting approach behaviors. In this study, we used in vivo optogenetic stimulation to study the function and anatomy of the ACC to PAG projection, confirming that stimulation of the projection increases approach behavior towards the mentioned threats, and volume electron microscopy, showing that ACC axons establish axo-dendritic and axo-somatic synapses onto *Vglut2*+ and non-glutamatergic, non-GABAergic cells in dPAG, pointing to the role of a neuromodulator neuron class mediating dPAG inhibition. Moreover, we performed 1 photon calcium imaging recordings in freely moving mice in glutamatergic and GABAergic cells in dPAG, uncovering their activity patterns in correlation with defensive behaviors of interest. Further experiments will analyze the expression profile of dPAG cells, with a focus on ACC synaptic partners, using spatially resolved transcriptomics, and will explore the functional role of dPAG candidate neuromodulatory neurons in defensive behaviors, such as enkephalin expressing neurons. In conclusion, our study characterized the connectivity and function of a brainstem neural circuit that modulates innate defensive behaviors towards aggressive conspecifics, predators and prey in mice. Keywords: dPAG, ACC, defensive behavior, approach and avoidance, optogenetics, volume electron microscopy, 1 photon calcium recordings, enkephalin.

AUTISM SPECTRUM DISORDER-RELATED VOLTAGE-GATED POTASSIUM CHANNEL MUTATION KV7.3 R2C DECREASES DOPAMINE NEURON EXCITABILITY AND SOCIAL INTERACTION IN MICE

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Chris Tschumi[1], Julia Hayano[1], Barbara Juarez[2], Meagan Quinlan[2], Larry Zweifel[1,2]

Disruption of ion channel function is increasingly associated with neurodevelopmental disorders (NDDs) such as autism spectrum disorder (ASD). ASD has complex etiology and symptoms, but recent studies suggest that individuals with ASD have disrupted mesostriatal network activity associated with social interaction deficits. Although mutated ion channels play a key role in NDDs, the degree to which they disrupt mesostriatal network activity is not well understood. The Kv7 family of voltage-gated potassium channels encoded by KCNQ1-5 genes are increasingly linked to NDDs including ASD. These channels are broadly expressed, including within the ventral tegmental area (VTA), a nucleus of the mesostriatal pathway that plays an important role in social behavior. Here we assessed the impact of the ASD-associated variant KCNQ3(R2C) on VTA dopamine neuron excitability and social behavior in mice. We used a viral-based strategy to conditionally inactivate endogenous Kv7.3 with CRISPR/SaCas9 and re-express human wildtype (hKv7.3/WT) or mutant (hKv7.3/R2C) KCNQ3. Whole-cell patch clamp electrophysiology in brain slices revealed that hKv7.3/R2C significantly decreased excitability of dopamine neurons. In a social-reward operant task either inactivation of kcnq3 or re-expression of hKv7.3/R2C decreased the number of lever presses performed by experimental mice to receive access to a second mouse. These results suggest that kcnq3 is a critical regulator of dopamine neuron activity, and either kcnq3 inactivation-induced hyperexcitability or hKv7.3/R2C-induced hypoexcitability may both disrupt mesostriatal network activity that results in decreased social interaction.

Autism-associated mutations in K7 channels induce gating pore current.
Autism spectrum disorder (ASD) adversely impacts >1% of children in the United States, causing social interaction deficits, repetitive behaviors, and communication disorders. Genetic analysis of ASD has advanced dramatically through genome sequencing, which has identified >500 genes with mutations in ASD. Mutations that alter arginine gating charges in the voltage sensor of the voltage-gated potassium (K) channel K7 (KCNQ) are among those frequently associated with ASD. We hypothesized that these gating charge mutations would induce gating pore current (also termed ω-current) by causing an ionic leak through the mutant voltage sensor. Unexpectedly, we found that wild-type K7 conducts outward gating pore current through its native voltage sensor at positive membrane potentials, owing to a glutamine in the third gating charge position. In bacterial and human K7 channels, gating charge mutations at the R1 and R2 positions cause inward gating pore current through the resting voltage sensor at negative membrane potentials, whereas mutation at R4 causes outward gating pore current through the activated voltage sensor at positive potentials. Remarkably, expression of the K7.3/R2C ASD-associated mutation in vivo in midbrain dopamine neurons of mice disrupts action potential generation and repetitive firing. Overall, our results reveal native and mutant gating pore current in K7 channels and implicate altered control of action potential generation by gating pore current through mutant K7 channels as a potential pathogenic mechanism in autism.

Diverse actions of the modulatory peptide neurotensin on central synaptic transmission.
Neurotensin (NT) is a 13 amino acid neuropeptide that is expressed throughout the central nervous system and is implicated in the etiology of multiple diseases and disorders. Many primary investigations of NT-induced modulation of neuronal excitability at the level of the synapse have been conducted, but they have not been summarized in review form in nearly 30 years. Therefore, the goal of this review is to discuss the many actions of NT on neuronal excitability across brain regions as well as NT circuit architecture. In the basal ganglia as well as other brain nuclei, NT can act through diverse intracellular signaling cascades to enhance or depress neuronal activity by modulating activity of ion channels, ionotropic and

metabotropic neurotransmitter receptors, and presynaptic release of neurotransmitters. Further, NT can produce indirect effects by evoking endocannabinoid release, and recently has itself been identified as a putative retrograde messenger. In the basal ganglia, the diverse actions and circuit architecture of NT signaling allow for input-specific control of reward-related behaviors.

Acute and subchronic PCP attenuate D2 autoreceptor signaling in substantia nigra dopamine neurons.
Phencyclidine (PCP) administration is commonly used to model schizophrenia in laboratory animals. While PCP is well-characterized as an antagonist of glutamate-sensitive N-methyl-D-aspartate (NMDA) receptors, its effects on dopamine signaling are not well understood. Here we used whole-cell and cell-attached patch-clamp electrophysiology of substantia nigra dopamine neurons to determine the effects of acute and subchronic PCP exposure on both dopamine D2 autoreceptor-mediated currents and burst firing evoked by glutamate receptor activation. Acute PCP affected D2 autoreceptor-mediated currents through two apparently distinct mechanisms: a low-concentration dopamine transporter (DAT) inhibition and a high-concentration potassium (GIRK) channel inhibition. Subchronic administration of PCP (5 mg/kg, i.p., every 12 h for 7 days) decreased sensitivity to low dopamine concentrations, and also enhanced evoked burst firing of dopamine neurons. These findings suggest the effects of PCP on dopaminergic signaling in the midbrain could enhance burst firing and contribute to the development of schizophreniform behavior.

Translating the atypical dopamine uptake inhibitor hypothesis toward therapeutics for treatment of psychostimulant use disorders.
Medication-assisted treatments are unavailable to patients with cocaine use disorders. Efforts to develop potential pharmacotherapies have led to the identification of a promising lead molecule, JJC8-091, that demonstrates a novel binding mode at the dopamine transporter (DAT). Here, JJC8-091 and a structural analogue, JJC8-088, were extensively and comparatively assessed to elucidate neurochemical correlates to their divergent behavioral profiles. Despite sharing significant structural similarity, JJC8-088 was more cocaine-like, increasing extracellular DA concentrations in the nucleus accumbens shell (NAS) efficaciously and more potently than JJC8-091. In contrast, JJC8-091 was not self-administered and was effective in blocking cocaine-induced reinstatement to drug seeking. Electrophysiology experiments confirmed that JJC8-091 was more effective than JJC8-088 at inhibiting cocaine-mediated enhancement of DA neurotransmission. Further, when VTA DA neurons in DAT-cre mice were optically stimulated, JJC8-088 produced a significant leftward shift in the stimulation-response curve, similar to cocaine, while JJC8-091 shifted the curve downward, suggesting attenuation of DA-mediated brain reward. Computational models predicted that JJC8-088 binds in an outward facing conformation of DAT, similar to cocaine. Conversely, JJC8-091 steers DAT towards a more occluded conformation. Collectively, these data reveal the underlying molecular mechanism at DAT that may be leveraged to rationally optimize leads for the treatment of cocaine use disorders, with JJC8-091 representing a compelling candidate for development.

A history of ethanol drinking increases locomotor stimulation and blunts enhancement of dendritic dopamine transmission by methamphetamine.
Ethanol and psychostimulant use disorders exhibit comorbidity in humans and cross-sensitization in animal models, but the neurobiological underpinnings of this are not well understood. Ethanol acutely increases dopamine neuron excitability, and psychostimulants such as cocaine or methamphetamine increase extracellular dopamine through inhibition of uptake through the dopamine transporter (DAT) and/or vesicular monoamine transporter 2 (VMAT2). Psychostimulants also depress dopamine neuron activity by enhancing dendritic dopamine neurotransmission. Here, we show that mice with a previous history of ethanol drinking are more sensitive to the locomotor-stimulating effects of a high dose (5 mg/kg), but not lower doses (1 and 3 mg/kg) of methamphetamine or any tested dose of cocaine (3, 10, and 18 mg/kg), compared with water-drinking controls. We next investigated the impact of a history of ethanol drinking, in a separate group of mice, on methamphetamine- or cocaine-induced enhancement of dendritic dopamine transmission using whole-cell voltage clamp electrophysiology in mouse brain slices. Methamphetamine, applied at a concentration (10 μM) that affects both DAT and VMAT2, enhanced D2 receptor-mediated inhibitory postsynaptic currents (D2-IPSCs) in both groups, but this effect was blunted in mice with a history of ethanol drinking. As methamphetamine action at VMAT2 disrupts dopamine neurotransmission, these results may suggest enhanced action of methamphetamine at VMAT2. Furthermore, there were no differences in low-dose methamphetamine or cocaine-induced enhancement of D2-IPSCs, suggesting intact DAT function. Disruption of methamphetamine-induced enhancement of dendritic dopamine transmission would result in decreased

inhibition of dopamine neurons, ultimately increasing downstream release and the behavioral effects of methamphetamine.

Neurotensin speeds inhibition of dopamine neurons through temporal modulation of GABA and GABA receptor-mediated synaptic input.
Midbrain dopamine neurons play physiological roles in many processes including reward learning and motivated behavior, and are tonically inhibited by γ-aminobutyric acid (GABA)ergic input from multiple brain regions. Neurotensin (NT) is a neuropeptide which acutely modulates midbrain dopamine neuron excitability through multiple mechanisms, one of which is a decrease of GABA-mediated inhibition. However, the mechanisms through which NT depresses GABA signaling are not known. Here we used whole cell patch-clamp electrophysiology of dopamine neurons in mouse brain slices to show that NT acts both presynaptically to increase GABA and postsynaptically to decrease GABA receptor-mediated currents in the substantia nigra. The active peptide fragment NT enhanced GABA signaling presynaptically by causing an increase in the size of the readily releasable pool of GABA via activation of the NT type-1 receptor and protein kinase A. Conversely, NT depressed GABA signaling postsynaptically via the NT type-2 receptor in a process that was modulated by protein kinase C. Both forms of plasticity could be observed simultaneously in single dopamine neurons. Thus, as the kinetics of GABA signaling are significantly faster than those of GABA signaling, NT functionally speeds GABAergic input to midbrain dopamine neurons. This finding contributes to our understanding of how neuropeptide-induced plasticity can simultaneously differentiate and integrate signaling by a single neurotransmitter in a single cell and provides a basis for understanding how neuropeptides use temporal shifts in synaptic strength to encode information.

Effects of consuming a diet high in fat and/or sugar on the locomotor effects of acute and repeated cocaine in male and female C57BL/6J mice.
Drug abuse and obesity are serious public health problems. Dopamine plays a central role in mediating the reinforcing effects of drugs and food. Prolonged use of drugs is known to alter the function and/or sensitivity of many neurotransmitter systems, including dopamine; however, the impact of consuming foods high in fat and/or sugar is less clear. These studies characterized the locomotor effects of acute and repeated cocaine in male and female C57BL/6J mice consuming 1 of 4 diets: (a) standard chow + water; (b) standard chow + 10% sucrose solution; (c) high-fat chow + water; or (d) high-fat chow + 10% sucrose solution. The acute locomotor effects of cocaine (3.2-32.0 mg/kg) were evaluated 4 weeks after initiating dietary conditions; the effects of repeated cocaine administration were evaluated after 5, 6, 7, and 12 weeks. During acute tests, mice consuming a diet high in fat and/or sucrose exhibited greater locomotor responses to cocaine than mice consuming standard chow and water, regardless of sex. Although diet-induced enhancements persisted across repeated cocaine testing, locomotor sensitization developed more rapidly in females drinking sucrose (and consuming either standard or high-fat chow) than in females consuming standard chow and water. In addition to providing evidence that consuming a diet high in fat and/or sugar enhances abuse-related effects of cocaine in ways that might increase vulnerability to abuse cocaine, these studies identified a potentially important sex-related difference in the interaction between nutrition and cocaine effects, with the impacts of sucrose consumption being greater in females than in males.

Ventral tegmental area astrocytes orchestrate avoidance and approach behavior.
The ventral tegmental area (VTA) is a heterogeneous midbrain structure, containing neurons and astrocytes, that coordinates behaviors by integrating activity from numerous afferents. Within neuron-astrocyte networks, astrocytes control signals from distinct afferents in a circuit-specific manner, but whether this capacity scales up to drive motivated behavior has been undetermined. Using genetic and optical dissection strategies we report that VTA astrocytes tune glutamatergic signaling selectively on local inhibitory neurons to drive a functional circuit for learned avoidance. In this circuit, astrocytes facilitate excitation of VTA GABA neurons to increase inhibition of dopamine neurons, eliciting real-time and learned avoidance behavior that is sufficient to impede expression of preference for reward. Loss of one glutamate transporter (GLT-1) from VTA astrocytes selectively blocks these avoidance behaviors and spares preference for reward. Thus, VTA astrocytes selectively

regulate excitation of local GABA neurons to drive a distinct avoidance circuit that opposes approach behavior. Nat Commun, 2019; 10

ROLE OF ACETYLCHOLINE RELEASE IN THE PREFRONTAL CORTEX DURING SOCIAL INTERACTION

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Cyril Lhopitallier[1], Anne Nosjean[2], Frédéric Chauveau[3], Sylvie Granon[2], Alexis Faure[2]
[1]NeuroPSI - Paris-Saclay Institute of Neuroscience CNRS – Paris-Saclay University Campus CEA Saclay,, Cognitive & Network Neuroscience (cnn), Saclay, France, [2]Paris-Saclay Institute of Neurosciences (NeuroPSI), Cognitive & Network Neuroscience Departement (cnn), Saclay, France, [3]INSTITUT DE RECHERCHE BIOMEDICALE DES ARMEES, Stress Neurophysiology, Brétigny-sur-Orge Cedex, France

Rational Previous studies showed that neuronal nicotinic receptors within the prefrontal cortex are necessary for showing adapted social interactions. However, the precise role of acetylcholine (Ach) in this process has never been studied. Aim: The aim of this study is to understand the role of prefrontal cholinergic input in social interaction. Methods We targeted opsin expression in cholinergic neurons for activating or inhibiting acetylcholine release in the prefrontal cortex of ChAT-IRES-Cre mice while they are interacting socially in dyads of males. We recorded ultrasonic vocalization (USV) that we showed to be a marker of emotional status and to be promoted by social interaction. Result Our results show that inhibition of Ach release increased social approach, together with a decrease of USV frequency. By contrast, Ach release decreased social approach, thus changing social hierarchy within the dyad. Moreover, Ach release increased USV frequencies, suggesting an boost of positive emotions. In addition, Ach modulation always induced escape behaviors from the non stimulated mouse. It is, therefore, possible that increased Ach release in the PFC, that trigger higher USV frequency during social approach, may generate an abnormal emotional signal for the social conspecific, which, in turn escapes more frequently social contacts. Conclusion This study shows that Ach input in the prefrontal cortex modulates social emotional signal, used to establish and maintain social hierarchy.

POSTERIOR INTRALAMINAR THALAMIC CALBINDIN NEURONS CONTRIBUTE TO MATERNAL AND SOCIAL BEHAVIOR IN MICE

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Szilvia Oláh[1], Dániel Zahemszky[1], Péter Lőw[2], Árpád Dobolyi[1]
[1]ELTE Laboratory of Molecular and Systems Neurobiology, Department Of Physiology And Neurobiology, Eötvös Loránd And Eötvös Loránd University, Budapest, Hungary, [2]Institute of Biology, Eötvös Loránd University, Department Of Anatomy, Cell And Developmental Biology, Budapest, Hungary

Posterior intralaminar thalamic (PIL) neurons may convey somatosensory information towards hypothalamus and other forebrain areas. Tuberoinfundibular peptide 39 (TIP39) is expressed in PIL neurons. It has been suggested that TIP39 promotes maternal and social behaviors. This neuropeptide is expressed in calbindin positive neurons of the PIL in rats. In contrast, calbindin and TIP39 are located in distinct cell populations in mice. Therefore, in the present study, we focused on the characterization of calbindin-containing PIL neurons in the mice. We determined their projections and examined their function related to maternal, social and anxiety-like behavior using chemogenetics. We injected stimulatory, control and inhibitory (rAAV5-hSyn-DIO-hM4D, Gq,-,Gi/-mCherry) adeno-associated viruses (AAVs) into the PIL of calbindin-Cre mice to induce Cre-dependent cell type specific expression of designer receptors exclusively activated by designer drugs (DREADDs). The validation of the stimulatory DREADDs was verified by appearance of c-Fos following CNO injection.In the virally injected animals, we mapped the projections of PIL calbindin neurons and we performed different behavioral tests. The results demonstrated that stimulation of PIL neurons increased anxiety-related behavior, reduced maternal and social behavior, while the inhibition of the same neurons had opposite effect. Our data suggests that PIL calbindin neurons are involved in the regulation of different behaviors. The authors declare that they have no conflict of interest. Maternally involved galanin neurons in the preoptic area of the rat.
Recent selective stimulation and ablation of galanin neurons in the preoptic area of the hypothalamus established their critical role in control of maternal behaviors. Here, we identified a group of galanin neurons in the anterior commissural nucleus (ACN), and a distinct group in the medial preoptic area (MPA). Galanin neurons in ACN but not the MPA co-expressed oxytocin. We used immunodetection of phosphorylated STAT5 (pSTAT5), involved in prolactin receptor signal transduction, to evaluate the effects of suckling-induced prolactin release and found that 76 % of galanin cells in ACN, but only 12 % in MPA were prolactin responsive. Nerve terminals containing tuberoinfundibular peptide 39 (TIP39), a neuropeptide that mediates effects of suckling on maternal motivation, were abundant around galanin neurons in both preoptic regions. In the ACN and MPA, 89 and 82 % of galanin neurons received close somatic appositions, with an average of 2.9 and 2.6 per cell, respectively. We observed perisomatic innervation of galanin neurons using correlated light and electron microscopy. The connection was excitatory based on the glutamate content of TIP39 terminals demonstrated by post-embedding immunogold electron microscopy. Injection of the anterograde tracer biotinylated dextran amine into the TIP39-expressing posterior intralaminar complex of the thalamus (PIL) demonstrated that preoptic TIP39 fibers originate in the PIL, which is activated by suckling. Thus, galanin neurons in the preoptic area of mother rats are innervated by an excitatory neuronal pathway that conveys suckling-related information. In turn, they can be topographically and neurochemically divided into two distinct cell groups, of which only one is affected by prolactin.

Complement component 1q subcomponent binding protein in the brain of the rat.
Complement component 1q subcomponent binding protein (C1qbp) is a multifunctional protein involved in immune response, energy homeostasis of cells as a plasma membrane receptor, and a nuclear, cytoplasmic or mitochondrial protein. Recent reports suggested its neuronal function, too, possibly in axon maintenance, synaptic function, and neuroplasticity. Therefore,

we addressed to identify C1qbp in the rat brain using in situ hybridization histochemistry and immunolabelling at light and electron microscopic level. C1qbp has a topographical distribution in the brain established by the same pattern of C1qbp mRNA-expressing and protein-containing neurons with the highest abundance in the cerebral cortex, anterodorsal thalamic nucleus, hypothalamic paraventricular (PVN) and arcuate nuclei, spinal trigeminal nucleus. Double labelling of C1qbp with the neuronal marker NeuN, with the astrocyte marker S100, and the microglia marker Iba1 demonstrated the presence of C1qbp in neurons but not in glial cells in the normal brain, while C1qbp appeared in microglia following their activation induced by focal ischemic lesion. Only restricted neurons expressed C1qbp, for example, in the PVN, magnocellular neurons selectively contained C1qbp. Further double labelling by using the mitochondria marker Idh3a antibody suggested the mitochondrial localization of C1qbp in the brain, confirmed by correlated light and electron microscopy at 3 different brain regions. Post-embedding immunoelectron microscopy also suggested uneven C1qbp content of mitochondria in different brain areas but also heterogeneity within single neurons. These data suggest a specific function of C1qbp in the brain related to mitochondria, such as the regulation of local energy supply in neuronal cells.

Prolactin-induced and neuronal activation in the brain of mother mice.
Nursing has important consequences on mothers. To separate the prolactin-mediated and the neuronally-mediated actions of nursing, neurons directly affected by prolactin were visualized using pSTAT5 immunohistochemistry in relation to Fos-expressing neurons in suckled mother mice. In response to pup exposure following 22-h pup deprivation, we found a markedly elevated number of pSTAT5-containing neurons in several brain regions, including the lateral septum, medial amygdaloid nucleus, subparafascicular area, caudal periaqueductal gray, dorsal raphe, lateral parabrachial nucleus, nucleus of the solitary tract, and the periventricular, medial preoptic, paraventricular, arcuate and ventromedial nuclei of the hypothalamus. Pup exposure also induced Fos expression in all of these brain regions except the arcuate and ventromedial hypothalamic nuclei. Bromocriptine treatment known to reduce prolactin levels eliminated pSTAT5 from most brain regions while it did not affect Fos activation following suckling. The degree of colocalization for pSTAT5 and Fos ranged from 8 to 80% in the different brain regions suggesting that most neurons responding to pup exposure in mother mice are driven either by prolactin or direct neuronal input from the pups, while the number of neurons affected by both types of inputs depends on the examined brain area. In addition, both pSTAT5 and Fos were also double-labeled with estrogen receptor alpha (ERα) in mother mice, which revealed a very high degree of colocalization between pSTAT5 and ERα with much less potential interaction between Fos- and ERα-containing neurons suggesting that estrogen-sensitive neurons are more likely to be affected by prolactin than by direct neuronal activation.

Secretion and Function of Pituitary Prolactin in Evolutionary Perspective.
The hypothalamo-pituitary system developed in early vertebrates. Prolactin is an ancient vertebrate hormone released from the pituitary that exerts particularly diverse functions. The purpose of the review is to take a comparative approach in the description of prolactin, its secretion from pituitary lactotrophs, and hormonal functions. Since the reproductive and osmoregulatory roles of prolactin are best established in a variety of species, these functions are the primary subjects of discussion. Different types of prolactin and prolactin receptors developed during vertebrate evolution, which will be described in this review. The signal transduction of prolactin receptors is well conserved among vertebrates enabling us to describe the whole subphylum. Then, the review focuses on the regulation of prolactin release in mammals as we have the most knowledge on this class of vertebrates. Prolactin secretion in response to different reproductive stimuli, such as estrogen-induced release, mating, pregnancy and suckling is detailed. Reproduction in birds is different from that in mammals in several aspects. Prolactin is released during incubation in avian species whose regulation and functional significance are discussed. Little information is available on prolactin in reptiles and amphibians; therefore, they are mentioned only in specific cases to explain certain evolutionary aspects. In turn, the osmoregulatory function of prolactin is well established in fish. The different types of pituitary prolactin in fish play particularly important roles in the adaptation of eutherian species to fresh water environments. To achieve this function, prolactin is released from lactotrophs in hyposmolarity, as they are directly osmosensitive in fish. In turn, the released prolactin acts on branchial epithelia, especially ionocytes of the gill to retain salt and excrete water. This review will highlight the points where comparative data give new ideas or suggest new approaches for investigation in other taxa.

The mycotoxin deoxynivalenol activates GABAergic neurons in the reward system and inhibits feeding and maternal behaviours.
Deoxynivalenol (DON) or vomitoxin, is a trichothecene mycotoxin produced mainly by Fusarium graminearum and culmorum.

Mycotoxins or secondary metabolic products of mold fungi are micro-pollutants, which may affect human and animal health. The neuronal and behavioural actions of DON were analysed in the present study. To address, which neurons can be affected by DON, the neuronal activation pattern following intraperitoneal injection of DON (1 mg/kg) was investigated in adult male rats and the results were confirmed in mice, too. DON-induced neuronal activation was assessed by c-Fos immunohistochemistry. DON injection resulted in profound c-Fos activation in only the elements of the reward system, such as the accumbens nucleus, the medial prefrontal cortex, and the ventral tegmental area. Further double labelling studies suggested that GABAergic neurons were activated by DON treatment. To study the behavioural relevance of this activation, we examined the effect of DON on feed intake as an example of reward-driven behaviours. Following DON injection, feed consumption was markedly reduced but returned to normal the following day suggesting an inhibitory action of DON on feed intake without forming taste-aversion. To further test how general the effect of DON on goal-directed behaviours is, its actions on maternal behaviour was also examined. Pup retrieval latencies were markedly increased by DON administration, and DON-treated mother rats spent less time with nursing suggesting reduced maternal motivation. In a supplementary control experiment, DON did not induce conditioned place preference arguing against its addictive or aversive actions. The results imply that acute uptake of the mycotoxin DON can influence the reward circuit of the brain and exert inhibitory actions on goal-directed, reward-driven behaviours. In addition, the results also suggest that DON exposure of mothers may have specific implications.

A NOVEL BEHAVIOURAL TEST FOR STUDYING SOCIAL AVOIDANCE AND CHASE IN MICE

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Sukrita Deb, Cornelius Gross
European Molecular Biology Laboratory, Epigenetics And Neurobiology Unit, Monterotondo, Italy

Defensive behaviours are a range of strategies an animal employs to cope with threatening stimuli and the exact choice of response depends on the nature and intensity of the perceived danger. Aggression from conspecifics is a common source of threat in social species where aggression is used to ensure access to food, shelter, and mates. Defensive strategies for coping with such risks include avoidance, escape, and submissive displays aimed at de-escalating aggression. We are investigating the neural correlates of social defense in the ventrolateral subdivision of the ventromedial hypothalamus (VMHvl) where we have identified two classes of neurons whose firing encodes a sensory-motor transformation for escape behavior. However, present behavioural tests for social defense are suboptimal because they do not allow for examining the full range of social defense strategies. Here we present the validation and application of a novel circular chase arena that allows us to investigate the neural correlates of the full range of social defensive strategies, including high speed pursuit, passive and active approach, and submissive behaviors. This behavior test has increased ethological validity and for the first time allows for a quantitative behavioral assessment coupled to circuit recording and manipulation for the full repertoire of social defensive behaviors in the laboratory mouse.

Serotonin regulates mitochondrial biogenesis and function in rodent cortical neurons via the 5-HT receptor and SIRT1-PGC-1α axis.
Mitochondria in neurons, in addition to their primary role in bioenergetics, also contribute to specialized functions, including regulation of synaptic transmission, Ca homeostasis, neuronal excitability, and stress adaptation. However, the factors that influence mitochondrial biogenesis and function in neurons remain poorly elucidated. Here, we identify an important role for serotonin (5-HT) as a regulator of mitochondrial biogenesis and function in rodent cortical neurons, via a 5-HT receptor-mediated recruitment of the SIRT1-PGC-1α axis, which is relevant to the neuroprotective action of 5-HT. We found that 5-HT increased mitochondrial biogenesis, reflected through enhanced mtDNA levels, mitotracker staining, and expression of mitochondrial components. This resulted in higher mitochondrial respiratory capacity, oxidative phosphorylation (OXPHOS) efficiency, and a consequential increase in cellular ATP levels. Mechanistically, the effects of 5-HT were mediated via the 5-HT receptor and master modulators of mitochondrial biogenesis, SIRT1 and PGC-1α. SIRT1 was required to mediate the effects of 5-HT on mitochondrial biogenesis and function in cortical neurons. In vivo studies revealed that 5-HT receptor stimulation increased cortical mtDNA and ATP levels in a SIRT1-dependent manner. Direct infusion of 5-HT into the neocortex and chemogenetic activation of 5-HT neurons also resulted in enhanced mitochondrial biogenesis and function in vivo. In cortical neurons, 5-HT enhanced expression of antioxidant enzymes, decreased cellular reactive oxygen species, and exhibited neuroprotection against excitotoxic and oxidative stress, an effect that required SIRT1. These findings identify 5-HT as an upstream regulator of mitochondrial biogenesis and function in cortical neurons and implicate the mitochondrial effects of 5-HT in its neuroprotective action.

ROLE OF IMMEDIATE EARLY GENES IN NEURAL PLASTICITY DURING SOCIAL DEFEAT

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Rahul Sureka, Demetra Avincola, Cornelius Gross
European molecular biology laboratory, Epigenetics And Neurobiology Unit, Monterotondo, Italy

Defensive behaviors such as social aggression and avoidance are expressed by territorial animals in threatening situations and are crucial for their survival. Activity in the ventrolateral part of the ventromedial hypothalamus (VMHvl) has been shown to mediate both social aggression and avoidance across vertebrates. Interestingly, previous studies have shown that functional reorganization of neural activity that elicits avoidance behavior upon optogenetic stimulation in the VMHvl occurs only after social defeat and is accompanied by the expression of several immediate early genes (IEGs). While IEGs have been used as a proxy for plasticity, the precise nature of plastic changes varies between different brain regions, contexts, and behaviors. Moreover, whether plasticity in the VMHvl is essential for coping with social defeat is still an open question. In this study, we take a transcriptional approach to block induction of plasticity in VMHvl in order to answer this question. We downregulate different IEGs or knockout their master regulators (e.g. serum response factor, SRF) in specific cell types. This approach, for the first time, allows us to manipulate precise molecular pathways and elucidate the molecular mechanisms of plasticity of social defensive behaviors in VMH.

Comparison of Nuclear Matrix and Mitotic Chromosome Scaffold Proteins in S2 Cells-Transmission of Hallmarks of Nuclear Organization Through Mitosis.
Chromatin condenses several folds to form mitotic chromosomes during cell division and decondenses post-mitotically to reoccupy their nuclear territory and regain their specific transcriptional profile in a precisely lineage specific manner. This necessitates that the features of nuclear architecture and DNA topology persist through mitosis. We compared the proteome of nuclease and high salt resistant fraction of interphase nucleus known as nuclear matrix (NuMat) and an equivalent biochemical fraction in the mitotic chromosome known as mitotic chromosome scaffold (MiCS). Our study elucidates that as much as 67% of the NuMat proteins are retained in the MiCS indicating that the features of nuclear architecture in interphase nucleus are retained on the mitotic chromosomes. Proteins of the NuMat/MiCS have large dynamic range of MS signal and were detected in sub-femtomolar amounts. Chromatin/RNA binding proteins with hydrolase and helicase activity are highly enriched in NuMat as well as MiCS. Although several transcription factors involved in functioning of interphase nucleus are present exclusively in NuMat, protein components responsible for assembly of membrane-less nuclear bodies are uniquely retained in MiCS. Our study clearly indicates that the features of nuclear architecture, in the structural context of NuMat, are retained in MiCS and possibly play an important role in maintenance of cell lineage specific transcriptional status during cell division and thereby, serve as components of cellular memory.

Identification of Evolutionarily Conserved Nuclear Matrix Proteins and Their Prokaryotic Origins.
Compared to prokaryotic cells, a typical eukaryotic cell is much more complex along with its endomembrane system and membrane-bound organelles. Although the endosymbiosis theories convincingly explain the evolution of membrane-bound organelles such as mitochondria and chloroplasts, very little is understood about the evolutionary origins of the nucleus, the defining feature of eukaryotes. Most studies on nuclear evolution have not been able to take into consideration the underlying structural framework of the nucleus, attributed to the nuclear matrix (NuMat), a ribonucleoproteinaceous structure. This can largely be attributed to the lack of annotation of its core components. Since NuMat has been shown to provide a structural platform for facilitating a variety of nuclear functions such as replication, transcription, and splicing, it is important to identify its protein components to better understand these processes. In this study, we address this issue using the developing embryos of and and identify 362 core NuMat proteins that are conserved between the two organisms. We further compare our results with publicly available NuMat dataset and cellular localization dataset to define the core homologous NuMat proteins consisting of 252 proteins. We find that of them, 86 protein groups have originated from pre-existing proteins in prokaryotes.

While 36 were conserved across all eukaryotic supergroups, 14 new proteins evolved before the evolution of the last eukaryotic common ancestor and together, these 50 proteins out of the 252 core conserved NuMat proteins are conserved across all eukaryotes, indicating their indispensable nature for nuclear function for over 1.5 billion years of eukaryotic history. Our analysis paves the way to understand the evolution of the complex internal nuclear architecture and its functions.

REPRESENTATION OF ETHOLOGICAL EVENTS BY BASOLATERAL AMYGDALA NEURONS

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Cristina Mazuski, John O'Keefe
University College London, Sainsbury Wellcome Centre, London, United Kingdom

The accurate interpretation of ethologically-relevant stimuli is crucial for survival. Before deciding whether to approach or avoid a stimulus, an animal processes multisensory cues to develop a new, or activate an existing, internal representation. While the role of BLA neurons in fear-conditioning is well-studied, little is known about how BLA neurons respond during naturalistic events. Cells in the basolateral amygdala were recorded from freely-moving male rats as they interacted with different ethological stimuli: several male and female rats, a moving toy mouse, and sweet rice. 42% of the cells reliably responded to one or more of these stimuli, with over half of these identifying one of the four classes of stimuli to the exclusion of the rest. In addition to strong activation when interacting with their preferred stimulus, these *event-specific* cells signaled micro-behavioral interactions such as social contact with the head or tail of the conspecific. Firing activity persisted in 30% of responsive cells for several minutes after the removal of the eliciting stimulus. Circuit analysis at the sub-millisecond level revealed a directional flow of information from event-specific neurons to less specific *panresponsive* neurons and increases in connection strength after the event. We conclude that individual basolateral amygdala neurons identify specific ethological events and their microstructure, with circuit-wide activity being driven by these event-specific neurons during and after the termination of those events likely facilitating active short-term memory consolidation.

THE ROLE OF SOMATOSTATIN INTERNEURONS IN REGULATION OF EMOTIONAL CONTAGION

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Tomasz Nikolaev[1], Natalia Roszkowska[2], Ksenia Meyza[1]
[1]Nencki Institute of Experimental Biology, Braincity, Warsaw, Poland, [2]Cardinal Stefan Wyszyński University in Warsaw, Faculty Of Biology And Environmental Sciences, Warsaw, Poland

Aims The aim of the study was to assess the role of Somatostatin interneurons in amygdala and prefrontal cortex in emotional contagion – the simplest form of empathy in mice. **Methods** To study empathic abilities in mice we employed behavioural paradigm - Remote Transfer of Fear, in which mice are housed in pairs for three weeks, one labelled an Observer, and the other a Demonstrator. In the test session, the Demonstrator is subjected to aversive stimuli (10 foot shocks 0.6mA 1s long), outside of the home cage, while the Observer remains there undisturbed. Then, the Demonstrator returns to the home cage, where it can freely interact with the Observer. First ten minutes of interactions are recorded. Ninety minutes after the onset of the interaction animals were sacrificed for immunochemistry. To check the activity of somatostatin cells we used mice expressing fluorescence marker (dTomato) in somatostatin cells combined with immunochemistry against c-Fos, a standard neuronal novelty marker. **Results** Our results indicate that emotional contagion took place and that somatostatin interneurons in the prefrontal cortex, but not in the amygdala, are involved in the process. We observed increased expression of an immediate early gene (c-Fos) in somatostatin cells in both pre and infralimbic prefrontal cortex. **Conclusions** This study confirms pivotal role of the prefrontal cortex and somatostatin interneurons within this structure in emotional contagion and allows us to study this phenomenon further to better pinpoint its exact neuronal mechanism.

CONTRIBUTION OF GIRK CHANNELS EXPRESSED IN VTA GABAERGIC NEURONS TO ANXIETY, SOCIAL BEHAVIORS AND HIPPOCAMPAL-DEPENDENT MEMORY

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Guillermo Iborra-Lázaro[1], Jocelyn Grosse[2], Eva Ramos Fernandez[2], Olivia Zanoletti[2], Marie-Isabelle Guillot De Suduiraut[2], Carmen Sandi[2], Juan Navarro-López[1], Lydia Jiménez-Díaz[1]
[1]University of Castilla-La Mancha, Neurophysiology & Behavior Laboratory, Centro Regional De Investigaciones Biomédicas, Facultad De Medicina De Ciudad Real, Ciudad Real, Spain, [2]EPFL, Laboratory Of Behavioural Genetics, Brain Mind Institute, Lausanne, Switzerland

G-protein-gated inwardly rectifying potassium (GirK) channels contribute to the neuronal resting membrane potential and cell excitability in many brain regions. In the ventral tegmental area (VTA), GIRK1-containing channels are exclusively expressed in GABAergic cells. Since dopaminergic efferents of the VTA are under the inhibitory control of local GABAergic interneurons, GIRK1-containing channels may play a key role in dopamine release into projection brain areas such as the nucleus accumbens (NAc) -which is involved in anxiety-related and social behaviors- and the hippocampus -crucially implicated in cognition-. We performed intra-VTA injections of Tertiapin-Q, selective blocker of GIRK1-containing channels, to elucidate the effects of the specific modulation of GirK channel activity in VTA GABAergic neurons on anxiety-like behavior, sociability, social competitivenes and hippocampal-dependent contextual memory through a battery of behavioral tests. Subsequently, dopamine content and mitochondrial respiration in the NAc and hippocampus was measured. We found that Tertiapin-Q administration induced a significant decrease in dopamine levels and mitochondrial respiration in the NAc, but not in the hippocampus. However, these changes were not accompanied by behavioral alterations. Our results indicate that GIRK1-containing channels expressed in VTA GABAergic neurons modulate dopaminergic neurotransmission and suggest that higher dose of the drug used in this study might be required to induce significant changes at the behavioral level. *Funding: grants BFU2017-82494-P and PID2020-115823-GB100 funded by MCIN/AEI/10.13039/501100011033 and by the European Union, both to LJ-D and JDN-L, and by intramural funding from EPFL to C.S. Impairments of Synaptic Plasticity Induction Threshold and Network Oscillatory Activity in the Hippocampus Underlie Memory Deficits in a Non-Transgenic Mouse Model of Amyloidosis.
In early Alzheimer disease (AD) models synaptic failures and upstreaming aberrant patterns of network synchronous activity result in hippocampal-dependent memory deficits. In such initial stage, soluble forms of Amyloid- (A) peptides have been shown to play a causal role. Among different A species, A has been identified as the biologically active fragment, as induces major neuropathological signs related to early AD stages. Consequently, it has been extensively used to acutely explore the pathophysiological events related with neuronal dysfunction induced by soluble A forms. However, the synaptic mechanisms underlying its toxic effects on hippocampal-dependent memory remain unresolved. Here, in an in vivo model of amyloidosis generated by intracerebroventricular injections of A we studied the synaptic dysfunction mechanisms underlying hippocampal cognitive deficits. At the synaptic level, long-term potentiation (LTP) of synaptic excitation and inhibition was induced in CA1 region by high frequency simulation (HFS) applied to collaterals. A was found to alter metaplastic mechanisms of plasticity, facilitating long-term depression (LTD) of both types of LTP. In addition, aberrant synchronization of hippocampal network activity was found while at the behavioral level, deficits in hippocampal-dependent habituation and recognition memories emerged. Together, our results provide a substrate for synaptic disruption mechanism underlying hippocampal cognitive deficits present in A amyloidosis model.

Hippocampal long-term synaptic depression and memory deficits induced in early amyloidopathy are prevented by enhancing

G-protein-gated inwardly rectifying potassium channel activity.
Hippocampal synaptic plasticity disruption by amyloid-β (Aβ) peptides + thought to be responsible for learning and memory impairments in Alzheimer's disease (AD) early stage. Failures in neuronal excitability maintenance seems to be an underlying mechanism. G-protein-gated inwardly rectifying potassium (GirK) channels control neural excitability by hyperpolarization in response to many G-protein-coupled receptors activation. Here, in early in vitro and in vivo amyloidosis mouse models, we study whether GirK channels take part of the hippocampal synaptic plasticity impairments generated by Aβ . In vitro electrophysiological recordings from slices showed that Aβ alters synaptic plasticity by switching high-frequency stimulation (HFS) induced long-term potentiation (LTP) to long-term depression (LTD), which led to in vivo hippocampal-dependent memory deficits. Remarkably, selective pharmacological activation of GirK channels with ML297 rescued both HFS-induced LTP and habituation memory from Aβ action. Moreover, when GirK channels were specifically blocked by Tertiapin-Q, their activation with ML297 failed to rescue LTP from the HFS-dependent LTD induced by Aβ . On the other hand, the molecular analysis of the recorded slices by western blot showed that the expression of GIRK1/2 subunits, which form the prototypical GirK channel in the hippocampus, was not significantly regulated by Aβ . However, immunohistochemical examination of our in vivo amyloidosis model showed Aβ to down-regulate hippocampal GIRK1 subunit expression. Together, our results describe an Aβ-mediated deleterious synaptic mechanism that modifies the induction threshold for hippocampal LTP/LTD and underlies memory alterations observed in amyloidosis models. In this scenario, GirK activation assures memory formation by preventing the transformation of HFS-induced LTP into LTD.

34261700: Djebari S, Iborra-Lázaro G, Temprano-Carazo S, Sánchez-Rodríguez I, Nava-Mesa MO, Múnera A, Gruart A, Delgado-García JM, Jiménez-Díaz L, Navarro-López JD
G-Protein-Gated Inwardly Rectifying Potassium (Kir3/GIRK) Channels Govern Synaptic Plasticity That Supports Hippocampal-Dependent Cognitive Functions in Male Mice.
The G-protein-gated inwardly rectifying potassium (Kir3/GIRK) channel is the effector of many G-protein-coupled receptors (GPCRs). Its dysfunction has been linked to the pathophysiology of Down syndrome, Alzheimer's and Parkinson's diseases, psychiatric disorders, epilepsy, drug addiction, or alcoholism. In the hippocampus, GIRK channels decrease excitability of the cells and contribute to resting membrane potential and inhibitory neurotransmission. Here, to elucidate the role of GIRK channels activity in the maintenance of hippocampal-dependent cognitive functions, their involvement in controlling neuronal excitability at different levels of complexity was examined in C57BL/6 male mice. For that purpose, GIRK activity in the dorsal hippocampus CA3-CA1 synapse was pharmacologically modulated by two drugs: ML297, a GIRK channel opener, and Tertiapin-Q (TQ), a GIRK channel blocker. , using dorsal hippocampal slices, we studied the effect of pharmacological GIRK modulation on synaptic plasticity processes induced in CA1 by Schaffer collateral stimulation. , we performed acute intracerebroventricular (i.c.v.) injections of the two GIRK modulators to study their contribution to electrophysiological properties and synaptic plasticity of dorsal hippocampal CA3-CA1 synapse, and to learning and memory capabilities during hippocampal-dependent tasks. We found that pharmacological disruption of GIRK channel activity by i.c.v. injections, causing either function gain or function loss, induced learning and memory deficits by a mechanism involving neural excitability impairments and alterations in the induction and maintenance of long-term synaptic plasticity processes. These results support the contention that an accurate control of GIRK activity must take place in the hippocampus to sustain cognitive functions. Cognitive processes of learning and memory that rely on hippocampal synaptic plasticity processes are critically ruled by a finely tuned neural excitability. G-protein-gated inwardly rectifying K (GIRK) channels play a key role in maintaining resting membrane potential, cell excitability and inhibitory neurotransmission. Here, we demonstrate that modulation of GIRK channels activity, causing either function gain or function loss, transforms high-frequency stimulation (HFS)-induced long-term potentiation (LTP) into long-term depression (LTD), inducing deficits in hippocampal-dependent learning and memory. Together, our data show a crucial GIRK-activity-mediated mechanism that governs synaptic plasticity direction and modulates subsequent hippocampal-dependent cognitive functions.

CSF-ApoER2 fragments as a read-out of reelin signaling: Distinct patterns in sporadic and autosomal-dominant Alzheimer disease.
Reelin is a glycoprotein associated with synaptic plasticity and neurotransmission. The malfunctioning of reelin signaling in the brain is likely to contribute to the pathogenesis of Alzheimer's disease (AD). Reelin binding to Apolipoprotein E receptor 2 (ApoER2) activates downstream signaling and induces the proteolytic cleavage of ApoER2, resulting in the generation of soluble fragments. To evaluate the efficiency of reelin signaling in AD, we have quantified the levels of reelin and soluble ectodomain fragments of ApoER2 (ectoApoER2) in the cerebrospinal fluid (CSF). CSF from sporadic AD patients (sAD; n = 14, age 54-83 years) had lower levels of ecto-ApoER2 (~31% reduction; p = .005) compared to those in the age-matched controls (n = 10, age 61-80), and a higher reelin/ecto-ApoER2 ratio. In contrast, autosomal dominant AD patients, carriers of

PSEN1 mutations (ADAD; n = 7, age 31-49 years) had higher ecto-ApoER2 levels (~109% increment; p = .001) and a lower reelin/ecto-ApoER2 ratio than the non-mutation carriers from the same families (n = 7, age 25-47 years). Our data suggest that the levels of ecto-ApoER2 in CSF could be a suitable read-out of an impaired reelin signaling in AD, but also indicate differences between sAD and ADAD.

NEURAL CIRCUITS UNDERLYING SOCIALLY ACQUIRED FEAR MEMORIES IN MICE

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Verónica De La Fuente
Universidad de Buenos Aires, Ifibyne-uba-conicet, BUENOS AIRES, Argentina

Social learning is one of the most important ways in which animals, especially humans, acquire new information. However, brain mechanisms underlying the processing of fear-related stimuli have been mostly studied in non-human animal models where subjects experience fear directly. Social transmission of fear in non-human animals has comparatively recently emerged. In particular, the study of socially acquired fear and its processing across time from a circuitry perspective that considers the identity of molecules and cells involved is scarce. Several studies support the role of two distinct but interconnected brain regions for observational fear learning and social cognition in rodents, non-human primates and humans: the anterior cingulate cortex (ACC) and the basolateral amygdala (BLA). In this project I will show preliminary results setting up a paradigm to study fear observational learning and memory using mice. By putting particular emphasis in open source tools for stimuli delivery and for behavioral data analysis, we will discuss ongoing and future experiments to further understand the role of both ACC->BLA and BLA->ACC projecting neurons in the consolidation of observational fear memories. We will also consider protocols for studying the reconsolidation of this type of social acquired memories. Studying the mechanisms underlying social fear learning in non-human animals is key to model and better understand vicarious learning in humans and eventually develop therapeutic strategies for disorders of the central nervous system involving deficits of empathy or social learning such as autism.

LIMK, Cofilin 1 and actin dynamics involvement in fear memory processing.
Long-term memory has been associated with morphological changes in the brain, which in turn tightly correlate with changes in synaptic efficacy. Such plasticity is proposed to rely on dendritic spines as a neuronal canvas on which these changes can occur. Given the key role of actin cytoskeleton dynamics in spine morphology, major regulating factors of this process such as Cofilin 1 (Cfl1) and LIM kinase (LIMK), an inhibitor of Cfl1 activity, are prime molecular targets that may regulate dendritic plasticity. Using a contextual fear conditioning paradigm in mice, we found that pharmacological induction of depolymerization of actin filaments through the inhibition of LIMK causes an impairment in memory reconsolidation, as well as in memory consolidation. On top of that, Cfl1 activity is inhibited and its mRNA is downregulated in CA1 neuropil after re-exposure to the training context. Moreover, by pharmacological disruption of actin cytoskeleton dynamics, the process of memory extinction can either be facilitated or impaired. Our results lead to a better understanding of the role of LIMK, Cfl1 and actin cytoskeleton dynamics in the morphological and functional changes underlying the synaptic plasticity of the memory trace.

The lateral neocortex is critical for contextual fear memory reconsolidation.
Memories are a product of the concerted activity of many brain areas. Deregulation of consolidation and reprocessing of mnemonic traces that encode fearful experiences might result in fear-related psychopathologies. Here, we assessed how pre-established memories change with experience, particularly the labilization/reconsolidation of memory, using the whole-brain analysis technique of positron emission tomography in male mice. We found differences in glucose consumption in the lateral neocortex, hippocampus and amygdala in mice that underwent labilization/reconsolidation processes compared to animals that did not reactivate a fear memory. We used chemogenetics to obtain insight into the role of cortical areas in these phases of memory and found that the lateral neocortex is necessary for fear memory reconsolidation. Inhibition of lateral neocortex during reconsolidation altered glucose consumption levels in the amygdala. Using an optogenetic/neuronal recording-based strategy we observed that the lateral neocortex is functionally connected with the amygdala, which, along with retrograde labeling using fluorophore-conjugated cholera toxin subunit B, support a monosynaptic connection between these areas and

poses this connection as a hot-spot in the circuits involved in reactivation of fear memories.

Sustained CaMKII Delta Gene Expression Is Specifically Required for Long-Lasting Memories in Mice.
Although important information is available on the molecular mechanisms of long-term memory formation, little is known about the processes underlying memory persistence in the brain. Here, we report that persistent gene expression of CaMKIIδ isoform participates in object recognition long-lasting memory storage in mice hippocampus. We found that CaMKIIδ mRNA expression was sustained up to one week after training and paralleled memory retention. Antisense DNA infusion in the hippocampus during consolidation or even after consolidation impairs 7-day- but not 1-day-long memory, supporting a role of CaMKIIδ in memory persistence. CaMKIIδ gene expression was accompanied by long-lasting nucleosome occupancy changes at its promoter. This epigenetic mechanism is described for the first time in a memory process and offers a novel mechanism for persistent gene expression in neurons. CaMKIIδ protein is mainly present in nucleus and presynaptic terminals, suggesting a role in these subcellular compartments for memory persistence. All these results point to a key function of the sustained gene expression of this overlooked CaMKII isoform in long-lasting memories.

Effects of Hippocampal LIMK Inhibition on Memory Acquisition, Consolidation, Retrieval, Reconsolidation, and Extinction.
Long-lasting changes in dendritic spines provide a physical correlate for memory formation and persistence. LIM kinase (LIMK) plays a critical role in orchestrating dendritic actin dynamics during memory processing, since it is the convergent downstream target of both the Rac1/PAK and RhoA/ROCK pathways that in turn induce cofilin phosphorylation and prevent depolymerization of actin filaments. Here, using a potent LIMK inhibitor (BMS-5), we investigated the role of LIMK activity in the dorsal hippocampus during contextual fear memory in rats. We first found that post-training administration of BMS-5 impaired memory consolidation in a dose-dependent manner. Inhibiting LIMK before training also disrupted memory acquisition. We then demonstrated that hippocampal LIMK activity seems to be critical for memory retrieval and reconsolidation, since both processes were impaired by BMS-5 treatment. Contextual fear memory extinction, however, was not sensitive to the same treatment. In conclusion, our findings demonstrate that hippocampal LIMK activity plays an important role in memory acquisition, consolidation, retrieval, and reconsolidation during contextual fear conditioning.

NF-κB transcription factor role in consolidation and reconsolidation of persistent memories.
Transcriptional regulation is an important molecular process required for long-term neural plasticity and long-term memory (LTM) formation. Thus, one main interest in molecular neuroscience in the last decades has been the identification of transcription factors that are involved in memory processes. Among them, the nuclear factor κB (NF-κB) family of transcription factors has gained interest due to a significant body of evidence that supports a key role of these proteins in synaptic plasticity and memory. In recent years, the interest was particularly reinforced because NF-κB was characterized as an important regulator of synaptogenesis. This function may be explained by its participation in synapse to nucleus communication, as well as a possible local role at the synapse. This review provides an overview of experimental work obtained in the last years, showing the essential role of this transcription factor in memory processes in different learning tasks in mammals. We focus the review on the consolidation and reconsolidation memory phases as well as on the regulation of immediate-early and late genes by epigenetic mechanisms that determine enduring forms of memories.

Nuclear factor kappa B-dependent Zif268 expression in hippocampus is required for recognition memory in mice.
Long-term memory formation requires gene expression after acquisition of new information. The first step in the regulation of gene expression is the participation of transcription factors (TFs) such as nuclear factor kappa B (NF-κB), which are present before the neuronal activity induced by training. It was proposed that the activation of these types of TFs allows a second step in gene regulation by induction of immediate-early genes (IEGs) whose protein products are, in turn, TFs. Between these IEGs, zif268 has been found to play a critical role in long-term memory formation and reprocessing after retrieval. Here we found in mice hippocampus that, on one hand, NF-κB was activated 45 min after training in a novel object recognition (NOR) task and that inhibiting NF-κB immediately after training by intrahippocampal administration of NF-κB Decoy DNA impaired NOR memory consolidation. On the other hand, Zif268 protein expression was induced 45 min after NOR training and the administration of DNA antisense to its mRNA post-training impaired recognition memory. Finally, we found that the inhibition of NF-κB by NF-κB Decoy DNA reduced significantly the training-induced Zif268 increment, indicating that NF-κB is involved in the regulation of Zif268 expression. Thus, the present results support the involvement of NF-κB activity-dependent Zif268

expression in the hippocampus during recognition memory consolidation.

Protein degradation by ubiquitin-proteasome system in formation and labilization of contextual conditioning memory.
The ubiquitin-proteasome system (UPS) of protein degradation has been evaluated in different forms of neural plasticity and memory. The role of UPS in such processes is controversial. Several results support the idea that the activation of this system in memory consolidation is necessary to overcome negative constrains for plasticity. In this case, the inhibition of the UPS during consolidation impairs memory. Similar results were reported for memory reconsolidation. However, in other cases, the inhibition of UPS had no effect on memory consolidation and reconsolidation but impedes the amnesic action of protein synthesis inhibition after retrieval. The last finding suggests a specific action of the UPS inhibitor on memory labilization. However, another interpretation is possible in terms of the synthesis/degradation balance of positive and negative elements in neural plasticity, as was found in the case of long-term potentiation. To evaluate these alternative interpretations, other reconsolidation-interfering drugs than translation inhibitors should be tested. Here we analyzed initially the UPS inhibitor effect in contextual conditioning in crabs. We found that UPS inhibition during consolidation impaired long-term memory. In contrast, UPS inhibition did not affect memory reconsolidation after contextual retrieval but, in fact, impeded memory labilization, blocking the action of drugs that does not affect directly the protein synthesis. To extend these finding to vertebrates, we performed similar experiments in contextual fear memory in mice. We found that the UPS inhibitor in hippocampus affected memory consolidation and blocked memory labilization after retrieval. These findings exclude alternative interpretations to the requirement of UPS in memory labilization and give evidence of this mechanism in both vertebrates and invertebrates.

Calcineurin phosphatase as a negative regulator of fear memory in hippocampus: control on nuclear factor-κB signaling in consolidation and reconsolidation.
Protein phosphatases are important regulators of neural plasticity and memory. Some studies support that the Ca(2+) /calmodulin-dependent phosphatase calcineurin (CaN) is, on the one hand, a negative regulator of memory formation and, on the other hand, a positive regulator of memory extinction and reversal learning. However, the signaling mechanisms by which CaN exerts its action in such processes are not well understood. Previous findings support that CaN negatively regulate the nuclear factor kappaB (NF-κB) signaling pathway during extinction. Here, we have studied the role of CaN in contextual fear memory consolidation and reconsolidation in the hippocampus. We investigated the CaN control on the NF-κB signaling pathway, a key mechanism that regulates gene expression in memory processes. We found that post-training intrahippocampal administration of the CaN inhibitor FK506 enhanced memory retention one day but not two weeks after training. Accordingly, the inhibition of CaN by FK506 increased NF-κB activity in dorsal hippocampus. The administration of the NF-κB signaling pathway inhibitor sulfasalazine (SSZ) impeded the enhancing effect of FK506. In line with our findings in consolidation, FK506 administration before memory reactivation enhanced memory reconsolidation when tested one day after re-exposure to the training context. Strikingly, memory was also enhanced two weeks after training, suggesting that reinforcement during reconsolidation is more persistent than during consolidation. The coadministration of SSZ and FK506 blocked the enhancement effect in reconsolidation, suggesting that this facilitation is also dependent on the NF-κB signaling pathway. In summary, our results support a novel mechanism by which memory formation and reprocessing can be controlled by CaN regulation on NF-κB activity.

Epigenetic mechanisms and memory strength: a comparative study.
Memory consolidation requires de novo mRNA and protein synthesis. Transcriptional activation is controlled by transcription factors, their cofactors and repressors. Cofactors and repressors regulate gene expression by interacting with basal transcription machinery, remodeling chromatin structure and/or chemically modifying histones. Acetylation is the most studied epigenetic mechanism of histones modifications related to gene expression. This process is regulated by histone acetylases (HATs) and histone deacetylases (HDACs). More than 5 years ago, we began a line of research about the role of histone acetylation during memory consolidation. Here we review our work, presenting evidence about the critical role of this epigenetic mechanism during consolidation of context-signal memory in the crab Neohelice granulata, as well as during consolidation of novel object recognition memory in the mouse Mus musculus. Our evidence demonstrates that histone acetylation is a key mechanism in memory consolidation, functioning as a distinctive molecular feature of strong memories. Furthermore, we found that the strength of a memory can be characterized by its persistence or its resistance to extinction. Besides, we found that the role of this epigenetic mechanism regulating gene expression only in the formation of strongest memories is evolutionarily conserved.

CDK5-mediated phosphorylation of p19INK4d avoids DNA damage-induced neurodegeneration in mouse hippocampus and prevents loss of cognitive functions.
DNA damage, which perturbs genomic stability, has been linked to cognitive decline in the aging human brain, and mutations in DNA repair genes have neurological implications. Several studies have suggested that DNA damage is also increased in brain disorders such as Alzheimer's disease, Parkinson's disease and amyotrophic lateral sclerosis. However, the precise mechanisms connecting DNA damage with neurodegeneration remain poorly understood. CDK5, a critical enzyme in the development of the central nervous system, phosphorylates a number of synaptic proteins and regulates dendritic spine morphogenesis, synaptic plasticity and learning. In addition to these physiological roles, CDK5 has been involved in the neuronal death initiated by DNA damage. We hypothesized that p19INK4d, a member of the cell cycle inhibitor family INK4, is involved in a neuroprotective mechanism activated in response to DNA damage. We found that in response to genotoxic injury or increased levels of intracellular calcium, p19INK4d is transcriptionally induced and phosphorylated by CDK5 which provides it with greater stability in postmitotic neurons. p19INK4d expression improves DNA repair, decreases apoptosis and increases neuronal survival under conditions of genotoxic stress. Our in vivo experiments showed that decreased levels of p19INK4d rendered hippocampal neurons more sensitive to genotoxic insult resulting in the loss of cognitive abilities that rely on the integrity of this brain structure. We propose a feedback mechanism by which the neurotoxic effects of CDK5-p25 activated by genotoxic stress or abnormal intracellular calcium levels are counteracted by the induction and stabilization of p19INK4d protein reducing the adverse consequences on brain functions.

CHEMOGENETIC EVIDENCE THAT POSTERIOR INTRALAMINAR THALAMIC NEURONS MODULATES AGGRESSIVE BEHAVIOR IN RATS

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Tamás Láng[1], Dávid Keller[1,2], Árpád Dobolyi[2]

In a previous study, we established the activation of the posterior intralaminar thalamic (PIL) neurons during social interactions between adult female rats. In this study we focused on the role of PIL in intermale aggressive behavior. For manipulation of PIL neurons, adeno-associated virus was stereotaxically injected into the PIL. The virus expressed DREADD fused with mCherry in the infected cells. Excitatory and inhibitory DREADDs were used, activated by clozapine-N-oxide (CNO). Behavioral tests were recorded during the chemogenetic manipulation. After perfusion of the animals, we verified the injection sites and performed histological analysis. We identified the brain areas activated by aggressive behavior using c-Fos method. We found neuronal activation in the infralimbic cortex, medial preoptic area (MPOA) and the lateral septum. To induce aggression, the animals were separated at an early age. The behavioral tests were performed at the age 5 month. On the first day of the experiment, vehicle was injected to the animal. We performed aggressive behavioral test, where an unfamiliar intruder was placed in the subject animal's cage resulting in an aggressive response. On the second day, the same test was repeated starting 1,5 hours after CNO administration. Chemogenetic stimulation significantly decreased aggression and increased the duration of positive valance contact, while inhibiting the PIL resulted in the increase of aggression and decreased the duration of positive valance contact. Based on the results, PIL neurons may participate in the regulation of aggressive behavior conveying sensory inputs from the conspecific to higher brain areas. PHARMACOLOGICAL INACTIVATION OF THE BED NUCLEUS OF THE STRIA TERMINALIS INCREASES PROSOCIAL BEHAVIOR IN RHESUS MACAQUES

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Jessica Jacobs, Hannah Waguespack, Rafael Maior, Carolina Campos-Rodriguez, Patrick Forcelli, Ludise Malkova
Georgetown University, Pharmacology & Physiology, Washington, United States of America

The bed nucleus of the stria terminalis (BNST) is a subcortical structure that plays an important role in response to stress, extended-duration fear states, and social behavior. Dysregulation of the BNST has been found in individuals with generalized anxiety and social anxiety disorder and increased activity in the BNST has been found after exposure to aggressive and anxiety-inducing stimuli. Based on these findings, we hypothesized that bilateral inactivation of the BNST in nonhuman primates would result in increased social interaction between conspecifics. To test this hypothesis, we performed intracerebral microinfusions of the GABA-A agonist muscimol directly into the BNST of three adult male rhesus macaques, two additional males served as non-injected partners. Following drug infusion, the experimental animal was placed in an observation cage with a highly familiar non-injected partner and their behavior was recorded for 60 minutes. Behavior was assessed in five dyads. Compared to saline, muscimol infusion into the BNST significantly increased total social contact between animals (paired t-test, $p = 0.03$) but did not notably impact specific social behaviors, such as grooming of the conspecific. An increase in passive social contact between animals approached significance (paired t-test, $p = 0.11$). These results further support a critical role for the BNST in the regulation of social behavior and are consistent with a similar role for the amygdala previously found in our lab. While activation of the BNST is associated with anxiety and aggression, here we show that inactivation of the BNST promotes affiliative social behavior in conspecifics.

Amyloid-Related Imaging Abnormalities in an Aged Squirrel Monkey with Cerebral Amyloid Angiopathy.
Amyloid-related imaging abnormalities (ARIA) in magnetic resonance imaging scans have emerged as indicators of potentially serious side effects in clinical trials of therapeutics for Alzheimer's disease. These anomalies include an edematous type (ARIA-E) that appears as hyperintense (bright) regions by T2-weighted MRI, and a type characterized by the deposition of hemosiderin (ARIA-H) that elicits a hypointense signal, especially in T2* susceptibility weighted images. ARIA in general has been linked to the presence of amyloid-β (Aβ)-type cerebral amyloid angiopathy, an accumulation of misfolded Aβ protein in the vascular wall that impairs the integrity of brain blood vessels. However, the pathobiology of ARIA remains poorly understood, in part due to the absence of an animal model of the disorder that would enable a contemporaneous analysis of tissue integrity in the affected region. Here we describe both ARIA-E and ARIA-H in an aged squirrel monkey (Saimiri sciureus), a nonhuman primate model of naturally occurring cerebral amyloid angiopathy. Histopathologic examination of the anomalous region revealed reactive astrocytosis and microgliosis, infiltration of systemic inflammatory/immune cells, damage to axons and myelin, and hemosiderin deposition. The disruption of axons in particular suggests that ARIA-E could have functional consequences for affected regions. The squirrel monkey model can be useful for studying the pathogenesis and long-term effects of ARIA, and for testing the safety and efficacy of emerging therapies for Alzheimer's disease.

Correlates of Auditory Decision-Making in Prefrontal, Auditory, and Basal Lateral Amygdala Cortical Areas.
Spatial selective listening and auditory choice underlie important processes including attending to a speaker at a cocktail party and knowing how (or whether) to respond. To examine task encoding and the relative timing of potential neural substrates underlying these behaviors, we developed a spatial selective detection paradigm for monkeys, and recorded activity in primary auditory cortex (AC), dorsolateral prefrontal cortex (dlPFC), and the basolateral amygdala (BLA). A comparison of neural responses among these three areas showed that, as expected, AC encoded the side of the cue and target characteristics before dlPFC and BLA. Interestingly, AC also encoded the choice of the monkey before dlPFC and around the time of BLA. Generally, BLA showed weak responses to all task features except the choice. Decoding analyses

suggested that errors followed from a failure to encode the target stimulus in both AC and dlPFC, but again, these differences arose earlier in AC. The similarities between AC and dlPFC responses were abolished during passive sensory stimulation with identical trial conditions, suggesting that the robust sensory encoding in dlPFC is contextually gated. Thus, counter to a strictly PFC-driven decision process, in this spatial selective listening task AC neural activity represents the sensory and decision information before dlPFC. Unlike in the visual domain, in this auditory task, the BLA does not appear to be robustly involved in selective spatial processing. We examined neural correlates of an auditory spatial selective listening task by recording single-neuron activity in behaving monkeys from the amygdala, dorsolateral prefrontal cortex, and auditory cortex. We found that auditory cortex coded spatial cues and choice-related activity before dorsolateral prefrontal cortex or the amygdala. Auditory cortex also had robust delay period activity. Therefore, we found that auditory cortex could support the neural computations that underlie the behavioral processes in the task.

Social interactions are essential for survival in many species, but the neural mechanisms of initiation and maintaining social interaction remain poorly understood. In this study, we identified a crucial role of the neuronal circuit comprising the central amygdala (CeA), ventral tegmental area (VTA), anterior cingulate cortex (ACC), and orbitofrontal cortex (OFC) in promoting social interaction. Through opsins targeted to behaviorally activated neurons and projection-specific chemogenetic manipulations, we found the projections critical for the initiation and maintenance of social interaction. Moreover, in parallel, we investigated the role of the CeA-VTA-ACC/OFC circuit in food motivation. We found that the CeA-VTA and dopaminergic VTA-ACC and VTA-OFC projections mediate social interaction but not food motivation. Together, these findings establish the role of the CeA-VTA-ACC/OFC circuit in regulating social interaction and provide new insights into the regulation of social and food rewards.

Distinct circuits in rat central amygdala for defensive behaviors evoked by socially signaled imminent versus remote danger. Animals display a rich repertoire of defensive responses adequate to the threat proximity. In social species, these reactions can be additionally influenced by the behavior of fearful conspecifics. However, the majority of neuroscientific studies on socially triggered defensive responses focuses on one type of behavior, freezing. To study a broader range of socially triggered reactions and underlying mechanisms, we directly compared two experimental paradigms, mimicking occurrence of the imminent versus remote threat. Observation of a partner currently experiencing aversive stimulation evokes passive defensive responses in the observer rats. Similar interaction with a partner that has just undergone the aversive stimulation prompts animals to increase active exploration. Although the observers display behaviors similar to those of the aversively stimulated demonstrators, their reactions are not synchronized in time, suggesting that observers' responses are caused by the change in their affective state rather than mimicry. Using opsins targeted to behaviorally activated neurons, we tagged central amygdala (CeA) cells implicated in observers' responses to either imminent or remote threat and reactivated them during the exploration of a novel environment. The manipulation revealed that the two populations of CeA cells promote passive or active defensive responses, respectively. Further experiments confirmed that the two populations of cells at least partially differ in expression of molecular markers (protein kinase C-δ [PKC-δ] and corticotropin-releasing factor [CRF]) and connectivity patterns (receiving input from the basolateral amygdala or from the anterior insula). The results are consistent with the literature on single subjects' fear conditioning, suggesting that similar neuronal circuits control defensive responses in social and non-social contexts.

The trait 'pessimism' does not interact with cognitive flexibility but makes rats more vulnerable to stress-induced motivational deficits: Results from the attentional set-shifting task.
In the present study, we have investigated the effects of the traits 'optimism' and 'pessimism' on cognitive flexibility in an animal model of depression based on chronic restraint stress. For this, first, we trained and tested the rats in a series of ambiguous-cue interpretation (ACI) tests, which allowed us to classify them as 'optimistic' or 'pessimistic'. Subsequently, we re-trained and re-tested the animals in the Attentional Set Shifting Task (ASST), which allowed evaluation of the differences

between 'optimists' and 'pessimists' in terms of cognitive flexibility. Finally, we subjected half of the 'optimistic' and half of the 'pessimistic' rats to chronic (2 weeks) restraint stress and assessed the interaction between cognitive judgement bias and stress in the ASST. Although we did not observe statistically significant effects of the investigated traits and stress on cognitive flexibility, the 'pessimistic' animals subjected to chronic restraint stress showed significantly longer latencies to approach experimental rewards than their 'optimistic' conspecifics. This effect may indicate a stress-induced motivational deficit that is specific to 'pessimistic' animals. The results of the present study, along with our previous reports, indicate that the trait 'pessimism' determines animals' vulnerability to stress.

Inhibition of the glucocorticoid synthesis reverses stress-induced decrease in rat's 50-kHz ultrasonic vocalizations.
The playful, experimenter-administered manual somatosensory stimulation of rats results in a positive affect that triggers emission of ~50-kHz ultrasonic vocalizations (USVs), which have been proposed to index positive emotions akin to human joy and laughter. Our earlier findings showed that restraint stress decreased rat's tendency to emit 50-kHz USVs. Here we investigated whether the effects of stress on "tickling"-induced vocalizations could be alleviated by the glucocorticoid synthesis inhibitor, metyrapone. After the daily tickling sessions carried out until the USV response to tickling has stabilized, the rats were subjected to either handling, handling and metyrapone treatment, restraint stress lasting one week or the restraint stress and metyrapone treatment. Our results confirmed that animals exposed to restraint stress diminish the number of "tickling"-induced vocalizations as compared to the "tickled" but handled conspecifics. Metyrapone treatment prevented this effect in stressed animals having no effects in handled rats. The off-line analysis revealed that the majority (82-88%) of "tickling"-induced USVs were of the 50-kHz frequency modulated type and that the flat USVs appeared much less frequently (8.5-12%) while the 22-kHz alarm calls appeared sporadically (0.3-8%). Moreover, the acoustic parameters of the 50-kHz frequency modulated and flat USVs resembled the calls described earlier in adult rats. The results of the present study offer a way of identifying anti-stress and perhaps anti-depressant action of novel compounds based on the measurement of a positive affect of animals.

Rats are highly social animals, and communication between individuals occurs via means of ultrasonic vocalization. These facts were used to elicit and then evaluate the affective state caused by a 21-day social isolation. To study social-seeking-behavior based on spatial cues, a group of rats were trained in pairs in a specially designed four-corner cage containing light-spatial cues. One individual was placed in a specific corner behind the transparent and perforated plexiglass (conditioned), and the other in the center of the arena (conditioning). This arrangement limited social interactions to those in which the emphasis was on the role of ultrasonic vocalization. After 6 days of training, a single rat tests was performed. To determine the neuronal population activity depicting the early response genes (Arc and Homer1 RNAs) in the nuclei of nerve cells of the various brain structures involved in the emotion and spatial information processing, we used the catFISH fluorescence in situ hybridization methodology. The obtained information became the basis for the mathematical model of the relationship between neuronal activation and behavior and a model of the interplay of brain structures in a social context-seeking task. Interestingly, we demonstrated individual differences in spatial-cued contextual responses in both conditioning and conditioned rats. We observed a different pattern of neuronal activation by colocalizing Arc and Homer1a RNAs in several brain structures and the relationships between them. Our study explores the function of individual brain structures in processing spatial information related to the affective emotional state induced by social interactions. In the brain, Neuropeptide Y (NPY) modulates anxiety via amygdalar circuits or regulates energy homeostasis and stress response via hypothalamic nuclei, including the arcuate nucleus (ARC). Within the ARC, the orexogenic NPY/Agouti-related peptide (NPY/AgRP) neurons are responsive to variation of the metabolic state, hormones, GABAergic transmission, and nicotine. Interestingly, nicotine consumption is associated with a reduction of food intake and an increase of the hypothalamo-pituitary-adrenal stress response, whereas NPY release to the hypothalamic paraventricular nucleus (PVN) stimulates feeding behavior. We hypothesize that cholinergic activation of NPY-expressing neurons of the ARC is implicated in the modulation of NPY release. To test this hypothesis, we crossed beta2-flox/flox mice with NPY-IRES-Cre to delete beta2-containing nicotinic acetylcholine receptors (nAChRs) in all the NPY-expressing cells. We used in situ hybridization for NPY and beta2-nAChRs to confirm the presence of nAChRs on NPY/AgRP neurons of the ARC in control animals, and the beta2 deletion in the floxed mutants. Then, we induced stress by restraining and we measured its effect in selected behavioral tasks. Given the sexual dimorphism related to stress and alterations in feeding, we decided to test male and female mice, both during light and dark regimen. In females, the deletion of beta2-nAChRs increases the susceptibility to daily stressors and impairs the preference for social interaction, while in males it influences metabolism and body weight. The phenotype observed suggests a more complex interplay between the cholinergic system and NPY release, with possible recruitment of other types of nAChRs and compensatory mechanisms that need further investigation.

Nicotinic Acetylcholine Receptors Expressed by Striatal Interneurons Inhibit Striatal Activity and Control Striatal-Dependent Behaviors.
Acetylcholine is an important modulator of striatal activity, and it is vital to controlling striatal-dependent behaviors, including motor and cognitive functions. Despite this significance, the mechanisms determining how acetylcholine impacts striatal signaling are still not fully understood. In particular, little is known about the role of nAChRs expressed by striatal interneurons. In the present study, we used FISH to determine which neuronal types express the most prevalent beta2 nicotinic subunit in the mouse striatum. Our data support a common view that nAChR expression is mostly restricted to striatal interneurons. Surprisingly though, cholinergic interneurons were identified as a population with the highest expression of beta2 nicotinic subunit. To investigate the functional significance of beta2-containing nAChRs in striatal interneurons, we deleted them by injecting the AAV-Cre vector into the striatum of male mice. The deletion led to alterations in several behavioral domains, namely, to an increased anxiety-like behavior, decrease in sociability ratio, deficit in discrimination learning, and increased amphetamine-induced hyperlocomotion and c-Fos expression in mice with beta2 deletion. Further colocalization analysis showed that the increased c-Fos expression was present in both medium spiny neurons and presumed striatal interneurons. The present study concludes that, despite being relatively rare, beta2-containing nAChRs are primarily expressed in striatal neurons by cholinergic interneurons and play a significant role in behavior. A large variety of nAChRs are expressed in the striatum, a brain region that is crucial in the control of behavior. The complexity of receptors with different functions is hindering our understanding of mechanisms through which striatal acetylcholine modulates

behavior. We focused on the role of a small population of beta2-containing nAChRs. We identified neuronal types expressing these receptors and determined their impact in the control of explorative behavior, anxiety-like behavior, learning, and sensitivity to stimulants. Additional experiments showed that these alterations were associated with an overall increased activity of striatal neurons. Thus, the small population of nicotinic receptors represents an interesting target for a modulation of response to stimulant drugs and other striatal-based behavior.

REVERSING ESCALATED COCAINE INTAKE WITH SOCIAL CONTACT AND OPTOGENETIC MODULATION OF THE SUBTHALAMIC NUCLEUS

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Cassandre Vielle[1], Lucie Vignal[1], Alix Tiran-Cappello[1], Nicolas Maurice[1], Mickaël Degoulet[1], Cécile Brocard[1], Yann Pelloux[2], Christelle Baunez[1]

Despites decades of neuroscience research on cocaine addiction, only social therapies have proven effective in helping cocaine abusers regain the control of their drug consumption. However, while the immediate presence of a stranger peer, naïve to the drug, was shown to reduce recreational cocaine intake in rats, its effects on later stages of cocaine use disorder has not been investigated. Besides, the subthalamic nucleus (STN) has been identified as a potential surgical target in cocaine addiction, since its manipulation with lesions or deep brain stimulation has been shown to reduce motivation for cocaine, prevent cocaine escalation and re-escalation and reduce compulsive drug seeking. Here, rats first subjected to a cocaine escalation procedure, consisting in extended access (6h) to the drug over 20 days, were then tested for 2h self-administration sessions alone or in presence of an observing peer. We assessed the effects of STN optogenetic inhibition and high-frequency stimulation in these two various conditions. In the alone condition, both optogenetic STN inhibition and stimulation drastically reduced cocaine intake. The presence of a peer reduced the level of cocaine intake in control rats but did not reduce it further in the STN inhibited and stimulated groups. These results confirm the beneficial effects of social contact and STN modulation on cocaine abuse in rats, and suggest that the STN plays a key role in the influence of the peer's presence on drug consumption.

NEURAL CIRCUIT BASIS UNDERLYING A HUNGER-GATED PARENTAL SWITCH

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Mingran Cao, Rachida Ammari, Johannes Kohl
Francis Crick Institute, Francis Crick Institute, London, United Kingdom

Animals have sets of instinctive behaviours such as feeding, drinking, mating, parenting and aggression that are crucial for survival and procreation. Different instinctive behaviours are characterised by stereotypic actions in response to specific cues (e.g. parenting towards infants, aggression towards conspecifics). Despite their stereotypy, these behaviours can exhibit a large degree of flexibility due to experience or changes in internal states. While considerable advances have been made in understanding how individual instinctive behaviours are controlled by dedicated neural circuits, how these circuits interact to balance competing needs is less clear. Specifically, it remains unknown how identical sensory stimuli can result in different, or even opposing, instinctive responses due to organisms' conflicting instinctive drives. Here we address this question by characterising interactions between circuits for food-seeking and those controlling parental behaviour. We find that food deprivation switches female mice from parental behaviour to pup-directed aggression. Remarkably, this 'parental switch' is highly target-specific, rather than a state of general aggressivity. Chemogenetic activation of AgRP neurons in the arcuate nucleus is sufficient to elicit the switch, and we have identified candidate nodes of parenting circuits that are both targeted by AgRP neuron projections and the activity of which is suppressed when animals switch towards pup-directed aggression. We are currently performing projection-specific optogenetic manipulations and *in vivo* recordings from postsynaptic neurons in parenting centres to characterise hunger-induced plasticity mechanisms underlying this drastic behavioural switch.

THE CIRCUIT BASIS OF OLFACTORY MATE RECOGNITION AND LOCALISATION

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Istvan Taisz, Dana Galili, Gregory Jefferis
MRC Laboratory of Molecular Biology, Neurobiology Division, Cambridge, United Kingdom

Sex pheromones are key social signals in most animals. In Drosophila a dedicated olfactory channel senses a male pheromone, cis-vaccenyl acetate (cVA) that promotes female courtship while repelling males. Here we show that flies can use cVA information from both antennae for sex-specific orientation. We find that cVA olfactory neurons are exquisitely sensitive to concentration differences in a 5 mm range around a male fly. In line with this, second order projection neurons (PNs) detect bi-antennal differences in cVA concentration, which can reliably encode the angular position of a male. We identify an active circuit mechanism increasing left-right response differences in PNs including an interneuron well placed to perform this function by providing contralateral inhibition. At the third layer of the circuit, one neuron population is selectively tuned to an approaching male with speed dependent responses: an olfactory looming signal. A second population responds tonically to a male fly's presence and controls female mating-decisions. Our results show that the olfactory system generates a range of complex percepts in discrete populations of central neurons. Spatial tuning is generated by integration of bilateral sensory information like the auditory system while separation of what and where pathways is reminiscent of the visual cortex.

AN EARLY LIFE MATERNAL NEGLECT PARADIGM INDUCES ALTERATIONS ON ANTICIPATORY BEHAVIOUR, PREFRONTAL SIGNALLING AND SOCIAL STATUS STABILITY IN ADULT RATS.

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Ermis Ryakiotakis
National and Kapodistrian University of Athens, Faculty Of Nursing, Athens, Greece

Adverse early life experiences affect neuronal growth and maturation of dopaminergic circuits that modify behaviour under rewarding conditions. Previous studies demonstrate that rats undergoing denial of expected reward in the form of maternal contact (DER) during early post-natal life develop anhedonia and reduced prefrontal cortex dopaminergic activity. To investigate the potential impact of the DER experience on the manifestation of anticipatory behaviour induced by natural rewards, we evaluated in adult male rats their naive sexual preference and performance as well as their anticipatory behaviour during a 2-phase food anticipation task composed of a context-dependent and a cue-dependent trial. DER rats efficiently spent time in the vicinity of and initiated sexual intercourse with receptive females suggesting an intact sexual reward motivation. Interestingly, during the context-dependent phase of food anticipation DER rats displayed chance level preference for the area where food was expected to be delivered, in contrast to control animals. Moreover, during the subsequent cue-dependent phase DER rats displayed an abnormally rapid loss of preference for the area where food was expected, implying a dysregulated dopaminergic function resulting in accelerated devaluation of the expected reward. This behavioural deficit in DER animals was accompanied by elevated pCREB levels in the ventral prefrontal cortex on the last day of the food anticipation task. In addition, the establishment of food approach priority was significantly disrupted in the groups of DER animals. These findings provide additional highlights to the importance of mother-infant contact on reward associated behavioural strategies, brain activation and establishment of social hierarchy.

FUNCTIONAL HEMISPHERIC ASYMMETRY OF MEDIAL HABENULA-TO-INTERPEDUNCULAR NUCLEUS SYNAPSES AND ITS IMPLICATIONS IN EMOTION-RELATED BEHAVIORS IN MICE

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Cihan Önal, Peter Koppensteiner, Ryuichi Shigemoto
Institute of Science and Technology Austria, Neuroscience, Klosterneuburg, Austria

The habenula is a phylogenetically conserved bilateral brain structure known to modulate negative emotions. Hemispheric asymmetry in cortical areas plays a key role in behavior and cognition in human and experimental animals. Although habenular asymmetry is prominent in several vertebrate species, there is no evidence for left-right asymmetry in the mammalian habenula. To investigate the asymmetry in synaptic transmission in the medial habenula (MHb) to the interpeduncular nucleus (IPN) pathway in mice, we performed targeted electrical stimulation of left or right MHb-derived axons in acute slices. We discovered that the probability of neurotransmitter release from left MHb terminals was significantly lower than that of right MHb terminals. Furthermore, activation of presynaptic $GABA_B$ receptors potentiated the release from left MHb terminals significantly stronger than that of right MHb terminals. Finally, we selectively suppressed left or right cholinergic MHb neurons using stereotaxic injection of floxed inhibitory DREADDs-expressing AAV into ChAT-Cre mice and performed cued fear conditioning. Chemogenetic inhibition of left but not right MHb significantly decreased the expression of auditory cue-conditioned fear memory. Our study provides the first evidence for a functional asymmetry of the MHb-IPN pathway in mammals and its potential involvement in emotion-related behavior. Physiologically, the right MHb dominates neurotransmission at rest, whereas activation of $GABA_B$ receptors equalized synaptic strength across hemispheres due to stronger potentiation of left side-derived synapses compared to right side-derived synapses. The side-specific silencing effect on the fear expression may reflect the laterality in the $GABA_B$-mediated regulation of this pathway.

33913808: Bhandari P, Vandael D, Fernández-Fernández D, Fritzius T, Kleindienst D, Önal C, Montanaro J, Gassmann M, Jonas P, Kulik A, Bettler B, Shigemoto R, Koppensteiner P
GABA receptor auxiliary subunits modulate Cav2.3-mediated release from medial habenula terminals.
The synaptic connection from medial habenula (MHb) to interpeduncular nucleus (IPN) is critical for emotion-related behaviors and uniquely expresses R-type Ca channels (Cav2.3) and auxiliary GABA receptor (GBR) subunits, the K-channel tetramerization domain-containing proteins (KCTDs). Activation of GBRs facilitates or inhibits transmitter release from MHb terminals depending on the IPN subnucleus, but the role of KCTDs is unknown. We therefore examined the localization and function of Cav2.3, GBRs, and KCTDs in this pathway in mice. We show in heterologous cells that KCTD8 and KCTD12b directly bind to Cav2.3 and that KCTD8 potentiates Cav2.3 currents in the absence of GBRs. In the rostral IPN, KCTD8, KCTD12b, and Cav2.3 co-localize at the presynaptic active zone. Genetic deletion indicated a bidirectional modulation of Cav2.3-mediated release by these KCTDs with a compensatory increase of KCTD8 in the active zone in KCTD12b-deficient mice. The interaction of Cav2.3 with KCTDs therefore scales synaptic strength independent of GBR activation.

SOCIAL ATTENTION AND SOCIAL REINFORCEMENT LEARNING – A NATURALISTIC EYE TRACKING PARADIGM AND COMPUTATIONAL MODELLING OF RESPONSES TO EMOTIONAL POINT-LIGHT-DISPLAYS (PLD'S)

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Raimund Bühler, Giorgia Silani
University of Vienna, Department Of Clinical And Health Psychology, Vienna, Austria

Attention to socially important regions of the face is a key component of daily social interaction and precedes fundamental social skills such as emotion recognition, nonverbal communication and mentalizing. It is also an essential prerequisite to social learning, i. e. when integrating emotional feedback to one's behavior. Direct eye contact is a salient social signal and, along with the aforementioned social skills, is often found to be atypical in disorders characterized by social impairments such as autism spectrum disorder (ASD). However, studies investigating eye gaze on faces often rely on static picture stimuli, which differ remarkably from real-life social interaction. Here, we developed a novel eye tracking paradigm which uses mobile eye tracking in conjunction with AI face-recognition software, to allow fixations to eyes, mouth and face to be measured during a real-life conversation. Performance in the task was investigated in association to 1) social learning in a reinforcement learning task using point-light-displays (PLD's) of emotional faces and 2) levels of autistic traits in a neurotypical sample measured by the Autism Spectrum Quotient (AQ). Computational modelling of trial-by-trial responses was used to determine more comprehensively which parameters of learning were modulated by attention to socially relevant regions and autistic traits. With this study, we aim to provide a method to investigate social attention in a more naturalistic context, which will pave the way for more precise and valid studies on social attention and ASD.

The ability to reason about another individual's mental state to predict their behavior is still controversial in non-human primates. This ability would be particularly useful to navigate optimally within a social group, and even more so within a social hierarchy. [E1] Many groups of social primates exhibit hierarchical structures and hierarchy directly influences social interactions and social behavior. Little is known about the computational mechanisms by which hierarchy influences social decision learning. A computational modeling approach might help to elucidate the sophistication of Theory of Mind (ToM) abilities in monkeys and the influence of social hierarchy on their social decision learning. Here we analyzed the behavior of seven baboons (*Papio papio*) who played a Coordination Game (CG) in a unique experimental setup in a social group of eighteen. Mentalizing models captured baboons' behavior when they interacted in a coordination game better than traditional reinforcement learning models or heuristics. Their coordination learning was also influenced by the difference in hierarchical status between individuals coordinating with one another. We provide evidence that coordination learning not only depended on the presence of another individual, but was also modulated by the difference in dominance status between the two individuals. Thus, an influence model that also incorporated the influence of the relative difference of social dominance best explained the learning. These findings provide a computational account of how baboons may actively track social hierarchy social decision making to modulate how they mentalize their influence on the other interacting individual, and to adapt their learning process.

NEUROCOMPUTATIONAL MECHANISMS ENGAGED IN DETECTING COOPERATIVE AND COMPETITIVE INTENTIONS OF OTHERS

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Rémi Philippe[1], Rémi Janet[2], Koosha Khalvati[3], Rajesh Rao[3,4], Daeyeol Lee[5], Jean-Claude Dreher[1]
[1]CNRS, Institut Des Sciences Cognitives Marc Jeannerod, Bron, France, [2]CNRS, Institut De Sciences Cognitives Marc Jeannerod, Bron, France, [3]University of Washington, Allen School Of Computer Science And Engineering, Seattle, United States of America, [4]University of Washington, Center For Neurotechnology, Seattle, United States of America, [5]Johns Hopkins University, Department Of Neurosciece, Department Of Psychologicnal And Brain Sciences, Baltimore, United States of America

Humans frequently interact with other agents whose intentions can fluctuate over time between competitive and cooperative strategies. How does the brain decide whether the others' intentions are to cooperate or compete when the nature of the interactions is not explicitly signaled? We used model-based fMRI and a task in which participants thought they were playing with another player. In fact, this agent was an algorithm alternating without signaling between cooperative and competitive strategies. A neurocomputational mechanism (controller) underlying arbitration between competitive and cooperative experts outperforms other learning models in predicting choice behavior. These two mentalizing experts anticipate the effect of there own action on the decision of others either under competitive or cooperative assumption. We found that the ventral striatum and ventromedial prefrontal cortex tracked the reliability of the arbitration process between the two experts at the decision making stage. At the time of receiving the winning/losing outcome, a common network encoded reward Prediction Error (rPE) for trials classified as competitive or cooperative (e.g. Ventral Striatum, rostral Anterior Cingulate Cortex). When the controller attributed competitive intentions, the right Temporoparietal Junction and the right dorsolateral Prefrontal Cortex encoded a rPE more robustly for trials classified as competitive than for trials classified as cooperative. These findings provide a neurocomputational account of how the brain dynamically arbitrates between cooperative and competitive intentions when making adaptive social decisions.

KNOCKDOWN OF PRIMARY CILIARY COMPONENT GENE IN HYPOTHALAMIC PARAVENTRICULAR NUCLEUS OXYTOCIN NEURONS IMPAIRS SOCIAL BEHAVIOR

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Seree Park[1], Hyunyoung Kim[1,2], Jihoon Kim[1], Keetae Kim[1], Hyungju Park[1,2], Han Kyoung Choe[1]
[1]Daegu Gyeongbuk Institute of Science & Technology, Department Of Brain Science, Daegu, Korea, Republic of, [2]Korea Brain Research Institute, Neurovascular Unit Research Group, Daegu, Korea, Republic of

The neuropeptide oxytocin (Oxt) originating from the paraventricular nucleus of hypothalamus (PVN) broadly modulates social behaviors across diverse species. While the impact of PVN-Oxt system on physiological, social, and cognitive functions is extensively studied, how subcellular organelles maintain the function of Oxt neurons is less explored. Primary cilia are especially known to play an important role in cells among various organelles. The present study investigated how the primary cilia in PVN-Oxt neurons affect the activities of PVN-Oxt neurons and thereby social behaviors. Knockdown of *Ift88*, a ciliogenesis gene, with a specific viral expression of shRNA in PVN-Oxt neurons selectively disrupted social recognition and memory. To determine whether the knockdown of ciliogenesis gene in PVN-Oxt neurons induces change in neuronal response, we performed whole-cell patch-clamp and fiber photometry. It was revealed that the neural activities in *Ift88* knockdown PVN-Oxt neurons display differential patterns in basal activities and social cue-interacting conditions. Overall, we suggest the importance of primary cilia of the PVN-Oxt neurons in the maintenance of baseline activities of PVN-Oxt neurons and the scaling the appropriate sizes of response to different social cues. Our finding also pinpoints the role of Oxt neurons in social cognition, extending recent evidence suggesting a causal role of Oxt neuronal activities in the social investigatory approach. Finally, it will be a first step toward appreciating the clinical implication of ciliary function in PVN-Oxt neurons.

EXPLORING THE NEURAL SUBSTRATE OF SOCIAL FEAR

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Shelly Singh, Shai Netser, Shlomo Wagner
University of Haifa, Sagol Department Of Neurobiology, Haifa, Israel

Background: Social anxiety disorder (SAD) or social phobia involves persistent avoidance and fear of a specific social stimulus or all social situations (generalized SAD). It has high lifetime prevalence risks and occurs in significant comorbidity with other neuropsychiatric disorders. Its treatment options are limited and unspecific, mostly because of lack of animal models and proper experimental design to study it. Method: We have developed a novel paradigm that relies on the behavioral response of approach to a neutral social stimulus of the same strain (C57BL/6J) and avoidance learning towards BALB/cJ mice. The paradigm consists of a baseline stage of habituation interleaved with social preference tests with C57BL/6J and BALB/cJ adult mice, followed by habituation in a shock delivery apparatus and social fear conditioning (SFC) session, where the approach of the subject towards BALB/cJ mouse is coupled with mild foot shocks. Early and late recall tests were conducted 20 minutes and 24 hours post-SFC, respectively. The behavioral phenotypes were automatically quantified using custom code in MATLAB (TrackRodent). As subjects, we have used Arc-dVenus transgenic mice, which express a destabilized venus fluorescence protein construct under the immediate-early gene Arc promoter. Results: The quantification of Arc positive cells across the entire forebrain revealed significant activation in the NAc, BLA and mPFC, specifically following the encounter with aversive BALB/cJ mouse, which is consistent with previous reports which show the role of these regions in stress responses and social isolation. A better understanding of social decision-making circuit will help in the emission of social fear with targeted therapy and reduce the risk of comorbid disorders.

THE INFLUENCE OF CHILDHOOD TRAUMA AND EPIGENETIC VARIATION IN OXTR ON ANXIETY PRONENESS AND STRUCTURAL NEUROIMAGING MEASURES IN A SOUTH AFRICAN ADOLESCENT COHORT

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Thomas Rust[1], Jacqueline Womersley[2], Sian Hemmings[2], Soraya Seedat[2]
[1]Stellenbosch University, Biomedical Sciences, Cape Town, South Africa, [2]Stellenbosch University, Psychiatry, Cape Town, South Africa

Aims: Anxiety proneness (AP), an endophenotype of anxiety disorders, is a risk factor for anxiety disorder development. We investigated whether (epi)genetic variation in the oxytocin receptor gene (*OXTR*), implicated in anxiety, interacted with childhood trauma (CT) to influence AP and structural brain differences in adolescents of Xhosa or South African Coloured (SAC) ethnicities. **Methods:** We examined the CT x genetic variant effects on AP (n = 951). We assessed methylation of cytosine-guanine dinucleotide (CpG) units in exon 1 using EpiTYPER MassARRAY technology and examined SNP and methylation contributions to structural MRI data for six bilateral brain regions in a subset of participants grouped according to AP and CT severity (n = 90). **Results:** The rs53576 A allele was associated with increased AP in SAC males and interacted with higher CT to predict increased methylation (chr3:8811004-8811010;chr3:8810970-8810974). Higher CT was associated with increased and decreased AP in SAC male and female rs2254298 GA carriers, respectively. The effect of high CT on methylation (chr3:8811254-8811260) was dependent on AP severity, with increased methylation in the high AP groups. rs2254298 and rs53576 GG genotypes were associated with increased left amygdala volume, with the latter genotype also associated with increased left hippocampal and thalamic volumes. Methylation (chr3:8811027-8811028) was proportionally associated with left thalamus and anterior cingulate cortex (ACC) volumes, with inverse associations between methylation and right amygdala (chr3:8811254-8811260), thalamus (chr3:8811173-8811177) and ACC (chr3:8811004-8811010) volumes prior to multiple testing correction. **Conclusions:** CT and *OXTR* (epi)genetic variation are implicated in AP and brain structure in adolescence.

A SYSTEMATIC REVIEW OF THE NEURAL BASES OF EMOTIONAL INTELLIGENCE.

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Victor Martín-Aguiar, Pablo Fernández-Berrocal, Alberto Megías-Robles
University of Malaga, Department Of Basic Psychology, Málaga, Spain

Aims. There has been an undeniable growing interest in Emotional Intelligence (EI) in recent years. Although it has important implications for our social and personal life, little is known about the brain bases that underlie EI. This work aims to review the available literature exploring the neural correlates of EI. Methods. A systematic search following the Cochrane guidelines was conducted in the main databases (Medline, PsycINFO, Scopus, and Web of Science). The inclusion criteria were empirical articles published in a peer-reviewed journal, written in Spanish or English, and that included an objective EI measurement and a neuroimaging technique. Results and Conclusions. Twenty-eight articles were finally identified. According to the results of the selected articles, the main brain regions identified were the dlPFC, OFC, vmPFC, amygdala, and insula. The authors, in general, related these areas to a neural network for social cognition, processes of cognitive and affective integration, and the somatic marker circuitry. Differences between emotional and cognitive intelligence at neural level were also considered. Finally, we identified a number of limitations and propose future lines of research. This research has been funded by the Research Plan of the University of Malaga (project B1-2019_08).

SOCIAL CUES MODULATE CIRCUIT DYNAMICS TO CONTROL THE CHOICE BETWEEN COMMUNICATION SIGNALS IN DROSOPHILA.

POSTER SESSION 06 - SECTION: CIRCUITS FOR SOCIAL BEHAVIOR

Elsa Steinfath[1,2], Afshin Khalili[2], Melanie Stenger[2], Kimia Alizadeh[2], Adrian Palacios Munoz[1,2], Jan Clemens[2]
[1]International Max Planck Research School, Neuroscience, Göttingen, Germany, [2]European Neuroscience Institute, Neural Computation And Behavior, Göttingen, Germany

Communication is multi-modal - when interacting, we speak, gesticulate, and touch. However, the neural computations and circuits that choose these communication signals are unclear. We address this issue in *Drosophila* which thanks to its complex social behavior and genetic toolbox is ideal for dissecting the neural basis of communication. During courtship, male flies produce two types of communication signals to woo the female: air-borne song and substrate-borne vibrations.
Using statistical modeling of pose tracking data alongside signal recordings during courtship, we found that female locomotion controls the choice between song and vibration: When the female moves, the male sings, when she is stationary, he vibrates. Optogenetic control of female locomotion confirms the results.
Combining optogenetics and network models, we next elucidated the circuit mechanisms underlying this choice. Two groups of neurons in the central brain, “P1a“ and “pC2”, drive both signals with complex dynamics: While activation of P1a in solitary males primarily drives persistent vibrations, pC2 induces first song and then vibrations. A circuit model reveals that these complex dynamics emerge from a combination of recurrence and mutual inhibition.
Lastly, we show how sensory cues modify the intrinsic circuit dynamics: P1a is activated by female chemical cues, accordingly we observe higher vibration production in the presence of a dead, immobile female. pC2 is activated when visual motion cues are provided and we find that chasing an alive female drives more song.
Overall, we show how intrinsic circuit dynamics are modified by sensory cues to produce context-dependent signals during social interactions.

BRAIN STRESS AND NORADRENERGIC SYSTEM MEDIATE THE MECHANISMS UNDERLYING RELAPSE CAUSED BY EXPOSURE TO SOCIAL DEFEAT IN THE NUCLEUS ACCUMBENS IN MORPHINE DEPENDENT MICE

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Alberto Cánovas, Javier Teruel-Fernández, M.Luisa Laorden, Pilar Almela, Javier Navarro-Zaragoza
University of Murcia, Department Of Pharmacology, Murcia, Spain

Aims: Addiction to substances of abuse is a chronic neurological disorder characterized by drug-seeking, compulsive consumption, and frequent relapses after long periods of abstinence. Many studies have proposed that stress has a key role in the development of drug addiction. In this study, we have investigated the influence of *Social Defeat* (SD)in relapse through the model of conditioned-place aversion (CPA). We have also analyzed pERK1/2 expression in nucleus accumbens (NAcc) during this paradigm. **Methods**: 60 C57BL/6J mice were rendered dependent on morphine and injected acutely with naloxone before paired to confinement in a naloxone-associated compartment. After extinction of the aversive memory, animals received CP-154,526 (CRF1 receptor antagonist), propranolol (beta-adrenergic receptor antagonist) or vehicle and were exposed to SD to induce relapse. pERK1/2 expression was analyzed in NAcc by Western Blot. **Results**: Our results show that application of SD after extinction induced relapse. The administration of CP-154,526 and propranolol antagonized this effect. Besides, a significant increase in pERK1/2 expression was observed in NAcc in the group exposed to stress receiving vehicle compared to the non-stress group. **Conclussions:** These results show the important relationship between stress and compulsive drug seeking, as well as a potential therapeutic value of propranolol and CP-154,526 in the treatment of relapses.

Pubmed:

Naloxone-induced conditioned place aversion score and extinction period are higher in C57BL/6J morphine-dependent mice than in Swiss: Role of HPA axis.
Intense associative memories develop between drug-paired contextual cues and the drug withdrawal associated aversive feeling. They have been suggested to contribute to the high rate of relapse. Our study was aimed to elucidate the involvement of hypothalamic-pituitary-adrenocortical (HPA) axis activity in the expression and extinction of aversive memory in Swiss and C57BL/6J (B6) mice. The animals were rendered dependent on morphine by i.p. injection of increasing doses of morphine (10-60 mg/kg). The negative state associated with naloxone (1 mg/kg s.c.) precipitated morphine withdrawal was examined by using conditioned place aversion (CPA) paradigm. B6 mice obtained a higher aversion score and took longer to extinguish the aversive memory than Swiss mice. In addition, corticosterone levels were increased after CPA expression. Moreover, corticosterone levels were decreased during CPA extinction in Swiss mice without changes in B6 mice. Pre-treatment with the selective CRF1 receptor antagonist CP-154,526 before naloxone, impaired morphine-withdrawal aversive memory acquisition and decreased the extinction period. CP-154,526 also antagonized the increased levels of corticosterone observed after CPA expression in Swiss mice, without any changes in B6 mice. These results indicate that HPA axis could be a critical factor governing opioid withdrawal memory storage and retrieval, but in a strain or stock-specific manner. The differences observed between Swiss and B6 mice suggest that the treatment of addictive disorders should consider different individual predisposition to associate the aversive learning with the context.

Cholesterol is one of the major brain lipids and plays an important role in different brain functions. Some studies show that drugs of abuse alter brain cholesterol metabolism, suggesting that cholesterol may participate in the mechanisms of addiction. Here, we investigated whether manipulations of cholesterol metabolism could alter addiction-related behaviors. For this, rats underwent 10 sessions of cocaine self-administration; then at the beginning of abstinence period, using viral approaches we overexpressed CYP46A1 (the main enzyme responsible for cholesterol degradation) or GFP (for control animals) in the dorsal striatum (DSt) or the anterior cingulate cortex (ACC). Six weeks after the last self-administration session, drug seeking was measured in an extinction session. Using a similar protocol, we also investigated the effects of striatal CYP46A1 overexpression on sucrose seeking. Finally, we overexpressed CYP46A1 in the DSt before the beginning of the self-administration of cocaine and measured potential changes in drug intake, motivation and resistance to punishment. We found that overexpression of CYP46A1 in DSt, but not in ACC, reduced the cocaine seeking. CYP46A1 overexpression had no effect on sucrose seeking. No change in levels of cocaine intake, motivation, and resistance to punishment was found when CYP46A1 was overexpressed before self-administration. Our results suggest that manipulating cholesterol metabolism in the DSt during abstinence might reduce risks of relapse to addiction, without changing motivation for natural reward or the direct rewarding effects of the drug. Therefore, we propose that cholesterol metabolism might represent a new therapeutic target to prevent relapse to cocaine addiction.

Epigenetics play a major role in the acquisition and maintenance of drug addiction. While many other drugs have been extensively investigated, nicotine stands out as having been poorly characterized in terms of its epigenetic effects. We used RNA sequencing from the PFC of nicotine (n=15), cocaine (n=8), and saline (n=8) self-administering rats 1 or 6 days after extinction to investigate the persistent changes in gene expression as a result of the drugs administration. Differential expression analyses showed unique expression profiles for cocaine and nicotine both on the first and 6th day of extinction. For example, cocaine self-administration led to an upregulation of a larger number of genes, however, the genes were mostly IEGs associated with acute drug response. Conversely, nicotine extinction led to a regulation of a smaller set of genes involved in the phosphorylation of MAPK pathways. Further network connectivity analyses using WGCNA revealed separate networks associated with general drug administration, nicotine administration, and cocaine administration. Interestingly the module of genes associated with extinction of nicotine self-administration was related to the regulation MAPK pathways. In conclusion, nicotine and cocaine lead to unique changes in RNA expression in the PFC during extinction, that are associated with separate gene networks, thus providing further evidence that it is important to look at these drugs of abuse individually.

Aims: The neurobiological substrate for the facilitation of brain stimulation reward and cocaine-seeking behavior is believed to involve the mesolimbic dopamine pathway. We have previously demonstrated that acupuncture at Shenmen (HT7) acupoints suppressed cocaine-induced dopamine release in the nucleus accumbens and cocaine-primed reinstatement through activation of GABA neurons in the ventral tegmental area. The aim of this study was to determine whether acupuncture would alter brain reward thresholds and their responses to cocaine. **Methods:** To assess the effects of HT7 stimulation on brain reward function, rats were used in intracranial self-stimulation paradigm with the frequency-rate curve-shift procedure. Rats were trained to lever-press for electrical stimulation of medial forebrain bundle of the lateral hypothalamus. Brain reward thresholds were monitored following acupuncture stimulation in rats under baseline conditions and exposure to acute cocaine (3.2 mg/kg, i.p.). **Results:** Results showed that acupuncture at HT7 acupoints, but not at Sanyinjiao (SP6) points, triggered a rightward shift of the frequency-rate curve and elevated reward thresholds under baseline conditions in drug-naïve rats. Also, HT7 stimulation tended to attenuate the threshold-lowering effects of cocaine. **Conclusions:** These results provide evidence that acupuncture at HT7 effectively modulates brain reward function.

Rationale Cannabis addiction is a multifactorial chronically relapsing disorder, which lacks effective treatment despite cannabis being the most used illicit drug worldwide. Regular consumption typically begins during adolescence, a critical developmental stage, leading to suggest that adolescent cannabinoid exposure might increase the risk for drug addiction in adulthood. **Aims** This study investigated the development of cannabis addiction in adult male mice after adolescent exposure to the main psychoactive component of cannabis, Δ^9-tetrahydrocannabinol (THC), to unravel the neurobiological correlates of resilience and vulnerability. **Methods** Adolescent mice were exposed to 5 mg/kg of THC from postnatal days 37 to 57. Operant self-administration sessions of WIN 55,212-2 (WIN), a synthetic cannabinoid full agonist (12.5mg/kg/injection), were conducted for 10 days. Mice were tested for three addiction-like criteria (persistence to response, motivation and compulsivity) and two vulnerability phenotypic traits (impulsivity and cue-induced reinstatement of drug-seeking), characterizing addicted and non-addicted mice. qPCRs were performed to detect differentially expressed genes in the mesocorticolimbic pathway of addicted and non-addicted mice. **Results** Adolescent THC-exposed mice displayed an impulsive-like behavior in adulthood during WIN self-administration, that was more pronounced in addicts, while it did not modify the reinforcement of WIN nor the development of cannabis addiction. Moreover, findings showed a downregulated dopamine D_2 receptor (D_2R) expression in the nucleus accumbens (NAc) of THC-exposed mice. Viral-mediated D_2R overexpression was performed to functionally validate these results. **Conclusions** These findings suggest that adolescent THC exposure under these particular conditions produces impulsivity-like behavior in adulthood, possibly mediated by a downregulation in NAc D_2R expression.

Decreased striatal adenosine A-dopamine D receptor heteromerization in schizophrenia.
According to the adenosine hypothesis of schizophrenia, the classically associated hyperdopaminergic state may be secondary to a loss of function of the adenosinergic system. Such a hypoadenosinergic state might either be due to a reduction of the extracellular levels of adenosine or alterations in the density of adenosine A receptors (ARs) or their degree of functional heteromerization with dopamine D receptors (DR). In the present study, we provide preclinical and clinical evidences for this latter mechanism. Two animal models for the study of schizophrenia endophenotypes, namely the phencyclidine (PCP) mouse model and the AR knockout mice, were used to establish correlations between behavioural and molecular studies. In addition, a new AlphaLISA-based method was implemented to detect native AR-DR heteromers in mouse and human brain. First, we observed a reduction of prepulse inhibition in AR knockout mice, similar to that observed in the PCP animal model of sensory gating impairment of schizophrenia, as well as a significant upregulation of striatal DR without changes in AR expression in PCP-treated animals. In addition, PCP-treated animals showed a significant reduction of striatal AR-DR heteromers, as demonstrated by the AlphaLISA-based method. A significant and pronounced reduction of AR-DR heteromers was next demonstrated in postmortem caudate nucleus from schizophrenic subjects, even though both DR and AR were upregulated. Finally, in PCP-treated animals, sub-chronic administration of haloperidol or clozapine counteracted the reduction of striatal AR-DR heteromers. The degree of AR-DR heteromer formation in schizophrenia might constitute a hallmark of the illness, which indeed should be further studied to establish possible correlations with chronic antipsychotic treatments.

ROLE OF ACTIVITY-DEPENDENT TRANSMITTER SWITCHING IN DRUG-INDUCED CHANGES IN BEHAVIOR

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Marta Pratelli[1], Nicholas Spitzer[1,2]
[1]University of California San Diego, Kavli Institute For Brain & Mind, La Jolla, United States of America, [2]University of California San Diego, Neurobiology, San Diego, United States of America

Drugs of abuse alter neuronal activity and cause widespread neuroplasticity that results in behavioral alterations. We investigated whether exposure to drugs causes a form of activity-dependent plasticity called neurotransmitter switching. This plasticity occurs when neurons lose the transmitter they have expressed before and gain a different one, and can influence behavior. We treated mice with either phencyclidine or methamphetamine, two drugs that differ in their molecular targets, but both cause hyperactivity of prefrontal cortex glutamatergic neurons. After a 10-day exposure to either drug, we discovered that ~600 prelimbic cortex (PrL) pyramidal neurons have gained GABA and exhibit decreased expression of the vesicular glutamate transporter. Overriding the gain of GABA in PrL glutamatergic neurons, using an RNA-interference strategy, prevented the appearance of drug-induced memory deficits in the novel object recognition test and spontaneous alternation task as well as locomotor sensitization. These results indicate that the switch is causally linked to these behavioral alterations. Because neurotransmitter switching is activity-dependent, we tested whether drug-induced hyperactivity of PrL glutamatergic neurons drives the transmitter switch. To suppress PrL hyperactivity we combined drug-administration with chemogenetic activation of PV+ interneurons that provide perisomatic inhibition of glutamatergic cells. This intervention was sufficient to block the transmitter switch and prevent the changes in behavior. Remarkably, suppression of drug-induced elevation of PrL neuron activity, after the switch has occurred, reversed the change in transmitter identity and rescued the behavioral deficits. The results suggest therapeutic opportunities for mitigating drug-induced cognitive deficits through manipulation of prefrontal cortex electrical activity.

Decoding Neurotransmitter Switching: The Road Forward.
Neurotransmitter switching is a form of brain plasticity in which an environmental stimulus causes neurons to replace one neurotransmitter with another, often resulting in changes in behavior. This raises the possibility of applying a specific environmental stimulus to induce a switch that can enhance a desirable behavior or ameliorate symptoms of a specific pathology. For example, a stimulus inducing an increase in the number of neurons expressing dopamine could treat Parkinson's disease, or one affecting the number expressing serotonin could alleviate depression. This may already be producing successful treatment outcomes without our knowing that transmitter switching is involved, with improvement of motor function through physical activity and cure of seasonal depression with phototherapy. This review presents prospects for future investigation of neurotransmitter switching, considering opportunities and challenges for future research and describing how the investigation of transmitter switching is likely to evolve with new tools, thus reshaping our understanding of both normal brain function and mental illness.

Fluoxetine Induces Morphological Rearrangements of Serotonergic Fibers in the Hippocampus.
Serotonin (5-HT)-releasing fibers show substantial structural plasticity in response to genetically induced changes in 5-HT content. However, whether 5-HT fibers appear malleable also following clinically relevant variations in 5-HT levels that may occur throughout an individual's life has not been investigated. Here, using confocal imaging and 3D modeling analysis in knock-in mice, we show that chronic administration of the antidepressant fluoxetine dramatically affects the morphology of 5-HT fibers innervating the dorsal and ventral hippocampus resulting in a reduced density of fibers. Importantly, GFP fluorescence levels appeared unaffected in the somata of both dorsal and median 5-HT neurons, arguing against potential fluoxetine-mediated down-regulation of the promoter driving GFP expression in the mouse model. In keeping with this notion, mice bearing the pan-serotonergic driver partnered with a Cre-responsive tdTomato allele also showed similar morphological alterations in hippocampal 5-HT circuitry following chronic fluoxetine treatment. Moreover 5-HT fibers innervating the cortex

showed proper density and no overt morphological disorganization, indicating that the reported fluoxetine-induced rearrangements were hippocampus specific. On the whole, these data suggest that 5-HT fibers are shaped in response to subtle changes of 5-HT homeostasis and may provide a structural basis by which antidepressants exert their therapeutic effect.

Serotonergic neurotransmission manipulation for the understanding of brain development and function: Learning from Tph2 genetic models.
Serotonin (5-hydroxytriptamine; 5-HT) is a fascinating neurotransmitter that thanks to an extensive axonal network is released throughout the entire central nervous system (CNS) and exerts its action on the modulation of a countless number of physiological, behavioral and cognitive processes. In addition, cumulating evidences have linked alteration in 5-HT neurotransmission with the onset of psychiatric and neurodevelopmental disorders, such as depression, autisms and schizophrenia. Nevertheless only 5% of the total body content of serotonin exerts its action in the CNS, while the rest is synthetized and stored in peripheral tissues where it acts as an autacoid. In 2003 it became evident that two distinct isoforms of tryptophan hydroxylase (Tph), the rate-limiting enzyme for the synthesis of serotonin, are selectively expressed in peripheral tissues and in the CNS, with Tph2 as the brain specific isoform. In the present review we describe how the discovery of Tph2 has improved our understanding on the role of serotonergic neurotransmission. We mainly focus on the analysis of animal models generated by genetic manipulation of Tph2, in which the synthesis of brain serotonin was either reduced or disrupted. The consequences of an altered serotonergic neurotransmission on brain development, as well as on physiological and behavioral processes will be assessed. Finally, we report on several association studies that have linked single nucleotide polymorphisms (SNPs) in the human TPH2 gene with behavioral disturbances and neuropsychiatric disorders.

Development of Serotonergic Fibers in the Post-Natal Mouse Brain.
Serotonin (5-HT)-synthetizing neurons, which are confined in the nuclei of the rhombencephalon, provide a pervasive innervation of the central nervous system (CNS) and are involved in the modulation of a plethora of functions in both developing and adult brain. Classical studies have described the post-natal development of serotonergic axons as a linear process of terminal field innervation. However, technical limitations have hampered a fine morphological characterization. With the advent of genetic mouse models, the possibility to label specific neuronal populations allowed the rigorous measurement of their axonal morphological features as well as their developmental dynamics. Here, we used the knock-in mouse line, in which GFP expression allows punctual identification of serotonergic neurons and axons, for confocal microscope imaging and we performed 3-dimensional reconstruction in order to morphologically characterize the development of serotonergic fibers in specified brain targets from birth to adulthood. Our analysis highlighted region-specific developmental patterns of serotonergic fiber density ranging from a linear and progressive colonization of the target (Caudate/Putamen, Basolateral Amygdala, Geniculate Nucleus and Substantia Nigra) to a transient increase in fiber density (medial Prefrontal Cortex, Globus Pallidus, Somatosensory Cortex and Hippocampus) occurring with a region-specific timing. Despite a common pattern of early post-natal morphological maturation in which a progressive rearrangement from a dot-shaped to a regular and smooth fiber morphology was observed, starting from post-natal day 28 serotonergic fibers acquire the region specific morphological features present in the adult. In conclusion, we provided novel, target-specific insights on the morphology and temporal dynamics of the developing serotonergic fibers.

A Tph2 Reporter Stem Cell Line To Model in Vitro and in Vivo Serotonergic Neuron Development and Function.
Modeling biological systems in vitro has contributed to clarification of complex mechanisms in simplified and controlled experimental conditions. Mouse embryonic stem (mES) cells can be successfully differentiated toward specific neuronal cell fates, thus representing an attractive tool to dissect, in vitro, mechanisms that underlie complex neuronal features. In this study, we generated and characterized a reporter mES cell line, called Tph2, in which the vital reporter GFP replaces the tryptophan hydroxylase 2 (Tph2) gene. Tph2 mES cells selectively express GFP upon in vitro differentiation toward the serotonergic fate, they synthesize serotonin, possess excitable membranes, and show the typical morphological, morphometrical, and molecular features of in vivo serotonergic neurons. Thanks to the vital reporter GFP, we highlighted by time-lapse video microscopy several dynamic processes such as cell migration and axonal outgrowth in living cultures. Finally, we demonstrated that predifferentiated Tph2 cells are able to terminally differentiate, integrate, and innervate the host brain when grafted in vivo. On the whole, the present study introduces the Tph2 mES cell line as a useful tool allowing accurate developmental and dynamic studies and representing a reliable platform for the study of serotonergic neurons in

health and disease.

Perturbation of Serotonin Homeostasis during Adulthood Affects Serotonergic Neuronal Circuitry.
Growing evidence shows that the neurotransmitter serotonin (5-HT) modulates the fine-tuning of neuron development and the establishment of wiring patterns in the brain. However, whether serotonin is involved in the maintenance of neuronal circuitry in the adult brain remains elusive. Here, we use a conditional knockout (cKO) mouse line to assess the impact of serotonin depletion during adulthood on serotonergic system organization. Data show that the density of serotonergic fibers is increased in the hippocampus and decreased in the thalamic paraventricular nucleus (PVN) as a consequence of brain serotonin depletion. Strikingly, these defects are rescued following reestablishment of brain 5-HT signaling via administration of the serotonin precursor 5-hydroxytryptophan (5-HTP). Finally, 3D reconstruction of serotonergic fibers reveals that changes in serotonin homeostasis affect axonal branching complexity. These data demonstrate that maintaining proper serotonin homeostasis in the adult brain is crucial to preserve the correct serotonergic axonal wiring.

Generation of a Tph2 Conditional Knockout Mouse Line for Time- and Tissue-Specific Depletion of Brain Serotonin.
Serotonin has been gaining increasing attention during the last two decades due to the dual function of this monoamine as key regulator during critical developmental events and as neurotransmitter. Importantly, unbalanced serotonergic levels during critical temporal phases might contribute to the onset of neuropsychiatric disorders, such as schizophrenia and autism. Despite increasing evidences from both animal models and human genetic studies have underpinned the importance of serotonin homeostasis maintenance during central nervous system development and adulthood, the precise role of this molecule in time-specific activities is only beginning to be elucidated. Serotonin synthesis is a 2-step process, the first step of which is mediated by the rate-limiting activity of Tph enzymes, belonging to the family of aromatic amino acid hydroxylases and existing in two isoforms, Tph1 and Tph2, responsible for the production of peripheral and brain serotonin, respectively. In the present study, we generated and validated a conditional knockout mouse line, Tph2flox/flox, in which brain serotonin can be effectively ablated with time specificity. We demonstrated that the Cre-mediated excision of the third exon of Tph2 gene results in the production of a Tph2null allele in which we observed the near-complete loss of brain serotonin, as well as the growth defects and perinatal lethality observed in serotonin conventional knockouts. We also revealed that in mice harbouring the Tph2null allele, but not in wild-types, two distinct Tph2 mRNA isoforms are present, namely Tph2Δ3 and Tph2Δ3Δ4, with the latter showing an in-frame deletion of amino acids 84-178 and coding a protein that could potentially retain non-negligible enzymatic activity. As we could not detect Tph1 expression in the raphe, we made the hypothesis that the Tph2Δ3Δ4 isoform can be at the origin of the residual, sub-threshold amount of serotonin detected in the brain of Tph2null/null mice. Finally, we set up a tamoxifen administration protocol that allows an efficient, time-specific inactivation of brain serotonin synthesis. On the whole, we generated a suitable genetic tool to investigate how serotonin depletion impacts on time-specific events during central nervous system development and adulthood life.

Generation of Pet1210-Cre transgenic mouse line reveals non-serotonergic expression domains of Pet1 both in CNS and periphery.
Neurons producing serotonin (5-hydroxytryptamine, 5-HT) constitute one of the most widely distributed neuronal networks in the mammalian central nervous system (CNS) and exhibit a profuse innervation throughout the CNS already at early stages of development. Serotonergic neuron specification is controlled by a combination of secreted molecules and transcription factors such as Shh, Fgf4/8, Nkx2.2, Lmx1b and Pet1. In the mouse, Pet1 mRNA expression appears between 10 and 11 days post coitum (dpc) in serotonergic post-mitotic precursors and persists in serotonergic neurons up to adulthood, where it promotes the expression of genes defining the mature serotonergic phenotype such as tryptophan hydroxylase 2 (Tph2) and serotonin transporter (SERT). Hence, the generation of genetic tools based on Pet1 specific expression represents a valuable approach to study the development and function of the serotonergic system. Here, we report the generation of a Pet1(210)-Cre transgenic mouse line in which the Cre recombinase is expressed under the control of a 210 kb fragment from the Pet1 genetic locus to ensure a reliable and faithful control of somatic recombination in Pet1 cell lineage. Besides Cre-mediated recombination accurately occurred in the serotonergic system as expected and according to previous studies, Pet1(210)-Cre transgenic mouse line allowed us to identify novel, so far uncharacterized, Pet1 expression domains. Indeed, we showed that in the raphe Pet1 is expressed also in a non-serotonergic neuronal population intermingled with Tph2-expressing cells and mostly localized in the B8 and B9 nuclei. Moreover, we detected Cre-mediated recombination also in the developing pancreas and in the ureteric bud derivatives of the kidney, where it reflected a specific Pet1 expression. Thus, Pet1(210)-Cre transgenic mouse line faithfully drives Cre-mediated recombination in all Pet1 expression domains

representing a valuable tool to genetically manipulate serotonergic and non-serotonergic Pet1 cell lineages. PLoS One, 2014; 9

A NEURAL CIRCUIT FOR CONTROLLING LONG-TERM VOLUNTARY ALCOHOL CONSUMPTION.

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Arnauld Belmer[1], Ronan Depoortere[2], Adrian Newman-Tancredi[2], Selena Bartlett[1]
[1]Translational Research Institute, Faculty Of Health, School Of Clinical Sciences, Woolloongabba, Australia, [2]Neurolixis, Neurolixis Sas, Castres, France

Alcohol-use-disorders (AUDs) are chronic relapsing illnesses, with alcohol often self-medicated to cope with distressing symptoms of various mental health issues. Given that the brain serotonin (5-HT) system is closely involved in stress responses to social isolation, fear, anxiety and depression, we hypothesized that alterations in brain 5-HT transmission contributes to the reinforcement of alcohol drinking behaviour. Long-term alcohol consumption alters the expression and function of 5-HT1A receptors, and raphe 5-HT neurons signaling. We demonstrated that a chronic treatment with partial 5-HT1A receptor agonists reduces ethanol intake, withdrawal-induced anxiety-like behaviour and the deficits in hippocampal neurogenesis after long-term ethanol intake. However, the contribution of 5-HT1A auto- vs heteroreceptors and the role played by raphe 5-HTergic transmission in alcohol consumption is less understood. We used highly selective 5-HT1A agonist (F13640) or biased agonists that preferentially target 5-HT1A auto- (F13714) or heteroreceptors (F5599)to determine which of the 5-HT1A receptor population mediates the effect of 5-HT1A agonists on the reduction of ethanol intake. Brain cannulation and local injections of agonists allowed us to identify which raphe nucleus, dorsal or median, mediates the reduction of ethanol intake following short- vs long-term exposure. We used CRE-dependent DREADDs in *pet1*-5-HT neurons, in combination with local injections of the designer drug CNO to identify 5-HTergic circuits that control long-term ethanol intake. Using this strategy, we discovered that 5-HT neuronal circuits switched after long-term drinking from DR to MR-DG, and suggests that drugs targeting those particular circuits might represent viable therapeutic strategies for the treatment of AUDs.

Dissecting the contribution of 5-HT auto- and heteroreceptors in sucrose overconsumption in mice.
The rise in obesity prevalence has been linked to overconsumption of high-sugar containing food and beverages. Recent evidence suggests that chronic sucrose consumption leads to changes in serotonergic neuroplasticity within the neural circuits involved in feeding control. Although there is a relationship between serotonin signalling in the brain and diet-induced obesity, the specific serotonin (5-HT) receptors or pathways involved remain unknown. The 5-HT receptor subtype plays a role in regulating mood, anxiety, and appetite, and has been associated with reversing addiction to substances of abuse. However, the respective role of 5-HT auto- vs heteroreceptors in sucrose consumption has not been examined. Mice were given controlled access to either 5%, 10% or 25% w/v sucrose, or water as a control, for 12 weeks using the well-established "drinking in the dark" protocol (n = 6-8 mice per group). Ligands selectively targeting 5-HT auto- and/or heteroreceptors (NLX-112, unbiased 5-HT receptor agonist; NLX-101, preferential heteroreceptor agonist; F13714, preferential autoreceptor agonist) were administered i.p. acutely after 6 and 12 weeks of sucrose consumption. The specific involvement of 5-HT receptors in these effects was verified by blockade with the selective 5-HT receptors antagonist WAY-100,635. The specific subpopulation of 5-HT receptors involved in sucrose consumption was dependent on the concentration of sucrose solution and the duration of exposure to sucrose (6 weeks vs 12 weeks). Long-term sucrose consumption leads to accentuated 5-HT autoreceptor function. Thus, targeting 5-HT autoreceptors might represent an effective therapeutic strategy to combat the rise in obesity resulting from the overconsumption of high-sugar diet.

Long-Term Overconsumption of Sugar Starting at Adolescence Produces Persistent Hyperactivity and Neurocognitive Deficits in Adulthood.
Sugar has become embedded in modern food and beverages. This has led to overconsumption of sugar in children, adolescents, and adults, with more than 60 countries consuming more than four times (>100 g/person/day) the WHO recommendations (25 g/person/day). Recent evidence suggests that obesity and impulsivity from poor dietary habits leads to

further overconsumption of processed food and beverages. The long-term effects on cognitive processes and hyperactivity from sugar overconsumption, beginning at adolescence are not known. Using a well-validated mouse model of sugar consumption, we found that long-term sugar consumption, at a level that significantly augments weight gain, elicits an abnormal hyperlocomotor response to novelty and alters both episodic and spatial memory. Our results are similar to those reported in attention deficit and hyperactivity disorders. The deficits in hippocampal-dependent learning and memory were accompanied by altered hippocampal neurogenesis, with an overall decrease in the proliferation and differentiation of newborn neurons within the dentate gyrus. This suggests that long-term overconsumption of sugar, as that which occurs in the Western Diet might contribute to an increased risk of developing persistent hyperactivity and neurocognitive deficits in adulthood.

Axonal Non-segregation of the Vesicular Glutamate Transporter VGLUT3 Within Serotonergic Projections in the Mouse Forebrain.
A subpopulation of raphe 5-HT neurons expresses the vesicular glutamate transporter VGLUT3 with the co-release of glutamate and serotonin proposed to play a pivotal role in encoding reward- and anxiety-related behaviors. Serotonin axons are identifiable by immunolabeling of either serotonin (5-HT) or the plasma membrane 5-HT transporter (SERT), with SERT labeling demonstrated to be only partially overlapping with 5-HT staining. Studies investigating the colocalization or segregation of VGLUT3 within SERT or 5-HT immunolabeled boutons have led to inconsistent results. Therefore, we combined immunohistochemistry, high resolution confocal imaging, and 3D-reconstruction techniques to map and quantify the distribution of VGLUT3 immunoreactive boutons within 5-HT vs. SERT-positive axons in various regions of the mouse forebrain, including the prefrontal cortex, nucleus accumbens core and shell, bed nucleus of the stria terminalis, dorsal striatum, lateral septum, basolateral and central amygdala, and hippocampus. Our results demonstrate that about 90% of 5-HT boutons are colocalized with SERT in almost all the brain regions studied, which therefore reveals that VGLUT3 and SERT do not segregate. However, in the posterior part of the NAC shell, we confirmed the presence of a subtype of 5-HT immunoreactive axons that lack the SERT. Interestingly, about 90% of the 5-HT/VGLUT3 boutons were labeled for the SERT in this region, suggesting that VGLUT3 is preferentially located in SERT immunoreactive 5-HT boutons. This work demonstrates that VGLUT3 and SERT cannot be used as specific markers to classify the different subtypes of 5-HT axons.

Positive regulation of raphe serotonin neurons by serotonin 2B receptors.
Serotonin is a neurotransmitter involved in many psychiatric diseases. In humans, a lack of 5-HT receptors is associated with serotonin-dependent phenotypes, including impulsivity and suicidality. A lack of 5-HT receptors in mice eliminates the effects of molecules that directly target serotonergic neurons including amphetamine derivative serotonin releasers, and selective serotonin reuptake inhibitor antidepressants. In this work, we tested the hypothesis that 5-HT receptors directly and positively regulate raphe serotonin neuron activity. By ex vivo electrophysiological recordings, we report that stimulation by the 5-HT receptor agonist, BW723C86, increased the firing frequency of serotonin Pet1-positive neurons. Viral overexpression of 5-HT receptors in these neurons increased their excitability. Furthermore, in vivo 5-HT-receptor stimulation by BW723C86 counteracted 5-HT autoreceptor-dependent reduction in firing rate and hypothermic response in wild-type mice. By a conditional genetic ablation that eliminates 5-HT receptor expression specifically and exclusively from Pet1-positive serotonin neurons (Htr2b mice), we demonstrated that behavioral and sensitizing effects of MDMA (3,4-methylenedioxy-methamphetamine), as well as acute behavioral and chronic neurogenic effects of the antidepressant fluoxetine, require 5-HT receptor expression in serotonergic neurons. In Htr2b mice, dorsal raphe serotonin neurons displayed a lower firing frequency compared to control Htr2b mice as assessed by in vivo extracellular recordings and a stronger hypothermic effect of 5-HT-autoreceptor stimulation was observed. The increase in head-twitch response to DOI (2,5-dimethoxy-4-iodoamphetamine) further confirmed the lower serotonergic tone resulting from the absence of 5-HT receptors in serotonin neurons. Together, these observations indicate that the 5-HT receptor acts as a direct positive modulator of serotonin Pet1-positive neurons in an opposite way as the known 5-HT-negative autoreceptor.

5-HT1A receptor-dependent modulation of emotional and neurogenic deficits elicited by prolonged consumption of alcohol.

Repeated episodes of binge-like alcohol consumption produce anxiety, depression and various deleterious effects including alterations in neurogenesis. While the involvement of the serotonin receptor 1 A (5-HT) in the regulation of anxiety-like behavior and neurogenesis is well documented, its contribution to alcohol withdrawal-induced anxiety and alcohol-induced deficits in neurogenesis is less documented. Using the Drinking-In-the-Dark (DID) paradigm to model chronic long-term (12 weeks) binge-like voluntary alcohol consumption in mice, we show that the selective partial activation of 5-HT receptors by tandospirone (3 mg/kg) prevents alcohol withdrawal-induced anxiety in a battery of behavioral tests (marble burying, elevated-plus-maze, open-field), which is accompanied by a robust decrease in binge-like ethanol intake (1 and 3 mg/kg). Furthermore, using triple immunolabelling of proliferation and neuronal differentiation markers, we show that long-term DID elicits profound deficits in neurogenesis and neuronal fate specification in the dorsal hippocampus that are entirely reversed by a 2-week chronic treatment with the 5-HT partial agonist tandospirone (3 mg/kg/day). Together, our results confirm previous observations that 5-HT receptors play a pivotal role in alcohol drinking behavior and the associated emotional and neurogenic impairments, and suggest that 5-HT partial agonists represent a promising treatment strategy for alcohol abuse.

Mapping the connectivity of serotonin transporter immunoreactive axons to excitatory and inhibitory neurochemical synapses in the mouse limbic brain.
Serotonin neurons arise from the brainstem raphe nuclei and send their projections throughout the brain to release 5-HT which acts as a modulator of several neuronal populations. Previous electron microscopy studies in rats have morphologically determined the distribution of 5-HT release sites (boutons) in certain brain regions and have shown that 5-HT containing boutons form synaptic contacts that are either symmetric or asymmetric. In addition, 5-HT boutons can form synaptic triads with the pre- and postsynaptic specializations of either symmetrical or asymmetrical synapses. However, due to the labor intensive processing of serial sections required by electron microscopy, little is known about the neurochemical properties or the quantitative distribution of 5-HT triads within whole brain or discrete subregions. Therefore, we used a semi-automated approach that combines immunohistochemistry and high-resolution confocal microscopy to label serotonin transporter (SERT) immunoreactive axons and reconstruct in 3D their distribution within limbic brain regions. We also used antibodies against key pre- (synaptophysin) and postsynaptic components of excitatory (PSD95) or inhibitory (gephyrin) synapses to (1) identify putative 5-HTergic boutons within SERT immunoreactive axons and, (2) quantify their close apposition to neurochemical excitatory or inhibitory synapses. We provide a 5-HTergic axon density map and have determined the ratio of synaptic triads consisting of a 5-HT bouton in close proximity to either neurochemical excitatory or inhibitory synapses within different limbic brain areas. The ability to model and map changes in 5-HTergic axonal density and the formation of triadic connectivity within whole brain regions using this rapid and quantitative approach offers new possibilities for studying neuroplastic changes in the 5-HTergic pathway.

Serotonergic Neuroplasticity in Alcohol Addiction.
Alcohol addiction is a debilitating disorder producing maladaptive changes in the brain, leading drinkers to become more sensitive to stress and anxiety. These changes are key factors contributing to alcohol craving and maintaining a persistent vulnerability to relapse. Serotonin (5-Hydroxytryptamine, 5-HT) is a monoamine neurotransmitter widely expressed in the central nervous system where it plays an important role in the regulation of mood. The serotonin system has been extensively implicated in the regulation of stress and anxiety, as well as the reinforcing properties of all of the major classes of drugs of abuse, including alcohol. Dysregulation within the 5-HT system has been postulated to underlie the negative mood states associated with alcohol use disorders. This review will describe the serotonergic (5-HTergic) neuroplastic changes observed in animal models throughout the alcohol addiction cycle, from prenatal to adulthood exposure. The first section will focus on alcohol-induced 5-HTergic neuroadaptations in offspring prenatally exposed to alcohol and the consequences on the regulation of stress/anxiety. The second section will compare alterations in 5-HT signalling induced by acute or chronic alcohol exposure during adulthood and following alcohol withdrawal, highlighting the impact on the regulation of stress/anxiety signalling pathways. The third section will outline 5-HTergic neuroadaptations observed in various genetically-selected ethanol preferring rat lines. Finally, we will discuss the pharmacological manipulation of the 5-HTergic system on ethanol- and anxiety/stress-related behaviours demonstrated by clinical trials, with an emphasis on current and potential treatments.

DISENTANGLING THE MOLECULAR MECHANISMS UNDERLYING THE RETRIEVAL AND EXTINCTION OF MORPHINE WITHDRAWAL-ASSOCIATED MEMORIES IN THE BASOLATERAL AMYGDALA AND DENTATE GYRUS

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Aurelio Franco, Francisco José Fernández-Gómez, Victoria Gomez-Murcia, Juana Hidalgo, Cristina Núñez, Victoria Milanés
University of Murcia, Pharmacology, Murcia, Spain

Opiates prescription remains controversial due to their addictive potential. Relapse in drug use is a significant problem for addiction treatment, being drug-associated memories among its main triggers. Consequently, the extinction of these memories has been proposed as a therapeutic tool. Hence, by using the conditioned place aversion (CPA) paradigm in rats we investigated some of the molecular mechanisms occurring during the retrieval and extinction of morphine withdrawal memories in the basolateral amygdala (BLA) and the hippocampal dentate gyrus (DG), which control emotional and episodic memories, respectively. Retrieval of aversive memories associated with the abstinence syndrome paralleled with decreased mTOR activity and increased Arc and GluN1 expressions in DG. *Arc* mRNA levels in this nucleus very strongly correlated with the CPA score exhibited by the opiate-treated rats. On the other hand, despite the unaltered mTOR phosphorylation Arc augmented in BLA. After the extinction test, Arc and GluN1 expressions raised in both DG and BLA of control and morphine-treated animals. Remarkably, Homer1 expression in both areas correlated almost perfectly with the extinction showed by morphine-dependent animals. Also, Arc expression in DG correlated strongly with the extinction of the CPA manifested by the morphine-treated group. Finally, our results support coordinated activity of some of these neuroplastic proteins for the extinction of morphine activity in a regional-dependent manner. Present data provide evidence of differential expression and activity of synaptic molecules during retrieval and extinction of aversive memories of opiate withdrawal in amygdalar and hippocampal regions that will likely permit the development of therapeutic strategies.

Blockade of D3 receptor prevents changes in DAT and D3R expression in the mesolimbic dopaminergic circuit produced by social stress- and cocaine prime-induced reinstatement of cocaine-CPP.
Cocaine may cause persistent changes in the brain, which are more apparent in DA transporter (DAT) and DA receptor availability within the nucleus accumbens (NAc). On the other hand, the DA D3 receptor (D3R) has emerged as a promising pharmacotherapeutic target for substance use disorders.

Distinct Regulation of Dopamine D3 Receptor in the Basolateral Amygdala and Dentate Gyrus during the Reinstatement of Cocaine CPP Induced by Drug Priming and Social Stress.
Relapse in the seeking and intake of cocaine is one of the main challenges when treating its addiction. Among the triggering factors for the recurrence of cocaine use are the re-exposure to the drug and stressful events. Cocaine relapse engages the activity of memory-related nuclei, such as the basolateral amygdala (BLA) and the hippocampal dentate gyrus (DG), which are responsible for emotional and episodic memories. Moreover, D3 receptor (D3R) antagonists have recently arisen as a potential treatment for preventing drug relapse. Thus, we have assessed the impact of D3R blockade in the expression of some dopaminergic markers and the activity of the mTOR pathway, which is modulated by D3R, in the BLA and DG during the reinstatement of cocaine-induced conditioned place preference (CPP) evoked by drug priming and social stress. Reinstatement of cocaine CPP paralleled an increasing trend in D3R and dopamine transporter (DAT) levels in the BLA. Social stress, but not drug-induced reactivation of cocaine memories, was prevented by systemic administration of SB-277011-A (a selective D3R antagonist), which was able, however, to impede D3R and DAT up-regulation in the BLA during CPP reinstatement evoked by both stress and cocaine. Concomitant with cocaine CPP reactivation, a diminution in mTOR phosphorylation (activation) in the BLA and DG occurred, which was inhibited by D3R blockade in both nuclei before the social stress episode and only in the BLA when CPP reinstatement was provoked by a cocaine prime. Our data, while supporting a main role for D3R signalling in the BLA in the reactivation of cocaine memories evoked by social stress, indicate

that different neural circuits and signalling mechanisms might mediate in the reinstatement of cocaine-seeking behaviours depending upon the triggering stimuli.

Introduction and Hypothesis Binge drinking, abusive alcohol consumption in a short period of time, leads to serious consequences in memory function. The kynurenine pathway is altered both by ethanol intake and in several pathologies displaying cognitive impairment. Since the main target of kynurenine is the aryl hydrocarbon receptor (AhR), our hypothesis is that allosteric modulation of AhR by 3,3'-diindolylmethane (DIM) prevents binge ethanol-induced memory alterations. **Aims** To assess the effect of treatment with DIM on memory deficits and alterations in glutamate receptor expression and metalloproteinase activity caused by binge ethanol. **Methods** Recognition memory of mice exposed to binge ethanol and treated with DIM was evaluated using the novel object recognition test 20 h after the last dose of ethanol. In addition, metalloproteinase (MMP)-9 and MMP-2 activity and glutamate receptor NMDA expression were measured by zymography and western blot, respectively, at 1 h and 20 h after ethanol. **Results** Binge ethanol induced memory deficits at 20 h which were prevented by DIM treatment. MMP-9 activity was decreased 1 h after the last ethanol dose and increased at 20 h, while DIM prevented the increase in activity at 20 h. NMDAR-2A expression was increased both at 1 h and 20 h after ethanol, and this was prevented by DIM only at 1 h. **Conclusions** The results indicate that binge drinking produced changes in MMP-9 activity and NMDAR-2A expression that were attenuated by DIM, suggesting modulation of AhR may represent a novel target for the prevention of ethanol-induced memory deficits.

Addiction and the kynurenine pathway: A new dancing couple?
Drug use poses a serious threat to health systems throughout the world and the number of consumers rises relentlessly every year. The kynurenine pathway, main pathway of tryptophan degradation, has drawn interest in this field due to its relationship with addictive behaviour. Recently it has been confirmed that modulation of kynurenine metabolism at certain stages of the pathway can reduce, prevent or abolish drug seeking-like behaviours in studies with several different drugs. In this review, we present an up-to-date summary of the evidences of a relationship between drug use and the kynurenine pathway, both the alterations of the pathway due to drug use as well as modulation of the pathway as a potential approach to treat drug addiction. The review discusses ethanol, nicotine, cannabis, amphetamines, cocaine and opioids and new prospects in the drug research field are proposed.

Increased kynurenine concentration attenuates serotonergic neurotoxicity induced by 3,4-methylenedioxymethamphetamine (MDMA) in rats through activation of aryl hydrocarbon receptor.
3,4-Methylenedioxymethamphetamine (MDMA) is an amphetamine derivative that has been shown to produce serotonergic damage in the brains of primates, including humans, and of rats. Tryptophan, the precursor of serotonin, is primarily degraded through the kynurenine (KYN) pathway, producing among others KYN, the main metabolite of this route. KYN has been reported as an endogenous agonist of the aryl hydrocarbon receptor (AhR), a transcription factor involved in several neurological functions. This study aims to determine the effect of MDMA on the KYN pathway and on AhR activity and to

establish their role in the long-term serotonergic neurotoxicity induced by the drug in rats. Our results show that MDMA induces the activation of the KYN pathway, mediated by hepatic tryptophan 2,3-dioxygenase (TDO). MDMA also activated AhR as evidenced by increased AhR nuclear translocation and CYP1B1 mRNA expression. Autoradiographic quantification of serotonin transporters showed that both the TDO inhibitor 680C91 and the AhR antagonist CH-223191 potentiated the neurotoxicity induced by MDMA, while administration of exogenous l-kynurenine or of the AhR positive modulator 3,3'-diindolylmethane (DIM) partially prevented the serotonergic damage induced by the drug. The results demonstrate for the first time that MDMA increases KYN levels and AhR activity, and these changes appear to play a role in limiting the neurotoxicity induced by the drug. This work provides a better understanding of the physiological mechanisms that attenuate the brain damage induced by MDMA and identify modulation of the KYN pathway and of AhR as potential therapeutic strategies to limit the negative effects of MDMA.

Influx of kynurenine into the brain is involved in the reduction of ethanol consumption induced by Ro 61-8048 after chronic intermittent ethanol in mice.
The kynurenine pathway has been proposed as a target for modulating drug abuse. We previously demonstrated that inhibition of kynurenine 3-monooxygenase (KMO), using Ro 61-8048, reduces ethanol consumption in a binge drinking model. Here, we investigate the effect of the kynurenine pathway modulation in ethanol-dependent mice.

Decreased kynurenine pathway potentiate resilience to social defeat effect on cocaine reward.
The kynurenine (KYN) pathway of tryptophan (TRP) degradation is activated by stress and inflammatory factors. It is now well established that social stress induces the activation of the immune system, with central inflammation and KYN metabolism being two of the main factors linking stress with depression. The aim of the present study was to evaluate the long-lasting changes in the KYN pathway induced by social defeat (SD) associated with the resilience or susceptibility to an increase in the conditioned rewarding effects of cocaine. Mice were exposed to repeated SD and 3 weeks later, a conditioned place preference (CPP) induced by a subthreshold dose of cocaine (1.5 mg/kg) was developed. KYN levels in plasma, cerebellum, hippocampus, striatum and limbic forebrain were studied at the end of the CPP procedure. Changes in the KYN pathway after exposure to pharmacological (oxytocin and indomethacin) and environmental interventions (environmental enrichment) were also evaluated. Our results showed that defeated susceptible (SD-S) mice had higher conditioning scores than resilient mice (SD-R). In addition, although KYN concentration was elevated in all defeated mice, SD-R mice showed smaller increases in KYN concentration in the cerebellum than SD-S mice. Oxytocin or Indomethacin treatment before SD normalized cocaine-induced CPP, although the increase in the KYN pathway was maintained. However, environmental enrichment before SD normalized cocaine-induced CPP and prevented the increase in the KYN pathway. The present study highlights the role of the KYN pathway and anti-inflammatory drugs acting on TRP metabolism as pharmacological targets to potentiate resilience to social stress effects.

Plasma tryptophan and kynurenine pathway metabolites in abstinent patients with alcohol use disorder and high prevalence of psychiatric comorbidity.
Alterations in tryptophan (TRP) metabolism has been linked to drug exposure and mental disorders. However, most of studies have been performed without considering the co-occurrence of both disorders in the context of addiction. This cross-sectional study examines TRP metabolism through the serotonin (5-HT) and kynurenine (KYN) pathways in subjects with alcohol use disorders (AUD) and high prevalence of psychiatric comorbidity.

Increasing kynurenine brain levels reduces ethanol consumption in mice by inhibiting dopamine release in nucleus accumbens.
Recent research suggests that ethanol (EtOH) consumption behaviour can be regulated by modifying the kynurenine (KYN) pathway, although the mechanisms involved have not yet been well elucidated. To further explore the implication of the kynurenine pathway in EtOH consumption we inhibited kynurenine 3-monooxygenase (KMO) activity with Ro 61-8048 (100 mg/kg, i.p.), which shifts the KYN metabolic pathway towards kynurenic acid (KYNA) production. KMO inhibition decreases voluntary binge EtOH consumption and EtOH preference in mice subjected to "drinking in the dark" (DID) and

"two-bottle choice" paradigms, respectively. This effect seems to be a consequence of increased KYN concentration, since systemic KYN administration (100 mg/kg, i.p.) similarly deters binge EtOH consumption in the DID model. Despite KYN and KYNA being well-established ligands of the aryl hydrocarbon receptor (AhR), administration of AhR antagonists (TMF 5 mg/kg and CH-223191 20 mg/kg, i.p.) and of an agonist (TCDD 50 µg/kg, intragastric) demonstrates that signalling through this receptor is not involved in EtOH consumption behaviour. Ro 61-8048 did not alter plasma acetaldehyde concentration, but prevented EtOH-induced dopamine release in the nucleus accumbens shell. These results point to a critical involvement of the reward circuitry in the reduction of EtOH consumption induced by KYN and KYNA increments. PNU-120596 (3 mg/kg, i.p.), a positive allosteric modulator of α7-nicotinic acetylcholine receptors, partially prevented the Ro 61-8048-induced decrease in EtOH consumption. Overall, our results highlight the usefulness of manipulating the KYN pathway as a pharmacological tool for modifying EtOH consumption and point to a possible modulator of alcohol drinking behaviour.

ACUTE D3 ANTAGONIST GSK598809 MODULATES NEURAL RESPONSE DURING NEGATIVE EMOTIONAL PROCESSING IN SUBSTANCE DEPENDENCE

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Ioanna Artemis Vamvakopoulou[1], Leon Fonville[1], John Mcgonigle[1], Rebecca Elliott[2], Karen Ersche[3,4,5], Remy Flechais[1], Csaba Orban[1], Anna Murphy[2], Smith Dana[3,6], John Suckling[3,4], Eleanor Taylor[2], William Deakin[2], Trevor Robbins[3,6], David Nutt[1], Anne Lingford-Hughes[1], Louise Paterson[1]
[1]Imperial College London, Division Of Psychiatry, Department Of Brain Sciences, London, United Kingdom, [2]University of Manchester, Neuroscience And Psychiatry Unit, Institute Of Brain, Behaviour And Mental Health, Manchester, United Kingdom, [3]University of Cambridge, Behavioural And Clinical Neuroscience Institute, Cambridge, United Kingdom, [4]University of Cambridge, Department Of Psychiatry, Cambridge, United Kingdom, [5]University Medical Centre Hamburg-Eppendorf, Department Of Systems Neuroscience, Hamburg, Germany, [6]University of Cambridge, Department Of Psychology, Cambridge, United Kingdom

Aim: Negative affective states play a role in the chronic-relapsing nature of addiction and new treatments are needed. We investigated the effects of D3 receptor antagonism on neural response to negative emotional processing in substance dependence. **Methodology:** Functional MRI was used to investigate BOLD response during an evocative image task, following acute administration of GSK598809 (60mg) or placebo in a multi-site, double-blind, pseudo-randomised design. Whole-brain and *a priori* ROI analyses were conducted in abstinent substance dependent individuals (n=19 alcohol-only and n=17 cocaine-alcohol dependent), and matched controls (n=32). The task consisted of aversive (non-drug/alcohol) and neutral images presented in a block design. **Results:** Evocative image processing (aversive>neutral contrast) resulted in increased BOLD response in amygdala, thalamus, and insula, with reductions in medial prefrontal regions including anterior cingulate cortex. No overall differences were found between dependent and controls, but exploratory analysis revealed increased BOLD response in alcohol-only vs alcohol-cocaine groups, suggesting differential task response by substance. GSK598809 was found to enhance BOLD response across groups relative to placebo in the thalamus, caudate, putamen, and pallidum. **Conclusion:** The modulatory effects of GSK598809 on the BOLD response to evocative processing, suggests that D3R antagonism may impact emotional regulation. Enhanced BOLD response to the drug within D3-rich mesolimbic regions is consistent with its pharmacology. However, the non-specific effect across groups, makes it difficult to ascertain whether the response is likely to be restorative in our abstinent population. Further study is needed to determine whether GSK598809 should be recommended as a potential treatment for substance dependence.

Opioids are the reference treatment for severe pain. Yet their chronic consumption associates with adverse consequences, including addiction, a chronic relapsing disease. One main hypothesis to explain such prolonged effects implicates epigenetic mechanisms. There are well-known clinical differences in opioid addiction across men and women, but whether they are mediated by distinct molecular routes is poorly studied. Here, focusing on the nucleus accumbens, we seek to characterize how epigenetic plasticity, in particular DNA methylation, contributes to sex-differences in opioid effects, combining high-throughput sequencing, optogenetics and behavioral modelling. RNA-Sequencing analyses showed that chronic morphine exposure triggers very distinct gene expression changes across male (n=1546) and female mice (n=1073), with moderate overlap (21.3%). Surprisingly, these effects appear mediated by even more strongly divergent, sex-specific epigenetic processes. Indeed, large collections of genomic sites showing evidence of differential DNA methylation were identified in both males (n=2983) and females (n=3373), with extremely little overlap (<1%). Nevertheless, these sites partly associate with a set of common genes across sexes, suggesting functional convergence. Towards understanding behavioral relevance of these adaptations, we also characterize morphine-induced alterations in neuronal activity (fiber photometry) and reward processing (optogenetics). Preliminary results uncover in vivo kinetics of the decrease in calcium activity of opioid-responsive neurons during morphine exposure. Building on these data, our current studies seek to characterize how experimental manipulation of genes that are epigenetically reprogrammed by morphine may disrupt its impact on neuronal activity and reward function. In the long-term, this may help identify sex-specific therapeutics targets in addiction.

ERK PHOSPHORYLATION IN DG AND NACC AFTER MORPHINE CPP EXTINCTION. INVOLVEMENT OF MORPHINE ENCAPSULATION IN LIPOSOMES.

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Pilar Almela, Irene García-Masegosa, Celia Martínez-Fernández, Victoria Gomez-Murcia, Javier Navarro-Zaragoza
University of Murcia, Department Of Pharmacology, Murcia, Spain

Aims: Opioids like morphine have a great ability to induce addiction. It is well established that the faster a drug crosses the CNS, the higher addictive potential produces. Multilamelar (MLV) and pegylated (PEG-L) liposomes ensure prolonged plasmatic drug circulation periods. Because little is known about morphine encapsulation effects in the addictive process, we have investigated the consequences of morphine administration, free or encapsulated, on pERK levels during the conditioned place preference (CPP) paradigm. **Methods:** To evaluate the rewarding effects of free- and encapsulated morphine, mice received an injection of the drug on days 1, 3 and 5, and saline on days 2, 4 and 6. Extinction of CPP was also performed. Body weight gain was calculated. pERK was analyzed by western blot. **Results:** Animals receiving free-morphine, PEG-L and MLV showed a significant lower body weight gain than saline-treated animals. Morphine administration, either free or encapsulated, induced the acquisition of CPP. Animals treated with free-morphine presented preference for the drug-paired compartment for a longer time (43 days), followed by MLV (23 days) and PEG-L (8 days). Besides, a significant decrease in pERK1/2 expression was observed in dentate gyrus in the group treated with free-morphine compared to control group during CPP extinction that was reverted in the MLV group. Similar results were observed in nucleus accumbens. **Conclusions**: This study provides novel data on the potential use of drug delivery systems based on nanotechnology to transform morphine in a drug with less addictive potential, although future studies are necessary to reach solid conclusions.

Our group recently showed that Maged1 inactivation induces insensitivity to cocaine, impairs cocaine-evoked release of dopamine and plasticity in the NAc. However, the molecular mechanisms involving Maged1 in drug addiction was still unknown. Here, we have identified where and how Maged1 regulates addictive behaviours. First, we showed that expression of Maged1 in vGluT2 neurons of the paraventricular thalamus (PVT) is mandatory for a normal cocaine acute effect and cocaine-evoked locomotor sensitization. Second, by transcriptomic, chIP-Seq, and proteomic we discovered an interaction between Maged1, USP7 deubiquitinase -a PRC1 member-, and histone H2A, that is modified by chronic cocaine administration. Third, we demonstrated that chronic cocaine administration increases H2A mono-ubiquitination in prefrontal cortex and the thalamus. Remarkably, this increase was altered in the thalamus after Maged1 inactivation in vGluT2 neurons or by USP7 inhibition, along with impaired cocaine sensitization. These results show a Maged1-UPS7 control of cocaine-induced H2A mono-ubiquitination in the thalamus regulating drug addiction. Finally, to extend our discovery to human, we performed a genomic analysis on polydrug users revealing 9 SNPs mutations on Maged1 conferring a shortened transition to cocaine addiction and one SNP mutation on USP7 associated to reduced aggressivity during cocaine use. Moreover, we confirmed interaction between Maged1 and USP7 in two human cell lines. In conclusion, these findings establish a role for a Maged1-USP7-dependent epigenetic mark in the PVT in chronic cocaine-related behaviours and pave the way for the development of new treatments for cocaine use disorder.

ANKK1: A METABOLIC SENSOR OF UNDERNUTRITION IN REWARD CIRCUITS

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Heloise Hamelin[1,2]
[1]Inserm, Ipnp, Cachan, France, [2]Inserm, Ipnp U1266, Paris, France

AnKK1 gene is encoding for « Ankyrin repeat and kinase domain containing 1 » involved in signal transduction pathways. AnKK1 is adjacent to the DRD2 gene, which regulates reward, food-seeking, and goal-directed behavior. A polymorphism of AnKK1, Taq1A, is associated with a reduction of dopamine signalling and is described to be a risk factor in addictive behaviors. Taq1A is also associated with increased vulnerability to anorexia nervosa (AN), a complex psychiatric disorder that encompasses multiple risk factors and is characterized by an addictive-like compulsive food restriction and physical activity. Aims. We aim to understand how AnKK1 is regulated by chronic undernutrition and its role in AN symptoms using mouse models that mimic the undernutrition state of AN patients. Methods. We measured the expression of AnKK1 in brain structures involved in feeding, goal-directed behavior or reward in young female mice submitted to 50% food restriction with access to a running wheel (FRW). Results. In FRW, we show a reduction of AnKK1 expression in the hypothalamus, dorsal striatum (DS), and nucleus accumbens. We are also exploring a new mouse model in which AnKK1 can be selectively silenced in the DS. This knock-out (KO) doesn't impair learning or spatial memory and we are currently testing its impact on cognitive flexibility, goal-directed and reward-related behaviors that are impaired in AN. Conclusions. These data suggest that Ankk1 is a sensor of undernutrition in brain structures involved in feeding and reward and may have a key role in modulating reward circuits in response to undernutrition.

Introduction Opioids such as fentanyl are highly effective analgesics widely employed to treat moderate to severe pain. The rise of opioid use outside of their clinical application poses a major public health risk because of the addictive potential and overdose liability of these drugs. Unravelling the molecular mechanisms involved in the addictive behaviour induced by this group of drugs and developing new strategies to lessen their abuse has become a priority for health systems. Mounting evidence points to the kynurenine pathway as a novel target to modulate drug abuse, seeking and reinstatement. **Aims** To assess the effect of the kynurenine monoxygenase inhibitor, Ro 61-8041 on (1) fentanyl-induced addictive behaviours and (2) on kynurenine levels in plasma and hippocampus. **Methods** Male adult Long Evans rats were catheterised in the right yugular vein. Animals underwent operant intravenous self-administration for fentanyl (3,2 µg/kg/infusion). Ro 61-8048 pretreatment (100 mg/kg) was given intraperitoneally 30 minutes before the 2-hour self administration session. **Results** Ro 61-8048 pretreatment lowered fentanyl intake in early acquisition and during maintenance, facilitated extinction and prevented the reinstatement of seeking behavior in the drug priming-induced reinstatement test. Plasma and hippocampal kynurenine levels were increased 2.5 hours after Ro 61-8048 administration. **Conclusions** These findings show for the first time that modulating the kynurenine pathway using Ro 61-8048 positively affects the addictive behaviours induced by fentanyl in rats. Ro 61-8048 is a promising drug that could be useful in the clinical setting in the future.

Influx of kynurenine into the brain is involved in the reduction of ethanol consumption induced by Ro 61-8048 after chronic intermittent ethanol in mice.
The kynurenine pathway has been proposed as a target for modulating drug abuse. We previously demonstrated that inhibition of kynurenine 3-monooxygenase (KMO), using Ro 61-8048, reduces ethanol consumption in a binge drinking model. Here, we investigate the effect of the kynurenine pathway modulation in ethanol-dependent mice.

Addiction and the kynurenine pathway: A new dancing couple?
Drug use poses a serious threat to health systems throughout the world and the number of consumers rises relentlessly every year. The kynurenine pathway, main pathway of tryptophan degradation, has drawn interest in this field due to its relationship with addictive behaviour. Recently it has been confirmed that modulation of kynurenine metabolism at certain stages of the pathway can reduce, prevent or abolish drug seeking-like behaviours in studies with several different drugs. In this review, we present an up-to-date summary of the evidences of a relationship between drug use and the kynurenine pathway, both the alterations of the pathway due to drug use as well as modulation of the pathway as a potential approach to treat drug addiction. The review discusses ethanol, nicotine, cannabis, amphetamines, cocaine and opioids and new prospects in the drug research field are proposed.

Changes in brain kynurenine levels gut microbiota and gut-barrier disruption induced by chronic ethanol exposure in mice. Inflammatory processes have been shown to modify tryptophan (Trp) metabolism. Gut microbiota appears to play a significant role in the induction of peripheral and central inflammation. Ethanol (EtOH) exposure alters gut permeability, but its effects on Trp metabolism and the involvement of gut microbiota have not been studied. We analyzed several parameters of gut-barrier and of peripheral and central Trp metabolism following 2 different EtOH consumption patterns in mice, the binge model, drinking in the dark (DID), and the chronic intermittent (CI) consumption paradigm. Antibiotic treatment was used to evaluate gut microbiota involvement in the CI model. Mice exposed to CI EtOH intake, but not DID, show bacterial translocation and increased plasma LPS immediately after EtOH removal. Gut-barrier permeability to FITC-dextran is increased by CI, and, furthermore, intestinal epithelial tight-junction (TJ) disruption is observed (decreased expression of zonula occludens 1 and occludin) associated with increased matrix metalloproteinase (MMP)-9 activity and iNOS expression. CI EtOH, but not DID, increases kynurenine (Kyn) levels in plasma and limbic forebrain. Intestinal bacterial decontamination prevents the LPS increase but not the permeability to FITC-dextran, TJ disruption, or the increase in MMP-9 activity and iNOS expression. Although plasma Kyn levels are not affected by antibiotic treatment, the elevation of Kyn in brain is prevented, pointing to an involvement of microbiota in CI EtOH-induced changes in brain Trp metabolism. Additionally, CI EtOH produces depressive-like symptoms of anhedonia, which are prevented by the antibiotic treatment thus pointing to an association between anhedonia and the increase in brain Kyn and to the involvement of gut microbiota.-Giménez-Gómez, P., Pérez-Hernández, M., O'Shea, E., Caso, J. R., Martín-Hernández, D., Cervera, L. A., Centelles. M. L. G.-L., Gutiérrez-Lopez, M. D., Colado, M. I. Increased kynurenine concentration attenuates serotonergic neurotoxicity induced by 3,4-methylenedioxymethamphetamine (MDMA) in rats through activation of aryl hydrocarbon receptor.
3,4-Methylenedioxymethamphetamine (MDMA) is an amphetamine derivative that has been shown to produce serotonergic damage in the brains of primates, including humans, and of rats. Tryptophan, the precursor of serotonin, is primarily degraded through the kynurenine (KYN) pathway, producing among others KYN, the main metabolite of this route. KYN has been reported as an endogenous agonist of the aryl hydrocarbon receptor (AhR), a transcription factor involved in several neurological functions. This study aims to determine the effect of MDMA on the KYN pathway and on AhR activity and to establish their role in the long-term serotonergic neurotoxicity induced by the drug in rats. Our results show that MDMA induces the activation of the KYN pathway, mediated by hepatic tryptophan 2,3-dioxygenase (TDO). MDMA also activated AhR as evidenced by increased AhR nuclear translocation and CYP1B1 mRNA expression. Autoradiographic quantification of serotonin transporters showed that both the TDO inhibitor 680C91 and the AhR antagonist CH-223191 potentiated the neurotoxicity induced by MDMA, while administration of exogenous l-kynurenine or of the AhR positive modulator 3,3'-diindolylmethane (DIM) partially prevented the serotonergic damage induced by the drug. The results demonstrate for the first time that MDMA increases KYN levels and AhR activity, and these changes appear to play a role in limiting the neurotoxicity induced by the drug. This work provides a better understanding of the physiological mechanisms that attenuate the brain damage induced by MDMA and identify modulation of the KYN pathway and of AhR as potential therapeutic strategies to limit the negative effects of MDMA.

During the past few years, research on treatments for Psychiatric disorders have been marked by a psychedelic revival. Among the psychedelic substances, psilocybin is being investigated for its therapeutic potential for treating a variety of psychiatric disorders such as obsessive compulsive disorders, depression or substance abuse disorders. Clinical trials are already being conducted but pre-clinical evidence of the impact of psilocybin on the brain are yet to be investigated. Thus the aim of this project was to identify the acute effect of psilocybin injection on the mouse brain. We injected intra-peritoneally wild type C57Bl6 mice with either a psilocybin or a vehicle solution 90 minutes before collecting their brains. The samples were then processed following the iDisco protocol which consist in a clearing protocol coupled with fluorescent immunostaining. Here we labeled the immediate early gene c-Fos considered, in a neuron, as a marker of recent stimulation. After light-sheet microscope imaging and analysis with the Clearmap pipeline we could run a 3D reconstruction of the expression of cFos in whole hemispheres of both groups. With these techniques, we were able to identify brain areas stimulated by the psilocybin and establish a first whole-brain mapping of this psychedelic in the mouse brain.

Learned associations between the rewarding effects of drugs and the context in which they are experienced are decisive for precipitated drug-seeking and relapse in addiction. These associative memories are stored in sparse and highly discriminative populations of concomitantly activated neurons defining drug-recruited neuronal ensembles. In this study, we explore the dynamics and molecular mechanisms of both the recruitment of these ensembles upon initial drug exposure and their contribution to the encoding, strengthening and ultimately expression of drug-associated memories. Additionally, we explore the intrinsic and acquired cellular properties favoring the allocation of specific cells to these ensembles and/or predicting their further reactivation. Capitalizing on the activity-dependent labeling in Arc-CreER^{T2} mice (Denny et al., 2014), we captured and permanently tagged (fluorophores, channel-rhodopsin) cocaine-activated cells in the nucleus accumbens for further characterization, optogenetics, and nuclei sorting. We identified subsets of neurons activated at both early and late stages of drug exposure and show that the reactivation of an initial ensemble correlates with behavioral sensitization. Similarly, re-exposure to a cocaine-paired context in a conditioned place preference (CPP) paradigm triggered cocaine ensembles' reactivation. Using optogenetics-mediated artificial reactivation, we found that populations recruited at early versus late stages of drug exposure had opposite roles in CPP expression. Single nucleus RNA Sequencing was then performed on FACS-isolated tagged neurons, and we successfully isolated a cluster of reactivated cells within the initially activated ensemble. Together, this ensemble-specific approach represents a pivotal step in identifying highly specific cellular processes involved in the encoding of pathological memories associated with drug addiction.

Studies demonstrate that the increase in drug-seeking following forced abstinence periods (known as incubation of drug craving) is correlated to adaptations within the neuronal ensembles, which is a small pattern of neurons sparsely distributed in the brain and connected by strong synapses. Nucleus accumbens is a brain region involved in the incubation of drug craving. Parvalbumin interneurons (PVs) from the nucleus accumbens are important neurons involved in drug-behavior. Using restricted (1h/day for 12 days) or extended (6h/day for 12 days) access protocol to cocaine self-administration, we investigated if the transition from occasional to compulsive drug use and the incubation of cocaine craving are related to alterations in the engagement of nucleus acumbens (NAc) parvalbumin interneurons (PVs) in neuronal ensembles activated by drug-related cues. Wistar rats were catheterized for cocaine self-administration, trained and reexposed to drug environment cues after 1 or 30 days of abstinence. Double labeling for Fos and parvalbumin was performed (Ethical Committee number: 4183030918). Both self-administration protocols produced the same NAc PVs recruitment after 1 day of abstinence. The incubation of craving was observed only in rats submitted to extended access to cocaine self-administration and was accompanied by a decrease in the percentage of PVs from NAc core activated by drug cues. Our data suggests that incubation of cocaine craving may be correlated with a shift in the engagement of NAc PVs. Acknowledgements: FAPESP 2018/15505-4 and 2018/14153-7, CAPES

Dorsal hippocampus plays a causal role in context-induced reinstatement of alcohol-seeking in rats.
Drug addiction is a chronic mental disorder characterized by frequent relapses. Contextual cues associated with drug use to play a critical causal role in drug-seeking behavior. The hippocampus has been implicated in encoding drug associative memories. Here we examine whether the dorsal hippocampus mediates context-induced reinstatement of alcohol-seeking. Male Long-Evans rats were trained to self-administer alcohol in Context A. Alcohol self-administration was extinguished in a distinct context (Context B). On the test day, animals were re-exposed to the alcohol Context A or the extinction Context B. Next, to assess a causal role for the dorsal hippocampus in context-induced alcohol-seeking, on the test day, we injected cobalt chloride (CoCl2; a nonselective synapse inhibitor) or vehicle into the dorsal hippocampus, and 15 min later, rats were tested by re-exposing them to the drug-associated context. The re-exposure to the alcohol-associated Context A reinstated alcohol seeking and increased Fos-positive cells in the dorsal hippocampus neurons (CA1, CA3, and Dentate Gyrus). Pharmacological inactivation with cobalt chloride of the dorsal hippocampus attenuated the reinstatement of alcohol-seeking. Our data suggest that the dorsal hippocampus may be involved in context-induced alcohol-seeking behavior.

Central muscarinic and LPBN mechanisms on sodium intake.
Central cholinergic activation stimulates water intake, but also NaCl intake when the inhibitory mechanisms are blocked with injections of moxonidine (α adrenergic/imidazoline agonist) into the lateral parabrachial nucleus (LPBN). In the present study, we investigated the involvement of central M and M muscarinic receptors on NaCl intake induced by pilocarpine (non-selective muscarinic agonist) intraperitoneally combined with moxonidine into the LPBN or by muscimol (GABA agonist) into

the LPBN. Male Holtzman rats with stainless steel cannulas implanted bilaterally in the LPBN and in the lateral ventricle were used. Pirenzepine (M muscarinic antagonist, 1 nmol/1 µl) or methoctramine (M muscarinic antagonist, 50 nmol/1 µL) injected intracerebroventricularly (i.c.v.) reduced 0.3 M NaCl and water intake in rats treated with pilocarpine (0.1 mg/100 g of body weight) injected intraperitoneally combined with moxonidine (0.5 nmol/0.2 µL) into the LPBN. In rats treated with muscimol (0.5 nmol/0.2 µL) into the LPBN, methoctramine i.c.v. also reduced 0.3 M NaCl and water intake, however, pirenzepine produced no effect. The results suggest that M and M muscarinic receptors activate central pathways involved in the control of water and sodium intake that are under the influence of the LPBN inhibitory mechanisms.

THE EFFECT OF COCAINE AND ALCOHOL POLY-CONSUMPTION ON DRUG SEEKING BEHAVIOR IN YOUNG ADULT RATS

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Lucía Matilla, Alberto Marcos, Mario Moreno-Fernández, Marcos Ucha, Celia Poza, Alejandro Higuera-Matas, Emilio Ambrosio
UNED, Psychobiology, Madrid, Spain

AIM The poly-consumption of cocaine and alcohol is very prevalent in western countries, moreover, the risk of relapse is very high in recovering addicts. In the light of this, the main objective of this study was to explore the psychobiological mechanism that may be involved in this type of poly-consumption. METHODS Young male and female rats intravenously self-administered during 10 sessions (6h) in Skinner boxes: cocaine and alcohol (C+A; 1mg/kg bodyweight cocaine + 0,133mg/kg bodyweight alcohol); cocaine (Coc; 1mg/kg bodyweight) and 0,9% NaCl (Sal). After a withdrawal period (Wd2 or Wd30), rats were subjected to a relapse test to measure their seeking behaviour. Blood and different brain structures was collected for metabolomic, genetic and protein studies, that are currently in process. RESULTS Self-administration behavior of Coc and C+A groups was significantly higher than Sal group, without differences between sexes. Regarding the relapse test, we observed a higher response rate in Coc and C+A compared to Sal, both on Wd2 and Wd30. However, we only found statistical significance in Coc vs. Sal on Wd30 ($p=0.07$). In the Coc group, but not in C+A, we found a significant higher response in Wd30 vs. Coc Wd2 ($p=0.024$). CONCLUSION This study shows that young adult rats will easily self-administer combined cocaine and alcohol when they have an extended access, without differences between sexes. The drug-seeking behavior test revealed an incubation of craving in the Wd30 Coc group. We believe that this study might contribute to understand the underpinnings of poly-consumption of cocaine and alcohol.

DOPAMINE D3 RECEPTOR ANTAGONISM BLOCKED THE AKT/MTOR PATHWAY DOWNREGULATION IN THE DENTATE GYRUS AFTER THE REINSTATEMENT OF COCAINE INDUCED CPP EVOKED BY PHYSIOLOGICAL STRESS.

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Cristina Núñez, Aurelio Franco, Victoria Gomez-Murcia, Juana Hidalgo, Rocío Guerrero-Bautista, Victoria Milanés
University of Murcia, Pharmacology, Murcia, Spain

Relapse in cocaine seeking and intake is one of the main challenges when treating its addiction. Among the triggering factors for the recurrence of cocaine use are stressful events. Cocaine relapse engages the activity of memory-related nuclei such as the hippocampal dentate gyrus (DG), which is responsible for episodic memories. Moreover, D3 receptor (D3R) antagonists have recently arisen as a potential treatment for preventing drug relapse. Thus, we have assessed the impact of D3R blockade in the activity of the mammalian (or mechanistic) target of Rapamycin (mTOR) pathway, which is modulated by this receptor, in the DG during the reinstatement of cocaine-induced conditioned place preference (CPP) evoked by tail pinch as a physiological stressor. For that, we systemically administered two doses (24 or 48 mg/kg, i.p.) of SB-277011-A, a selective D3R antagonist, 15 min before the stressful episode. The higher dose of the D3R antagonist blocked the reinstatement of cocaine CPP induced by tail pinch. Additionally, we observed a trend towards diminution of mTOR phosphorylation during the reinstatement of cocaine CPP in the DG, which was inhibited by SB-277011-A (48 mg/kg). We also found a significant increase of phospho-Akt levels in the group treated with the higher dose of the antagonist when compared with animals that received vehicle and, thus, relapsed in cocaine CPP. Our data support a main role for D3R signalling, through the modulation of the Akt/mTOR pathway in the DG, in the reactivation of cocaine memories evoked by physiological stress.

PREDICTION AND PREVENTION OF COMPULSIVE BEHAVIORS BY CLOSED-LOOP OPTOGENETIC RECRUITMENT OF STRIATAL INTERNEURONS

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Sirenia Lizbeth Mondragón González, Christiane Schreiweis, Eric Burguière
Sorbonne Université, Institut du Cerveau - Paris Brain Institute - ICM, Inserm, CNRS, AP-HP, Neurophysiololgy Of Repetitive Behaviors, Paris, France

Dysregulation in the cortico-striatal circuits has been shown to be related to pathologic repetitive behaviors. Striatal positive parvalbumin interneurons (PVIs) receive strong cortical inputs and form a powerful feedforward inhibition network that controls spike timing in medium spiny neurons, thereby are a key element that regulates the striatal output. To prove the role of PV interneurons in reducing aberrant repetitive behaviors we used the Sapap3 mutant mice, which exhibit excessive self-grooming and increased anxiety. Using optogenetics activation of PV interneurons in the dorsomedial striatum, we were able to reduce compulsive behavior to normality. Interestingly, this continuous optogenetic stimulation significantly reduced the number of grooming sequences rather than their duration. Moreover, we found that an increase in power within the 1.5-4 Hz frequency band in the orbitofrontal cortex temporally predicted grooming initialization. Our results from PVI continuous stimulation suggested that the recruitment of PVI was essential at the initiation of the compulsive event. To test this hypothesis, we used a combination of extracellular signal acquisition, optogenetics manipulation, and online data processing in a closed-loop design that allowed us to predict grooming onset and provide on-demand stimulation of striatal PV interneurons. We found that both closed-loop optogenetics and continuous open-loop stimulation robustly decreased excessive grooming. Acute on-demand stimulation had the advantage of requiring significantly less total stimulation delivery. These results highlight how the modulation of PVIs can positively influence the rescuing of pathologic repetitive behaviors and point to their involvement in the dysfunction mechanism that is associated with the cortico-striatal circuits.

Aims: Addiction to substances of abuse is a chronic neurological disorder characterized by drug-seeking, compulsive consumption, and frequent relapses after long periods of abstinence. Many studies have proposed that stress has a key role in the development of drug addiction. In this study, we have investigated the influence of *Tail Pinch* (TP) in relapse through the model of conditioned-place aversion (CPA). We have also analyzed pCREB expression in dentate gyrus (DG) during this paradigm. **Methods**: C57BL/6J mice were rendered dependent on morphine and injected acutely with naloxone before paired to confinement in a naloxone-associated compartment. After extinction of the aversive memory, animals received CP-154,526 (CRF1 receptor antagonist), propranolol (beta-adrenergic receptor antagonist) or vehicle and were exposed to TP to induce relapse. pCREB expression was analyzed in DG by Western Blot. **Results**: Our results show that application of TP after extinction induced relapse. The administration of CP-154,526 and propranolol antagonized this effect. Besides, a significant increase in pCREB expression was observed in DG in the group exposed to stress receiving vehicle compared to the non-stress group. **Conclussions**: These results show the important relationship between stress and compulsive drug seeking, as well as a potential therapeutic value of propranolol and CP-154,526 in the treatment of relapses.

Drug addiction is defined as a compulsive pattern of drug-seeking/taking behaviors, with recurrent episodes of abstinence and relapse. Addictive drugs increase dopamine in the nucleus accumbens (NAc), where it persistently shapes excitatory glutamate transmission, thereby hijacking natural reward processing. Herein, we provide evidence, from mice to humans, that an underlying mechanism relies on a drug-evoked heteromerization of glutamate NMDA receptors (NMDAR) with dopamine receptor 1 (D1R) or 2 (D2R) triggered by both psychostimulants and opiates. Using temporally-controlled inhibition of D1R-NMDAR heteromerization, we show their selective implication in early phases of cocaine-evoked, whereas preventing D2R-NMDAR heteromerization blocked the persistence of these adaptations. Notably, interfering with these receptor heteromers spared natural reward processing. Because the high prevalence of comorbidities between addiction and mood disorders suggests that brain dysfunctions underlying drug addiction and other psychiatric disorders may rely on partly shared mechanisms, we asked whether receptor heteromerization in the NAc could constitute a common molecular switch in addiction and depression. Using the chronic defeat stress paradigm as a preclinical model of depression, we indeed found that mice developing depressive-like behavior, but not resilient mice, exhibit an increased dopamine-glutamate receptor heteromerization, which blockades fully prevents the onset and persistence of depressive-like symptoms. These findings contribute to a better understanding of common molecular mechanisms underlying addiction and depression and uncover dopamine-glutamate heteromer as targets with potential therapeutic value for multiple psychiatric diseases associated with alterations in dopamine and glutamate-dependent transmissions.

Aim: Europe is the heaviest drinking region in the world, approximately 23 million Europeans are alcohol dependent. A large number of brain alterations has been associated with alcohol use disorders (AUD). A causal link between alcohol and many of these alterations, however, is difficult to establish due to the complexity of AUD and associated comorbidities. In a translational study in AUD patients and the msP rat model, we have shown a causal link between alcohol drinking and a progressing white matter alteration during abstinence. Here, we combine ultra-high field diffusion magnetic resonance imaging (MRI) with immunohistochemistry analysis, with the goal of characterising this alteration. **Methods/results:** We used a total of 28 msP rats, 18 underwent a longitudinal MRI examination with time points at baseline and after one month of alcohol drinking in a two bottles free-choice paradigm. Another 10 age-matched animals (5 controls and 5 exposed to alcohol) were used for histological quantification of myelin basic protein (MBP) and neurofilament to asses myelin content and axonal integrity, respectively, in the corpus callosum and fimbria/fornix. Alcohol consumption reached levels of 4 to 6 g/Kg/day. Multi-shell diffusion imaging combined with multi-compartment modelling unveiled a reduction in the fraction of water undergoing restricted diffusion, a surrogate measure of axonal density, and increase in estimated axonal diameter. The histological analysis showed decreased MBP and increased neurofilament staining intensity in the alcohol group, overall suggesting an early process of axonal degeneration. **Conclusion:** We present convergent evidence of axonal pathology induced by chronic alcohol drinking in rats.

MODULATING THE EFFECTS OF A LESION IN LVIII OF THE CEREBELLAR VERMIS ON COCAINE-INDUCED CPP THROUGH CHEMOGENETIC INHIBITION OF THE INTERPOSED NUCLEUS ACTIVITY

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Ignasi Melchor Eixea[1], Julián Guarque Chabrera[1,2], Marta Miquel Salgado-Araujo[1,2]

Our research group have shown that cocaine-induced conditioned place preference (CPP) increases the activity at LVIII of cerebellar vermis (Carbo-Gas et al. 2014). Furthermore, a lesion of this region increased the probability of cocaine-induced CPP acquisition (Gil-Miravet et al. 2019). Monosynaptic tracing studies indicated that there is a monosynaptic projection from the deep cerebellar nuclei (DCN) to the ventral tegmental area (VTA) that also receives Purkinje axons from LVIII (Gil-Miravet et al. 2020). This projection may control the activity and perineuronal net expression in the medial prefrontal cortex and striatum (Gil-Miravet et al., 2019). The objective of the present investigation was to test whether chemogenetic inhibition of the interposed nucleus (IP) would prevent the effects of a lesion of LVIII on the acquisition of CPP. To that end, we expressed the designer receptors exclusively activated by designer drugs (DREADDs): AAV5-hSyn-hM4D(Gq) or AAV5-CaMKIIa-hM4D(Gq) in quinolinicc acid (QA)-treated rats. The viral vectors and QA were infused by stereotaxic surgery, and DREADDs were activated by intracranial infusion of clozapine N-oxide (CNO) into IP. Our results indicated that the inhibition of the IP prevents the facilitation of cocaine-induced CPP acquisition by QA in lobule VIII and could decrease the activity in other cortico-limbic-striatal regions. When the front fails, the rear wins. Cerebellar correlates of prefrontal dysfunction in cocaine-induced memory in male rats. Reciprocal pathways connecting the cerebellum to the prefrontal cortex provide a biological and functional substrate to modulate cognitive functions. Dysfunction of both medial prefrontal cortex (mPFC) and cerebellum underlie the phenotypes of several neuropsychiatric disorders that exhibit comorbidity with substance use disorder (SUD). In people with SUD, cue-action-reward associations appears to be particularly strong and salient, acting as powerful motivational triggers for craving and relapse. Studies of cue reactivity in human with SUD have shown cerebellar activations when drug-related cues are presented. Our preclinical research showed that cocaine-induced conditioned preference increases neural activity and upregulates perineuronal nets (PNNs) around Golgi interneurons in the posterior cerebellar cortex. In the present investigation, we aimed at evaluating cerebellar signatures of conditioned preference for cocaine when drug learning is established under mPFC impairment. We used lidocaine to temporarily inactivate in male rats either the Prelimbic (PL) or the Infralimbic (IL) cortices during cocaine-induced conditioning. The inactivation of the IL, but not the PL, encouraged the acquisition of preference for cocaine-related cues, increased posterior cerebellar cortex activity, and upregulated the expression of PNNs around Golgi interneurons. Moreover, IL impairment not only increased vGluT2- and vGAT-related activity around Golgi cells but also regulated PNNs differently on subpopulations of Golgi cells, increasing the number of neurogranin+ PNN-expressing Golgi cells. Our findings suggest that IL dysfunction may facilitate the acquisition of cocaine-induced memory and cerebellar drug-related learning hallmarks. Overall, IL perturbation during cocaine-induced Pavlovian learning increased cerebellar activity and drug effects. Importantly, cerebellum involvement requires a contingent experience with the drug, and it is not the effect of a mere inactivation of IL cortex.

From back to front: A functional model for the cerebellar modulation in the establishment of conditioned preferences for cocaine-related cues.
It is now increasingly clear that the cerebellum may modulate brain functions altered in drug addiction. We previously

demonstrated that cocaine-induced conditioned preference increased activity at the dorsal posterior cerebellar vermis. Unexpectedly, a neurotoxic lesion at this region increased the probability of cocaine-induced conditioned preference acquisition. The present research aimed at providing an explanatory model for such as facilitative effect of the cerebellar lesion. First, we addressed a tracing study in which we found a direct projection from the lateral (dentate) nucleus to the ventral tegmental area (VTA) that also receives Purkinje axons from lobule VIII in the vermis. This pathway might control the activity and plasticity of the cortico-striatal circuitry. Then we evaluated cFos expression in different regions of the medial prefrontal cortex and striatum after a lesion in lobule VIII before conditioning. Additionally, perineuronal net (PNN) expression was assessed to explore whether the cerebellar lesion might affect synaptic stabilization mechanisms in the medial prefrontal cortex (mPFC). Damage in this region of the vermis induced general disinhibition of the mPFC and striatal subdivisions that receive dopaminergic projections, mainly from the VTA. Moreover, cerebellar impairment induced an upregulation of PNN expression in the mPFC. The major finding of this research was to provide an explanatory model for the function of the posterior cerebellar vermis on drug-related memory. In this model, damage of the posterior vermis would release striatum-cortical networks from the inhibitory tonic control exerted by the cerebellar cortex over VTA, thereby promoting drug effects.

Addiction could be considered the result of pathological learning in which drug-related memories make the brain inflexible. Perineuronal nets (PNNs) are cartilage-like structures of extracellular matrix which enwrap the cell-body and proximal dendrites of special sets of neurons to stabilize their connections and restrict plasticity. We showed that both drug-induced conditioned memories and protracted abstinence increase expression of PNNs around Golgi inhibitory interneurons in the cerebellar cortex. In cocaine self-administration studies, we found decreased expression of cerebellar PNNs at 24 hours in rats with a limited cocaine experience (ShA). PNN expression around Golgi cells increased after protracted abstinence (28 days) only in rats with extended access to cocaine self-administration (LgA). In the present study, we assessed the relative levels of key components of PNNs on ShA and LgA groups at two times of withdrawal (24h or 28 days). Rats were catheterized and trained to self-administer cocaine (0.75mg/kg/infusion), 1h/day for the ShA group and 6h/day for the LgA group for 12 days. Western-blot analysis showed a reduction in the relative amount of protein (tenascin-R) in the ShA group at 24h when compared to the naïve and LgA groups. At this time point, there was no difference between the LgA group and the naïve group. The results indicate that cocaine self-administration effect on the relative expression of PNN components parallel the dynamic seen with Wisteria Floribunda Agglutinin intensity, suggesting that while a short experience with cocaine can increase plasticity by reducing PNNs, extended access upregulates PNN components and may stabilize drug-induced memory.

A Working Hypothesis for the Role of the Cerebellum in Impulsivity and Compulsivity.
Growing evidence associates cerebellar abnormalities with several neuropsychiatric disorders in which compulsive symptomatology and impulsivity are part of the disease pattern. Symptomatology of autism, addiction, obsessive-compulsive (OCD), and attention deficit/hyperactivity (ADHD) disorders transcends the sphere of motor dysfunction and essentially entails integrative processes under control of prefrontal-thalamic-cerebellar loops. Patients with brain lesions affecting the cortico-striatum thalamic circuitry and the cerebellum indeed exhibit compulsive symptoms. Specifically, lesions of the posterior cerebellar vermis cause affective dysregulation and deficits in executive function. These deficits may be due to impairment of one of the main functions of the cerebellum, implementation of forward internal models of the environment. Actions that are independent of internal models may not be guided by predictive relationships or a mental representation of the goal. In this review article, we explain how this deficit might affect executive functions. Additionally, regionalized cerebellar lesions have been demonstrated to impair other brain functions such as the emergence of habits and behavioral inhibition, which are also altered in compulsive disorders. Similar to the infralimbic cortex, clinical studies and research in animal models suggest that the cerebellum is not required for learning goal-directed behaviors, but it is critical for habit formation. Despite this accumulating data, the role of the cerebellum in compulsive symptomatology and impulsivity is still a matter of discussion. Overall, findings point to a modulatory function of the cerebellum in terminating or initiating actions through regulation of the prefrontal cortices. Specifically, the cerebellum may be crucial for restraining ongoing actions when environmental conditions change by adjusting prefrontal activity in response to the new external and internal stimuli, thereby promoting flexible behavioral control. We elaborate on this explanatory framework and propose a working hypothesis for the involvement of the cerebellum in compulsive and impulsive endophenotypes.

Time-dependent regulation of perineuronal nets in the cerebellar cortex during abstinence of cocaine-self administration.
The probability of structural remodeling in brain circuits may be modulated by molecules of perineuronal nets (PNNs) that restrict neuronal plasticity to stabilize circuits. Animal research demonstrates that addictive drugs can remodel PNNs in different brain regions, including the cerebellum.

STRIATAL CHOLINERGIC INTERNEURONS CONTROL NICOTINE WITHDRAWAL VIA MUSCARINIC SIGNALING

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Baeksun Kim[1], Junsung Woo[2], Han Ah Kim[1], Changjoon Lee[3], Heh-In Im[1]
[1]Korea Institute of Science and Technology, Brain Science Institute, Seoul, Korea, Republic of, [2]Baylor College of Medicine, Center For Cell And Gene Therapy, Houston, United States of America, [3]Institute for Basic Science, Center For Cognition And Sociality, Daejeon, Korea, Republic of

Striatal cholinergic interneurons (ChIs) provide cholinergic tone to the dorsal striatum and essentially regulate movement control. Nicotine withdrawal leads to perturbations in striatal neurophysiology and motor function, yet the role of striatal ChIs in nicotine withdrawal remains unclear. Here, we demonstrate that RNAi-mediated inhibition of the striatal ChIs leads to effective mitigation of somatic signs of nicotine withdrawal in mice. Bioinformatics analysis of miRNA databases predicted miR-137 as a putative inhibitor of the major sodium channel subtypes expressed in the striatal ChIs. Selective overexpression of miR-137 in the striatal ChIs (ChI^{FIN}, functional inhibition of ChIs) resulted in knockdown of sodium channel subunit $Na_V1.1$ and elevation of action potential threshold, consequently inhibiting action potential generation in the ChIs. In a comprehensive battery of behavioral tests, ChI^{FIN} mice displayed a reduction in somatic signs of nicotine withdrawal. Multi-electrode array recording showed that repeated nicotine exposure enhanced the number of population spikes in the dorsal striatum, which was substantially abolished by ChI^{FIN}. Interestingly, the clinically-approved muscarinic antagonist procyclidine was able to mimic the effect of ChI^{FIN}; procyclidine inhibited the repeated nicotine-evoked increase in striatal population spikes and ameliorated somatic withdrawal signs from nicotine. Collectively, these data indicate that striatal cholinergic interneurons control the motor aspect of nicotine withdrawal, and that drug repurposing of clinically approved muscarinic antagonists is a promising approach for developing new therapeutics against nicotine withdrawal syndrome.

Subanesthetic ketamine rapidly alters medial prefrontal miRNAs involved in ubiquitin-mediated proteolysis.
Ketamine is a dissociative anesthetic and a non-competitive NMDAR antagonist. At subanesthetic dose, ketamine can relieve pain and work as a fast-acting antidepressant, but the underlying molecular mechanism remains elusive. This study aimed to investigate the mode of action underlying the effects of acute subanesthetic ketamine treatment by bioinformatics analyses of miRNAs in the medial prefrontal cortex of male C57BL/6J mice. Gene Ontology and KEGG pathway analyses of the genes putatively targeted by ketamine-responsive prefrontal miRNAs revealed that acute subanesthetic ketamine modifies ubiquitin-mediated proteolysis. Validation analysis suggested that miR-148a-3p and miR-128-3p are the main players responsible for the subanesthetic ketamine-mediated alteration of ubiquitin-mediated proteolysis through varied regulation of ubiquitin ligases E2 and E3. Collectively, our data imply that the prefrontal miRNA-dependent modulation of ubiquitin-mediated proteolysis is at least partially involved in the mode of action by acute subanesthetic ketamine treatment.

Chronic nicotine impairs sparse motor learning via striatal fast-spiking parvalbumin interneurons.
Nicotine can diversely affect neural activity and motor learning in animals. However, the impact of chronic nicotine on striatal activity in vivo and motor learning at long-term sparse timescale remains unknown. Here, we demonstrate that chronic nicotine persistently suppresses the activity of striatal fast-spiking parvalbumin interneurons, which mediate nicotine-induced deficit in sparse motor learning. Six weeks of longitudinal in vivo single-unit recording revealed that mice show reduced activity of fast-spiking interneurons in the dorsal striatum during chronic nicotine exposure and withdrawal. The reduced firing

of fast-spiking interneurons was accompanied by spike broadening, diminished striatal delta oscillation power, and reduced sample entropy in local field potential. In addition, chronic nicotine withdrawal impaired motor learning with a weekly sparse training regimen but did not affect general locomotion and anxiety-like behavior. Lastly, the excitatory DREADD hM3Dq-mediated activation of striatal fast-spiking parvalbumin interneurons reversed the chronic nicotine withdrawal-induced deficit in sparse motor learning. Taken together, we identified that chronic nicotine withdrawal impairs sparse motor learning via disruption of activity in striatal fast-spiking parvalbumin interneurons. These findings suggest that sparse motor learning paradigm can reveal the subtle effect of nicotine withdrawal on motor function and that striatal fast-spiking parvalbumin interneurons are a neural substrate of nicotine's effect on motor learning.

Methyl-CpG Binding Protein 2 in Alzheimer Dementia.
Despite decades of research on Alzheimer disease, understanding the complexity of the genetic and molecular interactions involved in its pathogenesis remains far from our grasp. Methyl-CpG Binding Protein 2 (MeCP2) is an important epigenetic regulator enriched in the brain, and recent findings have implicated MeCP2 as a crucial player in Alzheimer disease. Here, we provide comprehensive insights into the pathophysiological roles of MeCP2 in Alzheimer disease. In particular, we focus on how the alteration of MeCP2 expression can impact Alzheimer disease through risk genes, amyloid-β and tau pathology, cell death and neurodegeneration, and cellular senescence. We suggest that Alzheimer disease can be adversely affected by upregulated MeCP2-dependent repression of risk genes (MEF2C, ADAM10, and PM20D1), increased tau accumulation, and neurodegeneration through neuronal cell death (excitotoxicity and apoptosis). In addition, we propose that the progression of Alzheimer disease could be caused by reduced MeCP2-mediated enhancement of astrocytic and microglial senescence and consequent glial SASP (senescence-associated secretory phenotype)-dependent neuroinflammation. We surmise that any imbalance in MeCP2 function would accelerate or cause Alzheimer disease pathogenesis, implying that MeCP2 may be a potential drug target for the treatment and prevention of Alzheimer disease.

The role of the dorsal striatum in choice impulsivity.
It has long been recognized that the dorsal striatum is an essential brain region for control of action selection based on action-outcome contingency learning, particularly when the available actions are bound to rewarding outcomes. In principle, intertemporal choice in the delay-discounting task-a validated measure of choice impulsivity-involves reward-associated actions that require the recruitment of the dorsal striatum. Here, we conjecture about ways the dorsal striatum is involved in choice impulsivity. Based on a selective body of studies, we begin with a brief history of research on choice impulsivity and the dorsal striatum, and then provide a comprehensive summary of contemporary studies utilizing human neuroimaging and animal models to search for links between choice impulsivity and the dorsal striatum. In particular, we discuss in-depth the converging evidence for the associations of choice impulsivity with the reward valuation coded by the caudate, a ventral-to-dorsal gradient in the dorsal striatum, the origins of striatal afferents, and developmental maturation of frontostriatal connectivity during adolescence.

Pathophysiological Role of Neuroinflammation in Neurodegenerative Diseases and Psychiatric Disorders.
Brain diseases and disorders such as Alzheimer disease, Parkinson disease, depression, schizophrenia, autism, and addiction lead to reduced quality of daily life through abnormal thoughts, perceptions, emotional states, and behavior. While the underlying mechanisms remain poorly understood, human and animal studies have supported a role of neuroinflammation in the etiology of these diseases. In the central nervous system, an increased inflammatory response is capable of activating microglial cells, leading to the release of pro-inflammatory cytokines including interleukin (IL)-1β, IL-6, and tumor necrosis factor-α. In turn, the pro-inflammatory cytokines aggravate and propagate neuroinflammation, degenerating healthy neurons and impairing brain functions. Therefore, activated microglia may play a key role in neuroinflammatory processes contributing to the pathogenesis of psychiatric disorders and neurodegeneration.

Multiplexed Detection of Epigenetic Markers Using Quantum Dot (QD)-Encoded Hydrogel Microparticles.
Epigenetic alterations in gene expression are influenced by experiences and environment, resulting in significant variation of epigenetic markers from individual to individual. Therefore, it is imperative to measure various epigenetic markers simultaneously from samples of individual subjects to accurately analyze the epigenetic markers in biological samples. Moreover, the individualized genome-wide analysis has become a critical technology for recent trends in clinical applications such as early diagnosis and personalized medicine screening of numerous diseases. The array-based detection of modified

histones, conventionally used for multiplexed analysis of epigenetic changes, requires pooling of samples from many subjects to analyze population-wise differences in the expression of histone markers and does not permit individualized analysis. Here, we report multiplexed detection of genome-wide changes in various histone modifications at a single-residue resolution using quantum dot (QD)-encoded polyethylene glycol diacrylate (PEGDA) hydrogel microparticles. To demonstrate the potential of our methodology, we present the simultaneous detection of (1) acetylation of lysine 9 of histone 3 (Ac-H3K9), (2) dimethylation of H3K9 (2Me-H3K9), and (3) trimethylation of H3K9 (3Me-H3K9) from three distinct regions in the brain [nucleus accumbens (NAc), dorsal striatum (DSt), and cerebellum (Cbl)] of cocaine-exposed mice. Our hydrogel-based epigenetic assay enabled relative quantification of the three histone variants from only 10 μL of each brain lysate (protein content = ~ 1 μg/μL) per mouse. We verified that the exposure to cocaine induced a significant increase of acetylation while a notable decrease in methylation in NAc.

Gamma oscillation in functional brain networks is involved in the spontaneous remission of depressive behavior induced by chronic restraint stress in mice.
Depression is one of the most prevalent mood disorders, and is known to be associated with abnormal functional connectivity in neural networks of the brain. Interestingly, a significant proportion of patients with depression experience spontaneous remission without any treatment. However, the relationship between electroencephalographic (EEG) functional connectivity and the spontaneous remission in depression remains poorly understood. Here, we investigated regional and network brain activity using EEG signals from a chronic restraint stress (CRS)-induced mouse model of depression. After 1 (CRS1W) or 3 weeks (CRS3W) following the cessation of a 4-week-long CRS, mice were subjected to depression-associated behavioral tasks. EEG signals were obtained from eight cortical regions (frontal, somatosensory, parietal, and visual cortices in each hemisphere).

Tracing the evolution of multi-scale functional networks in a mouse model of depression using persistent brain network homology.
Many brain diseases or disorders, such as depression, are known to be associated with abnormal functional connectivity in neural networks in the brain. Some bivariate measures of electroencephalography (EEG) for coupling analysis have been used widely in attempts to explain abnormalities related with depression. However, brain network evolution based on persistent functional connections in EEG signals could not be easily unveiled. For a geometrical exploration of brain network evolution, here, we used persistent brain network homology analysis with EEG signals from a corticosterone (CORT)-induced mouse model of depression. EEG signals were obtained from eight cortical regions (frontal, somatosensory, parietal, and visual cortices in each hemisphere). The persistent homology revealed a significantly different functional connectivity between the control and CORT model, but no differences in common coupling measures, such as cross correlation and coherence, were apparent. The CORT model showed a more localized connectivity and decreased global connectivity than the control. In particular, the somatosensory and parietal cortices were loosely connected in the CORT model. Additionally, the CORT model displayed altered connections among the cortical regions, especially between the frontal and somatosensory cortices, versus the control. This study demonstrates that persistent homology is useful for brain network analysis, and our results indicate that the CORT-induced depression mouse model shows more localized and decreased global connectivity with altered connections, which may facilitate characterization of the abnormal brain network underlying depression.

Differential regulation of observational fear and neural oscillations by serotonin and dopamine in the mouse anterior cingulate cortex.
The aberrant regulation of serotonin (5-HT) and dopamine (DA) in the brain has been implicated in neuropsychiatric disorders associated with marked impairments in empathy, such as schizophrenia and autism. Many psychiatric drugs bind to both types of receptors, and the anterior cingulate cortex (ACC) is known to be centrally involved with empathy. However, the relationship between the 5-HT/DA system in the ACC and empathic behavior is not yet well known.

Symptom comorbidity is frequently observed in neuropsychiatric disorders with repetitive behaviours, including obsessive-compulsive disorder (OCD) and Tourette syndrome, and complicates clinical diagnosis and appropriate treatments. Driven by such observations, we reevaluated the behaviour of Sapap3 knockout mice, a current reference mouse model for studying the neurobiology of compulsive-like behaviours. In line with clinical comorbidity observations, we detected previously unreported elements of pathologically repetitive behaviours other than compulsive-like rodent syntactic grooming. Such repetitive behaviours included body and head twitches, aberrant hindpaw scratching, as well as isolated grooming phases. When pharmacologically challenging these phenotypes by a single administration of aripiprazole, a first-line treatment for tic-like symptoms in Tourette Syndrome, we significantly reduced the number of head/body twitches and isolated grooming phases, but not the number of syntactic grooming nor scratching events. We furthermore provide evidence that the flagship-like lesions of Sapap3 knockout mice are due to scratching, not syntactic self-grooming behaviours. Our observations are in line with high comorbidity of tic- and compulsive-like symptoms in Tourette, OCD and trichotillomania patients as well as with the hypothesis of shared neurobiological mechanisms. We suggest to reconsider the Sapap3 knockout mouse model as a comorbid model of pathological repetitive behaviours, including not only compulsive-like but also tic-like elements.

Tobacco smoking is a major contributor to the burden of mental health disease worldwide. Nicotine is the primary reinforcing and main addictive component of tobacco. Nicotine addiction is a chronic relapsing disorder associated with multiple psychiatric comorbidities, and few effective interventions currently exist to curb addiction to nicotine. The neurocircuitry underlying nicotine addiction is broad, complex and depends on the stages of the disease process. It is well-acknowledged that nicotine impacts the reward system with prominent alterations of the firing properties of VTA DA neurons consequently biasing the responses to natural and addictive rewards. Yet the underlying mechanisms responsible of VTA DA alterations remain elusive. Here, we exposed mice to chronic nicotine in their drinking water to mimic the prolonged and intermittent nicotine absorption of nicotine in humans. Combining viral tracers and optogenetic approaches, we aim to investigate the effects of long-term nicotine intake on inputs to the reward system, establishing a parallel between circuit-based electrophysiological analyses and behavioral assessments in an operant conditioning task. We will present data showing that chronic nicotine consumption induces cellular alterations within inputs to the reward system that relate to changes in motivational state for natural rewards. These changes may influence the incentive attribution process induced by drugs of abuse in the addiction process.

ROLE OF THE BLOCKADE OF A2A RECEPTOR IN THE ACQUISITION OF MORPHINE WITHDRAWAL-INDUCED CPA

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Victoria Gomez-Murcia, Aurelio Franco, Juana Hidalgo, Victoria Milanés, Cristina Núñez
University of Murcia, Pharmacology, Murcia, Spain

The purinergic system, through the A2A adenosine receptor(A2AR), is involved in addiction induced by different drugs of abuse. It has been previously demonstrated that A2A gene deletion in mice modifies some of the behavioral effects of morphine. To discriminate whether the A2AR participates in the acquisition or in the expression of morphine-induced behaviors and, thus, to design effective pharmacological treatments targeted to A2AR to prevent behaviors responsible for the maintenance and relapse in opiate addiction, we have used the condition place aversion (CPA) paradigm and administered an A2AR antagonist to morphine-dependent and control mice prior the conditioning sessions with naloxone. To induce opiates dependence mice were subcutaneously implanted with morphine (MOR) or placebo (PLA) pellet. An A2RA antagonist (sch58261; 1mg/kg) or its vehicle was administered intraperitoneally 15 min before the conditioning sessions with naloxone (NX; 0.1 mg/kg, s.c.). CPA has been used to study the aversive emotional aspects of naloxone-precipitated morphine. As expected, opiate dependent animals spent significantly less time in the morphine withdrawal-paired chamber during the CPA test comparing to PLA mice. Nonetheless, when sch58261 was injected before naloxone conditioning to morphine dependent mice they spent more time in compartment associated with withdrawal than MOR vehicle mice (&& $p<0.01$ vs MOR vehicle). Our results reveal that the blockade of A2AR in morphine dependent mice prevented the aversion to the withdrawal paired-compartment indicates that this receptor is essential for the acquisition of morphine withdrawal-induced behaviors, pointing out that A2AR antagonists might be effective pharmacological tools to treat addiction to opiates.

Both idebenone and idebenol are localized near the lipid-water interface of the membrane and increase its fluidity. Idebenone is a synthetic analog of coenzyme Q; both share a quinone moiety but idebenone has a shorter lipophilic tail ending with a hydroxyl group. Differential scanning calorimetry experiments showed that both idebenone and idebenol widened and shifted the phase transition of 1,2-dipalmitoylphosphatidylcholine (DPPC) to a lower temperature and a phase separation with different concentrations of these molecules was observed. Also small angle X-ray diffraction and wide angle X-ray diffraction revealed that both, idebenone and idebenol, induced laterally separated phases in fluid membranes when included in DPPC membranes. Electronic profiles showed that both forms, idebenone and idebenol, reduced the thickness of the fluid membrane. (2)H NMR measurements showed that the order of the membrane decreased at all temperatures in the presence of idebenone or idebenol, the greatest disorder being observed in the segments of the acyl chains close to the lipid-water interface. (1)H NOESY MAS NMR spectra were obtained using 1-palmitoyl-2-oleoyl-phosphatidylcholine membranes and results pointed to a similar location in the membrane for both forms, with the benzoquinone or benzoquinol rings and their terminal hydroxyl group of the hydrophobic chain located near the lipid/water interface of the phospholipid bilayer and the terminal hydroxyl group of the hydrophobic chain of both compounds located at the lipid/water interface. Taken together, all these different locations might explain the different physiological behavior shown by the idebenone/idebenol compared with the ubiquinone-10/ubiquinol-10 pair in which both compounds are differently localized in the membrane.

Impact of chronic doxycycline treatment in the APP/PS1 mouse model of Alzheimer's disease.
Due to the pathophysiological complexity of Alzheimer's disease, multitarget approaches able to mitigate several pathogenic mechanisms are of interest. Previous studies have pointed to the neuroprotective potential of Doxycycline (Dox), a safe and inexpensive second-generation tetracycline. Dox has been particularly reported to slow down aggregation of misfolded proteins but also to mitigate neuroinflammatory processes. Here, we have evaluated the pre-clinical potential of Dox in the APP/PS1 mouse model of amyloidogenesis. Dox was provided to APP/PS1 mice from the age of 8 months, when animals already exhibit amyloid pathology and memory deficits. Spatial memory was then evaluated from 9 to 10 months of age. Our data demonstrated that Dox moderately improved the spatial memory of APP/PS1 mice without exerting major effect on

amyloid lesions. While Dox did not alleviate overall glial reactivity, we could evidence that it rather enhanced the amyloid-dependent upregulation of several neuroinflammatory markers such as CCL3 and CCL4. Finally, Dox exerted differentially regulated the levels of synaptic proteins in the hippocampus and the cortex of APP/PS1 mice. Overall, these observations support that chronic Dox delivery does not provide major pathophysiological improvements in the APP/PS1 mouse model.

IL-17 triggers the onset of cognitive and synaptic deficits in early stages of Alzheimer's disease.
Neuroinflammation in patients with Alzheimer's disease (AD) and related mouse models has been recognized for decades, but the contribution of the recently described meningeal immune population to AD pathogenesis remains to be addressed. Here, using the 3xTg-AD model, we report an accumulation of interleukin-17 (IL-17)-producing cells, mostly γδ T cells, in the brain and the meninges of female, but not male, mice, concomitant with the onset of cognitive decline. Critically, IL-17 neutralization into the ventricles is sufficient to prevent short-term memory and synaptic plasticity deficits at early stages of disease. These effects precede blood-brain barrier disruption and amyloid-beta or tau pathology, implying an early involvement of IL-17 in AD pathology. When IL-17 is neutralized at later stages of disease, the onset of short-memory deficits and amyloidosis-related splenomegaly is delayed. Altogether, our data support the idea that cognition relies on a finely regulated balance of "inflammatory" cytokines derived from the meningeal immune system.

A comparison of the location in membranes of curcumin and curcumin-derived bivalent compounds with potential neuroprotective capacity for Alzheimer's disease.
Curcumin and two bivalent compounds, namely 17MD and 21MO, both obtained by conjugation of curcumin with a steroid molecule that acts as a membrane anchor, were comparatively studied. When incorporated into 1,2-dipalmitoyl-sn-glycero-3-phosphocholine the compounds showed a very limited solubility in the model membranes. Curcumin and the two bivalent compounds were also incorporated in membranes of 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphocholine and quenching the fluorescence of pure curcumin or of the curcumin moiety in the bivalent compounds by acrylamide it was seen that curcumin was accessible to this water soluble quencher but the molecule was somehow located in a hydrophobic environment. This was confirmed by quenching with doxyl-phosphatidylcholines, indicating that the curcumin moieties of 17MD and 21MO were in a more polar environment than pure curcumin itself. H NOESY MAS-NMR analysis supports this notion by showing that the orientation of curcumin was parallel to the plane of the membrane surface close to C2 and C3 of the fatty acyl chains, while the curcumin moiety of 17MD and 21MO positioned close to the polar part of the membrane with the steroid moiety in the centre of the membrane. Molecular dynamics studies were in close agreement with the experimental results with respect to the likely proximity of the protons studied by NMR and show that 17MD and 21MO have a clear tendency to aggregate in a fluid membrane. The anchorage of the bivalent compounds to the membrane leaving the curcumin moiety near the polar part may be very important to facilitate the bioactivity of the curcumin moiety when used as anti-Alzheimer drugs.

Hyperexcitability and seizures in the THY-Tau22 mouse model of tauopathy.
Epileptic seizures constitute a significant comorbidity of Alzheimer's disease (AD), which are recapitulated in transgenic mouse models of amyloidogenesis. Here, we sought to evaluate the potential role of tau pathology regarding seizure occurrence. To this end, we performed intra-hippocampal electroencephalogram (EEG) recordings and PTZ (pentylenetetrazol) seizure threshold tests in THY-Tau22 transgenic mice of AD-like tau pathology. We demonstrate that despite a lack of spontaneous epileptiform activity in Tau22 mice, the animals display increased PTZ-induced seizure susceptibility and mortality. The increased propensity for induced seizures in THY-Tau22 mutants correlates with astrogliosis and increased expression of adenosine kinase, consistent with increased network excitability. These data support an impact of tau pathology toward AD-associated seizures and suggest that tau pathology may contribute to seizure generation in AD independent of Aβ pathology.

Liposome-Encapsulated Morphine Affords a Prolonged Analgesia While Facilitating Extinction of Reward and Aversive Memories.
Morphine is thoroughly used for pain control; however, it has a high addictive potential. Opioid liposome formulations produce controlled drug release and have been thoroughly tested for pain treatment although their role in addiction is still unknown. This study investigated the effects of free morphine and morphine encapsulated in unilamellar and multilamellar liposomes on

antinociception and on the expression and extinction of the positive and negative memories associated with environmental cues. The hot plate test was used to measure central pain. The rewarding effects of morphine were analyzed by the conditioned-place preference (CPP) test, and the aversive aspects of naloxone-precipitated morphine withdrawal were evaluated by the conditioned-place aversion (CPA) paradigm. Our results show that encapsulated morphine yields prolonged antinociceptive effects compared with the free form, and that CPP and CPA expression were similar in the free- or encapsulated-morphine groups. However, we demonstrate, for the first time, that morphine encapsulation reduces the duration of reward and aversive memories, suggesting that this technological process could transform morphine into a potentially less addictive drug. Morphine encapsulation in liposomes could represent a pharmacological approach for enhancing extinction, which might lead to effective clinical treatments in drug addiction with fewer side effects.

Exacerbation of C1q dysregulation, synaptic loss and memory deficits in tau pathology linked to neuronal adenosine A2A receptor.
Accumulating data support the role of tau pathology in cognitive decline in ageing and Alzheimer's disease, but underlying mechanisms remain ill-defined. Interestingly, ageing and Alzheimer's disease have been associated with an abnormal upregulation of adenosine A2A receptor (A2AR), a fine tuner of synaptic plasticity. However, the link between A2AR signalling and tau pathology has remained largely unexplored. In the present study, we report for the first time a significant upregulation of A2AR in patients suffering from frontotemporal lobar degeneration with the MAPT P301L mutation. To model these alterations, we induced neuronal A2AR upregulation in a tauopathy mouse model (THY-Tau22) using a new conditional strain allowing forebrain overexpression of the receptor. We found that neuronal A2AR upregulation increases tau hyperphosphorylation, potentiating the onset of tau-induced memory deficits. This detrimental effect was linked to a singular microglial signature as revealed by RNA sequencing analysis. In particular, we found that A2AR overexpression in THY-Tau22 mice led to the hippocampal upregulation of C1q complement protein-also observed in patients with frontotemporal lobar degeneration-and correlated with the loss of glutamatergic synapses, likely underlying the observed memory deficits. These data reveal a key impact of overactive neuronal A2AR in the onset of synaptic loss in tauopathies, paving the way for new therapeutic approaches.

The Adenosinergic Signaling: A Complex but Promising Therapeutic Target for Alzheimer's Disease.
Alzheimer's disease (AD) is the most common neurodegenerative disorder in elderly people. AD is characterized by a progressive cognitive decline and it is neuropathologically defined by two hallmarks: extracellular deposits of aggregated β-amyloid (Aβ) peptides and intraneuronal fibrillar aggregates of hyper- and abnormally phosphorylated Tau proteins. AD results from multiple genetic and environmental risk factors. Epidemiological studies reported beneficial effects of caffeine, a non-selective adenosine receptors antagonist. In the present review, we discuss the impact of caffeine and of adenosinergic system modulation on AD, in terms of pathology and therapeutics.

Insights into the Impact of a Membrane-Anchoring Moiety on the Biological Activities of Bivalent Compounds As Potential Neuroprotectants for Alzheimer's Disease.
Bivalent compounds anchoring in different manners to the membrane were designed and biologically characterized to understand the contribution of the anchor moiety to their biological activity as neuroprotectants for Alzheimer's disease. Our results established that the anchor moiety is essential, and we identified a preference for diosgenin, as evidenced by 17MD. Studies in primary neurons and mouse brain mitochondria also identified 17MD as exhibiting activity on neuritic outgrowth and the state 3 oxidative rate of glutamate while preserving the coupling capacity of the mitochondria. Significantly, our studies demonstrated that the integrated bivalent structure is essential to the observed biological activities. Further studies employing bivalent compounds as probes in a model membrane also revealed the influence of the anchor moiety on how they interact with the membrane. Collectively, our results suggest diosgenin to be an optimal anchor moiety, providing bivalent compounds with promising pharmacology that have potential applications for Alzheimer's disease.

Development of Poly(lactide-co-glicolide) Nanoparticles Incorporating Morphine Hydrochloride to Prolong its Circulation in Blood.

Formulations incorporating nanoparticles (NPs) are widely used to prolong drug release. In this regard, poly(lactide-co-glicolide) (PLGA) is often used in their preparation due to its high degree of biocompatibility and biodegradability. In the present study, morphine HCl is incorporated in PLGA-NPs and different preparation alternatives are evaluated for their effects on the properties, stability and capacity of encapsulation.

Drug addiction, like most other addictions, takes place in a social environment that can influence the use of drugs. Alcohol is generally known as a social facilitator due to its disinhibiting properties[1]. Despite these widely known effects, few preclinical studies have so far looked at social factors at the time of consumption (proximal social factors). In rats, we use an alcohol self-administration task to assess the effect of the presence of a peer on alcohol intake. We used operant chambers with two compartments separated by a grid allowing the rats to interact. During sessions, only one rat has access to the alcohol. Our results showed that the presence of a peer increases alcohol intake for consumer rats. Previous studies showed the strong involvement of the subthalamic nucleus (STN) in motivated behavior, particularly in drug seeking[2-3-4]. In this study, we showed that STN deep brain stimulation at 130Hz reduces alcohol seeking when the animal is alone and reduces the influence of the presence of a peer on alcohol consumption.

Cocaine is a highly addictive stimulant and still cocaine use disorder is a serious problem worldwide. The psychostimulant effect of cocaine is known to be developed through mesocorticolimbic system, yet there is a need to better understand specific mechanism of addiction. Our previous studies have shown that transient receptor potential Ankyrin 1 (TRPA1) channel can be a promising target to treat cocaine addiction. Here, we investigated the role of TRPA1 specifically in the medial prefrontal cortex (mPFC) to nucelus accumbens (NAc) pathway in mice using microinjection and optogenetic techniques. In cocaine psychomotor test, bilateral microinjection of TRPA1 antagonist into the NAc inhibited hyperactivity by acute cocaine treatment and cocaine-primed expression of cocaine sensitization. In the conditioned place preference (CPP) test, intra-NAc infusions of TRPA1 antagonist during conditioning period inhibited cocaine CPP acquisition. In addition, cocaine-primed reinstatement of cocaine CPP was also inhibited by intra-NAc infusions of TRPA1 antagonist on the reinstatement day. Through ELISA-based glutamate assay studies, we found that repeated cocaine injection increased glutamate levels both in the mPFC and NAc which was inhibited by TRPA1 pretreatment. Based on these results, we targeted glutamatergic neurons extending from mPFC to NAc by viral channelrhodopsin expression. When those neurons are specifically activated by optogenetic stimulation, it produced CPP in mice which was attenuated by systemic injection of TRPA1 antagonist. Taken together, present studies suggest that crucial role of TRPA1 in NAc on cocaine addiction and especially glutamatergic neurons extending from mPFC to NAc is considered as major pathway.

A hallmark of addiction is the ability of drugs of abuse to trigger relapse, even after periods of prolonged abstinence. Growing evidence implicates altered gene regulation in mediating the persistent effects of drugs of abuse in the nucleus accumbens (NAc), a key brain region of reward learning. Changes in the epigenetic landscape are hypothesized to cause the latent dysregulation of gene expression linked to relapse; however, the molecular mechanisms underlying this maladaptive process remains unclear. The NAc is composed of two functionally distinct types of medium spiny neurons (MSNs), the D1 and D2 dopamine receptor-expressing subtypes, thus making the identification of subtype-specific epigenetic changes critical. We surveyed circuit-specific chromatin accessibility in combination with unbiased histone modification profiling by mass spec and ChIP-seq. We discovered that chronic cocaine persistently alters NAc chromatin structure, especially in D1 MSNs, involving dramatic depletion of the histone variant H2A.Z, a recently identified memory suppressor, at key neuronal genes. Curiously, genome accessibility in D1 MSNs is prominently increased at these genes even after prolonged withdrawal, and is linked to aberrant gene expression upon relapse. The histone chaperone ANP32E is promotes the removal of H2A.Z, and we demonstrate that D1 MSN-selective ANP32E knockdown effectively blocks cocaine conditioned place preference (CPP). Together, our studies investigate an emerging view of epigenetic adaptation that may contribute to substance use disorder, providing novel insight into circuit-specific epigenetic priming as an important mechanism whereby drugs of abuse alter gene expression and behavior in lasting ways.

ANABOLIC ANDROGENIC STEROID USE IN PROFESSIONAL AND AMATEUR ATHLETES: ASSOCIATION WITH OTHER SUBSTANCE USE

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Daria Piacentino[1], Georgios Kotzalidis[2], Gabriele Sani[2]
[1]National Institutes of Health, Clinical Psychoneuroendocrinology And Neuropsychopharmacology Section, Baltimore, United States of America, [2]Catholic University of Rome, Neuroscience, Rome, Italy

Aim Evidence regarding the association between anabolic androgenic steroid (AAS) and other substance use in athletes is controversial. A low prevalence of polysubstance use in AAS users has been reported by some studies; other studies have hypothesized that AASs use may be a gateway for the consumption of misused substances, especially opioids, possibly due to opioids' analgesic action on muscle pain caused by overtraining or their ability to counteract AAS-induced insomnia/irritability. Yet, the gateway hypothesis remains controversial. Last, AAS-induced alterations of the endogenous opioidergic system may lead to increased sensitivity to opioids. This multisite, cross-sectional study in professional and recreational athletes in Italy, assessed the use of AASs and other substances in biological samples, based on the hypothesis that AAS-using athletes would be more focused on being fit and not take other substances. **Methods** 122 athletes (age=18-45 years; females=38) all completed toxicological examinations, i.e., blood, urine, and hair testing for AASs and misused drugs. **Results** There was slight-to-moderate agreement among the three biological samples used for AAS and other substance testing (Fleiss' κ=0.251-0.474). Contrary to our hypothesis, we found AAS users to consume more misused substances than nonusers (χ^2=0.082, p<0.01), especially cannabinoids (25.8% vs. 18.7%), opioids (16.1% vs. 3.3%), amphetamines (12.9% vs. 4.4%), and cocaine (9.7% vs. 6.6%). **Conclusions** These findings align with some studies in athletes that describe the concurrent use of AASs and other substances, often in a context of polysubstance use. Further research is needed to investigate the association between AAS and other substance use, especially opioids.

EFFECTS OF THE MONOAMINE STABILIZER OSU6162 ON COMPULSIVE ALCOHOL-RELATED BEHAVIOR IN RATS.

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Fanny Joly, Raphaël Goutaudier, Sebastien Carnicella
Grenoble Institute of Neurosciences, Physiopathology Of Motivation, La Tronche, France

Alcohol addiction is a chronic relapsing disease characterized by the inability to control alcohol consumption, the degradation of affective and emotional state during abstinence and ultimately by the development of compulsive seeking despite knowledge of having negative consequences. Still, the shift between a controlled alcohol consumption and the development of compulsive behavior remain unclear. It has been shown that alcohol-use disorder alters dopaminergic (DA) transmission in both mesolimbic and nigrostriatal pathways, which functionality are fundamental for incentive motivated behaviors in positive and negative reinforcements and motor control. More precisely, it has been shown that acute alcohol consumption increased DA release and phasic DA transmission in the nucleus accumbens (NAcc), while long-term consumption leads to a chronic decrease of DA level, with a tonic hypodopaminergic transmission in the NAcc. We have recently showed that compulsive alcohol-related behavior in rats was rather associated with a decrease of DA release in the anterior dorsolateral striatum (aDLS), and a selective induction of hypodopaminergia in the nigrostriatal pathway triggered compulsive alcohol use in rats. In the current study, we aim to investigate whether restoration of normal dopaminergic transmission by the monoamine stabilizer OSU6162 could restore a normal behavior in compulsive alcohol-related rats.

[1]Pavlov Institute of Physiology RAS, Laboratory Of Regulation Of Brain Neuronal Functions, Saint-Petersburg, Russian Federation, [2]Saint-Petersburg State University, Department Of Biochemistry, Saint-Petersburg, Russian Federation, [3]Institute of Citology RAS, Group Of Molecular Genetic Of Cancer Cells, Saint-Petersburg, Russian Federation

The role of damaging factors in prenatal period as basis of drug addiction in offspring is of great interest. Our investigation aims to study the effects and possible mechanisms of prenatal hypoxia (PSH) on the vulnerability to nicotine addiction in adult 3-months old rats. In PSH group, we have revealed an increased tendency to nicotine consumption in behavioral tests. In an attempt to find out an explanation for the addictive behavior of PSH rats, we previously revealed increased amount of phosphorylated at the 34th threonine residue DARPP-32 protein (known as the relay for dopamine and glutamate signaling) in the nucleus accumbens (NAc). The observed proportion of DARPP-32/phosphoDARPP-32 could not be explained by alterations in the amount of dopamine and its receptors in the NAc. As a protentional, explanation, we consider the decreasing of glutamatergic stimulation of NAc neurons from projections of ventral hippocampus, in which we found decreased glucocorticoid-dependent transcription of genes of glutamate metabolism. Meanwhile, another potential explanation might be increasing expression of the *chrna7* gene, which codes nicotinic acetylcholine receptors of type 7 localized on presynapses of glutamatergic projections to such structures of the mesocortical pathway, as the prefrontal cortex (PFC) and ventral tegmental area (VTA), in which an increase in VGluT2-positive glutamatergic terminals were also found. Thus, the accelerated development of nicotine addiction in experimental rats is probably associated with PSH-related phenotype of acetylcholine and glutamatergic systems, namely with increased glutamatergic stimulation of VTA and PFC neurons and decreased stimulation of NAc from hippocampal glutamatergic projections.

Prenatal Hypoxia Induces Premature Aging Accompanied by Impaired Function of the Glutamatergic System in Rat Hippocampus.
Prenatal hypoxia is among leading causes of progressive brain pathologies in postnatal life. This study aimed to analyze the characteristics of the hippocampal glutamatergic system and behavior of rats in early (2 weeks), adult (3 months) and advanced (18 months) postnatal ontogenesis after exposure to prenatal severe hypoxia (PSH, 180 Torr, 5% O2, 3 h) during the critical period in the formation of the hippocampus (days 14-16 of gestation). We have shown an age-dependent progressive decrease in the hippocampal glutamate levels, a decrease of the neuronal cell number in the CA1 hippocampal region, as well as impairment of spatial long-term memory in the Morris water navigation task. The gradual decrease of glutamate was accompanied by decreased expression of the genes that mediate glutamate metabolism and recycling in the hippocampus. That deficiency apparently correlated with an increase of the metabotropic glutamate receptor type 1 (mGluR1) and synaptophysin expression. Generation of the lipid peroxidation products in the hippocampus of adult rats subjected to prenatal severe hypoxia (PSH rats) was not increased compared to the control animals when tested in a model of glutamate excitotoxicity induced by severe hypoxia. This demonstrates that excessive glutamate sensitivity in PSH rats does not compensate for glutamate deficiency. Our results show a significant contribution of the glutamate system dysfunction to age-associated decrease of this mediator, cognitive decline, and early neuronal loss in PSH rats.

The integrated stress response (ISR) is a stress sensing pathway that reprograms cellular translation to promote proteostasis in response to nutrient poor conditions, changes in the redox state, infection by double stranded RNA viruses, and accumulation of unfolded proteins in the ER. Aberrant ISR activation has been associated with many neuropathologies of the brain including Vanishing White Matter Disease, Alzheimer Disease, and Downs Syndrome. ISR activation mediates changes in translation via phosphorylation of a translation initiation factor (eIF2), which regulates levels of initiation of protein synthesis. To understand the contribution of the ISR to disease we generated a novel mouse model that expresses a mutant component of the phosphatase that catalyzes removal of the phosphate on eIF2. This mutant phosphatase causes accumulation of phosphorylated eIF2, and thus, sustained activation of the ISR in the brain. Consistent with ISR activation, we saw increased phosphorylated eIF2, and ATF4 target genes in the brain. Previous work had suggested the ISR contributes to impaired cognition in mouse models. We observed impaired memory in contextual fear conditioning experiments, and further studies revealed novel changes associated with the ISR that are relevant to human disease.

NEUROCOMPUTATIONAL MECHANISMS OF AVOIDANCE BEHAVIOUR IN OBSESSIVE-COMPULSIVE SYMPTOMOLOGY

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Tricia Seow[1,2], Tobias Hauser[1,2]
[1]University College London, Max Planck Ucl Centre For Computational Psychiatry And Ageing Research, London, United Kingdom, [2]University College London, Wellcome Centre For Human Neuroimaging, London, United Kingdom

Exposure therapy, the first-line treatment for obsessive-compulsive disorder (OCD), relies on aversive conditioning and extinction learning principles. However, little is known about how these principles go awry in unsuccessful exposure therapy. To probe their computational foundations, we designed a novel aversive conditioning task to examine acquisition and extinction learning via explicit contingency reports and avoidance actions. Participants had to learn the aversive contingencies of different stimuli (low (20%), mid (50%), high (80%)). Thereafter, they could perform actions to avoid the probabilistic aversive outcomes, whilst some stimuli were devalued. We collected data from 84 participants as they performed the task online and assessed their OCD symptomatology. We found that individuals scoring high in OCD symptomology overestimated the aversive contingencies of the stimuli initially (r=.27, p=.01) but corrected their biased contingency beliefs after learning (r<014, p>0.19). These individuals also excessively performed avoidance actions for the low contingency stimuli (20%) (r=0.26, p<0.001) and the non-devalued low contingency stimulus after extinction (r=0.37, p<0.001) despite reporting accurate contingency beliefs (r=0.17, p=0.11). This reveals a striking action-belief mismatch in those with high OCD symptoms. Our findings thus suggest that individuals with high OCD scores do not have impairments in learning and reporting accurate contingency beliefs after acquisition and extinction, but yet exhibit excessive avoidance to aversive outcomes of low probability.

How Local and Global Metacognition Shape Mental Health.
Metacognition is the ability to reflect on our own cognition and mental states. It is a critical aspect of human subjective experience and operates across many hierarchical levels of abstraction-encompassing local confidence in isolated decisions and global self-beliefs about our abilities and skills. Alterations in metacognition are considered foundational to neurologic and psychiatric disorders, but research has mostly focused on local metacognitive computations, missing out on the role of global aspects of metacognition. Here, we first review current behavioral and neural metrics of local metacognition that lay the foundation for this research. We then address the neurocognitive underpinnings of global metacognition uncovered by recent studies. Finally, we outline a theoretical framework in which higher hierarchical levels of metacognition may help identify the role of maladaptive metacognitive evaluation in mental health conditions, particularly when combined with transdiagnostic methods.

Reliability of web-based affective auditory stimulus presentation.
Web-based experimental testing has seen exponential growth in psychology and cognitive neuroscience. However, paradigms involving affective auditory stimuli have yet to adapt to the online approach due to concerns about the lack of experimental control and other technical challenges. In this study, we assessed whether sounds commonly used to evoke affective responses in-lab can be used online. Using recent developments to increase sound presentation quality, we selected 15 commonly used sound stimuli and assessed their impact on valence and arousal states in a web-based experiment. Our results reveal good inter-rater and test-retest reliabilities, with results comparable to in-lab studies. Additionally, we compared a variety of previously used unpleasant stimuli, allowing us to identify the most aversive among these sounds. Our findings demonstrate that affective sounds can be reliably delivered through web-based platforms, which

help facilitate the development of new auditory paradigms for affective online experiments.

Model-Based Planning Deficits in Compulsivity Are Linked to Faulty Neural Representations of Task Structure.
Compulsive individuals have deficits in model-based planning, but the mechanisms that drive this have not been established. We examined two candidates-that compulsivity is linked to (1) an impaired model of the task environment and/or (2) an inability to engage cognitive control when making choices. To test this, 192 participants performed a two-step reinforcement learning task with concurrent EEG recordings, and we related the neural and behavioral data to their scores on a self-reported transdiagnostic dimension of compulsivity. To examine subjects' internal model of the task, we used established behavioral and neural responses to unexpected events [reaction time (RT) slowing, P300 wave, and parietal-occipital alpha band power] measured when an unexpected transition occurred. To assess cognitive control, we probed theta power at the time of initial choice. As expected, model-based planning was linked to greater behavioral (RT) and neural (alpha power, but not P300) sensitivity to rare transitions. Critically, the sensitivities of both RT and alpha to task structure were weaker in those high in compulsivity. This RT-compulsivity effect was tested and replicated in an independent pre-existing dataset (= 1413). We also found that mid-frontal theta power at the time of choice was reduced in highly compulsive individuals though its relation to model-based planning was less pronounced. These data suggest that model-based planning deficits in compulsive individuals may arise, at least in part, from having an impaired representation of the environment, specifically how actions lead to future states. Compulsivity is linked to poorer performance on tasks that require model-based planning, but it is unclear what precise mechanisms underlie this deficit. Do compulsive individuals fail to engage cognitive control at the time of choice? Or do they have difficulty in building and maintaining an accurate representation of their environment, the foundation needed to behave in a goal-directed manner? With reaction time and EEG measures in 192 individuals who performed a two-step decision-making task, we found that compulsive individuals are less sensitive to surprising action-state transitions, where they slow down less and show less alpha band suppression following a rare transition. These findings implicate failures in maintaining an accurate model of the world in model-based planning deficits in compulsivity.

A dimensional investigation of error-related negativity (ERN) and self-reported psychiatric symptoms.
Alterations in error processing are implicated in a range of DSM-defined psychiatric disorders. For instance, obsessive-compulsive disorder (OCD) and generalised anxiety disorder show enhanced electrophysiological responses to errors-i.e. error-related negativity (ERN)-while others like schizophrenia have an attenuated ERN. However, as diagnostic categories in psychiatry are heterogeneous and also highly intercorrelated, the precise mapping of ERN enhancements/impairments is unclear. To address this, we recorded electroencephalograms (EEG) from 196 participants who performed the Flanker task and collected scores on 9 questionnaires assessing psychiatric symptoms to test if a dimensional framework could reveal specific transdiagnostic clinical manifestations of error processing dysfunctions. Contrary to our hypothesis, we found non-significant associations between ERN amplitude and symptom severity of OCD, trait anxiety, depression, social anxiety, impulsivity, eating disorders, alcohol addiction, schizotypy and apathy. A transdiagnostic approach did nothing to improve signal; there were non-significant associations between all three transdiagnostic dimensions (anxious-depression, compulsive behaviour and intrusive thought, and social withdrawal) and ERN magnitude. In these same individuals, we replicated a previously published transdiagnostic association between goal-directed learning and compulsive behaviour and intrusive thought. Possible explanations discussed are (i) that associations between the ERN and psychopathology might be smaller than previously assumed, (ii) that these associations might depend on a greater level of symptom severity than other transdiagnostic cognitive biomarkers, or (iii) that task parameters, such as the ratio of compatible to incompatible trials, might be crucial for ensuring the sensitivity of the ERN to clinical phenomena.

Transdiagnostic Phenotyping Reveals a Host of Metacognitive Deficits Implicated in Compulsivity.
Recent work suggests that obsessive-compulsive disorder (OCD) patients have a breakdown in the relationship between explicit beliefs (i.e. confidence about states) and updates to behaviour. The precise computations underlying this disconnection are unclear because case-control and transdiagnostic studies yield conflicting results. Here, a large online population sample (N = 437) completed a predictive inference task previously studied in the context of OCD. We tested if confidence, and its relationship to action and environmental evidence, were specifically associated with self-reported OCD symptoms or common to an array of psychiatric phenomena. We then investigated if a transdiagnostic approach would reveal

a stronger and more specific match between metacognitive deficits and clinical phenotypes. Consistent with prior case-control work, we found that decreases in action-confidence coupling were associated with OCD symptoms, but also 5/8 of the other clinical phenotypes tested (8/8 with no correction applied). This non-specific pattern was explained by a single transdiagnostic symptom dimension characterized by compulsivity that was linked to inflated confidence and several deficits in utilizing evidence to update confidence. These data highlight the importance of metacognitive deficits for our understanding of compulsivity and underscore how transdiagnostic methods may prove a more powerful alternative over studies examining single disorders.

Perceptual sensitivity is modulated by what others can see.
Previous work has established that social cues such as the direction of others' gaze or their perspective on a scene may influence one's own perceptual judgments. However, up until now it has remained unclear whether such influences are exerted at a perceptual or decisional locus, as most previous studies have used response times as their primary dependent measure. Here, we asked whether perceptual sensitivity is also dependent on social cognition. To test this hypothesis, we asked participants to evaluate whether low-contrast Gabor patterns embedded in noise were visible from either their own or an avatar's perspective. Across three experiments, we found that observers' detection performance was increased if an avatar also shared perception of the stimulus location. By leveraging signal detection modelling, we show that this effect is driven by a change in perceptual sensitivity (d'), independent of decisional or response interference. Furthermore, by "blindfolding" the avatar, we show that the boosting effect of shared perception on detection sensitivity is only obtained when the participant believes the avatar can also see the stimulus, ruling out an influence of low-level directional cues. We interpret these results within a framework in which the avatar's perspective boosts top-down spatial attention by prioritising particular spatial locations at which perception is shared. In summary, we reveal that perceptual sensitivity is modulated by the perspective of others.

Psychiatric Symptom Dimensions Are Associated With Dissociable Shifts in Metacognition but Not Task Performance.
Distortions in metacognition-the ability to reflect on and control other cognitive processes-are thought to be characteristic of poor mental health. However, it remains unknown whether such shifts in self-evaluation are due to specific alterations in metacognition and/or a downstream consequence of changes in decision-making processes.

Stimulus Novelty Energizes Actions in the Absence of Explicit Reward.
Novelty seeking has been tied to impulsive choice and biased value based choice. It has been postulated that novel stimuli should trigger more vigorous approach and exploration. However, it is unclear whether stimulus novelty can enhance simple motor actions in the absence of explicit reward, a necessary condition for energizing approach and exploration in an entirely unfamiliar situation. In this study human subjects were cued to omit or perform actions in form of button presses by novel or familiar images. We found that subjects' motor actions were faster when cued by a novel compared to a familiar image. This facilitation by novelty was strongest when the delay between cue and action was short, consistent with a link between novelty and impulsive choices. The facilitation of reaction times by novelty was correlated across subjects with trait novelty seeking as measured in the Tridimensional Personality Questionnaire. However, this li between high novelty-seeking and action facilitation was driven by trials with a long delay between cue and action. This prolonged time window of energization following novelty could hint at a mechanistic underpinning of enhanced vigour for approach and exploration frequently postulated for novelty seeking humans. In conclusion, we show that stimulus novelty enhances the speed of a cued motor action. We suggest this is likely to reflect an adaptation to changing environments but may also provide a source of maladaptive choice and impulsive behaviour.

SEX DIFFERENCES IN BEHAVIORAL AND NEUROCHEMICAL EFFECTS OF AMPHETAMINE MODULATED BY VASOPRESSIN IN THE LATERAL SEPTUM

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Georgina Renard[1], Macarena Gárate-Pérez[1], Francisca Tobar[1], Valeska Cid-Jofré[1], Daniela Cáceres[1], Ramón Sotomayor-Zárate[2]
[1]Universidad de Santiago de Chile, Centro De Investigación Biomédica Aplicada (cibap), Escuela De Medicina, Facultad De Ciencias Médicas, Santiago, Chile, [2]Universidad de Valparaíso, Laboratorio De Neuroquímica Y Neurofarmacología, Centro De Neurobiología Y Fisiopatología Integrativa (cenfi), Instituto De Fisiología, Facultad De Ciencias, Valparaiso, Chile

Lateral septum (LS) is a brain structure implicated in addictive behaviors, regulating the activation of dopamine (DA) neurons in the ventral tegmental area (VTA). Extended amygdala vasopressin (AVP) projections to LS are sexually dimorphic and could be responsible for the vulnerability to addiction in a sex-dependent manner. We demonstrated that AVP microinjection in LS reduces amphetamine (AMPH)-induced conditioned place preference (CPP) that it is associated to lower nucleus accumbens (NAc) DA release in male rats. The aim of this work was to examine sex differences in LS AVP system on AMPH-induced behavioral and neurochemical responses in female and male rats. Our results show that LS AVP microinjections avoid the AMPH-induced CPP expression in female rats, which it is reversed by co-microinjection of V_{1A} receptor antagonist. At neurochemical level, intra-LS AVP administration increases LS GABA release, and it decreases VTA DA release only in male rats. Interestingly, our data demonstrate that intra-LS AVP reduces AMPH-induced CPP in rats of both sexes, however at neurochemical level we observed sex differences. This research contributes to the knowledge about sex differences in the role of AVP in LS in regulating the reward circuit and addictive like behaviors. KEYWORDS: amphetamine, lateral septum, dopamine, ventral tegmental area, vasopressin, GABA, CPP This research was funded by ANID-Chile through FONDECYT Grant N°120–0474 to R.S-Z. and G.M.R and DICYT Grant Nº 022101RSSA to G.M.R.

LOFEXIDINE INHIBITS GASTROINTESTINAL AND SOMATIC, BUT NOT NEGATIVE AFFECTIVE OPIOID WITHDRAWAL SYMPTOMS IN MICE.

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Gabriella Guy[1,2], Nicholas Everett[1,2], Bianca Wilson[1,2], Michael Bowen[1,2]
[1]University of Sydney, School Of Psychology, Sydney, Australia, [2]University of Sydney, Brain And Mind Centre, Sydney, Australia

AIMS The alpha-2 adrenergic agonist lofexidine was repurposed and approved by the FDA for mitigation of opioid withdrawal symptoms. Despite this, there are no published preclinical lofexidine opioid studies. This limits lofexidine's utility as a comparator for drug discovery and hinders the ability to better understand its mechanism of action in mitigating withdrawal. Therefore, we used murine models to assess lofexidine effects on: i) multiple acute opioid withdrawal symptoms; ii) locomotor activity in opioid naïve mice; and iii) acquisition of withdrawal-induced conditioned place aversion (CPA). **METHODS** Male C57BL/6 mice were made physically dependent on oxycodone by repeated administration. Dose-dependent effects of lofexidine on acute gastrointestinal (fecal boli, diarrhea), somatic (tremors), and negative affective (jumping) symptoms were assessed using a naloxone-precipitated oxycodone withdrawal model. Impact on aversive stimulus effects of opioid withdrawal were assessed by examining lofexidine's effects on acquisition of CPA. Locomotor effects of lofexidine were assessed in opioid-naïve mice in an open-field. **RESULTS** Lofexidine reduced paw tremors and gastrointestinal symptoms during withdrawal but had no impact on withdrawal-induced jumping. Lofexidine was sedative and induced thigmotaxis across a broad dose range. Lofexidine did not affect acquisition of withdrawal-induced CPA at either sedating or non-sedating doses. **CONCLUSIONS** Consistent with the clinical literature, lofexidine appears efficacious for managing some, but not all aspects of the withdrawal syndrome. However, effects should be interpreted with caution, as they were not dissociable from pronounced sedation. Notably, lofexidine does not appear to be effective at managing negative affective aspects of the withdrawal syndrome.

VENTRAL PALLIDAL PERINEURONAL NETS REGULATE OPIOID RELAPSE

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Carley Miller, Nicholas Fayette, Brandi Wiedmeyer, Jasper Heinsbroek
University of Colorado Anschutz Medical Campus, Anesthesiology, Aurora, United States of America

Opioid use disorder remains a major health challenge worldwide. Neuronal activity in the ventral pallidum (VP) is critical for opioid reward, and for driving relapse to opioid seeking, but the precise neuronal mechanisms that mediate these behaviors are incompletely understood. A major population of VP neurons linked to drug relapse is characterized by expression of the calcium binding protein parvalbumin and are ensheathed by specialized extracellular structures known as perineuronal nets (PNNs). However, despite the dense expression of PNNs in the VP, the role of these structures in VP neuronal physiology and opioid seeking remains unknown. To investigate the role of PNNs in the VP on opioid relapse, male and female mice were implanted with intravenous catheters and trained to self administer heroin. Afterwards mice underwent extinction training, followed 24h later by a microinfusion of the PNN-depleting enzyme chondroitinase ABC (ChABC) or vehicle (0.1% BSA) into the VP. The next day, relapse to drug seeking was assessed. VP ChABC microinjection abolished PNNs in the proximity of the microinjector needle and attenuated cue-induced reinstatement of heroin seeking. Ongoing experiments are characterizing the role of PNNs on the physiology of VP neurons. Our results affirm that the VP is a critical regulator for opioid relapse, and expand our knowledge of the opioid addiction circuitry by showing that heroin seeking requires intact PNNs in the VP. Given the importance of PNNs for memory maintenance and behavioral plasticity, therapies aimed at modifying PNN structure might provide a useful novel avenue for treating opioid addiction.

OXYTOCIN AND OREXIN SYSTEMS BIDIRECTIONALLY REGULATE THE ABILITY OF OPIOID CUES TO BIAS CHOICE DURING RELAPSE

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

As opioid-related fatalities continue to rise, the need for novel opioid use disorder (OUD) treatments could not be more urgent. Two separate hypothalamic neuropeptide systems have shown promise in preclinical OUD models. The oxytocin system, originating in the paraventricular nucleus (PVN), may protect against OUD severity. By contrast, the orexin system, originating in the lateral hypothalamus (LH), may exacerbate OUD severity. Thus, activating the oxytocin system or inhibiting the orexin system are potential therapeutic strategies. The role of these systems with regard to specific OUD outcomes, however, is not fully understood. Here, we probed the therapeutic efficacy of pharmacological interventions targeting the orexin or oxytocin system on two distinct metrics of OUD severity in rats – heroin choice (versus choice for natural reward, i.e., food) and relapse. Using a preclinical model that generates approximately equal choice between heroin and food reward, we examined the impact of exogenously administered oxytocin, an oxytocin receptor antagonist (L-368,899), and a dual orexin receptor antagonist (DORA-12) on opioid choice. Whereas these agents did not alter heroin choice when rewards (heroin and food) were available, both agents significantly reduced heroin relapse in the presence of both types of reward cues when no rewards were available. In addition, we observed that the number of LH orexin neurons and PVN oxytocin neurons correlated with specific behavioral economic variables indicative of heroin versus food motivation. These data identify a novel bidirectional role of the oxytocin and orexin systems in the ability of opioid-related cues to bias choice during relapse.

EXTINCTION ATTENUATES HYPERALGESIA DURING WITHDRAWAL FROM SELF-ADMINISTERED HEROIN: ROLE OF THE PVT→NAC PATHWAY

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Giuseppe Giannotti[1], Sheng Gong[2], Nicholas Fayette[1], Jasper Heinsbroek[1], Christopher Ford[2], Jamie Peters[1,2]
[1]University of Colorado Anschutz Medical Campus, Anesthesiology, Aurora, United States of America, [2]University of Colorado Anschutz Medical Campus, Pharmacology, Aurora, United States of America

Aim: The paraventricular thalamus (PVT) to the nucleus accumbens (NAc) pathway has been recently identified as a key component in the neural circuitry of opioid use disorder. Here we used chemogenetics, in-vivo optogenetic LTD protocol and fiber photometry to investigate the contribution of the PVT→NAc pathway to heroin withdrawal-mediated hyperalgesia. Using withdrawal-related variables, a machine learning model was trainend to predict individual propensity to relapse. **Methods**: Rats underwent 12d of heroin self-administration. Hyperalgesia was assessed after 14d of withdrawal by using an electronic Von Frey apparatus, after J60 or vehicle pretreatment. A different cohort of rats received an in-vivo optogenetic LTD protocol stimulation (1Hz) after 14d of abstinence, before the cued relapse test. To validate the in-vivo LTD protocol, optogenetic-evoked calcium events were recorded by using fiber photometry before and after LTD stimulation. **Results:** Extinction training significantly attenuated heroin withdrawal-induced hyperalgesia and somatic signs compared to the abstinence group. Chemogenetic inhibition of the PVT→NAc pathway after abstinence reduced hyperalgesia to levels similar to those observed after extinction training. Finally, we found that multiple variables of the addiction model can be used to accurately predict individual relapse rates during cued relapse. **Conclusion:** Here we demonstrated that the PVT→NAc pathway promotes heroin withdrawal-induced hyperalgesia after abstinence but not after extinction training. Moreover, we successfully employed fiber photometry to validate the in-vivo optogenetic LTD protocol in the PVT→NAc pathway. Finally, by using withdrawal-related variables to train a regression machine learning model, we were able to accurately predict the individual propensity to relapse.

Alcohol intoxication at early ages is a risk factor for development of addictive behavior. To uncover neuronal molecular correlates of acute ethanol intoxication, we used stable-isotope labeled mice combined with quantitative mass spectrometry to screen over 2000 hippocampal proteins of which 72 changed synaptic abundance up to two-fold after ethanol exposure. Among those were mitochondrial proteins and proteins important for neuronal morphology, including MAP6 and Ankyrin-G. Based on these candidate proteins, we found acute and lasting molecular, cellular, and behavioral changes following a single intoxication in alcohol-naïve mice. Immunofluorescence analysis revealed a shortening of axon initial segments. Longitudinal two-photon *in vivo* imaging showed increased synaptic dynamics and mitochondrial trafficking in axons. Knockdown of mitochondrial trafficking in dopaminergic neurons abolished conditioned alcohol preference in *Drosophila*. This introduces mitochondrial trafficking as a process implicated in reward learning, and highlights the potential of high-resolution proteomics to identify cellular mechanisms relevant for addictive behavior.

Caffeine is the most consumed psychoactive substance worldwide. Strikingly, molecular pathways engaged by its regular consumption remain unclear. We herein addressed the mechanisms associated with habitual (chronic) caffeine consumption in the mouse hippocampus using untargeted orthogonal-omics techniques. Our results revealed that chronic caffeine exerts concerted pleiotropic effects in the hippocampus, at the epigenomic, proteomic and metabolomic levels. Caffeine lowers metabolic-related processes in the bulk tissue, while it induces neuronal-specific epigenetic changes at synaptic transmission/plasticity-related genes and increased experience-driven transcriptional activity. Altogether, these findings suggest that regular caffeine intake improves the signal-to-noise ratio during information encoding, in part through a fine-tuning of metabolic genes while boosting the salience of information processing during learning in neuronal circuits. Paiva I *et al*, Caffeine intake exerts dual genome-wide effects on hippocampal metabolism and learning-dependent transcription. J Clin Invest. May 10, 2022.

OPIOID WITHDRAWAL ABRUPTLY DISRUPTS AMYGDALA CIRCUIT FUNCTION BY REDUCING PEPTIDE ACTIONS

POSTER SESSION 06 - SECTION: SUBSTANCE USE AND ABUSE

Gabrielle Gregoriou[1], Sahil Patel[2], Roger Wang[1], Elena Bagley[1]
[1]The University of Sydney, School Of Pharmacy, Sydney, Australia, [2]UCL Institute of Neurology, Department Of Clinical And Experimental Epilepsy, London, United Kingdom

Withdrawal from opioid drugs has long-lasting effects on neuronal function and synaptic transmission in opioid-sensitive neurons throughout the brain. These persistent changes are thought to drive drug seeking and relapse behaviours, even after protracted abstinence. Despite this, the mechanisms and circuits underlying the altered behaviours following opioid withdrawal are only partially understood, limiting the development of treatments for addiction. Neural circuits within the amygdala mediate drug seeking and relapse behaviours, thus, we aimed to discover whether opioid withdrawal triggered neuroadaptations in opioid-sensitive amygdala cells. Under normal physiological conditions, glutamatergic transmission from principal neurons within the basolateral amygdala to GABAergic intercalated cells within the neighbouring main intercalated cell island is strongly inhibited by endogenous opioid peptides. Using patch-clamp electrophysiology in rat brain slices, we found that opioid withdrawal strongly reduced the ability of met-enkephalin, an opioid peptide, to inhibit this glutamatergic transmission (control inhibition = 25 ± 4 %, n = 12 vs. withdrawal inhibition = 14 ± 3 %, n = 12; unpaired Student's t-test, p = 0.043). Furthermore, we observed that the reduction in opioid inhibition was due to increased degradation of opioid peptides by the enkephalin-degrading peptidase, neprilysin. Our results highlight that opioid peptide activity is decreased during opioid withdrawal; a change that alters synaptic transmission between amygdala nuclei. As amygdala neural circuits are involved in the development of addiction behaviours, restoring endogenous opioid activity within the amygdala during withdrawal may return synaptic transmission to normal, mitigate withdrawal-induced neuroadaptations and rescue the addiction behaviours exhibited following opioid withdrawal.

Administration of cocaine increases synaptic dopamine levels by blocking dopamine reuptake and leads to increased locomotor activity and compulsive drug seeking. It has been suggested that lateral hypothalamus (LH) or lateral habenula (LHb) is associated with cocaine-induced drug seeking behaviors. To explore the role of an LH-LHb pathway in cocaine-induced psychomotor responses, we tested whether activation or inhibition of the LH-LHb pathway affects cocaine-induced locomotion. Cocaine-induced locomotor activity and dopamine release was suppressed by an activation of LH with PEPA, an AMPA receptor agonist. When LH was inhibited by microinjection of GABA mixtures prior to cocaine injection, the cocaine effects were enhanced. Furthermore, optogenetic activation of the LH-LHb pathway attenuated the cocaine-induced locomotion, while optogenetic inhibition of the LH-LHb pathway increased it. These findings suggest that the LH-LHb circuit plays a role in the modulation of cocaine-induced psychomotor responses. Aims Alcohol Use Disorder (AUD) presents an immense burden for patients and society. AUD patients show altered functional connectivity (FC) in default mode (DM), salience and frontoparietal networks [1,2]. This study aims at linking resting state FC in DM, salience and frontoparietal networks of AUD patients with the severity of AUD. **Methods** A total of 43 recently abstinent patients with AUD underwent functional magnetic resonance imaging (fMRI). Functional connectivity in resting-state fMRI data was assessed by using the Conn toolbox [3].The severity of AUD was assessed with the DSM-5 Alcohol Use Disorder Diagnostic Assessment (AUD-S) and Alcohol Use Disorders Identification Test (AUDIT-S) [4,5] scores as well as number of previous detoxifications and duration of problematic drinking. **Results** Higher scores in AUD-S are linked to higher FC in default mode, salience and frontoparietal networks, whereas higher AUDIT-S scores are correlated to higher FC in salience but not DM and frontoparietal networks. Furthermore, the number of previous detoxifications and duration of problematic drinking were linked to higher FC in these networks. **Conclusions** AUD Patients with higher AUD-S and AUDIT-S scores show stronger FC in DM (AUD-S), salience (AUD-S and AUDIT-S) and frontoparietal (AUD-S) networks. Higher number of previous detoxification and longer duration of problematic drinking showed significant positive correlation with FC in all investigated networks. Our results suggest that the neuronal representation of cognitive functioning is increasingly altered with higher AUD severity. Furthermore, the AUD-S seems to be more sensitive in predicting FC alterations in AUD patients when compared to AUDIT-S.

SOUND PROCESSING IN A MOUSE MODEL OF AUTISM SPECTRUM DISORDER

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Ana Margarida Gonçalves[1], Luis Jacinto[2], Nuno Sousa[1], Patricia Monteiro[3]
[1]University of Minho, Icvs - Life And Health Sciences Research Institute, Braga, Portugal, [2]University of Minho, Life And Health Sciences Research Institute (icvs) / School Of Medicine, Braga, Portugal, [3]University of Minho, School Of Medicine - Neuroscience Department, Braga, Portugal

Autism spectrum disorder (ASD) is a neurodevelopmental condition characterized by deficits in communication and social interaction, restricted interests and repetitive behaviours. Knowledge about ASD neurobiology is still scarce and currently there is no efficient treatment or cure. Although a single cause for ASD is unknown, several candidate genes have emerged from patient studies such as *SHANK3*, a gene that encodes a protein (SHANK3) in the postsynaptic density of excitatory synapses. Previous studies have shown that mutant mice carrying a human ASD-mutation in the *Shank3* gene (InsG3680), exhibit repetitive behaviours, anxiety and social interaction deficits. Social interaction is a complex behaviour that requires the ability to combine sensory information with emotional and cognitive content. Disruptions in sensory processing such as auditory hypersensitivity have also been reported in ASD patients and may relate to their social communication deficits. To test whether *Shank3*-mutant present auditory hypersensitivity, we developed a novel behavioural test where mice can choose between different “soundscapes” and found that *Shank3*-mutant mice tend to prefer quiet environments without sounds. Furthermore, *in vivo* recordings in the primary auditory cortex (A1) of anesthetized *Shank3*-mutant mice are also being performed to test central/higher auditory brain regions. Overall these results seem to be in accordance with the auditory hypersensitivity literature in ASD patients.

Polygenicity and genetic heterogeneity pose great challenges for studying mechanisms - such as brain connectivity - underlying neurodevelopmental conditions. Genetic-first approaches have been implemented in neuroimaging studies to address this issue. However, the effects on functional connectivity of genetic risks for psychiatric disorders are largely unknown. Our objectives were to estimate and compare the effect sizes on brain connectivity of neurodevelopmental disorders genomic risk factors with various levels of complexity: oligo-, multi-genic copy number variants (CNVs), and polygenic-scores (PRS) as well as idiopathic psychiatric conditions and traits. Resting-state functional-MRI data were processed using the same pipeline across nine datasets. Twenty-nine connectome-wide association studies were performed to characterize the effects of 15 CNVs (1003 carriers), 7 PRS, 4 idiopathic conditions (1022 individuals with either autism, schizophrenia, bipolar, or ADHD), and 2 traits (31424 non-CNV carriers or unaffected controls). Effect sizes on connectivity were largest for neurodevelopmental psychiatric CNVs (estimates: 0.2 to 0.65 z-score) followed by psychiatric conditions (0.15 to 0.42 z-score), neuroticism and fluid intelligence (0.02 to 0.03 z-score), and PRS (0.01 to 0.02 z-score). Effect sizes of CNVs on connectivity were correlated to their effects on cognition and risk for disease (r=0.9, p=5.93e-06) for each individual brain network. However, effect sizes of CNVs adjusted for the number of genes significantly decreased from small oligogenic to large multigenic CNVs (r=-0.88, p=8.78e-06). PRS had disproportionately low effect sizes on connectivity compared to CNVs conferring similar risk for disease. Heterogeneity and polygenicity impact our ability to detect brain connectivity alterations underlying psychiatric manifestations.

AGGRESSION AND REWARD PROCESSING IN AUTISM SPECTRUM DISORDER (ASD)

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Alexandra Hertz, Nigel Blackwood, Grainne Mcalonan, Marija Petrinovic
Institute of Psychiatry, Psychology and Neuroscience, King's College London, Forensic And Neurodevelopmental Sciences, London, United Kingdom

Aims: Aggression is a common form of challenging behavior among individuals with autism spectrum disorder (ASD). Affecting as many as 2-out-of-3 individuals with ASD, aggression has serious detrimental effects. Aggression often exacerbates core ASD symptoms and is the strongest predictor of parental stress, yet we lack effective treatments. Thus, a neurobiologically informed approach to the understanding and treatment of aggression in ASD is needed. To achieve this, this project is built upon 2 key pieces of evidence: i) aggression was shown to have rewarding properties and ii) the reward system shows aberrant activity following social stimuli in individuals with ASD. We aim to investigate if aggression in ASD has rewarding properties. **Methods:** We used *Neurexin1α* (*Nrxn1α*) knock-out (KO) mice as i) *Nrxn1α* is a category-1 classified ASD-linked gene and ii) because mutations in *Nrxn1α* were associated with aggression in humans and animal models of ASD. Mice were tested for sociability, aggression and conditioned place preference (CPP) for aggression (where 1-out-of-2 contexts is paired with an aggressive encounter). Furthermore, neural activity of the Ventral Tegmental Area (VTA) and Nucleus Accumbens (NAc) were investigated and correlated with behavior. **Results:** Our results show that *Nrxn1α* KO mice exhibit increased aggression compared to their wild-type (WT) littermates. In contrast to WTs, *Nrxn1α* KO mice acquired robust CPP to the aggression paired context, which was corelated with activity levels of the VTA and NAc. **Conclusions:** Our study suggests that aggressive behavior in the *Nrxn1α* KO mice is associated with aberrant recruitment of the reward system.

The endocannabinoid system is modulated in reward and homeostatic brain regions following diet-induced obesity in rats: a cluster analysis approach.
Increased availability of high-calorie palatable food in most countries has resulted in overconsumption of these foods, suggesting that excessive eating is driven by pleasure, rather than metabolic need. The behavior contributes to the rise in eating disorders, obesity, and associated pathologies like diabetes, cardiac disease, and cancers. The mesocorticolimbic dopamine and homeostatic circuits are interconnected and play a central role in palatable food intake. The endocannabinoid system is expressed in these circuits and represents a potent regulator of feeding, but the impact of an obesogenic diet on its expression is not fully known.

TSHZ3 is a risk gene for autism spectrum disorder (ASD). In mice, *Tshz3* deletion causes behavioral abnormalities relevant to the two main domains of ASD (social interaction deficits and restricted/repetitive patterns of behavior) and changes in glutamate synaptic transmission in the cortex and striatum (Caubit et al, 2016; Chabbert et al, 2019). In the adult mouse striatum, the majority (>90%) of cells expressing TSHZ3 are striatal cholinergic interneurons (CINs) and all CINs express TSHZ3, while TSHZ3 expression is absent or partial in the other main cholinergic brain systems. To study the possible role of CINs in the pathophysiology of *Tshz3*-linked ASD, we generated and characterized a conditional knockout (cKO) mouse model with selective *Tshz3* deletion in cholinergic neurons (*Chat-cKO*). *Chat-cKO* mice exhibit repetitive patterns of behavior but no social interaction deficits. While the number of CINs was unchanged, the proportion of CINs classified based on their discharge pattern as "typical" , i.e. showing sustained and regular discharge, and "atypical", with weaker and irregular activity, which is around 2/3 and 1/3 in control mice was inversed in *Chat-cKO*. Whether these populations show different molecular profile and distribution in control mice, how are they affected by *Tshz3* deletion and what are the consequences of the changes in their electrophysiological properties on the function of the corticostriatal network are major issues currently under investigation. Taken together, these results should provide useful insights concerning the cellular and molecular bases linking CIN dysfunction to stereotyped behavior. This study was supported by the ANR-17-CE16-0030 “TSHZ3inASD”.

Autism Spectrum Disorders (ASD), comprise heterogeneous neurodevelopmental disorders characterized by early onset of communication and social interaction difficulties, restricted interests, repetitive and stereotyped behaviors. Gene sequencing studies have identified hundreds of genes potentially implicated in ASD, which converge on two main biological pathways: gene expression regulation and neuronal communication. The projection neurons of the striatum, the input nucleus of the basal ganglia, are characterized by a particularly high expression of ASD-
associated genes. Indeed, structural and functional alterations of the striatum were described in ASD patients, and a correlation of the dorso-ventral anatomo-functional subdivisions of the striatum with specific domains of ASD symptoms was proposed. In our previous work, we described the loss of corticostriatal long-term depression (LTD) in the dorsal striatum of the R451C-Nlgn3 knock-in
(KI) mouse model of ASD. LTD was partially rescued by enhancing the endocannabinoid tone or activating CB1 receptors. Here, we aimed at identifying more effective strategies to rescue corticostriatal LTD. Activation of group I metabotropic glutamate receptors (mGlu1 and mGlu5 receptors) activates downstream signaling pathways, involving production of endocannabinoids. We therefore attempted a
pharmacological rescue of LTD in KI mice, by targeting group I mGlu receptors. The mixed mGlu1 and mGlu5 receptor agonist 3,5-DHPG was able to rescue LTD expression. By means of immunoblotting experiments, we found that the amount of mGlu5 receptor protein was significantly
reduced in the synaptosomes from the dorsal striatum of KI mice, suggesting a molecular basis of corticostriatal LTD impairment.

Plasticity, genetics and epigenetics in dystonia: An update.
Dystonia represents a group of movement disorders characterized by involuntary muscle contractions that result in abnormal posture and twisting movements. In the last 20 years several animal models have been generated, greatly improving our knowledge of the neural and molecular mechanism underlying this pathological condition, but the pathophysiology remains still poorly understood. In this review we will discuss recent genetic factors related to dystonia and the current understanding of synaptic plasticity alterations reported by both clinical and experimental research. We will also present recent evidence involving epigenetics mechanisms in dystonia.

Social interaction deficits result from early psychological traumas, genetic and/or environmental factors including autism spectrum disorders which are diagnosed on two behavioral symptoms: deficits in communication and social interaction and restricted and repetitive interests or behaviors. Oxytocin controls all types of social behavior through lifespan and could be involved in the etiology of those heterogenous disorders. First, we compared the effect of two types of social interactions (family or unknown congeners) in three mouse models of social interaction deficits (*Oprm1* KO, *Shank3* KO and isolated mice) and wildtype animals using standardized behavioral apparatus. Our results showed that *Oprm1* and *Shank3* KO mice display unique pattern of social interaction deficits and motor stereotypies whereas isolated mice only present sociability deficits. Then, we assessed if the oxytocin gene family levels are commonly impaired in these models using quantitative PCR. Finally, we studied the kinetic profile of oxytocin and plasticity family gene expression upon stimulation with two types of social stimuli (cage-mate or unknown sex-matched interactor) and a non-social stimulus in *Oprm1* mouse and wildtype brain structures involved in sociability. We identified that all the mouse models have unique and common variations of oxytocin family gene expression. In addition, we found that oxytocin and plasticity family genes respond specifically to cage-mate and/or unknown interactions and is dependent on genotypes, structures and sexual dimorphism. In conclusion, we highlight common and unique features of our three mouse models of social interaction deficits and oxytocin-related mechanisms underlying social interactions.

Background: Autism spectrum disorders (ASDs) are heterogeneous neurodevelopmental disorders characterized by two main symptoms: social deficits and repetitive behaviors. Autistic children often exhibit several secondary symptoms including epilepsy. Mutations in the Synapsin2 (SYN2) gene, associated with ASD and epilepsy in humans, are causative for an imbalance between excitatory and inhibitory systems. Synapsins are a family of neuron-specific phosphoproteins which control synaptic vesicle trafficking and modulate neurotransmitter release at the presynaptic terminal. Mice lacking SYN2 (SynII KO) display autistic-like traits with a strong reduction of ultrasonic vocalizations (USV) and social sniffing, repetitive behaviors (self-grooming) and mild cognitive impairments (deficit in social memory and recognition). Furthermore, SynII KO mice display epileptic seizures that appear at 2-3 months of age. Interestingly, we recently showed that the impaired USV phenotype strongly correlates with a reduced functional connectivity in the auditory cortex and hippocampus, two brain regions playing an important role in social behavior. **Aims:** Our goal was to clarify how synaptic alterations in these regions impact on the social brain circuitry generating pathological conditions. **Methods:** We characterized the synaptic alterations in the auditory cortex and hippocampus using western blotting analysis and immunohistochemistry. **Results:** Our results show a significant reduction in presynaptic and postsynaptic markers of the GABAergic system together with alterations in synaptic density in these areas of Syn II KO mice. **Conclusion:** These results indicate that developmental changes in the neural connectivity of specific cortical areas may underlie the epileptic and social phenotype of SynII KO mice.

[1]PT Government Associate Laboratory, Icvs/3b's, Braga/Guimarães, Portugal, [2]University of Minho, Life And Health Sciences Research Institute (icvs) / School Of Medicine, Braga, Portugal

Autism spectrum disorder (ASD) is a neurodevelopmental disorder affecting 1 in 160 children worldwide. ASD is typically characterized by difficulties in social communication and repetitive behaviors, often associated with hypo- or hypersensitivity to sensory stimuli. It has been hypothesized that ASD impairments in communication might be a consequence of the auditory hypersensitivity often observed in patients, where atypical neuronal activity in auditory cortex could underlie the noxious or unpleasant perception of auditory stimuli. For this reason, patients would avoid auditory stimulation, ultimately affecting their learning, communication, and quality of life. Albeit ASD presents a widely diverse etiology, there is a strong genetic component involved, with the *SHANK3* gene being considered a potential monogenic cause of ASD. Taking advantage from a mouse model of ASD that carries a patient mutation in the *Shank3* gene (*InsG3680-Shank3*), we have been investigating the link between ASD and auditory hypersensitivity. Preliminary data suggests an auditory hypersensitivity behavioral phenotype, together with molecular and functional alterations in the primary auditory cortex (A1) of adult *Shank3* mice. Using LC-MS (liquid chromatography–mass spectrometry) analysis, we found upregulated expression of hyperpolarization-activated cyclic nucleotide gated-channel 1 (HCN1) protein levels, together with increased transcript levels by RT-PCR. Whole-cell patch clamp recordings of intracellular currents mainly mediated by HCN channel (I_h currents), further revealed heightened hyperpolarization in the A1 of adult *Shank3* mice. Together these results suggest that HCN1 channelopathy might contribute to the auditory hypersensitivity behavioral phenotype observed in the *Shank3* mouse model of ASD.

Sensory abnormalities are a common feature in autism spectrum disorders (ASDs). Tactile responsiveness is altered in autistic individuals, with hypo-responsiveness being associated with the severity of ASD core symptoms. Similarly, sensory abnormalities have been described in mice lacking ASD-associated genes. Loss-of-function mutations in *CNTNAP2* result in cortical dysplasia-focal epilepsy syndrome (CDFE) and autism. Likewise, *Cntnap2*$^{-/-}$ mice show epilepsy and deficits relevant with core symptoms of human ASDs, and are considered a reliable model to study ASDs. Altered synaptic transmission and synchronicity found in the cerebral cortex of *Cntnap2*$^{-/-}$ mice would suggest a network dysfunction, but their neural substrates have been poorly investigated so far. Here, we investigated functional connectivity within somatosensory areas, whisker-dependent behavior, and whisker-induced c-*fos* mRNA expression in *Cntnap2*$^{+/+}$and *Cntnap2*$^{-/-}$ adult mice. When compared to controls, *Cntnap2*$^{-/-}$ mice showed focal hyper-connectivity within the primary somatosensory cortex (S1), suggesting the presence of impaired somatosensory processing in these mutants. Accordingly, *Cntnap2*$^{-/-}$ mice displayed impaired whisker-dependent discrimination in the textured novel object recognition test (tNORT), increased S1 c-*fos* mRNA induction following whisker stimulation, and upregulation of neocortical excitatory neuron markers compared to controls. S1 functional hyperconnectivity and increased E/I balance might underlie the aberrant whisker-dependent responses observed in *Cntnap2*$^{-/-}$mice, indicating that *Cntnap2* mice are a reliable model to investigate sensory abnormalities that characterize ASDs.

SHIFTED PARVALBUMIN INTERNEURON STATES ELICIT POST-TRAUMATIC STRESS DISORDER-LIKE MEMORY IN AUTISM

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Shaam Al Abed[1], Tiarne Allen[1], Azza Sellami[2], Noorya Ahmed[1], Aline Marighetto[2], Aline Desmedt[3], Nathalie Dehorter[1]
[1]Australian National University, The Eccles Institute Of Neuroscience, Acton, Australia, [2]INSERM, Neurocentre Magendie, Bordeaux, France, [3]Univ. Bordeaux, INSERM, Neurocentre Magendie U1215, Bordeaux, France

Autism Spectrum Disorder (ASD) presents with enhanced sensitivity to stress, yet vulnerability to trauma in this condition remains poorly explored. In this study, we aimed to investigate the predisposition to and impact of Post-Traumatic Stress Disorder (PTSD) in ASD and demonstrated a reciprocal relationship between the two disorders. We revealed that exposure to a mild stressful event induces PTSD-like memory in two mouse models of ASD, unlike in control conditions. Remarkably, PTSD-like memory exacerbated two key core symptoms associated with ASD (social impairments and repetitive movements). We determined that the susceptibility to developing PTSD-like memory in ASD stemmed from prefrontal cortex hyperactivation and changes in fine-tuning of the parvalbumin interneuron firing. These alterations were associated with the dysregulated expression of activity-dependent proteins: the Etv1/Er81 transcription factor, the parvalbumin protein, and the stress-related Neurokinin Receptor 3. Finally, we showed that PTSD-like memory formation in ASD could be prevented by normalizing parvalbumin interneuron activity through the activation of the Neurokinin 3 Receptor. Overall, this study reveals multi-level neurobiological mechanisms that explain the increased vulnerability of developing PTSD in ASD. It provides a framework for examining the impact of stress-induced traumatic memory and interneuron adaptation in autism to ultimately increase the success of therapeutic interventions.

Protocols to Induce, Prevent, and Treat Post-traumatic Stress Disorder-like Memory in Mice: Optogenetics and Behavioral Approaches.
One of the cardinal features of post-traumatic stress disorder (PTSD) is a paradoxical memory alteration including both for salient trauma-related cues and for the surrounding traumatic context. Interestingly, some clinical studies have suggested that contextual amnesia would causally contribute to the PTSD-related hypermnesia insofar as decontextualized, traumatic memory is prone to be reactivated in contexts that can be very different from the original traumatic context. However, most current animal models of PTSD-related memory focus exclusively on the emotional hypermnesia, , the persistence of a strong fear memory, and do not distinguish normal (adaptive) from pathological (PTSD-like) fear memory, leaving unexplored the hypothetical critical role of contextual amnesia in PTSD-related memory formation, and thus challenging the development of innovative treatments. Having developed the first animal model that precisely recapitulates the two memory components of PTSD in mice (emotional hypermnesia and contextual amnesia), we recently demonstrated that contextual amnesia, induced by optogenetic inhibition of the hippocampus (dorsal CA1), is a causal cognitive process of PTSD-like hypermnesia formation. Moreover, the hippocampus-dependent contextualization of traumatic memory, by optogenetic activation of dCA1 in traumatic condition, prevents PTSD-like hypermnesia formation. Finally, once PTSD-like memory has been formed, the re-contextualization of traumatic memory by its reactivation in the original traumatic context normalizes this pathological fear memory. Revealing the key role of contextual amnesia in PTSD-like memory, this procedure opens a therapeutic perspective based on trauma contextualization and the underlying hippocampal mechanisms.

A Second Wave for the Neurokinin Tac2 Pathway in Brain Research.
Despite promising advances in basic research of the neurokinin B/Tac2 pathway in both animals and humans, clinical applications are yet to be implemented. This is likely because of our limited understanding of the action of the pathway in the brain. While this system controls neuronal activity in multiple regions, the precise impact of Tac2-induced cellular responses on behavior remains unclear. Recently, elegant studies revealed a key contribution to stress-related behaviors and memory. Here, we discuss the crucial importance of bridging the gap between the Tac2 pathway's involvement in cell physiology and

cognition to comprehend its role in health and disease. We propose that a better understanding of the Tac2 pathway in the brain could provide an essential perspective for basic investigations, which in turn will feed clinical research.

Er81 Transcription Factor Fine-Tunes Striatal Cholinergic Interneuron Activity and Drives Habit Formation.
The molecular mechanisms tuning cholinergic interneuron (CIN) activity, although crucial for striatal function and behavior, remain largely unexplored. Previous studies report that the Etv1/Er81 transcription factor is vital for regulating neuronal maturation and activity. While Er81 is known to be expressed in the striatum during development, its specific role in defining CIN properties and the resulting consequences on striatal function is unknown. We report here that Er81 is expressed in CINs and its specific ablation leads to prominent changes in their molecular, morphologic, and electrophysiological features. In particular, the lack of Er81 amplifies intrinsic delayed-rectifier and hyperpolarization-activated currents, which subsequently alters the tonic and phasic activity of CINs. We further reveal that Er81 expression is required for normal CIN pause and time-locked responses to sensorimotor inputs in awake mice. Overall, this study uncovers a new cell type-specific control of CIN function in the striatum which drives habit formation in adult male mice. Although previous studies have shown that cholinergic interneurons drive striatal activity and habit formation, the underlying molecular mechanisms controlling their function are unknown. Here we reveal that key cholinergic interneuron physiological properties are controlled by Er81, a transcription factor regulating neuronal activity and development in a cell-specific manner. Moreover, our findings uncover a link between the Er81-dependent molecular control of cholinergic interneuron function and habit formation in mice. These insights will contribute to the future enhancement of our understanding of disorders that involve behavioral inflexibility, such as autism and addiction.

Age-related impairment of declarative memory: linking memorization of temporal associations to GluN2B redistribution in dorsal CA1.
GluN2B subunits of NMDA receptors have been proposed as a target for treating age-related memory decline. They are indeed considered as crucial for hippocampal synaptic plasticity and hippocampus-dependent memory formation, which are both altered in aging. Because a synaptic enrichment in GluN2B is associated with hippocampal LTP in vitro, a similar mechanism is expected to occur during memory formation. We show instead that a reduction of GluN2B synaptic localization induced by a single-session learning in dorsal CA1 apical dendrites is predictive of efficient memorization of a temporal association. Furthermore, synaptic accumulation of GluN2B, rather than insufficient synaptic localization of these subunits, is causally involved in the age-related impairment of memory. These challenging data identify extra-synaptic redistribution of GluN2B-containing NMDAR induced by learning as a molecular signature of memory formation and indicate that modulating GluN2B synaptic localization might represent a useful therapeutic strategy in cognitive aging.

Preventing and treating PTSD-like memory by trauma contextualization.
Post-traumatic stress disorder (PTSD) is characterized by emotional hypermnesia on which preclinical studies focus so far. While this hypermnesia relates to salient traumatic cues, partial amnesia for the traumatic context can also be observed. Here, we show in mice that contextual amnesia is causally involved in PTSD-like memory formation, and that treating the amnesia by re-exposure to all trauma-related cues cures PTSD-like hypermnesia. These findings open a therapeutic perspective based on trauma contextualization and the underlying hippocampal mechanisms.

Vangl2 in the Dentate Network Modulates Pattern Separation and Pattern Completion.
The organization of spatial information, including pattern completion and pattern separation processes, relies on the hippocampal circuits, yet the molecular and cellular mechanisms underlying these two processes are elusive. Here, we find that loss of Vangl2, a core PCP gene, results in opposite effects on pattern completion and pattern separation processes. Mechanistically, we show that Vangl2 loss maintains young postmitotic granule cells in an immature state, providing increased cellular input for pattern separation. The genetic ablation of Vangl2 disrupts granule cell morpho-functional maturation and further prevents CaMKII and GluA1 phosphorylation, disrupting the stabilization of AMPA receptors. As a functional consequence, LTP at lateral perforant path-GC synapses is impaired, leading to defects in pattern completion behavior. In conclusion, we show that Vangl2 exerts a bimodal regulation on young and mature GCs, and its disruption leads

to an imbalance in hippocampus-dependent pattern completion and separation processes.

Temporal binding function of dorsal CA1 is critical for declarative memory formation.
Temporal binding, the process that enables association between discontiguous stimuli in memory, and relational organization, a process that enables the flexibility of declarative memories, are both hippocampus-dependent and decline in aging. However, how these two processes are related in supporting declarative memory formation and how they are compromised in age-related memory loss remain hypothetical. We here identify a causal link between these two features of declarative memory: Temporal binding is a necessary condition for the relational organization of discontiguous events. We demonstrate that the formation of a relational memory is limited by the capability of temporal binding, which depends on dorsal (d)CA1 activity over time intervals and diminishes in aging. Conversely, relational representation is successful even in aged individuals when the demand on temporal binding is minimized, showing that relational/declarative memory per se is not impaired in aging. Thus, bridging temporal intervals by dCA1 activity is a critical foundation of relational representation, and a deterioration of this mechanism is responsible for the age-associated memory impairment.

Derivatization-free LC-MS/MS method for estrogen quantification in mouse brain highlights a local metabolic regulation after oral versus subcutaneous administration.
17β-Estradiol (17β-E) is a steroid with pleiotropic actions. In addition to being a sexual hormone, it is also produced in the brain where it modulates the reproductive axis. It has been shown that 17β-E also acts on synaptic plasticity and plays a role in neurological pathways and in neurodegenerative diseases. Assaying this steroid in the brain is thus interesting to improve our knowledge of 17β-E effects in the brain. However, 17β-E concentration in the central nervous system has been reported to be of a few nanograms per gram wet weight (nanomolar range concentration); therefore, its quantification requires both an efficient extraction process and a sensitive detection method. Herein is presented a derivatization-free procedure based on solid-phase extraction followed by LC-MS/MS analysis, targeted on 17β-E, its isomer17α-E, and its metabolites estrone (E) and estriol (E). This extraction process allowed reaching 96% 17β-E recovery from the mouse brain. Limit of detection (LOD) and limit of quantification (LOQ) values of 0.5 and 2.5 pmol mL, respectively, were reached for both 17α-E and 17β-E. LOD values for E and E were 0.01 and 0.025 pmol mL, respectively. The variation coefficients for intra- and inter-assays were 6 and 14%, respectively, for both estradiol forms. The method was applied to assess estrogen levels in the mouse brain and hippocampus after 17β-E acute (subcutaneous injection) and chronic (drinking water) physiological administration. Total estrogen levels were determined after enzymatic deconjugation and compared to free estrogen levels. While 17α-E was not detected in biological samples, 17β-E and metabolite measurements highlight a local biotransformation of estrogens after physiological administration via drinking water. Graphical abstract Method workflow: After oral or subcutaneous Estradiol administration, mouse brain or hippocampus was removed. Samples were homogenized and prepared according to a liquid-liquid extraction, followed by a solid-phase extraction. Then, LC-MS/MS was optimized to quantify 17ß-E, its isomer17α-E, its metabolites estrone (E) and estriol (E) and their conjugates.

Estradiol enhances retention but not organization of hippocampus-dependent memory in intact male mice.
Because estrogens have mostly been studied in gonadectomized females, effects of chronic exposure to environmental estrogens in the general population are underestimated. Estrogens can enhance hippocampus-dependent memory through the modulation of information storage. However, declarative memory, the hippocampus-dependent memory of facts and events, demands more than abilities to retain information. Specifically, memory of repetitive events of everyday life such as "where I parked" requires abilities to organize/update memories to prevent proactive interference from similar memories of previous "parking events". Whether such organizational processes are estrogen-sensitive is unknown. We here studied, in intact young and aged adult mice, drinking-water (1µM) estradiol effects on both retention and organizational components of hippocampus-dependent memory, using a radial-maze task of everyday-like memory. Demand on retention vs organization was manipulated by varying the time-interval separating repetitions of similar events. Estradiol increased performance in young and aged mice under minimized organizational demand, but failed to improve the age-associated memory impairment and diminished performance in young mice under high organizational demand. In fact, estradiol prolonged mnemonic retention of successive events without improving organization abilities, hence resulted in more proactive interference from irrelevant memories. c-Fos imaging of testing-induced brain activations showed that the deterioration of young memory was associated with dentate gyrus dysconnectivity, reminiscent of that seen in aged mice. Our findings support the view that

estradiol is promnesic but also reveal that such property can paradoxically impair memory. These findings have important outcomes regarding health issues relative to the impact of environmental estrogens in the general population.

Temporal Memory and Its Enhancement by Estradiol Requires Surface Dynamics of Hippocampal CA1 N-Methyl-D-Aspartate Receptors.
Identifying the underlying cellular mechanisms of episodic memory is an important challenge, since this memory, based on temporal and contextual associations among events, undergoes preferential degradation in aging and various neuropsychiatric disorders. Memory storage of temporal and contextual associations is known to rely on hippocampal N-methyl-D-aspartate receptor (NMDAR)-dependent synaptic plasticity, which depends ex vivo on dynamic organization of surface NMDARs. Whether NMDAR surface trafficking sustains the formation of associative memory, however, remains unknown.

OSCILLATORY ABNORMALITIES AND SENSORY PROCESSING DEFICITS IN NRXN1 RAT AND CNTNAP2 MOUSE MODELS FOR NEURODEVELOPMENTAL DISORDERS

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Philipp Janz[1], Marie Bainier[1], Miguel Valencia[2], Roger Redondo[1]
[1]F. Hoffmann-La Roche, Roche Innovation Center Basel, Neuroscience And Rare Diseases, Basel, Switzerland, [2]University of Navarra, Cima - Center For Applied Medical Research, Program Of Neuroscience, Pamplona, Spain

Neurexin 1 (NRXN1) and Contactin-associated protein-like 2 (CNTNAP2) belong to the family of neurexin genes, encoding for presynaptic cell adhesion proteins that are crucial for the proper development of neuronal circuits. While their genetic link to neurodevelopmental disorders is clear, there is limited understanding on how knock-outs of these genes alter complex circuit function. Therefore, we thoroughly investigated the electrophysiological endophenotypes of NRXN1a$^{-/-}$ rats and CNTNAP2$^{-/-}$ mice. Animals were implanted with surface ECoG and intracranial electrodes to study cortico-thalamic-striatal brain circuits. In addition to resting-state oscillations, we assessed auditory responses via chirp-evoked potentials or auditory steady-state responses and mismatch-negativity (MMN) paradigms. For both animal lines we found increased oscillatory power during resting-state conditions, mainly in gamma and higher frequency bands. Conversely, auditory-evoked oscillations appeared mainly altered in NRXN1a$^{-/-}$ rats, showing reduced chirp-evoked power in the theta band confined to cortical brain regions. Responses to simple tones were altered in a genotype-specific manner. Early peaks in the event-related potentials from CNTNAP2$^{-/-}$ showed increased power, but remained normal for NRXN1a$^{-/-}$ rats. Remarkably, in NRXN1a$^{-/-}$ rats the cortical event-related potentials displayed ectopic deflections at 70 ms after tone onset, indicative of abnormal cortical synaptic transmission. Finally, NRXN1a$^{-/-}$ rats showed strong attenuation of the prediction error and impaired adaptation during the MMN paradigm. In conclusion, both NRXN1a$^{-/-}$ rats and CNTNAP2$^{-/-}$ mice showed clear electrophysiological endophenotypes, which help to understand circuit dysfunction and may inform translational biomarkers and support drug development in neurodevelopmental disorders.

ANALYSIS OF HIPPOCAMPAL PARTICIPATION IN SOCIAL INTERACTIONS IN A GENETIC MODEL OF AUTISTIC SPECTRUM DISORDER

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Pilar Rodríguez-Martín[1], Almudena Sanz[1], Elisa Cintado[1], Eva Monserrat[1], Inés Colmena[1], Cristina Medina Menéndez[1], Véronique Lefebvre[2], José Luis Trejo[1], Aixa V. Morales[1]
[1]Cajal Institute, Molecular, Cellular And Developmental Neurobiology, Madrid, Spain, [2]Children's Hospital of Philadelphia, Orthopaedic Surgery, Philadelphia, United States of America

Many neurodevelopmental disorders associated with deficiencies in social interaction, language difficulties and repetitive behaviours are grouped under the name of autism spectrum disorders (ASD). Although the genetic causes of ASD are complex, one of the genes that have been associated with ASD is *SOX5* (#616803, LAMB-SHAFFER SYNDROME). *Sox5* encodes a transcription factor with important functions in the control of neurogenesis (Li et al., 2022) and in the specification of projection neurons of the cerebral cortex. It has been described that the CA2 region of the hippocampus is fundamental in social behaviour in mice, a region where we have previously shown that Sox5 is expressed (Fernandez-Lamo et al., 2019). Using conditional *Sox5* mutant mice specific for the CA2 region (*Sox5*^{Amigo2}), we have determined that robust lack of Sox5 expression causes PCP4 level decrease in more than half of the pyramidal neurons in CA2. Using several behavioural assays we have determined that Sox5^{Amigo2} mutant mice: i) exhibit normal basic reflexes, weight, locomotion, and anxiety levels; ii) exhibit a good performance in Morris water maze test and iii) present normal social preference. However, males lose social recognition memory while females even show an abnormal preference for a familiar animal over a stranger in social memory tests. Thus, we propose that Sox5^{Amigo2} mice could provide a new model of ASD, based on cellular and functional alterations of the CA2 region of the hippocampus, which serves to understand the hippocampal component in the pathophysiology of ASD and for the testing of new therapeutic strategies.

SoxD genes are required for adult neural stem cell activation.
The adult neurogenic niche in the hippocampus is maintained through activation of reversibly quiescent neural stem cells (NSCs) with radial glia-like morphology (RGLs). Here, we show that the expression of SoxD transcription factors Sox5 and Sox6 is enriched in activated RGLs. Using inducible deletion of Sox5 or Sox6 in the adult mouse brain, we show that both genes are required for RGL activation and the generation of new neurons. Conversely, Sox5 overexpression in cultured NSCs interferes with entry in quiescence. Mechanistically, expression of the proneural protein Ascl1 (a key RGL regulator) is severely downregulated in SoxD-deficient RGLs, and Ascl1 transcription relies on conserved Sox motifs. Additionally, loss of Sox5 hinders the RGL activation driven by neurogenic stimuli such as environmental enrichment. Altogether, our data suggest that SoxD genes are key mediators in the transition of adult RGLs from quiescence to an activated mitotic state under physiological situations.

GENERATING A 16P11.2 MOUSE MODEL ON A MIXED GENETIC BACKGROUND STRENGTHENS SOCIAL DEFICITS

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Anna Rusu[1], Claire Chevalier[2], Valérie Herault[1], Elodie Ey[3], Yann Herault[1]
[1]Université de Strasbourg, CNRS, INSERM, Institut de Génétique Biologie Moléculaire et Cellulaire, Umr7104, Illkirch, France, [2]University of Strasbourg -CNRS - INSERM, IGBMC, Translational Medicine And Neurogenetics, ILLKIRCH, France, [3]Université de Strasbourg, CNRS, Inserm, Institut de Génétique Biologie Moléculaire et Cellulaire, Umr7104, Illkirch, France

Autism spectrum disorders (ASD) affect more than one percent of the population, impairing social communication and increasing stereotyped behaviours. A micro-deletion of the 16p11.2 chromosomic region has been identified in one percent of ASD patients with intellectual disabilities. In mouse models generated to understand the mechanisms of this deletion, learning and memory difficulties were pervasive, while social communication deficits were scarcer and therefore more difficult to integrate when conducting pre-clinical therapeutic trials. Based on previous study (Arbogast et al. 2016 PLoS genetics), we hypothesized that using a mixed genetic background would increase the face validity of the model, especially in the social domain. We therefore itemized the social deficits displayed by a 16p11.2 mouse model on a hybrid C57BL/6NxC3B background. We recorded the spontaneous behaviours of male and female mice in mixed-genotype groups and in same-genotype female pairs freely moving in a home-cage-like environment. We identified robust social deficits across the different conditions, with mutant mice displaying shorter contacts with other mice, less specific contact types, and less social approaches compared to wild-type mice. In female pairs, these deficits were accompanied by a reduction of the emission of ultrasonic vocalisations, a shortening of their sequences and a modification of their acoustic features compared to wild-type pairs. Altogether, these results showed robust social deficits in a 16p11.2 mouse model on a hybrid background recapitulating more comprehensively the phenotype of patients. This model will therefore be a choice model for further identification of the neuronal circuits involved and pre-clinical targeted therapeutic trials.

Abnormal tactile response is considered an integral feature of Autism Spectrum Disorders (ASDs), and hypo-responsiveness to tactile stimuli is often associated with the severity of ASDs core symptoms. Patients with Phelan-McDermid syndrome (PMS), caused by mutations in the SHANK3 gene, show ASD-like symptoms associated with aberrant tactile responses. However, the neural underpinnings of these somatosensory abnormalities are still poorly understood. Here we investigated, in Shank3b$^{-/-}$ adult mice, the neural substrates of whisker-guided behaviors, a key component of rodents' interaction with the surrounding environment. To this aim, we assessed whisker-dependent behaviors in Shank3b$^{-/-}$ adult mice and age-matched controls, using the textured novel object recognition (tNORT) and whisker nuisance (WN) test. Shank3b$^{-/-}$ mice showed deficits in whisker-dependent texture discrimination in tNORT and behavioral hyporesponsiveness to repetitive whisker stimulation in WN. Notably, sensory hypo-responsiveness was accompanied by a significantly reduced activation of the primary somatosensory cortex (S1) and hippocampus, as measured by c-fos mRNA in situ hybridization, a proxy of neuronal activity following whisker stimulation. Moreover, resting-state fMRI showed a significantly reduced S1- hippocampal connectivity in Shank3b mutant mice. Together, these findings suggest that impaired crosstalk between hippocampus and S1 might underlie Shank3b−/− hypo-reactivity to whisker dependent cues, highlighting a potentially generalizable form of dysfunctional somatosensory processing in ASD.

Natural Antioxidants: A Novel Therapeutic Approach to Autism Spectrum Disorders?
Autism spectrum disorders (ASD) are a group of neurodevelopmental syndromes with both genetic and environmental origins. Several recent studies have shown that inflammation and oxidative stress may play a key role in supporting the pathogenesis and the severity of ASD. Thus, the administration of anti-inflammatory and antioxidant molecules may represent

a promising strategy to counteract pathological behaviors in ASD patients. In the current review, results from recent literature showing how natural antioxidants may be beneficial in the context of ASD will be discussed. Interestingly, many antioxidant molecules available in nature show anti-inflammatory activity. Thus, after introducing ASD and the role of the vitamin E/vitamin C/glutathione network in scavenging intracellular reactive oxygen species (ROS) and the impairments observed with ASD, we discuss the concept of functional food and nutraceutical compounds. Furthermore, the effects of well-known nutraceutical compounds on ASD individuals and animal models of ASD are summarized. Finally, the importance of nutraceutical compounds as support therapy useful in reducing the symptoms in autistic people is discussed.

Antioxidants N-Acetylcysteine and Vitamin C Improve T Cell Commitment to Memory and Long-Term Maintenance of Immunological Memory in Old Mice.
Aging is characterized by reduced immune responses, a process known as immunosenescence. Shortly after their generation, antigen-experienced adaptive immune cells, such as CD8 and CD4 T cells, migrate into the bone marrow (BM), in which they can be maintained for long periods of time within survival niches. Interestingly, we recently observed how oxidative stress may negatively support the maintenance of immunological memory in the BM in old age. To assess whether the generation and maintenance of immunological memory could be improved by scavenging oxygen radicals, we vaccinated 18-months (old) and 3-weeks (young) mice with alum-OVA, in the presence/absence of antioxidants vitamin C (Vc) and/or N-acetylcysteine (NAC). To monitor the phenotype of the immune cell population, blood was withdrawn at several time-points, and BM and spleen were harvested 91 days after the first alum-OVA dose. Only in old mice, memory T cell commitment was boosted with some antioxidant treatments. In addition, oxidative stress and the expression of pro-inflammatory molecules decreased in old mice. Finally, changes in the phenotype of dendritic cells, important regulators of T cell activation, were additionally observed. Taken together, our data show that the generation and maintenance of memory T cells in old age may be improved by targeting oxidative stress.

Oxidative Stress and Immune System Dysfunction in Autism Spectrum Disorders.
Autism Spectrum Disorders (ASDs) represent a group of neurodevelopmental disorders associated with social and behavioral impairments. Although dysfunctions in several signaling pathways have been associated with ASDs, very few molecules have been identified as potentially effective drug targets in the clinic. Classically, research in the ASD field has focused on the characterization of pathways involved in neural development and synaptic plasticity, which support the pathogenesis of this group of diseases. More recently, immune system dysfunctions have been observed in ASD. In addition, high levels of reactive oxygen species (ROS), which cause oxidative stress, are present in ASD patients. In this review, we will describe the major alterations in the expression of genes coding for enzymes involved in the ROS scavenging system, in both ASD patients and ASD mouse models. In addition, we will discuss, in the context of the most recent literature, the possibility that oxidative stress, inflammation and immune system dysfunction may be connected to, and altogether support, the pathogenesis and/or severity of ASD. Finally, we will discuss the possibility of novel treatments aimed at counteracting the interplay between ROS and inflammation in people with ASD.

Sensory Abnormalities in Autism Spectrum Disorders: A Focus on the Tactile Domain, From Genetic Mouse Models to the Clinic.
Sensory abnormalities are commonly recognized as diagnostic criteria in autism spectrum disorder (ASD), as reported in the last edition of the Diagnostic and Statistical Manual of Mental Disorder (DSM-V). About 90% of ASD individuals have atypical sensory experiences, described as both hyper- and hypo-reactivity, with abnormal responses to tactile stimulation representing a very frequent finding. In this review, we will address the neurobiological bases of sensory processing in ASD, with a specific focus of tactile sensitivity. In the first part, we will review the most relevant sensory abnormalities detected in ASD, and then focus on tactile processing deficits through the discussion of recent clinical and experimental studies. In the search for the neurobiological bases of ASD, several mouse models have been generated with knockout and humanized knockin mutations in many ASD-associated genes. Here, we will therefore give a brief overview of the anatomical structure of the mouse somatosensory system, and describe the somatosensory abnormalities so far reported in different mouse models of ASD. Understanding the neurobiological bases of sensory processing in ASD mouse models may represent an opportunity for a better comprehension of the mechanisms underlying sensory abnormalities, and for the development of novel effective therapeutic strategies.

Whisker Nuisance Test: A Valuable Tool to Assess Tactile Hypersensitivity in Mice.

Abnormal response to tactile stimulation, described as both hyper- and hypo-reactivity, is a common sensory impairment in multiple neuropsychiatric disorders. The neural bases of tactile sensitivity remain so far unknown. In the last years, animal studies have proven to be useful for shedding light on the cellular and molecular mechanism underlying sensory impairments. However, few behavioral tests have been developed in mice for assessing tactile perception abnormalities (, the whisker nuisance [WN] test and the tactile prepulse inhibition assay). Here we provide a modified version of the WN test, which is based on the previously developed method by McNamara (2010). The WN test permits to specifically detect tactile hypo/hyper-sensitivity relative to whisker stimulation in mice. The test starts with a habituation phase in which the mouse familiarizes itself with the experimental cage and the researcher/experimenter. After a sham session, the experimental session begins, consisting of bilateral whisker stimulation with a wooden stick. The advantages of using this protocol are many: it is relatively simple to set with no particular or expensive equipment needed, it is easily reproducible, it allows researchers to assess a variety of behavioral responses to a whisker-specific tactile perception in mice (, fearful behavior, stance, hyperventilation, aggressive behavior and evasiveness) and provides important translational opportunities.

PREFRONTAL CORTICAL CALRETININ INTERNEURONS INVOLVED IN AUTISM SPECTRUM DISORDER

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Krisztina Sáfár, Teadora Tyler, Erzsébet Frank, István Adorján
Semmelweis University, Department Of Anatomy, Histology And Embryology, Budapest, Hungary

Autism spectrum disorder (ASD) is a pervasive neurodevelopmental disorder, which is characterized by social deficits and repetitive, stereotypic behavior. A widely accepted hypothesis states that an imbalance of excitatory and inhibitory activity may play an important role in ASD. Our research group previously found the density of calretinin-immunopositive (CR+) neurons decreased in the caudate nucleus in ASD. Thus, we aimed to investigate the distribution of CR+ interneurons across the layers of the dorsolateral prefrontal cortex (DLPFC), Brodmann area 9, an area already proven to be affected in ASD. Formalin-fixed, paraffin-embedded tissue was requested from 13 ASD and 10 control brain samples from the Oxford Brain Bank. After immunohistochemical staining, slides were digitalized with a 3DHistech whole slide scanner. Immunopositive cells were annotated in Aperio ImageScope software after delineating cortical layers based on cytoarchitecture. For the evaluation of the data, linear mixed model and contrasts were used. According to our results the density of CR + interneurons was reduced by 20% in the in layer 2 of DLPFC of the ASD group (p=0,00036), suggesting that these cells may be affected in ASD. Interestingly, Velmeshev et al. (2019) identified VIP (CR+) neurons as one of the clusters with most abundant differentially expressed genes in the same brain region, in a larger cohort of ASD and CTR samples. These results inspire us to explore the cellular background of ASD further, by involving additional cell types and brain areas in forthcoming investigations and applying a multiscale research approach.

MGLU4 MODULATION OF THALAMO-AMYGDALA SYNAPTIC TRANSMISSION AND RELATION TO AUTISM SPECTRUM DISORDERS

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Julien Genty[1], Francine Acher[2], Cyril Goudet[3], Ingrid Ehrlich[4]
[1]University of Tübingen, Hertie Institute For Clinical Brain Research, Tübingen, Germany, [2]Université de Paris, Faculté Des Sciences Fondamentales Et Biomédicales, Paris cedex, France, [3]Institut de Génomique Fonctionnelle, Département De Neurosciences, Montpellier, France, [4]Institut fürBiomaterialen und biomolekulare Systeme, Department Of Neurobiology, Stuttgart, Gibraltar

Autism spectrum disorders (ASD) are neurodevelopmental conditions inducing social behavior impairments and stereotypies. Their neurobiology remains elusive, however activation of metabotropic glutamate receptor 4 (mGlu4) alleviates autistic symptoms in an ASD mouse model. Furthermore, mGlu4 modulates amygdala activity, a hub for processing of emotions and hypothesized to be involved in stereotypic and social behaviors. Here, we investigate connectivity and mGlu4 modulation of different thalamic regions to the basolateral amygdala (BLA) and intercalated cell clusters that may be relevant for ASD. We focused on the MGm/PIN and the paraventricular nucleus of the thalamus (PVT) and elucidated distinct innervation patterns from Calbindin-positive neurons in these regions to the amygdala. Subsequently, we confirmed functional connectivity employing an ex vivo optogenetic approach expressing Channelrhodopsin2 in thalamic regions while monitoring synaptic transmission in the amygdala in the absence and presence of a specific mGlu4 agonist (LSP4-2022). LSP4-2022 decreased glutamatergic transmission and increased paired pulse ratio (PPR), indicating a presynaptic depression. Modulation was found for MGm/PIN inputs to lateral amygdala principal neurons and to dorso-medial and lateral intercalated cell (dmITC and lITCs) clusters. PVT inputs innervated multiple ITCs clusters, including ventro-medial ITCs (vmITCs). Similarly to Mgm/PIN inputs, PVT inputs to dmITCs, lITCs, and vmITCs clusters were also presynaptically modulated by mGlu4. Overall, these thalamic nuclei project onto different amygdala sub-regions, overlapping only at distinct ITC clusters. Thalamic mGlu4-sensitive inputs onto ITCs, could be of great importance considering ITCs´ tightly interconnected network and involvement in emotional regulation.

IDENTIFYING ENVIRONMENT-DEPENDENT BEHAVIORAL DOMAINS PREDICTIVE OF AUTISM-LIKE PHENOTYPE

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Lucas Wahl[1], Amy Hassett[2], Arun Karim[1], Ihor Smal[3], Christian Van Der Zalm[1], Aleksandra Badura[1]
[1]Erasmus Medical Center, Neuroscience, Rotterdam, Netherlands, [2]University College Dublin, School Of Medicine & Medical Science, Dublin, Ireland, [3]Erasmus MC, Cell Biology & Molecular Genetics, Rotterdam, Netherlands

Genetic and environmental factors alike can contribute to the development of Autism Spectrum Disorder (ASD), making the studies on the underlying neural substrates highly complex. In our study, we aimed to develop a "behavioural fingerprint" for the *Shank2*$^{-/-}$ ASD mouse model raised in standard and enriched environments. To this end we employed a wide range of both discrete, standardized tests such as: elevated-plus-maze, social chamber, marble burying test, Y-maze assay, and open field test; as well as two multi-parametric behavioural assays: the Live Mouse Tracker (described in de Chaumont et al., 2019) and Motion Sequencing (MoSeq) developed by the Datta Lab. Our aim was to integrate our high dimensional data into one single platform, to classify differences in experimental groups along dimensions with maximum consistency and discriminative power. We have found that some behavioral phenotypes of *Shank2*$^{-/-}$ mice, such as impaired burying behavior and behavioral flexibility, as well as hyperactivity and decreased anxiety-like behavior, were consistently altered whereas other features were environment-dependent. Groups raised in enriched housing showed a distinct effect on the behavioral phenotype in both the discrete and multi-parametric assays. *Shank2*$^{-/-}$ mice showed a unique phenotypic profile based on housing conditions using both the Live Mouse tracker and the MoSeq analysis. The described identity domains captured variability in *Shank2*$^{-/-}$ mice reared in different housing conditions, suggesting the feasibility of reducing behavioral test batteries to multi-parametric assays. Together, our results provide a "behavioural fingerprint" of *Shank2*$^{-/-}$ mice, which is shown to be altered by different housing conditions during development.

REDUCED SOCIAL INTERACTION IN TWO RAT MODELS OF SYNGAP1 HAPLOINSUFFICIENCY

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Vanesa Salazar-Sanchez, Thomas Watson, Emma Wood, Peter Kind
The University of Edinburgh, Centre For Discovery Brain Sciences, Edinburgh, United Kingdom

SYNGAP1 haploinsufficiency is one of the most common monogenetic causes of intellectual disability (ID) and autism spectrum disorder (ASD). Some major features are seizures, social behaviour, and communication impairments. The SYNGAP protein is a major component of the postsynaptic density (Kim et al.1998). SYNGAP can function as both a scaffolding protein (Walkup et al, 2016) and a regulator of key enzymatic pathways, including ERK and P38MAPKs, via its GTPase activating protein (GAP) domain (Araki et al, 2015). Aim: To understand the role of SYNGAP in regulating social interaction dynamics and to identify the role of the GAP domain in this process. Methods: A conspecific habituation-dishabituation task was developed to assess social interactions. Furthermore, two olfaction tasks were performed to test impairments in detecting non-social and social odours. To distinguish between scaffolding and enzymatic function in social behaviour, two heterozygous rat models were used: one with a GAP-domain deletion (*Syngap*$^{+/\Delta GAP}$) and one with a null mutation (*Syngap*$^{+/-}$). Results: Both *Syngap*$^{+/\Delta GAP}$ and *Syngap*$^{+/-}$ rats demonstrate reduced social exploration with conspecifics compared to wildtype littermates; however, both lines habituate and discriminate. Furthermore, wildtype conspecific, “stimuli” rats show similar social exploration time regardless of the genotype of the paired animal. While both models can detect social and non-social odours, they do display decreased sniffing time in these olfaction tests. Conclusion: These findings suggest that while the enzymatic function of SYNGAP plays a crucial role in general interest in social interaction, SYNGAP does not appear to regulate the ability of animals to recognize novel conspecifics.

UNDERSTANDING THE CAUSES AND CONSEQUENCES OF INDIVIDUAL VARIATION IN STRIATAL OXTR EXPRESSION IN PRAIRIE VOLES: A MOLECULAR PHENOTYPE RELEVANT TO ASD

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Arjen Boender, Zack Johnson, Hasse Walum, Larry Young
Emory University, Center For Translational Social Neuroscience, ATLANTA, United States of America

Natural variation in oxytocin receptor (Oxtr) expression increases diversity in social behaviors within and across species. In the socially monogamous prairie vole (Microtus ochrogaster), variation in Oxtr expression in the nucleus accumbens (NAc) is associated with variation in pair bonding, alloparental behavior and resilience to neonatal social neglect. Previously, we found a set of intronic SNPs that largely explain individual variation of Oxtr expression, specifically in the NAc ($r^2>0.7$). We are using ATAC-seq, bulk and single nucleus RNA-seq (scRNA-seq) and nanopore-seq to investigate the mechanistic links between Oxtr SNPs and altered Oxtr gene expression in the NAc, as well as its downstream molecular consequences. RNA-seq revealed differential expression low- and high NAC Oxtr expressing genotypes, in both bulk RNA and single nucleus RNA sequencing data, with Oxtr as a top hit ($q<1x10-7$). The differential expressed gene sets are highly enriched for autism spectrum disorders genes (SFARI 2.0 database, $p<0.0001$), and are largest in astrocytes and oligodendrocytes; cell-types that express no to very little Oxtr. In parallel, we developed an AAV-CRISPR/Cas9 approach that disrupts the Oxtr coding sequence by introducing genetic edits, thereby significantly reducing OXTR binding (>80%). This tools allows for the investigation OXTR signaling-dependent transcriptome changes. By combining CRISPR/Cas9 and sequencing strategies, this project aims to identify and disrupt candidate regulatory regions that contribute to diversity in Oxtr expression and provide mechanistic insight into how individual variation in Oxtr expression shapes diversity in brain function and social behaviors.

Autism spectrum disorders (ASD) are characterized by atypical social communication and stereotyped behaviors. Mutations in the gene encoding the synaptic scaffolding protein SHANK3 are detected in 1-2% of patients with ASD and intellectual disability, but the mechanisms underpinning the symptoms remain largely unknown. To understand the potential mechanisms involved in the behavioral deficits present in ASD with *SHANK3* mutations, we performed a multi-scale characterization of the *Shank3* mutant mice deleted for exon 11 *(Shank3*$^{\Delta 11/\Delta 11}$ mice) that comprises: -A longitudinal study of the behavior of *Shank3*$^{\Delta 11/\Delta 11}$ mice by using the Live Mouse Tracker. -A transcriptomic analysis of gene expression in four brain areas and an analysis of genes/proteins of interest by quantitative RT-PCR and immunostaining. -A study of functional cerebral connectivity with functional ultrasound imaging (fUS). The behavioral analysis revealed decreased locomotor activity, increased stereotyped self-grooming and atypical socio-sexual interaction in *Shank3*$^{\Delta 11/\Delta 11}$ mice compared to wild-type littermates. The transcriptomic analysis, performed on the cortex, hippocampus, striatum and cerebellum, pointed to the striatum as the brain region the most impacted by the *Shank3*$^{\Delta 11}$ deletion. In addition, our results suggest an imbalance between the striosome and matrix compartments of the striatum in *Shank3*$^{\Delta 11/\Delta 11}$ mice. Finally, we did not observe significant alterations in functional connectivity in the brain of *Shank3*$^{\Delta 11/\Delta 11}$ mice at resting state, but we are now investigating it during specific behaviors. Overall, these studies allow a better understanding of the mechanisms involved in ASD with *SHANK3* mutations and may lead to potential new pharmacological treatments for this disorder.

Autism spectrum disorders (ASD) is a neurodevelopmental disease, difficult to diagnose and with no curative treatment. A wide range of symptoms have been identified in ASD patients. Among them, motor and gait disorders are often observed but are not fully included within the diagnosis criteria. Determination of cellular disturbances in brain regions underlying motor dysfunction (cerebellum, nigro-striatal pathway and motor cortex) may lead to propose quantitative and earlier diagnosis and potentially help develop new therapeutic approaches. In our study, we aimed at investigating whether various ASD mouse models manifest motor impairments and we strived to determine the neuronal network involved in these deficits. Secondly, we were interested in identifying differences between males and females as the sex ratio in ASD is 3 boys for 1 girl. We used both environmental (valproic acid and Poly IC) and transgenic (Shank3) mouse models to characterize different aspects of their behavior and we determined the neurohistological readouts underlying deficits. Our results demonstrate a decrease of the sociability, fine motor disorders, gait deficits and neuronal loss in ASD mice models. These deficits were present in a sex and model-specific manner. Additionally, a correlation analysis revealed relationships among motor difficulties, low social interactions and decreased number of Purkinje neurons within the cerebellum. This is of importance as it points out that motor disorders in ASD could be used as an early marker of severity of the disease and that the cerebellum could be a targeted for therapeutic strategies.

The autism spectrum disorder (ASD) is a non-lethal neurodevelopmental disorder-giving rise to cognitive, communication and affective symptoms, affecting 700 000 patients in France alone. ASD is highly investigated at the neurodevelopmental and juvenile stages and the ageing process in patients is described as an increase in comorbidities leading to a “frail” state over time. In fact, recent studies suggest that adult ASD patients undergo “premature ageing” as they present a significant number of comorbidities very early on in life. The current focus on ASD in development and early life leaves out of sight ASD adults by assuming the persistence of the initial dysfunction documented in children. Seen the time course of appearance of neuronal dysfunction, we hypothesize that the ASD brain undergoes premature ageing in an active state that does not result from developmental phenomena but is an additional ASD symptom focusing on the striatum. Thus, most of animal studies focused on glutamatergic alterations in ASD, leading to lack of knowledge about the GABAergic transmission. The work presented here aims to investigate the evolution of the motor symptoms in Shank3$^{\Delta C/\Delta C}$ mouse model of ASD and of the disturbances of the GABAergic transmission with aging. To assess such disturbances, we used behavioral tests, *ex vivo* electrophysiology, and confocal microscopy. Preliminary results show differences in aging processes regarding striatal MSNs among genotypes.

Autism Spectrum Disorder (ASD) is a progressive neurodevelopmental disorder characterized mainly by deficits in social communication and stereotyped behaviours and interests. One of the recurrent findings in several ASD animal models are deficits in social interactions. This is generally performed using the three chamber's test paradigm that is simple to implement and use but fails to detect complex social behavior on an extended period of time. Here, we set up a novel procedure entitled the Live Mouse Tracker (LMT) that detects several dozens of complex social behavior during three days in groups of 4 mice. For this we used a well characterised environmental animal model for ASD with valproic acid (VPA) injected to pregnant females at E12.5. Studies were performed on male and females offspring. Comparisons were made within groups of 4 animals with same sex and treatment and within groups of 4 animals with same sex but different treatments (saline versus VPA). We found that VPA mice showed major social deficits and that are different in nature and magnitude in relation with time (from 1 hour to 3 days) and the time period (day versus night). Social deficits were also different when VPA mice were tested together compared to when they are mixed with saline treated mice. This study points out to severe and various impact of VPA treatment on complex social behavior and stresses the need to explore more in depth this behavior in ASD animal models in relation with sex, time period, time window and group composition.

AUDITORY BRAINSTEM RESPONSES IN THE NRXN1 RAT AND CNTNAP2 MOUSE MODELS FOR NEURODEVELOPMENTAL DISORDERS: A LONGITUDINAL AND PHARMACOLOGICAL STUDY

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Samuel Marashli, Philipp Janz, Roger Redondo
Roche Innovation Center Basel, Neuroscience And Rare Diseases, Basel, Switzerland

Sensory processing abnormalities are core to neurodevelopmental disorders (NDD). In fact, auditory hypersensitivity affects up to 66% of children with autism spectrum disorders (ASDs). Developing efficient therapies require understanding the basic sensory pathways and finding the atypical alterations of the circuit during early development. We used auditory brainstem responses (ABRs) to detect the physiological response to auditory stimuli in two different rodent models of NDD; Nrxn1KO rats and Cntnap2KO mice. ABRs are valuable tools in detecting hearing thresholds and other biomarkers of auditory sensory processing. ABRs are highly translational due to the similarity of signal readout with humans. We performed a longitudinal ABR study, focusing on the different developmental stages of rodents (juvenile, adolescence and adult). Additionally, we tested several pharmacological compounds, which are highly relevant for auditory sensory gating, processing and filtering. We confirmed that ABR's waves increase in amplitude and decrease in latency upon brainstem maturation. In both rodent models, there were significant changes in signal latency and differences with controls. Such differences were detected at multiple ages. The pharmacological tests altered the ABR wave's peaks in a genotype-specific manner. Our results emphasize the role of ABR as a valuable biomarker in ASD and increase our understanding of gene manipulations linked to NDD.

UNRAVELING THE EFFECT OF ARC DELETION ON VARIOUS BEHAVIORS LINKED TO THE NEUROPSYCHIATRIC DISORDERS IN MICE

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Ana Dudas[1], Emmanuel Pecnard[1], Anne-Charlotte Trouillet[2], Lucie Pellissier[1]
[1]Centre INRAE Val de Loire, Unit Prc, Team Bios, Nouzilly, France, [2]Centre INRAE Val de Loire, Unit Prc, Team Inerc, Nouzilly, France

The neuronal immediate-early gene Arc is a master regulator of different forms of synaptic plasticity in mammals, such as long-term potentiation, depression, and memory consolidation. It is known to be implied in numerous neuropsychiatric disorders, such as schizophrenia, and autism spectrum disorders (ASD). Even though it has been evident that Arc plays an important role in memory, it still has not been investigated whether Arc acts on behaviors impaired in neuropsychiatric disorders. To address this issue, herein we performed broad behavioral phenotyping of *Arc*$^{-/-}$ mice in comparison to wild-type animals in C57BL/6J and mixed C57BL/6J;129S2 backgrounds, to exclude background-specific effects on behavior. We evaluated the implication of *Arc* deletion in different types of behavior impaired in neuropsychiatric disorders, such as social, stereotyped, and anxious-like behaviors, and finally memory tasks. Our results revealed autistic-like behavioral patterns in *Arc*$^{-/-}$ mice associated with other behavioral alterations. In addition to that, we discovered profound effects of the two different genetic backgrounds and sex in these different behavior tests, especially in *Arc*$^{-/-}$ mice. Altogether, we determined the role of Arc in different types of behavior and discovered that its dysregulation may result in severe behavioral impairments, some of which are reported in neuropsychiatric disorders.

CANNABIDIOL RESCUES AUTISTIC-LIKE SYMPTOMS IN A GENETIC MODEL OF AUTISM BASED ON FMR1 DELETION IN RATS

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Antonia Manduca[1], Valeria Buzzelli[1], Emilia Carbone[1], Alessandro Rava[1], Sara Schiavi[1], Vincenzo Micale[2], Martin Kuchar[3], Viviana Trezza[1]
[1]Roma Tre University, Science, Rome, Italy, [2]University of Catania, Biomedical And Biotechnological Sciences, Catania, Italy, [3]University of Chemistry and Technologies, Chemistry Of Natural Compounds, Prague, Czech Republic

Among the genetic causes of autism spectrum disorder (ASD), Fragile X syndrome (FXS) is the most common known inherited single-gene disorder with no specific treatment available. Recently, the use of cannabinoid compounds, especially cannabidiol (CBD), an abundant bioactive but non-psychotomimetic constituent of *Cannabis sativa*, has received increasing attention as treatment for the core symptoms and co-morbidities of ASD. Beyond anecdotal reports, however, there is limited current evidence supporting such an intervention and the use of CBD remains controversial. In the present work, we tested the effect of CBD in the autistic-like features displayed by the recently validated *Fmr1-$^{\Delta}$exon 8* rat model of ASD. Wild-type (WT) and *Fmr1-$^{\Delta}$exon 8* male rats on a Sprague-Dawley background were used. We assessed the behavioral effects of systemic administration of CBD in these animals through the novel object recognition, three-chamber and social discrimination tests from adolescence to adulthood and explored the underlying mechanisms. Our results showed that CBD rescued the cognitive and social dysfunctions displayed by *Fmr1-$^{\Delta}$exon 8* animals. Interestingly, intra-hippocampal blockade of the GPR55 receptors prevented the beneficial effect of systemic CBD in the impaired cognitive abilities of *Fmr1-$^{\Delta}$exon 8* rats, thus suggesting that the effects of CBD are mediated, at least in part, by antagonism of the lipid-activated G protein-coupled receptor GPR55 in the hippocampus. These findings demonstrated that CBD reduced autistic-like traits in a genetic model of autism based on FMR1 deletion in rats and provide initial mechanistic insights into its therapeutic actions.

Healing autism spectrum disorder with cannabinoids: a neuroinflammatory story.
Autism spectrum disorder (ASD) is a complex neurodevelopmental disorder with a multifactorial etiology. Latest researches are raising the hypothesis of a link between the onset of the main behavioral symptoms of ASD and the chronic neuroinflammatory condition of the autistic brain; increasing evidence of this connection is shedding light on new possible players in the pathogenesis of ASD. The endocannabinoid system (ECS) has a key role in neurodevelopment as well as in normal inflammatory responses and it is not surprising that many preclinical and clinical studies account for alterations of the endocannabinoid signaling in ASD. These findings lay the foundation for a better understanding of the neurochemical mechanisms underlying ASD and for new therapeutic attempts aimed at exploiting the renowned anti-inflammatory properties of cannabinoids to treat pathologies encompassed in the autistic spectrum. This review discusses the current preclinical and clinical evidence supporting a key role of the ECS in the neuroinflammatory state that characterizes ASD, providing hints to identify new biomarkers in ASD and promising therapies for the future.

Sex-dependent effects of in utero cannabinoid exposure on cortical function.
Cannabinoids can cross the placenta, thus may interfere with fetal endocannabinoid signaling during neurodevelopment, causing long-lasting deficits. Despite increasing reports of cannabis consumption during pregnancy, the protracted consequences of prenatal cannabinoid exposure (PCE) remain incompletely understood. Here, we report sex-specific differences in behavioral and neuronal deficits in the adult progeny of rat dams exposed to low doses of cannabinoids during gestation. In males, PCE reduced social interaction, ablated endocannabinoid long-term depression (LTD) and heightened excitability of prefrontal cortex pyramidal neurons, while females were spared. Group 1 mGluR and endocannabinoid signaling regulate emotional behavior and synaptic plasticity. Notably, sex-differences following PCE included levels of mGluR1/5 and TRPV1R mRNA. Finally, positive allosteric modulation of mGlu5 and enhancement of anandamide levels

restored LTD and social interaction in PCE adult males. Together, these results highlight marked sexual differences in the effects of PCE and introduce strategies for reversing detrimental effects of PCE.

Dopaminergic Neurotransmission in the Nucleus Accumbens Modulates Social Play Behavior in Rats.
Social play behavior is a highly rewarding form of social interaction displayed by young mammals. Social play is important for neurobehavioral development and it has been found to be impaired in several developmental psychiatric disorders. In line with the rewarding properties of social play, we have previously identified the nucleus accumbens (NAc) as an important site of action for endocannabinoid and opioid modulation of this behavior. NAc dopamine has a well-known role in certain components of reward processes, such as incentive motivation. However, its contribution to the positive emotional aspects of social interactions is less clear. Therefore, we investigated the role of dopaminergic neurotransmission in the NAc in social play behavior in rats. We found that intra-NAc infusion of the dopamine releaser/reuptake inhibitor amphetamine increased social play behavior that was dependent on activation of both D1 and D2 dopamine receptors. This increase in social play behavior was mimicked by intra-NAc infusion of the dopamine receptor agonist apomorphine, but not of the dopamine reuptake inhibitor GBR-12909. Blockade of either D1 or D2 NAc dopamine receptors reduced social play in animals highly motivated to play as a result of longer social isolation before testing. Last, blockade of NAc dopamine receptors prevented the play-enhancing effects of endocannabinoid and opioid receptor stimulation. These findings demonstrate an important modulatory role of NAc dopaminergic neurotransmission in social play. Thus, functional activity in the mesolimbic dopamine pathway plays an important role in adaptive social development, whereas abnormal NAc dopamine function may underlie the social impairments observed in developmental psychiatric disorders such as autism, attention deficit hyperactivity disorder or early-onset schizophrenia.

Endocannabinoids in amygdala and nucleus accumbens mediate social play reward in adolescent rats.
The brain endocannabinoid system plays a crucial role in emotional processes. We have previously identified an important role for endocannabinoids in social play behavior, a highly rewarding form of social interaction in adolescent rats. Here, we tested the hypothesis that endocannabinoid modulation of social play behavior occurs in brain regions implicated in emotion and motivation. Social play increased levels of the endocannabinoid anandamide in the amygdala and nucleus accumbens (NAc), but not in prefrontal cortex or hippocampus of 4- to 5-week-old male Wistar rats. Furthermore, social play increased phosphorylation of CB1 cannabinoid receptors in the amygdala. Systemic administration of the anandamide hydrolysis inhibitor URB597 increased social play behavior, and augmented the associated elevation in anandamide levels in the amygdala, but not the NAc. Infusion of URB597 into the basolateral amygdala (BLA) increased social play behavior, and blockade of BLA CB1 cannabinoid receptors with the antagonist/inverse agonist SR141716A prevented the play-enhancing effects of systemic administration of URB597. Infusion of URB597 into the NAc also increased social play, but blockade of NAc CB1 cannabinoid receptors did not antagonize the play-enhancing effects of systemic URB597 treatment. Last, SR141716A did not affect social play after infusion into the core and shell subregions of the NAc, while it reduced social play when infused into the BLA. These data show that increased anandamide signaling in the amygdala and NAc augments social play, and identify the BLA as a prominent site of action for endocannabinoids to modulate the rewarding properties of social interactions in adolescent rats.

Amplification of mGlu-Endocannabinoid Signaling Rescues Behavioral and Synaptic Deficits in a Mouse Model of Adolescent and Adult Dietary Polyunsaturated Fatty Acid Imbalance.
Energy-dense, yet nutritionally poor food is a high-risk factor for mental health disorders. This is of particular concern during adolescence, a period often associated with increased consumption of low nutritional content food and higher prevalence of mental health disorders. Indeed, there is an urgent need to understand the mechanisms linking unhealthy diet and mental

disorders. Deficiency in n-3 polyunsaturated fatty acids (PUFAs) is a hallmark of poor nutrition and mood disorders. Here, we developed a mouse model of n-3 PUFA deficiency lasting from adolescence into adulthood. Starting nutritional deficits in dietary n-3 PUFAs during adolescence decreased n-3 PUFAs in both medial prefrontal cortex (mPFC) and nucleus accumbens, increased anxiety-like behavior, and decreased cognitive function in adulthood. Importantly, we discovered that endocannabinoid/mGlu-mediated LTD in the mPFC and accumbens was abolished in adult n-3-deficient mice. Additionally, mPFC NMDAR-dependent LTP was also lacking in the n-3-deficient group. Pharmacological enhancement of the mGlu/eCB signaling complex, by positive allosteric modulation of mGlu or inhibition of endocannabinoid 2-arachidonylglycerol degradation, fully restored synaptic plasticity and normalized emotional and cognitive behaviors in malnourished adult mice. Our data support a model where nutrition is a key environmental factor influencing the working synaptic range into adulthood, long after the end of the perinatal period. These findings have important implications for the identification of nutritional risk factors for disease and design of new treatments for the behavioral deficits associated with nutritional n-3 PUFA deficiency. In a mouse model mimicking n-3 PUFA dietary deficiency during adolescence and adulthood, we found strong increases in anxiety and anhedonia which lead to decreases in specific cognitive functions in adulthood. We found that endocannabinoid/mGlu-mediated LTD and NMDAR-dependent LTP were lacking in adult n-3-deficient mice. Acute positive allosteric modulation of mGlu or inhibition of endocannabinoid degradation normalized behaviors and synaptic functions in n-3 PUFA-deficient adult mice. These findings have important implications for the identification of nutritional risk for disease and the design of new treatments for the behavioral deficits associated with nutritional n-3 PUFAs' imbalance.

Interacting Cannabinoid and Opioid Receptors in the Nucleus Accumbens Core Control Adolescent Social Play.
Social play behavior is a highly rewarding, developmentally important form of social interaction in young mammals. However, its neurobiological underpinnings remain incompletely understood. Previous work has suggested that opioid and endocannabinoid neurotransmission interact in the modulation of social play. Therefore, we combined behavioral, pharmacological, electrophysiological, and genetic approaches to elucidate the role of the endocannabinoid 2-arachidonoylglycerol (2-AG) in social play, and how cannabinoid and opioid neurotransmission interact to control social behavior in adolescent rodents. Systemic administration of the 2-AG hydrolysis inhibitor JZL184 or the opioid receptor agonist morphine increased social play behavior in adolescent rats. These effects were blocked by systemic pretreatment with either CB1 cannabinoid receptor (CB1R) or mu-opioid receptor (MOR) antagonists. The social play-enhancing effects of systemic morphine or JZL184 treatment were also prevented by direct infusion of the CB1R antagonist SR141716 and the MOR antagonist naloxone into the nucleus accumbens core (NAcC). Searching for synaptic correlates of these effects in adolescent NAcC excitatory synapses, we observed that CB1R antagonism blocked the effect of the MOR agonist DAMGO and, conversely, that naloxone reduced the effect of a cannabinoid agonist. These results were recapitulated in mice, and completely abolished in CB1R and MOR knockout mice, suggesting that the functional interaction between CB1R and MOR in the NAcC in the modulation of social behavior is widespread in rodents. The data shed new light on the mechanism by which endocannabinoid lipids and opioid peptides interact to orchestrate rodent socioemotional behaviors.

Strain- and context-dependent effects of the anandamide hydrolysis inhibitor URB597 on social behavior in rats.
Genetic and environmental factors play an important role in the cannabinoid modulation of motivation and emotion. Therefore, the aim of the present study was to test whether anandamide modulation of social behavior is strain- and context-dependent. We tested the effects of the anandamide hydrolysis inhibitor URB597 on social behavior and 50-kHz ultrasonic vocalizations (USVs) in adolescent and adult Wistar and Sprague-Dawley rats tested in different emotionally arousing conditions (familiarity/unfamiliarity to the test cage, low/high light). Under all experimental conditions, adolescent and adult Sprague-Dawley rats displayed higher levels of social behavior and emitted more 50-kHz USVs than Wistar rats. URB597 enhanced social play behavior in adolescent Wistar rats under all experimental conditions. However, URB597 only increased social interaction in adult Wistar rats under unfamiliar/high light conditions. URB597 did not affect adolescent social play behavior and adult social interaction in Sprague-Dawley rats under any experimental condition. Moreover, URB597 increased the USVs emitted during social interaction by adolescent Wistar and adult Sprague-Dawley rats tested under familiar/high light and unfamiliar/high light, respectively. These results show that anandamide has distinct roles in adolescent and adult social behaviors. Anandamide modulation of adolescent social play behavior is strain- but not context-dependent. Conversely, anandamide modulation of adult social behavior and USV emission depends upon both strain and experimental context. Furthermore, these results confirm that profound behavioral differences exist between Wistar and Sprague-Dawley rats, which may explain the sometimes contradictory effects of cannabinoid drugs on emotionality in different strains of rodents.

Distinct roles of the endocannabinoids anandamide and 2-arachidonoylglycerol in social behavior and emotionality at different developmental ages in rats.
To date, our understanding of the relative contribution and potential overlapping roles of the endocannabinoids anandamide (AEA) and 2-arachidonoylglycerol (2-AG) in the regulation of brain function and behavior is still limited. To address this issue, we investigated the effects of systemic administration of JZL195, that simultaneously increases AEA and 2-AG signaling by inhibiting their hydrolysis, in the regulation of socio-emotional behavior in adolescent and adult rats. JZL195, administered at the dose of 0.01mg/kg, increased social play behavior, that is the most characteristic social activity displayed by adolescent rats, and increased social interaction in adult animals. At both ages, these behavioral effects were antagonized by the CB1 cannabinoid receptor antagonist SR141716A and were associated with increased brain levels of 2-AG, but not AEA. Conversely, at the dose of 1mg/kg, JZL195 decreased general social exploration in adolescent rats without affecting social play behavior, and induced anxiogenic-like effects in the elevated plus-maze test both in adolescent and adult animals. These effects, mediated by activation of CB1 cannabinoid receptors, were paralleled by simultaneous increase in AEA and 2-AG levels in adolescent rats, and by an increase of only 2-AG levels in adult animals. These findings provide the first evidence for a role of 2-AG in social behavior, highlight the different contributions of AEA and 2-AG in the modulation of emotionality at different developmental ages and suggest that pharmacological inhibition of AEA and 2-AG hydrolysis is a useful approach to investigate the role of these endocannabinoids in neurobehavioral processes.

BRAIN CIRCUITS IMPLICATED IN AUTISTIC-LIKE BEHAVIORS IN HAPLOINSUFFICIENT NAV1.2 (SCN2A+/-) MICE.

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Wendy Marcantonio, Massimo Mantegazza, Isabelle Léna
IPMC, Alpes Maritimes, valbonne, France

Autism Spectrum Disorder (ASD) is characterized by deficits in social interactions and communication and restrictive/repetitive behaviors. Excitatory/Inhibitory (E/I) imbalance during brain development has been proposed to contribute to ASD. Mutations in the SCN2A gene, coding for the Nav1.2 voltage-gated sodium channel alpha subunit, has been identified among the most frequent mutations found in patients. Our team previously showed that *Scn2a*$^{+/-}$ mice exhibit core symptoms of ASD, as communication deficits and stereotypic behavior. Our first aim here was to identify the direction of the E/I imbalance using glutamatergic or GABAergic agonists. Glutamatergic agonists injected i.p. in *Scn2a*$^{+/-}$ mice were able to ameliorate social communication and to reduce stereotypic behavior, showing that these mice have global reduced excitatory transmission. Moreover, Western Blot analysis of several brain structures that are often dysfunctional in ASD revealed altered expression of glutamate receptor subunits in *Scn2a*$^{+/-}$ mice. Then, in order to identify brain regions implicated in the behavioral deficits observed in *Scn2a*$^{+/-}$ mice, we locally injected a glutamatergic agonist in different striatal regions. We have observed that reduced excitatory transmission in the Nucleus Accumbens is implicated in social communication deficits in males. We are currently investigating the possible involvement of the dorsal striatum in females. These results will pave the way to experiments in which we will perform optogenetic stimulations of different glutamatergic cortical projections to the striatum in order to rescue the E/I balance and uncover defective neural circuits responsible of behavioral deficits in *Scn2a*$^{+/-}$ mice.

POGZ DEFICIENCY IN MICE LEADS TO ASD-LIKE BEHAVIORS WITH A MALE-SPECIFIC INCREASE IN SOCIABILITY

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Reut Suliman-Lavie, Sunny Yanai, Sagiv Shifman
Hebrew University of Jerusalem, Neurogenetics, Jerusalem, Israel

Genes implicated in autism spectrum disorder (ASD) are enriched for chromatin regulators, but the mechanisms by which they lead to abnormal behavior and cognition remain unclear. POGZ is a key chromatin regulator that, when mutated in humans, leads to "white-Sutton syndrome". The syndrome is characterized by microcephaly, developmental delay, intellectual disability, ASD, and overly friendly behavior. In this study, we generate a mouse model harboring a heterozygous mutation in *Pogz*, mimicking the genetics of the human condition. We characterized this mouse model both anatomically and behaviorally and investigated possible molecular mechanisms that may underlie the observed phenotypes. We characterized *Pogz* heterozygote mutant (*Pogz*$^{+/-}$) male and female mice and found an overall reduction in brain and body weight, more pronounced in males. Adult neurogenesis in these mice was abnormal in proliferation and cell survival. Behavioral assays revealed impairments in motor and spatial learning skills as well as reduced anxiety. Furthermore, we identified an increase in social investigation time of stranger mice and social odors tests in *Pogz*$^{+/-}$ male mice. In agreement, analysis of cFos expression across the brain following exposure to social odors showed increased neuronal activity in regions within the amygdala and hypothalamus only in males *Pogz*$^{+/-}$. Our results establish *Pogz* deficient mouse as a valuable model of "White-Sutton syndrome," showing phenotypes that resemble the human condition, including the overly friendly behavior. Future research is needed to dissect the molecular and neuronal mechanisms for the male-specific changes in social behavior that were accompanied by activation of the amygdala and hypothalamus.

ROLE OF THE CORTICAL FEEDBACK ON THE NEURONAL REPRESENTATION OF CONTEXTUAL VISUAL INFORMATION IN THE SUPERIOR COLLICULUS OF AN AUTISTIC MOUSE MODEL

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Leiron Ferrarese, Hiroki Asari, Cornelius Gross
European Molecular Biology Laboratory, Epigenetics And Neurobiology Unit, Monterotondo, Italy

The brain is a predictive machine. It constantly generates a mental model of the outside world to predict future sensory inputs and adjust behavior accordingly. When the prediction differs from actual sensory inputs, the brain signals prediction errors and uses them to update the mental model to better predict future stimuli. An emerging hypothesis for autism spectrum disorder (ASD) is that symptoms arise from defective interpretation of the environment, due to unbalanced integration of actual sensory evidence and internally generated prior beliefs on the outside world. To test this hypothesis, here we examine neural processing of neurotypical (NT) and Scn2a-haploinsufficient ASD model mice in the context of visual implicit learning in the superior colliculus (SC). The SC is an ideal neural circuit to study an ASD-related imbalance between feedforward and feedback signals in the context of visual learning because it integrates sensory and perceptual information by receiving both direct input from the retina and feedback signals from the primary visual cortex (V1). We recorded the activity of SC neurons and V1 projections via two-photon calcium imaging in head-fixed mice exposed to a visual implicit learning task, where cue and outcome association probabilities change over time, following a Bayesian belief-update scheme. Here we show that 1) the environmental context affects the visual responses of SC to aversive stimuli; 2) ASD and NT mice differ in their neuronal adaptation to the environment; and 3) V1-to-SC feedback is responsible for the context-dependent modulation in both ASD and NT mice.

Rett Syndrome is a devastating neurodevelopmental disorder caused by mutations in the X-linked *MECP2* gene, characterised by a period of normal development prior to the onset of profound cognitive and sensorimotor deficits. While the symptomatic period has been extensively characterised in mouse models of the disorder, much less is known about how loss of MeCP2 impacts cognitive processing prior to the onset of overt motor phenotypes. Given that disrupted MeCP2 expression results in aberrant synaptic connectivity and excitability in individual brain areas, we hypothesised that MeCP2 regulates inter-areal cortical activity dynamics necessary for higher-order brain function. Loss of MeCP2 would result in a breakdown of cortex-wide communication, in turn leading to developmental cognitive deficits prior to phenotypes detectable by conventional symptomatic scoring. We used widefield calcium imaging of the dorsal cortex to assay how loss of MeCP2 affects cortex-wide neural dynamics at rest, during visual stimulation and across visuomotor learning. Female Mecp2$^{+/loxstop}$ mice displayed widespread resting state functional dysconnectivity, suggesting a breakdown in baseline cortical communication. In addition, we found hypoconnectivity during visual stimulation, with sensory information failing to propagate from primary sensory to higher order processing areas. We demonstrate that aberrant functional connectivity and disrupted inter-areal information propagation in Mecp2$^{+/loxstop}$ mice is associated with delayed learning in simple reward association and visual discrimination tasks. Our results suggest that loss of MeCP2 leads to aberrant cortical functional connectivity, which in turn drives sensorimotor processing and learning deficits prior to the onset of overt motor phenotypes.

A cerebellar-thalamocortical pathway drives behavioral context-dependent movement initiation.
Executing learned motor behaviors often requires the transformation of sensory cues into patterns of motor commands that generate appropriately timed actions. The cerebellum and thalamus are two key areas involved in shaping cortical output and movement, but the contribution of a cerebellar-thalamocortical pathway to voluntary movement initiation remains poorly understood. Here, we investigated how an auditory "go cue" transforms thalamocortical activity patterns and how these changes relate to movement initiation. Population responses in dentate/interpositus-recipient regions of motor thalamus reflect a time-locked increase in activity immediately prior to movement initiation that is temporally uncoupled from the go cue, indicative of a fixed-latency feedforward motor timing signal. Blocking cerebellar or motor thalamic output suppresses movement initiation, while stimulation triggers movements in a behavioral context-dependent manner. Our findings show how cerebellar output, via the thalamus, shapes cortical activity patterns necessary for learned context-dependent movement initiation.

SEX DIFFERENCES IN AUTISM SPECTRUM DISORDER: A PROTEOME ANALYSIS.

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Mara Uhl[1], Ute Distler[2], Stefan Tenzer[2], Karl-Heinz Smalla[3], Michael Schmeisser[1], Sven Schumann[1]
[1]Universitätsmedizin der Johannes-Gutenberg Universität Mainz, Institute For Microscopic Anatomy And Neurobiology, Mainz, Germany, [2]University Medical Center of the Johannes Gutenberg-University Mainz, Institute For Immunology, Mainz, Germany, [3]Leibniz Institute for Neurobiology, Speziallabor Molekularbiologische Techniken, Magdeburg, Germany

Autism spectrum disorder (ASD) is with around 1 % of the population the most commonly diagnosed neurodevelopmental disorder. A high difference in the prevalence of cases has been observed in woman and man. The reported male to female ratios varies between 2:1 and 4:1. Moreover, behavioral characteristics differ between the sexes. They tend to be more internalizing in females and externalizing in males. Sex differences have also been found in the behavior of ASD model mice, with females performing similar to control mice and males showing higher rates of restricted repetitive behavior, performing worse in reversal learning tasks and spending less time with a novel mouse in a 3-chamber social approach test. The underlying differences of these sex biases in prevalence and behavior are still unknown. Therefore, our project focusses on analyzing the synaptic proteome of male and female mice of this ASD model, to gain a deeper insight into the mechanisms of ASD and the reasons for the sexual dimorphism. In our analysis we found several proteins to be differentially expressed between female and male ASD model mice. A dimorphism was found in all three investigated brain regions: the hippocampus, the striatum and the cerebellum. Two of the proteins, which were changed in expression, have previously been characterized in ASD and further can be linked to pathways associated with neurodevelopmental disorders. Our efforts should serve as a neurobiological framework to better understand sex differences, in both health and disease.

EMBRYONIC EXPOSURE TO VALPROIC ACID IMPAIRS VISUAL PREFERENCES FOR FACE-LIKE STIMULI AND ALTERS DOPAMINERGIC DISTRIBUTION AND SIGNALING IN DOMESTIC CHICKS

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Alice Adiletta[1], Alessandra Pross[1,2], Nicolò Taricco[1], Samantha Pedrana[1], Orsola Rosa Salva[1], Paola Sgadò[1]

In recent years, an involvement of the dopaminergic (DA) population in the regulation of social and affiliative behavior has been largely observed both in human and in animal studies. Moreover, dysfunctions of the same neuromodulatory system have been reported also in children with Autism Spectrum Disorders (ASD) and in different ASD models. To further investigate the role of DA functioning in influencing social behavior, given the importance of early life experiences in shaping social cognitive functions, we chose to study an animal model known for its highly precocial behavioral features: the domestic chick. By embryonically exposing the animals to valproic acid (VPA), a compound largely used to model social disorders, we altered chicks' innate preference for Face-Like stimuli. Given the importance of face processing in ASD, we therefore consider the chick as the ideal model to study the neurobiological bases of such mechanisms. In addition, we examined the anatomical and functional layout of the mesencephalic DA population in VPA-treated chicks by immunolabeling dopaminergic TH^+ neurons and by analyzing the expression levels of several dopaminergic markers in both the mesencephalon and the septum, a DA-innervated brain region associated to social behavior. We observed that VPA exposure affects the rostro-caudal distribution of DA neurons in the mesencephalon and alters the expression of genes involved in DA signaling in the septum. Taken together, our data support the emerging hypothesis of a link between DA dysfunction and social cognitive deficits.

Spontaneous Visual Preference for Face-Like Stimuli Is Impaired in Newly-Hatched Domestic Chicks Exposed to Valproic Acid During Embryogenesis.
Faces convey a great amount of socially relevant information related to emotional and mental states, identity and intention. Processing of face information is a key mechanism for social and cognitive development, such that newborn babies are already tuned to recognize and orient to faces and simple schematic face-like patterns since the first hours of life. Similar to neonates, also non-human primates and domestic chicks have been shown to express orienting responses to faces and schematic face-like patterns. More importantly, existing studies have hypothesized that early disturbances of these mechanisms represent one of the earliest biomarker of social deficits in autism spectrum disorders (ASD). We used VPA exposure to induce neurodevelopmental changes associated with ASD in domestic chicks and tested whether VPA could impact the expression of the animals' approach responses to schematic face-like stimuli. We found that VPA impairs the chicks' preference responses to these social stimuli. Based on the results shown here and on previous studies, we propose the domestic chick as animal model to investigate the biological mechanisms underlying face processing deficits in ASD.

RESTING STATE FUNCTIONAL CONNECTIVITY NETWORKS IN TWINS WITH AUTISM: TOWARDS THE TURKISH LONGITUDINAL NEUROIMAGING AUTISM PROJECT (TURK-NAP) USING THE ABİDE DATABASE

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Basak Alpas
Ankara University, Neuroscience, Ankara, Turkey

Autism spectrum disorder -autism- is a lifelong early-onset neurodevelopmental disorder characterized by the 3 main symptom domains (social-communication difficulties, restricted and repetitive behaviors, and sensory abnormalities) (DSM-5; APA, 2013). One of the key characteristics of autism is phenotypical and neurobiological heterogeneity (Geschwind and Levitt, 2007; Minhew and Williams 2007). Big Data sets, such as the Autism Brain Imaging Date Exchange (ABIDE) (Di Martino et al., 2017), reporting both hyperconnectivity and hypoconnectivity, within and between various brain networks. **Aims:** The first goal of the TURK-NAP is to test the hypothesis that autism is associated with both hypoconnectivity and hyperconnectivity, and to characterize relationships between functional connectivity alterations. Second is to examine the clinical scores covering the 3 main symptom domains of the TURK-NAP. Third is to identify biomarkers in autism using Network Neuroscience Tools based on the ABIDE database. **Sample:** The sample of TURK-NAP is planned to consists of the norm study of the Turkish Vineland-II Adaptive Behavior Scales [84 autism (20 girls, 64 boys); 100 healthy developing (50 girls, 50 boys); age range: 8-18] **MRI Data Acquisition:** Resting state fMRI (rs-fMRI) and structural scans acquired at UMRAM (Bilkent University, Ankara) using 3 Tesla MRI (Siemens Magnetom Trio Tim). Resting state scans lasted 7 minutes for each of the children with their eyes closed. **Results:** The correlation between the brain networks and behavioral measurements of the twin sample was calculated by Canonical Correlation Analysis. **Conclusion:** The national and international contributions and limitations of the TURK-NAP Project will be discussed.

GUT MICROBIOTA FROM AUTISTIC CHILDREN INDUCE CHANGES IN THE CENTRAL NERVOUS SYSTEM OF HEALTHY MICE

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Arnas Kunevičius[1], Dominykas Varnas[2], Vaidotas Urbonas[2], Aurelijus Burokas[1]

Autism spectrum disorders (ASD) are a complex group of neurodevelopmental disorders with unclear etiology. ASD manifest in a variety of neuropsychiatric traits, but are most commonly characterized by impaired social interaction and stereotypical repetitive behavior. Current research reports that children with ASD have risk of gastrointestinal disturbances and showcase differences in gut microbiota composition. We hypothesize that transfer of gut microbiota from ASD patients can induce changes in the central nervous system of healthy mice. To test this hypothesis, we used fecal samples of ASD children to perform fecal microbiota transfer (FMT) to adult C57BL/6J mice. We measured the effect of gut microbiota from ASD children on autistic-like behaviors using several behavioral tests. Also, we analyzed gene expression in the hippocampus and medial prefrontal cortex using Real-Time PCR. The transfer of gut microbiota from ASD children to healthy mice affected cognitive functions of healthy animals and influenced changes in ASD associated gene expression. However, the observed effect was minor, possibly due to the gut microbiota variability between samples. These primary results suggest that the gut microbiota might contribute to the cognitive changes observed in ASD patients. Nevertheless, further gut microbiota diversity analysis is required to confirm the success of FMT and to establish the cause of observed changes.

Autism Spectrum Disorders (ASD) are neurodevelopmental disorders whose diagnosis relies on deficient social interaction and communication together with repetitive behavior. To date, no pharmacological treatment has been approved that ameliorates social behavior in patients with ASD. Based on the excitation/inhibition imbalance theory of autism, we hypothesized that bromide ions, long used as an antiepileptic medication, could relieve core symptoms of ASD. We evaluated the effects of chronic sodium bromide (NaBr) administration on autistic-like symptoms in three genetic mouse models of autism: *Oprm1*$^{-/-}$, *Fmr1*$^{-/-}$ and *Shank3*$^{\Delta ex13\text{-}16-/-}$ mice. We showed that chronic NaBr treatment relieved autistic-like behaviors in these three models. In *Oprm1*$^{-/-}$ mice, these beneficial effects were superior to those of chronic bumetanide administration. At transcriptional level, chronic NaBr in *Oprm1* null mice was associated with increased expression of genes coding for chloride ions transporters, $GABA_A$ receptor subunits, oxytocin and mGlu4 receptor. Lastly, we uncovered synergistic alleviating effects of chronic NaBr and a positive allosteric modulator (PAM) of mGlu4 receptor on autistic-like behavior in *Oprm1*$^{-/-}$ mice. We evidenced in heterologous cells that bromide ions behave as PAMs of mGlu4, providing a molecular mechanism for such synergy. Our data reveal the therapeutic potential of bromide ions, alone or in combination with a PAM of mGlu4 receptor, for the treatment of ASDs.

Fragile X syndrome (FXS) is the most frequent known single gene cause of autism spectrum disorder (ASD). To date, no pharmacological treatment exists that reliably relieves symptoms of autism in FXS. The striatum has been identified from clinical and preclinical studies as a critical brain substrate for autism etiopathology. Here we evidenced altered responses to dopaminergic challenge and modifications of gene expression in the mouse model of FXS, *Fmr1* knockout mice, pointing to striatal dysfunction. Using RNAscope® *in situ* hybridization technique, we revealed a reduction in the activity of D1- and D2-expressing medium spiny neurons (MSNs) in the caudate putamen (CPu) and nucleus accumbens (NAc) following social interaction in *Fmr1*$^{-/-}$ mice. In the NAc, this reduction affected significantly more D1- than D2-MSNs, resulting in an excessive D2-MSN/D1-MSN activity ratio. We had previously shown that administration of a positive allosteric modulator (PAM) of the mGlu4 glutamate receptor, that represses D2-MSN activity, alleviates autistic-like deficits in mouse models of autism or social/reward deficit. In the present study, chronic administration of the mGlu4 PAMs VU0155041 and ADX88178 or the orthosteric mGlu4/mGlu7 agonist LSP4-2022 relieved core autistic symptoms in *Fmr1*$^{-/-}$ mice, whilst chronic administration of the mGlu5 negative allosteric modulator GRN529 failed to rescue social behavior. Finally, administration of the photoswitchable mGlu4 PAM Optogluram in the ventral pallidum was sufficient to restore social interaction in *Fmr1*$^{-/-}$ mice. These results suggest a great therapeutic potential for compounds facilitating mGlu4 activity or, more generally, repressing D2-MSN activity, in FXS and autism.

LIGHT SHEET IMAGING OF BEHAVIOURALLY ACTIVATED AMYGDALA NEURONS IN THE FRAGILE-X KNOCKOUT RAT MODEL OF AUTISM SPECTRUM DISORDERS

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Cristina Martinez Gonzalez[1,2], Kirsty Craigie[1,2], Sally Till[1,2], Nathalie Rochefort[1,2], Ian Duguid[1,2], Peter Kind[1,2], Matthew Nolan[1,2]
[1]University of Edinburgh, Simons Initiative For The Developing Brain, Edinburgh, United Kingdom, [2]Univerisity of Edinburgh, Centre For Discovery Brain Science, Edinburgh, United Kingdom

Autism spectrum disorders (ASD) are characterized by social impairments and restricted behaviours. Activation in key brain regions involved in social and emotional processing, including the amygdala, has been studied using neuroimaging and histology. Nevertheless, changes in neuronal activity in ASD are largely unknown. To evaluated behaviourally activated neurons we used the Fragile-X knockout (Fmr1$^{-/y}$) rat model of ASD combined with whole-brain immunolabeling against cFos. Given the amygdala-dependent emotional processing is altered in Fragile-X syndrome individuals, we focus on behaviourally-induced cFos expression in Fmr1$^{-/y}$ rats compared to wild types (WT). To quantify cFos+ neurons in the amygdala, we created a pipeline combining immunolabeling, a modified iDISCO protocol, light-sheet microscopy, automatic quantification and a custom-made-3D atlas (Basolateral complex: lateral:LA, basal:BA and basomedial:BM; Central nucleus: CeA). We compared WT and Fmr1$^{-/y}$ animals that received a conditioned (CS:light) paired with unconditioned-stimulus (US:foot-shock), to CS-only, and home-caged (naive) groups. Brains were obtained 90 minutes after stimuli, immunolabeled, cleared and imaged. We observed an increase in cell density of cFos+neurons in the BA and BM of shocked WT and Fmr1$^{-/y}$, compared with naive rats. We also observed an increase in WT-CS-only, but not Fmr1$^{-/y}$-CS-only group. No changes were observed in LA or CeA (One-way ANOVA, Tukey post-hoc-test). Our approach identifies differential neuronal activation in the amygdala of Fmr1$^{-/y}$ rats in the CS-only group, but not in the conditioned or naive groups, suggesting that deletion of Fmr1 may cause a reduction in responsiveness of the Basolateral amygdala to sensory events associated with a new environmental context.

Multi-pronged neuromodulation intervention engages the residual motor circuitry to facilitate walking in a rat model of spinal cord injury.
A spinal cord injury usually spares some components of the locomotor circuitry. Deep brain stimulation (DBS) of the midbrain locomotor region and epidural electrical stimulation of the lumbar spinal cord (EES) are being used to tap into this spared circuitry to enable locomotion in humans with spinal cord injury. While appealing, the potential synergy between DBS and EES remains unknown. Here, we report the synergistic facilitation of locomotion when DBS is combined with EES in a rat model of severe contusion spinal cord injury leading to leg paralysis. However, this synergy requires high amplitudes of DBS, which triggers forced locomotion associated with stress responses. To suppress these undesired responses, we link DBS to the intention to walk, decoded from cortical activity using a robust, rapidly calibrated unsupervised learning algorithm. This contingency amplifies the supraspinal descending command while empowering the rats into volitional walking. However, the resulting improvements may not outweigh the complex technological framework necessary to establish viable therapeutic conditions.

Medial septal GABAergic neurons reduce seizure duration upon optogenetic closed-loop stimulation.
Seizures can emerge from multiple or large foci in temporal lobe epilepsy, complicating focally targeted strategies such as surgical resection or the modulation of the activity of specific hippocampal neuronal populations through genetic or optogenetic techniques. Here, we evaluate a strategy in which optogenetic activation of medial septal GABAergic neurons, which provide extensive projections throughout the hippocampus, is used to control seizures. We utilized the chronic intrahippocampal kainate mouse model of temporal lobe epilepsy, which results in spontaneous seizures and as is often the case in human patients, presents with hippocampal sclerosis. Medial septal GABAergic neuron populations were

immunohistochemically labelled and were not reduced in epileptic conditions. Genetic labelling with mRuby of medial septal GABAergic neuron synaptic puncta and imaging across the rostral to caudal extent of the hippocampus, also indicated an unchanged number of putative synapses in epilepsy. Furthermore, optogenetic stimulation of medial septal GABAergic neurons consistently modulated oscillations across multiple hippocampal locations in control and epileptic conditions. Finally, wireless optogenetic stimulation of medial septal GABAergic neurons, upon electrographic detection of spontaneous hippocampal seizures, resulted in reduced seizure durations. We propose medial septal GABAergic neurons as a novel target for optogenetic control of seizures in temporal lobe epilepsy.

Cortico-reticulo-spinal circuit reorganization enables functional recovery after severe spinal cord contusion.
Severe spinal cord contusions interrupt nearly all brain projections to lumbar circuits producing leg movement. Failure of these projections to reorganize leads to permanent paralysis. Here we modeled these injuries in rodents. A severe contusion abolished all motor cortex projections below injury. However, the motor cortex immediately regained adaptive control over the paralyzed legs during electrochemical neuromodulation of lumbar circuits. Glutamatergic reticulospinal neurons with residual projections below the injury relayed the cortical command downstream. Gravity-assisted rehabilitation enabled by the neuromodulation therapy reinforced these reticulospinal projections, rerouting cortical information through this pathway. This circuit reorganization mediated a motor cortex-dependent recovery of natural walking and swimming without requiring neuromodulation. Cortico-reticulo-spinal circuit reorganization may also improve recovery in humans.

Stellate Cells in the Medial Entorhinal Cortex Are Required for Spatial Learning.
Spatial learning requires estimates of location that may be obtained by path integration or from positional cues. Grid and other spatial firing patterns of neurons in the superficial medial entorhinal cortex (MEC) suggest roles in behavioral estimation of location. However, distinguishing the contributions of path integration and cue-based signals to spatial behaviors is challenging, and the roles of identified MEC neurons are unclear. We use virtual reality to dissociate linear path integration from other strategies for behavioral estimation of location. We find that mice learn to path integrate using motor-related self-motion signals, with accuracy that decreases steeply as a function of distance. We show that inactivation of stellate cells in superficial MEC impairs spatial learning in virtual reality and in a real world object location recognition task. Our results quantify contributions of path integration to behavior and corroborate key predictions of models in which stellate cells contribute to location estimation.

Divergent motor projections from the pedunculopontine nucleus are differentially regulated in Parkinsonism.
The pedunculopontine nucleus (PPN) is composed of neurons with different connectivity patterns that express different neurochemical markers, display distinct firing characteristics and are topographically organized in functional domains across its rostro-caudal axis. Previous reports have shown that the caudal region of the PPN is interconnected with motor regions of both the basal ganglia and brainstem/medulla. The co-distribution of ascending and descending motor outputs raises the question as to whether the PPN provides a coordinated or differential modulation of its targets in the basal ganglia and the medulla. To address this, we retrogradely labeled neurons in the two main PPN pathways involved in motor control and determined whether they project to one or both structures, their neurochemical phenotype, and their activity in normal and dopamine depleted rats, as indicated by Egr-1 expression. We show that ascending and descending motor pathways from the PPN arise largely from separate neurons that intermingle in the same region of the PPN, but have a distinct neurochemical composition and are differentially regulated in the Parkinsonian state. Thus, neurons projecting to the subthalamic nucleus consist of cholinergic, calbindin- and calretinin-expressing neurons, and Egr-1 is upregulated following a 6-hydroxydopamine lesion. In contrast, a larger proportion of neurons projecting to the gigantocellular nucleus are cholinergic, none express calbindin and the expression of Egr-1 is not changed by the dopamine lesion. Our results suggest that ascending and descending motor connections of the PPN are largely mediated by different sets of neurons and there are cell type-specific changes in Parkinsonian rats.

Subpopulations of cholinergic, GABAergic and glutamatergic neurons in the pedunculopontine nucleus contain calcium-binding proteins and are heterogeneously distributed.
Neurons in the pedunculopontine nucleus (PPN) are highly heterogeneous in their discharge properties, their neurochemical markers, their pattern of connectivity and the behavioural processes in which they participate. Three main transmitter

phenotypes have been described, cholinergic, GABAergic and glutamatergic, and yet electrophysiological evidence suggests heterogeneity within these subtypes. To gain further insight into the molecular composition of these three populations in the rat, we investigated the pattern of expression of calcium binding proteins (CBPs) across distinct regions of the PPN and in relation to the presence of other neurochemical markers. Calbindin- and calretinin-positive neurons are as abundant as cholinergic neurons, and their expression follows a rostro-caudal gradient, whereas parvalbumin is expressed by a low number of neurons. We observed a high degree of expression of CBPs by GABAergic and glutamatergic neurons, with a large majority of calbindin- and calretinin-positive neurons expressing GAD or VGluT2 mRNA. Notably, CBP-positive neurons expressing GAD mRNA were more concentrated in the rostral PPN, whereas the caudal PPN was characterized by a higher density of CBP-positive neurons expressing VGluT2 mRNA. In contrast to these two large populations, in cholinergic neurons expression of calretinin is observed only in low numbers and expression of calbindin is virtually non-existent. These findings thus identify novel subtypes of cholinergic, GABAergic and glutamatergic neurons based on their expression of CBPs, and further contribute to the notion of the PPN as a highly heterogeneous structure, an attribute that is likely to underlie its functional complexity.

21503154: Martinez-Gonzalez C, Bolam JP, Mena-Segovia J
Topographical organization of the pedunculopontine nucleus.
Neurons in the pedunculopontine nucleus (PPN) exhibit a wide heterogeneity in terms of their neurochemical nature, their discharge properties, and their connectivity. Such characteristics are reflected in their functional properties and the behaviors in which they are involved, ranging from motor to cognitive functions, and the regulation of brain states. A clue to understand this functional versatility arises from the internal organization of the PPN. Thus, two main areas of the PPN have been described, the rostral and the caudal, which display remarkable differences in terms of the distribution of neurons with similar phenotype and the projections that originate from them. Here we review these differences with the premise that in order to understand the function of the PPN it is necessary to understand its intricate connectivity. We support the case that the PPN should not be considered as a homogeneous structure and conclude that the differences between rostral and caudal PPN, along with their intrinsic connectivity, may underlie the basis of its complexity.

NEUROPLASTICITY PROFILE AND NEUROGENIC ACTIVITY IN FMR1 KNOCK OUT RATS, A MODEL OF THE FRAGILE X SYNDROME

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

George Ntoulas[1], Charalambos Brakatselos[1], Michalis Asprogerakas[1], Gerasimos Nakas[1], Olga Tsarna[1], Dimitrios Gkikas[2], Alexia Polissidis[3], Yiasemi Koutmani[3], Panagiotis Politis[2], Katerina Antoniou[1]

Fragile X Syndrome (FXS), is the most common monogenetic leading cause of inherited intellectual disability and autism. Experimental studies have been mainly focused on Fmr1 knock-out (KO) mice while a few studies have investigated behavioral and neurobiological alterations in Fmr1KO rats, given the fact that this is an animal model with improved translational value. In this study we evaluated the biophenotype of Fmr1KO rats with specific behavioral tasks that are related to cognitive functions along with neuroplasticity and neurogenesis biomarkers.

Male 12-16 weeks old rats, LE-Fmr1^{em2Mcwi} referred to as Fmr1 KO (n=20), and WT littermates (n=20), were used. Object recognition and location memory were assayed through the Object Recognition and Object Location Task tests. Neuroplasticity and Neurogenesis indices were evaluated in Prefrontal Cortex, Dorsal and Ventral Hippocampus.

Present findings have shown a specific bio-phenotype of Fmr1KO rats as compared to their WT counterparts. Fmr1KO rats displayed hyperactivity and impaired behavioral indices that are related to specific cognitive functions. In parallel, neuronal plasticity indices, including BDNF/Trkb protein expression levels and neurogenic activity of neural stem cells were found to be genotype dependent.

Based on our findings a differentiated behavioral and plasticity profile along with disrupted neurogenesis was observed between WT and KO Fmr1 rats. Present results contribute to issues related to translational studies focused on cognitive disabilities and autism spectrum disorders.

CBD Effects on Motor Profile and Neurobiological Indices Related to Glutamatergic Function Induced by Repeated Ketamine Pre-Administration.
Clinical evidence and experimental studies have shown the psychotomimetic properties induced by ketamine. Moreover, acute or chronic ketamine (KET) administration has been widely used for modeling schizophrenia-like symptomatology and pathophysiology. Several studies have reported the antipsychotic potential of cannabidiol (CBD), while there is limited information on the cannabidiol effect on KET-induced schizophrenia-like impairments. Therefore, the goal of the present study was to evaluate neuroplastic changes induced by repeated KET administration, which is used as an experimental model of schizophrenia-with a behavioral focus on positive-like symptomatology- and to assess the modulatory role of CBD treatment. The present findings have shown a robust increase in motor activity in KET-treated rats, following a 10-day period of chronic administration at the sub-anesthetic dose of 30 mg/kg (i.p), that was reversed to normal by subsequent chronic CBD treatment. Concerning the expression of glutamate receptors, the current findings have shown region-dependent KET-induced constitutional alterations in NMDA and AMPA receptors that were modified by subsequent CBD treatment. Additionally, repeated KET administration increased ERK1/2 phosphorylation state in all regions examined, apart from the ventral hippocampus that was modulated by subsequent CBD treatment. The present results show, for the first time, a

stimulated motor output coupled with a specific glutamatergic-related status and ERK1/2 activation following chronic KET administration that were attenuated by CBD treatment, in a region-dependent manner. These findings provide novel information concerning the antipsychotic potential of CBD using a specific design of chronic KET administration, thus contributing to experimental approaches that mirror the symptomatology and pathophysiology of schizophrenia.

FMR1 KO MICE EXHIBIT DEFICITS IN BEHAVIOR, EYE ALIGNMENT, AND CORTICAL ACTIVITY DURING STEREOSCOPIC DEPTH DISCRIMINATION COMPARED TO WILD TYPE MICE

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Jason Samonds[1], Carrie Barr[1], Howard Boone[2], Aaron Mcgee[2], Nicholas Priebe[1]

Autistic subjects generally have a higher incidence of strabismus and amblyopia than control subjects. Consequently, autism is associated with an overall deficit in stereoscopic depth perception. Fragile X syndrome (FXS) is the leading genetic cause of autism, driven by a mutation in the FMR1 gene, and leads to a deficit in binocular visual processing. We examined stereo vision in FMR1 knock-out (KO) and wild-type (WT) mice using three different assays: performance on a perceptual task, binocular eye alignment, and disparity selectivity in the visual cortex. Stereoscopic depth perception was significantly impaired using the pole descent visual cliff task in FMR1 KO mice relative to WT mice. While FMR1 KO mice were able to perform the task, they exhibited a larger depth discrimination threshold compared to WT mice. The binocular alignment of FMR1 KO mice had greater variability and offset during both saccades and fixation than WT mice, which reflect characteristics of strabismus. Finally, we measured binocular disparity tuning in the visual cortex of FMR1 KO and WT mice using two-photon microscopy. Disparity tuning in FMR1 KO mice was less selective and disparity-dependent responses were more variable across repeated trials compared to WT mice. Overall, FMR1 KO mice exhibit deficits in binocular vision from the perspective of the visual and motor systems that are analogous to those observed in Fragile X patients and autistic subjects. We propose that the mouse is an effective model for characterizing the consequences of FXS for visual processing.

Natural binocular depth discrimination behavior in mice explained by visual cortical activity.
In mice and other mammals, forebrain neurons integrate right and left eye information to generate a three-dimensional representation of the visual environment. Neurons in the visual cortex of mice are sensitive to binocular disparity, yet it is unclear whether that sensitivity is linked to the perception of depth. We developed a natural task based on the classic visual cliff and pole descent tasks to estimate the psychophysical range of mouse depth discrimination. Mice with binocular vision descended to a near (shallow) surface more often when surrounding far (deep) surfaces were progressively more distant. Occlusion of one eye severely impaired their ability to target the near surface. We quantified the distance at which animals make their decisions to estimate the binocular image displacement of the checkerboard pattern on the near and far surfaces. Then, we assayed the disparity sensitivity of large populations of binocular neurons in primary visual cortex (V1) using two-photon microscopy and quantitatively compared this information available in V1 to their behavioral sensitivity. Disparity information in V1 matches the behavioral performance over the range of depths examined and was resistant to changes in binocular alignment. These findings reveal that mice naturally use stereoscopic cues to guide their behavior and indicate a neural basis for this depth discrimination task.

Mice Discriminate Stereoscopic Surfaces Without Fixating in Depth.
Stereopsis is a ubiquitous feature of primate mammalian vision, but little is known about if and how rodents such as mice use stereoscopic vision. We used random dot stereograms to test for stereopsis in male and female mice, and they were able to discriminate near from far surfaces over a range of disparities, with diminishing performance for small and large binocular disparities. Based on two-photon measurements of disparity tuning, the range of disparities represented in the visual cortex aligns with the behavior and covers a broad range of disparities. When we examined their binocular eye movements, we found that, unlike primates, mice did not systematically vary relative eye positions or use vergence eye movements when presented with different disparities. Nonetheless, the representation of disparity tuning was wide enough to capture stereoscopic information over a range of potential vergence angles. Although mice share fundamental characteristics of stereoscopic vision with primates and carnivores, their lack of disparity-dependent vergence eye movements and wide

neuronal representation suggests that they may use a distinct strategy for stereopsis. Binocular vision allows us to derive depth information by comparing right and left eye information. We characterized binocular integration in mice because tools exist in these animals to dissect the underlying neural circuitry for binocular vision. Using random dot stereograms, we find that behavior and disparity tuning in the visual cortex share fundamental characteristics with primates, but we did not observe any evidence of disparity-dependent changes in vergence angle. We propose that mice use a distinct strategy of stereopsis compared with primates by using a broad range of disparities to encode depth over a large field of view and to compensate for nonstereoscopic changes in vergence angle that arise during natural behavior.

Motion Discrimination and the Motion Aftereffect in Mouse Vision.
Prolonged exposure to motion in one direction often leads to the illusion of motion in the opposite direction for stationary objects. This motion aftereffect likely arises across several visual areas from adaptive changes in the balance of activity and competitive interactions. We examined whether or not the mouse was susceptible to this same illusion to determine whether it would be a suitable model for learning about the neural representation of the motion aftereffect. Under a classical conditioning paradigm, mice learned to lick when presented with motion in one direction and not the opposite direction. When the mice were adapted to motion preceding this test, their lick behavior for zero coherence motion was biased for motion in the opposite direction of the adapting stimulus. Overall, lick count versus motion coherence shifted in the opposite direction of the adapting stimulus. This suggests that although the mouse has a simpler visual system compared with primates, it still is subject to the motion aftereffect and may elucidate the underlying circuitry.

Natural image and receptive field statistics predict saccade sizes.
Humans and other primates sample the visual environment using saccadic eye movements that shift a high-resolution fovea toward regions of interest to create a clear perception of a scene across fixations. Many mammals, however, like mice, lack a fovea, which raises the question of why they make saccades. Here we describe and test the hypothesis that saccades are matched to natural scene statistics and to the receptive field sizes and adaptive properties of neural populations. Specifically, we determined the minimum amplitude of saccades in natural scenes necessary to provide uncorrelated inputs to model neural populations. This analysis predicts the distributions of observed saccade sizes during passive viewing for nonhuman primates, cats, and mice. Furthermore, disrupting the development of receptive field properties by monocular deprivation changed saccade sizes consistent with this hypothesis. Therefore, natural-scene statistics and the neural representation of natural images appear to be critical factors guiding saccadic eye movements.

Nonuniform surround suppression of visual responses in mouse V1.
Complex receptive field characteristics, distributed across a population of neurons, are thought to be critical for solving perceptual inference problems that arise during motion and image segmentation. For example, in a class of neurons referred to as "end-stopped," increasing the length of stimuli outside of the bar-responsive region into the surround suppresses responsiveness. It is unknown whether these properties exist for receptive field surrounds in the mouse. We examined surround modulation in layer 2/3 neurons of the primary visual cortex in mice using two-photon calcium imaging. We found that surround suppression was significantly asymmetric in 17% of the visually responsive neurons examined. Furthermore, the magnitude of asymmetry was correlated with orientation selectivity. Our results demonstrate that neurons in mouse primary visual cortex are differentially sensitive to the addition of elements in the surround and that individual neurons can be described as being either uniformly suppressed by the surround, end-stopped, or side-stopped. NEW & NOTEWORTHY Perception of visual scenes requires active integration of both local and global features to successfully segment objects from the background. Although the underlying circuitry and development of perceptual inference is not well understood, converging evidence indicates that asymmetry and diversity in surround modulation are likely fundamental for these computations. We determined that these key features are present in the mouse. Our results support the mouse as a model to explore the neural basis and development of surround modulation as it relates to perceptual inference.

AUTISTIC-LIKE BEHAVIORAL EFFECTS OF PRENATAL STRESS IN THE FMR1-KO MOUSE MODEL OF FRAGILE X SYNDROME

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Fragile X Syndrome (FXS) is the most common heritable form of mental retardation and the main monogenic cause of autism spectrum disorder (ASD). FXS is due to a mutation in the X-linked FMR1 gene and is characterized by motor, cognitive and social alterations, mostly overlapping with ASD behavioral phenotypes. The severity of these symptoms and their timing may be exacerbated and/or advanced by environmental adversity interacting with the genetic mutation. We therefore tested the effects of the prenatal exposure to unpredictable chronic stress on the behavioral phenotype of the Fmr1 knock-out (KO) mouse model of FXS, including locomotion, spatial memory, social interaction and communication. Our findings demonstrate the relevance of early environmental stressors in interacting with genetic factors to influence the age-dependent appearance of selected FXS- and ASD-like phenotypes.

NO INTRINSIC NEUROVISCERAL INTEGRATION IN CHILDREN WITH ASD: AN INVESTIGATION OF AUTONOMIC AROUSAL AND AMYGDALA-FRONTAL CONNECTIVITY

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Aside the social deficits and repetitive behaviors that characterize individuals with an autism spectrum disorder (ASD), extremely high prevalence rates of co-occurring anxiety and (social) stress are often observed. Here, we aim to further investigate the occurrence of autonomic hyperarousal as well as the underlying neural processes in 59 school-aged (8-12 years old) children with ASD compared to 39 age- and IQ-matched typically developing children, thereby focusing on measures indexing heart rate variability (HRV) collected during concurrent neuroimaging during rest (rs-fMRI). In line with the model of Neurovisceral Integration by Thayer et al. (2012), diminished resting HRV was expected to be linked to an overall weaker functional coupling between the amygdala and prefrontal regions in children with ASD, related to the prefrontal inability to inhibit amygdala-centered circuits during states of autonomic hyperarousal. No significant differences in commonly addressed HRV-based estimates of autonomic arousal were noted between ASD and TD children however, indicating no evidence for excessive arousal in ASD children. Additionally, no group differences in functional connectivity between bilateral amygdalae and prefrontal regions were encountered. Significant negative associations between amygdala-frontal coupling and time-domain HRV-based measures of autonomic arousal were noted, but only in TD children. The absence of such central-autonomic associations in children with ASD may suggest a neurovisceral “decoupling” instead of integration, but further research is necessary to address this issue further.

Oxytocin enhances neural approach towards social and non-social stimuli of high personal relevance.
Oxytocin (OT) plays a pivotal role in a variety of complex social behaviors by modulating approach-avoidance motivational tendencies, but recently, its social specificity has been challenged. Here, a randomized, double-blind, placebo-controlled study was conducted with forty young adult men, investigating the effect of a single-dose of OT (24 IU) on behavioral and neural approach-avoidance. Frontal alpha asymmetry, indexing neurophysiological approach-avoidance, was obtained from electroencephalographic recordings while participants were presented with a series of pictures, individually rated in terms of personal relevance (i.e., high versus low positive/negative emotional evocativeness) and categorized as social or non-social. Additionally, participants could prolong (approach) or shorten (avoid) the viewing-time of each picture, providing a measure of behavioral approach-avoidance. Intranasal OT enhanced both behavioral and neural approach (increased viewing-time), particularly towards negatively valenced pictures of both social and non-social nature, thus challenging the notion that OT's effects are specific to social stimuli. Neurally, OT specifically amplified approach-related motivational salience of stimuli that were self-rated to have high personal relevance, but irrespective of their social nature or rated affective valence (positive/negative). Together, these findings provide support to the General Approach-Avoidance Hypothesis of OT, suggesting a role of OT in amplifying the motivational salience of environmental stimuli with high (personal) relevance, but irrespective of their social/non-social nature.Clinical Trial Number: The study design was registered at ClinicalTrials.gov (NCT04443647; 23/06/2020; https://clinicaltrials.gov/ct2/show/NCT04443647).

Tracking transient changes in the intrinsic neural frequency architecture: Oxytocin facilitates non-harmonic relationships between alpha and theta rhythms in the resting brain.
Shifts in the peak frequencies of oscillatory neural rhythms have been put forward as a principal mechanism by which cross-frequency coupling and decoupling is implemented in the brain. This notion is based on the mathematical reality that neural oscillations can only fully synchronize when their peak frequencies form harmonic 2:1 relationships (e.g., f=f/2). Non-

harmonic cross-frequency relationships, on the other hand (based on the irrational golden mean 1.618.:1), provide the highest physiologically possible desynchronized state (reducing the occurrence of spurious, noisy, background coupling), and are therefore anticipated to characterize the resting state of the brain, in which no selective information processing takes place. The present study sought to assess whether the transient occurrence of 1.6:1 non-harmonic and 2:1 harmonic relationships between peak frequencies in the alpha (8-14 Hz) and theta (4-8 Hz) bands - respectively facilitating states of decoupling or coupling between oscillatory rhythms - are impacted by the intranasal administration of a single-dose of oxytocin (OT) or placebo. To do so, continuous resting-state electroencephalography (5 min eyes open, 19 electrodes) was obtained from 96 healthy adult men before and after nasal spray administration. The transient formation of non-harmonic cross-frequency configurations between alpha and theta peak frequencies was significantly increased after OT nasal spray administration, indicating an effect of OT on reducing the intrinsic occurrence of spurious (noisy) background phase synchronizations during resting-state. As a group, the OT group also showed a significant parallel increase in high-frequency and decrease in low-frequency heart rate variability, confirming a homeostatic role of OT in balancing parasympathetic drive. Overall, non-harmonic cross-frequency configurations have been put forward to lay the ground for a healthy neural network allowing the opportunity for an efficient transition from resting state to activity. The observed effects of OT on cross-frequency dynamics are therefore interpreted to reflect a homeostatic role of OT in increasing the signal-to-noise properties of the intrinsic EEG neural frequency architecture, i.e., by precluding the occurrence of 'noisy', unwanted, spurious couplings among neural rhythms in the resting brain.

Enhanced mirroring upon mutual gaze: multimodal evidence from TMS-assessed corticospinal excitability and the EEG mu rhythm.
Previous research has demonstrated that eye contact between actor and observer specifically enhances the 'mirroring' of others' actions, as measured by transcranial magnetic stimulation (TMS)-induced motor evoked potentials (MEPs). However, it remains unknown whether other markers of mirror system activation, such as suppression of the EEG mu rhythm (8-13 Hz) over the sensorimotor strip, are also susceptible to perceived eye contact. Here, both TMS-induced MEPs and EEG mu suppression indices were assessed (in separate sessions) while 32 participants (mean age: 24y; 8m) observed a simple hand movement combined with direct or averted gaze from the actor. Both measures were significantly modulated by perceived eye gaze during action observation; showing an increase in MEP amplitude and an attenuation of the mu rhythm during direct vs. averted gaze. Importantly, while absolute MEP and mu suppression scores were not related, a significant association was identified between gaze-related changes in MEPs and mu suppression, indicating that both measures are similarly affected by the modulatory impact of gaze cues. Our results suggest that although the neural substrates underlying TMS-induced MEPs and the EEG mu rhythm may differ, both are sensitive to the social relevance of the observed actions, which might reflect a similar neural gating mechanism.

Oxytocin induces long-lasting adaptations within amygdala circuitry in autism: a treatment-mechanism study with randomized placebo-controlled design.
Intranasal administration of the neuropeptide oxytocin (IN-OT) is increasingly explored as a potential treatment for targeting the core symptoms of autism spectrum disorder (ASD). To date, however, the impact of multiple-dose IN-OT treatment on human neural circuitry is largely unknown, and also the possibility that long-term IN-OT use may induce long-lasting neural adaptations remains unexplored. Using a double-blind, randomized, placebo-controlled, between-subject design (including 38 adult men with ASD), this treatment-mechanism study showed that 4 weeks of daily oxytocin administration (24 IU/day) significantly altered intrinsic (resting-state fMRI) functional connectivity of the amygdala to core regions of the "social brain" (particularly orbitofrontal cortex and superior temporal sulcus) up to 4 weeks and 1 year post treatment. The neural adaptations in functional coupling of the amygdala to the orbitofrontal cortex were associated with reduced feelings of avoidance toward others and-at the trend level-reduced repetitive behaviors. These observations contribute to a deeper mechanistic understanding of the neural substrates that underlie behavioral effects of multiple-dose IN-OT treatment, and provide initial insights into the long-lasting neural consequences of chronic IN-OT use on amygdala circuitry. Future studies are however warranted to further elucidate the long-term impact of IN-OT treatment on human neural circuitry and its behavioral consequences.

Attachment styles have a modulatory impact on psychophysiological arousal evoked by reciprocated and unreciprocated gaze.
Gaze processing plays an essential role during social interactions. Here, it was investigated whether variations in attachment

style (secure, anxious and avoidant) were associated with differential expressions of sympathetic autonomic arousal upon live dyadic gaze interactions. To do so, 47 participants were presented with either reciprocated or unreciprocated eye gaze from a live model and skin conductance responses (SCRs) were collected. In line with previous observations, SCRs and subjective ratings of arousal were higher in response to reciprocated, compared to unreciprocated gaze. In terms of the modulation by attachment style, it was shown that participants with low attachment security and high attachment avoidance displayed overall higher sympathetic arousal upon the presentation of the live dyadic gaze cues, irrespective of whether the observed model showed reciprocal or unreciprocated gaze. Together, these observations indicate that attachment styles have a modulatory effect on individuals' psychophysiological responses to dyadic gaze interactions.

Eye contact enhances interpersonal motor resonance: comparing video stimuli to a live two-person action context.
Previous research has shown a link between eye contact and interpersonal motor resonance, indicating that the mirroring of observed movements is enhanced when accompanied with mutual eye contact between actor and observer. Here, we further explored the role of eye contact within a naturalistic two-person action context. Twenty-two participants observed simple hand movements combined with direct or averted gaze presented via a live model in a two-person setting or via video recordings, while transcranial magnetic stimulation was applied over the primary motor cortex (M1) to measure changes in M1 excitability. Skin conductance responses and gaze behavior were also measured to investigate the role of arousal and visual attention herein. Eye contact significantly enhanced excitability of the observer's M1 during movement observation within a two-person setting. Notably, participants with higher social responsiveness (Social Communication subscale of the Social Responsiveness Scale) displayed a more pronounced modulation of M1 excitability by eye gaze. Gaze-related modulations in M1 excitability were, however, not associated with differences in visual attention or autonomic arousal. In summary, the current study highlights the effectiveness and feasibility of adopting paradigms with high ecological validity for studying the modulation of mirror system processes by subtle social cues, such as eye gaze.

Multi-method brain imaging reveals impaired representations of number as well as altered connectivity in adults with dyscalculia.
Two hypotheses have been proposed about the etiology of neurodevelopmental learning disorders, such as dyslexia and dyscalculia: representation impairments and disrupted access to representations. We implemented a multi-method brain imaging approach to directly investigate these representation and access hypotheses in dyscalculia, a highly prevalent but understudied neurodevelopmental disorder in learning to calculate. We combined several magnetic resonance imaging methods and analyses, including univariate and multivariate analyses, functional and structural connectivity. Our sample comprised 24 adults with dyscalculia and 24 carefully matched controls. Results showed a clear deficit in the non-symbolic magnitude representations in parietal, temporal and frontal regions, as well as hyper-connectivity in visual brain regions in adults with dyscalculia. Dyscalculia in adults was thereby related to both impaired number representations and altered connectivity in the brain. We conclude that dyscalculia is related to impaired number representations as well as altered access to these representations.

To mirror or not to mirror upon mutual gaze, oxytocin can pave the way: A cross-over randomized placebo-controlled trial.
The eyes constitute a highly salient cue to communicate social intent. Previous research showed that direct eye contact between two individuals can readily evoke an increased propensity to 'mirror' other peoples' actions. Considering the implicated role of the prosocial neuropeptide oxytocin (OXT) in enhancing the saliency of social cues and modulating approach/avoidance motivational tendencies, the current study adopted the non-invasive brain stimulation technique transcranial magnetic stimulation (TMS) to explore whether a single dose of intranasal OXT (24 IU) modulated (enhanced) a person's propensity to show heightened mirroring or motor resonance upon salient social cues, such as eye contact. The study involved a double-blind, placebo-controlled, cross-over trial with twenty-seven healthy adult men (19-32 y). By applying single-pulse TMS over the primary motor cortex during movement observation, it was shown that motor resonance was significantly higher when movement observation was accompanied by direct, compared to averted gaze, but that a single dose of OXT did not uniformly enhance this effect. Significant moderations of the treatment effect were noted however, indicating that participants with high self-reports of attachment avoidance displayed a stronger OXT-treatment effect (enhancement of motor resonance upon direct eye contact), compared to participants with low attachment avoidance. Particularly, while participants with high attachment avoidance initially displayed a reduced propensity to increase their motor resonance upon direct eye contact, a single dose of OXT was able to promote an otherwise avoidant individual's propensity to engage in motor resonance upon a salient social cue such as eye contact.

Long-term oxytocin administration enhances the experience of attachment.
The neuropeptide 'oxytocin' (OT) is known to play a pivotal role in a variety of complex social behaviors by promoting a prosocial attitude and interpersonal bonding. Previous studies showed that a single-dose of exogenously administered OT can affect trust and feelings of attachment insecurity. With the present study, we explored the effects of two weeks of daily OT administration on measures of state and trait attachment using a double-blind between-subjects randomized placebo-controlled design. In 40 healthy young adult men state and trait attachment were assessed before and after two weeks of daily intranasal OT (24 IU) or placebo using the State Adult Attachment Scale and the Inventory of Parent and Peer Attachment. Mood, social responsiveness and quality of life were additionally assessed as secondary outcome measures. Reductions in attachment avoidance and increases in reports of attachment toward peers were reported after two weeks of OT treatment. Further, treatment-induced changes were most pronounced for participants with less secure attachment towards their peers. indicating that normal variance at baseline modulated treatment response. OT treatment was additionally associated with changes in mood, indicating decreases in feelings of tension and (tentatively) anger in the OT group, not in the placebo group. Further, at the end of the two-week trial, both treatment groups (OT, placebo) reported to experience an increase in social responsiveness and quality of life, but the effects were only specific to the OT-treatment in terms of reports on 'social motivation'. In summary, the observed improvements on state and trait dimensions of attachment after a multiple-dose treatment with OT provide further evidence in support of a pivotal role of OT in promoting the experience of attachment.

Direct eye contact enhances mirroring of others' movements: A transcranial magnetic stimulation study.
Direct eye contact is a powerful social cue to regulate interpersonal interactions. Previous behavioral studies showed a link between eye contact and motor mimicry, indicating that the automatic mimicry of observed hand movements is significantly enhanced when direct eye contact exists between the observer and the observed model. In the present study, we aim to investigate the neurophysiological basis of the previously reported behavioral enhancements. Here, transcranial magnetic stimulation (TMS) was applied to assess changes in cortico-motor excitability at the level of the primary motor cortex (M1) to explore whether and how the motor system is facilitated from observing others' hand movements and, in particular, how this process is modulated by eye contact. To do so, motor evoked potentials (MEPs) were collected from two hand muscles while participants received single-pulse TMS and naturally observed video clips of an actor showing hand opening movements or static hands. During the observation, either direct or averted eye gaze was established between the subject and the observed actor. Our findings show a clear effect of eye gaze on observation-induced motor facilitation. This indicates that the mapping or 'mirroring' of others' movements is significantly enhanced when movement observation is accompanied by direct eye gaze compared to averted eye gaze. Our results support the notion that eye contact is a powerful social signal with the ability to direct human non-verbal social behavior. Furthermore, our findings are important for understanding the role of the mirror motor system in the mapping of socially relevant actions.

MALE-FEMALE DIFFERENCES IN SOCIAL BEHAVIOUR OF CNTNAP2 MUTANT MICE CORRELATE WITH DISRUPTED SYNAPTIC CONNECTIVITY IN THE ANTERIOR CINGULATE CORTEX AND INCREASED MICROGLIA ACTIVITY

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Autism spectrum disorders (ASD) is a neurodevelopmental disorder encompassing impairments in social interaction, communication, and the exhibition of rigid and repetitive behaviours. Within the large heterogeneity observed for this disorder, there is an apparent higher incidence in boys than in girls, the aetiology of which is poorly understood. We have obtained data from analysis of a mouse line mutant for the ASD risk gene *Cntnap2*, which suggest that these mice are well suited to model the sex bias in ASD. Behavioural analyses uncover defects in social interactions in male, but not female *Cntnap2* mutant mice. This correlates with reduced spine densities of dendrites of pyramidal neurons in layer 1 of the anterior cingulate cortex (ACC) only in male mutant mice. This region represents an integration area of input from multiple brain regions engaged in processing social interaction, which has often been associated with ASD. Microglia, the brain resident immune cells, are known to be sexually dimorphic and to exert crucial functions in brain development by controlling synapse formation and pruning in an activity-dependent manner. Our analysis shows that in L1 of the ACC, microglia only of male mutant mice exert a higher phagocytotic activity, engulfing and removing synapses. Microglia activity appears unchanged comparing female wildtype and mutant mice. The ongoing focus of our lab is to better understand the nature of this sex-biased microglial activation, which leads to disrupted synapse formation in the ACC and reduced social interactions only in male *Cntnap2* mutant mice.

ENHANCED FEAR MAY LIMIT BEHAVIORAL FLEXIBILITY IN SHANK2 KNOCK-OUT MICE DESPITE OF INTACT LEARNING CAPABILITY

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Miru Yun[1], Eunjoon Kim[2], Min Jung[1]
[1]IBS/KAIST, Bioscience, Daejeon, Korea, Republic of, [2]KAIST (Korea Advanced Institute of Science and Technology) and IBS (Institute for Basic Science), Department Of Biological Sciences And Center For Synaptic Brain Dysfunctions, Daejeon, Korea, Republic of

Impaired behavioral flexibility has been proposed to underlie repetitive and restrictive patterns of behavior associated with autism spectrum disorder (ASD). We investigated whether and how behavioral flexibility is impaired in a mouse model of ASD by testing *Shank2*-knockout (*Shank2*-KO) mice in reversal learning. *Shank2*-KO mice were trained in probabilistic classical conditioning with two odor cues paired with water and air-puff deliveries. Upon the reversal of cue-outcome contingency, male *Shank2*-KO mice were significantly slower than wild-type control mice in reversing their anticipatory licking responses. Male *Shank2*-KO mice also showed stronger anticipatory eye closure responses than wild-type control mice to the air puff. In contrast, female *Shank2*-KO mice were intact in reversal learning and showed normal levels of anticipatory eye closure response. These results raise the possibility that impaired reversal learning in male Shank2-KO mice might be because of enhanced fear. Indeed, male *Shank2*-KO mice showed intact reversal learning when the strong air puff was replaced with a mild air puff. Male *Shank2*-KO mice also showed intact reversal learning between two odor cues predicting reward delivery with different probabilities. These results indicate that enhanced fear may suppress reversal learning despite of intact capability to learn cue-outcome contingency changes in male *Shank2*-KO mice. Our findings suggest that behavioral flexibility may be seriously limited by abnormal emotional responses in ASD.

The present study was designed to investigate the expression level of the cholinergic (alpha 7 nACh and M1) receptors in the medial prefrontal cortex (mPFC) in the behaviorally characterized rat prenatally exposed to valproic acid (VPA). Experiments were carried out on male offspring prenatally exposed to VPA at the age of 6 month. Sociability and preference for social novelty in VPA treated and control rats were evaluated in a three-chambered social interaction test. At the end of the behavioral experiments half of rats from each group were used in in immunoblotting (n = 6) studies. **Results.** The results of the sociability test showed that both groups spent more time in the compartment with an unfamiliar rat compared to an empty wire cage ($P < 0.001$). The results of the social novelty phase showed that the control rat spent more time in the compartment with an unfamiliar rat compared to familiar rat ($P < 0.001$). The preference for the social novelty in VPA treated rats was not statistically significant ($P = 0.377$). Immunoblotting studies revealed that the mean level of cholinergic (alpha 7 nACh and M1) receptors in the mPFC is significantly higher in VPA treated group as compared to control group ($p < 0.05$). **Summury.** Our results demonstrate that deficit of social behavior in the VPA induced rat model of autism is accompanied by significant changes in cholinergic activity in the mPFC. Changes in the balance of excitatory and inhibitory neurotransmission, especially in the early stages of brain development, are considered to be part of the pathophysiology of autism. Recently, several studies have shown that synaptic abnormalities observed in experimental models of autism are associated with deficits in cytoskeletal and scaffolding proteins and their interactions. The aim of the present studies was to evaluate excitatory and inhibitory neurotransmission markers using transgenic "SH3 and multiple Ankyrin repeat domains 3" (*Shank3*) deficient mice that exhibit behavioral symptomatology of autism spectrum disorders. We demonstrated significant differences in the expression of excitatory glutamatergic markers and postsynaptic scaffolding proteins in pups and adult *Shank3* deficient mice depending on a brain region. We observed a decrease in the expression of inhibitory GABAergic markers and GABA receptor subunits in the brain of *Shank3* deficient mice. Further analyzes indicated lower levels of GABAergic markers in the dopaminergic regions of the brain of adult transgenic mice. We confirmed that the deficit in *Shank3* is accompanied by abnormalities in the number and length of neurites in hippocampal neurons. Transient silencing of *Shank3* gene expression has led to reduced levels of some adhesion synaptic proteins (neurexins, neuroligins). These results suggest that abnormalities in *Shank3* lead to an imbalance in the structural proteins involved in both excitatory and inhibitory synapses. Pathophysiological changes in inhibitory neurotransmission in dopaminergic areas of the brain need to be taken into account when explaining the etiology of autism spectrum disorders. Supported by APVV-20-0114, VEGA 2/0148/21, VEGA 2/0155/20, and SK-FR-19-0015.

Mutations in over 100 genes are known to be implicated in autism spectrum disorder (ASD). Transcriptomics analysis of blood samples may offer clues for pathways dysregulated in ASD. To expand and validate findings of published RNA-sequencing (RNA-seq) studies, we performed RNA-seq of whole blood samples from a discovery cohort of eight male children with ASD compared with nine male age-matched neurotypical control children from the Shaare Zedek Medical Center (SZMC), Jerusalem, Israel. Our RNA-seq found 10 genes with differential expression in the ASD samples compared with controls. Using real-time qPCR, we compared whole blood samples from children with ASD and matched neurotypical children from SZMC for the 10 dysregulated genes detected by RNA-seq. Additionally, we compared our RNA-seq findings with whole blood samples of children with ASD from Phoenix Children's Hospital, Arizona, USA. Our qPCR analysis revealed dysregulated expression levels of several genes in the ASD compared to the control group (to be presented at FENS 2022). The implications of the dysregulated genes for pro-inflammatory phenotypes, immunity, and additional ASD-associated phenotypes will be discussed.

CDKL5'S ROLE IN MICROTUBULE-BASED TRANSPORT AND COGNITIVE FUNCTION

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

André Lopes[1], Ondine Janiv[2], Suzanne Claxton[1], Sila Ultanir[1]
[1]Francis Crick Institute, Kinases And Brain Development Laboratory, London, United Kingdom, [2]King's College London, Ioppn, London, United Kingdom

Cyclin-dependent kinase like 5 (CDKL5) is a serine-threonine kinase highly enriched in mammalian neurons. *CDKL5* is located on the X-chromosome and its loss of function leads to a severe neurodevelopmental disorder called CDKL5 deficiency disorder (CDD). Our lab showed that CDKL5 phosphorylates the microtubule-associated protein MAP1S and regulates its binding to microtubules. How CDKL5 phosphorylation affects microtubule function is not well understood. To address this question, we generated MAP1S phosphomutant mice, in which the CDKL5 phosphorylation sites S786 and S812 are mutated to Alanine. Using microtubule co-sedimentation assay, we showed that dynein binding to microtubules is severely reduced in the CDKL5 KO and MAP1S phosphomutant brain lysates. Next, we studied dynein motility in CDKL5 KO or MAP1S phosphomutant neurons and their WT littermates using time-lapse imaging. Data showed impaired dynein motility in both CDKL5 KO and MAP1S phosphomutant neurons. It was previously reported that dendrite-specific cargo, AMPA receptor subunit GluA2, is mislocalized to axons when dynein is inhibited. We found that in HA-GluA2 transfected neurons, GluA2 localization in axons is significantly increased, supporting an impairment of dynein function. We also tested if endogenous cargo transport is altered by CDKL5 phosphorylation by using lysosomal protein Lamp1-RFP. Overall, Lamp1 transport was impaired in dendrites but not in axons. Polarized neurons rely on proper cargo transport and delivery to the synapse. This will regulate synapse formation, maintenance and function which is critical for cognitive function. Behavioral phenotyping of MAP1S phosphomutant mice showed increased anxiety, impaired motor performance, social and memory deficits.

Aims: Autism spectrum disorders (ASD) are complex neurodevelopmental disorders characterized by deficient social communication and interaction together with restricted, stereotyped behaviors. Currently approved treatments relieve comorbidities rather than core symptoms. Since excitation/inhibition balance and synaptic plasticity are disrupted in ASD, molecules targeting excitatory synaptic transmission appear as highly promising candidates to treat this pathology. **Methods:** Among glutamatergic receptors, NMDA receptor has received particular attention along last decade through the development of novel modulators. Here, we evaluated the effects of positive NMDA receptor modulation by the spirocyclic β-lactam platform chemical zelquistinel (AGN-241751 or GATE-251) on autistic-like symptoms in two genetic and one environmental mouse models of ASD, using two routes of administration. **Results:** A single oral dose of zelquistinel rescued, in a dose-response manner, social deficits and stereotypic behavior in *Shank3*$^{\Delta ex13\text{-}16\text{-}/\text{-}}$ mice. Chronic intraperitoneal administration long-lastingly relieved autistic-like features in these mice. Subchronic mid-dose zelquistinel treatment demonstrated durable effects in *Shank3*$^{\Delta ex13\text{-}16\text{-}/\text{-}}$, *Fmr1*$^{-/-}$ and *in utero* valproate-exposed mice. Carry-over effects were best maintained in the *Fmr1* null mouse model, with social parameters being still fully recovered two weeks after treatment withdrawal. **Conclusions:** Among recently developed NMDA receptor modulators subunits, zelquistinel displays a promising therapeutic potential to relieve core symptoms in ASD patients, with oral bioavailability and long-lasting effects boding well for clinical applications. Efficacy in three mouse models with different etiologies supports high translational value. Further, this compound represents an innovative pharmacological tool to investigate plasticity mechanisms underlying behavioral deficits in animal models of ASD.

TWO AUTISM-RELATED MOUSE MODELS – DIFFERENCES IN THE HYPOTHALAMIC GENE EXPRESSION OF SYNAPTIC ADHESION MOLECULES AND INHIBITORY NEUROTRANSMITTER MARKERS

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Denisa Mihalj[1], Jan Bakos[1,2], Françoise Muscatelli[3], Alexandra Reichova[1], Stanislava Bukatova[1], Zuzana Bacova[1]
[1]Biomedical Research Center, Slovak Academy of Sciences, Department Of Neuroscience, Bratislava, Slovak Republic, [2]Faculty of Medicine, Comenius University, Institute Of Physiology, Bratislava, Slovak Republic, [3]Institut de neurobiologie de la méditerranée, INSERM, Aix-marseille University, Marseille, France

Autism spectrum disorder is a neurodevelopmental disease with heterogeneous etiology which is accompanied by defects in social communication and behaviour. Modifications in several genes affecting hypothalamic neuronal cell populations have been suggested to underlie neurodevelopmental abnormalities associated with autistic symptoms. The aim of the present study was to compare gene expression levels of synaptic cell-adhesion molecules and inhibitory neurotransmitter markers in the hypothalamus in two autism-related mouse models at postnatal day 5. *Shank3*- and *Magel2*-deficient mice were used, both known for displaying autism-like behavioral symptoms. We demonstrated significantly higher gene expression levels of cell-adhesion molecules *Neuroligin 2* and *Neurexins 1-2* in the hypothalamus isolated from *Shank3*-deficient mice compared to wild-type animals. Further analysis revealed lower expression levels of GABAergic markers (*Gad65*, *Gad67*) in *Shank3*-deficient mice. In contrast, we found higher gene expression levels of *Neuroligin 2* in *Magel2*-deficient mice, with no such changes observed in the gene expression of *Neurexin 1-2,* when compared to wild-type animals. Reduced expression of some inhibitory GABAergic markers (*Gad65, vGat*) and GABA receptor subunits (*Gabra2*) was found in *Magel2*-deficient mice. Overall, it appears that autism-like conditions are associated with a disrupted balance of cell-adhesion molecules essential for the formation of inhibitory synapses, which is reinforced by observation of altered expression GABAergic markers. In a view of our previous results using these mouse models, alterations in the ratio of excitatory and inhibitory synapses, especially in the early periods of postnatal brain development, are suggested in etiology of autism. Supported by VEGA 2/0148/21, VEGA 2/0155/20 and SK-FR-19-0015.

FACE PERCEPTION AND AUTISTIC TRAITS

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Johan Pieslinger[1], Kajsa Igelström[2]
[1]Linköping University, Department Of Biomedical And Clinical Sciences, Linköping, Sweden, [2]Linköping University, Department Of Biomedical And Clinical Sciences, Linköping University, Sweden

Developmental prosopagnosia, or face blindness, can severely affect higher-order social functions. Prosopagnosia is more common in autism than in the general population and has been suggested to be a potential endophenotype. We hypothesized that poor face recognition predicts socio-communicative autistic traits in a dimensional rather than categorical manner. We recruited 157 adults to an online experiment using the Prolific.co and Gorilla.sc platforms. Subjective face processing deficits were measured with the Prosopagnosia Index 20 (PI-20), and face recognition accuracy was measured with the Oxford Face Matching Task (OFMT). Social and nonsocial (e.g., rigidity) autistic traits were measured with the Comprehensive Autistic Traits Inventory (CATI-Social and CATI-RRB factor scores, respectively). In support of the hypothesis, we found that social autistic traits predicted poor face recognition, whereas the non-social traits did not.

MODALITY-SPECIFIC ASSOCIATIONS OF SENSORY DEFICITS WITH AUTISTIC TRAITS

POSTER SESSION 06 - SECTION: AUTISM SPECTRUM DISORDERS

Peter Bang, Kajsa Igelström
Linköping University, Department Of Biomedical And Clinical Sciences, Linköping, Sweden

Atypical sensory processing measured by self- or parent-report co-segregates with quantitative autistic traits (QAT) and has potential endophenotypic properties. It is not known whether this reflects a generalized sensory dysfunction or combinations of modality-specific mechanisms. We combined a Bayesian variable selection method with dominance analysis to obtain a more nuanced understanding of modality-specific associations. We recruited two independent cohorts of adults online to complete the Broad Autism Phenotype Questionnaire and the Glasgow Sensory Questionnaire (GSQ). For each QAT, we performed stochastic search variable selection (SSVS) on GSQ subscales to test which modalities predicted QAT while controlling for uncertainty in the other variables. Dominance analysis was applied to the models identified by SSVS to evaluate the modalities' relative importance in predicting QAT. Only auditory scores reliably predicted all QATs when other modalities were accounted for. The proprioceptive scale, which included motor and interoceptive deficits, specifically predicted communicative QAT. The tactile scale, which included atypical touch/pain/temperature processing, specifically predicted social QAT. Although the findings must be interpreted in light of the limitations of the questionnaires, the study suggests that deficits in the auditory modality may be more likely than those in other senses to be a sensory endophenotype relevant to autism.

BACKGROUND Fragile X syndrome (FXS) is characterized by physical abnormalities, anxiety, intellectual disability, hyperactivity, autistic behaviors and seizures. Abnormal neuronal development in Fragile X syndrome (FXS) is poorly understood. Data on FXS patients remain scarce and FXS animal models have failed to yield successful therapies. *In vitro* models do not fully recapitulate the morphology and function of human neurons. METHODS To mimick human neuron development *in vivo*, we co-injected neural precursor cells from FXS patient-derived and corrected isogenic control induced pluripotent stem cells into the brain of neonatal immune-deprived mice. RESULTS The transplanted cells populated the brain and a proportion differentiated into neurons and glial cells. Immunofluorescence and single and bulk RNA sequencing analyses showed accelerated maturation of FXS neurons after an initial delay. Additionally, increased percentages of Arc- and Egr1-positive FXS neurons and wider dendritic protrusions of mature FXS striatal medium spiny neurons suggested an increase in synaptic activity and synaptic strength as compared to control. CONCLUSIONS This transplantation approach provides new insights into the alterations of neuronal development in FXS by facilitating physiological development of cells in a 3D context.

Aims: Microglia, the tissue-resident macrophages of the central nervous system, actively participate in brain development by supporting neuronal maturation and refining synaptic connections. Accumulating evidence points towards the involvement of cellular metabolism in the regulation of immune cells, including microglia. In particular, lactate, which is key to sustain synaptic activity, also modulates responses of peripheral immune cells. However, its effect on microglia is largely unknown. Here, we aim to shed light on lactate's physiological roles in the modulation of microglial function. **Methods**: We combined confocal microscopy and biochemical assays to investigate how primary microglial cultures respond to lactate exposure. We next generated and characterized a conditional knock out (cKO) mouse model for the monocarboxylate transporter 4 (MCT4), aiming to selectively impair microglial lactate transport. **Results**: We found that lactate exposure leads to the upregulation of MCT4 in microglia. Exogenously given lactate is readily shuttled into primary microglia, and correlates with an increase in lysosomal acidification. Primary cKO microglia exhibit reduced uptake of amyloid beta, a well-known microglial cargo. Two weeks-old cKO mice present alterations in hippocampal microglial density and in CD68+ phagolysosomal structures. This is associated with increased levels of presynaptic markers, indicating that microglial MCT4 depletion is sufficient to affect neuronal circuitries development. In adulthood, cKO mice display an anxiety-like phenotype. **Conclusions**: In summary, this study highlights the importance of microglial MCT4 for brain maturation. Given the established role of microglia in neuropathology, a mechanistic understanding of lactate-dependent microglial modulation may be relevant for targeting microglia in brain diseases.

Microglial metabolic flexibility: emerging roles for lactate.
Microglia, the resident macrophages of the central nervous system (CNS), play important functions in the healthy and diseased brain. In the emerging field of immunometabolism, progress has been made in understanding how cellular metabolism can orchestrate the key responses of tissue macrophages, such as phagocytosis and inflammation. However, very little is known about the metabolic control of microglia. Lactate, now recognized as a crucial metabolite and a central substrate in metabolic flexibility, is emerging not only as a novel bioenergetic fuel for microglial metabolism but also as a potential modulator of cellular function. Parallels with macrophages will help in understanding how microglial lactate metabolism is implicated in brain physiology and pathology, and how it could be targeted for therapeutic purposes.

All-polymeric transient neural probe for prolonged in-vivo electrophysiological recordings.
Transient bioelectronics has grown fast, opening possibilities never thought before. In medicine, transient implantable devices are interesting because they could eliminate the risks related to surgical retrieval and reduce the chronic foreign body reaction. Despite recent progress in this area, the potential of transient bioelectronics is still limited by their short functional lifetime owed to the fast dissolution rate of degradable metals, which is typically a few days or weeks. Here we report that a switch from degradable metals to an entirely polymer-based approach allows for a slower degradation process and a longer lifetime of the transient probe, thus opening new possibilities for transient medical devices. As a proof-of-concept, we fabricated all-polymeric transient neural probes that can monitor brain activity in mice for a few months, rather than a few days or weeks. Also, we extensively evaluated the foreign body reaction around the implant during the probe degradation. This kind of devices might pave the way for several applications in neuroprosthetics.

Comparative Gene Expression Analysis of Two Mouse Models of Autism: Transcriptome Profiling of the BTBR and En2 (-/-) Hippocampus.
Autism spectrum disorders (ASD) are characterized by a high degree of genetic heterogeneity. Genomic studies identified common pathological processes underlying the heterogeneous clinical manifestations of ASD, and transcriptome analyses revealed that gene networks involved in synapse development, neuronal activity, and immune function are deregulated in ASD. Mouse models provide unique tools to investigate the neurobiological basis of ASD; however, a comprehensive approach to identify transcriptional abnormalities in different ASD models has never been performed. Here we used two well-recognized ASD mouse models, BTBR T(+) Itpr3 (tf) /J (BTBR) and Engrailed-2 knockout (En2 (-/-)), to identify conserved ASD-related molecular signatures. En2 (-/-) mice bear a mutation within the EN2 transcription factor homeobox, while BTBR is an inbred strain with unknown genetic defects. Hippocampal RNA samples from BTBR, En2 (-/-) and respective control (C57Bl/6J and En2 (+/+)) adult mice were assessed for differential gene expression using microarrays. A total of 153 genes were similarly deregulated in the BTBR and En2 (-/-) hippocampus. Mouse phenotype and gene ontology enrichment analyses were performed on BTBR and En2 (-/-) hippocampal differentially expressed genes (DEGs). Pathways represented in both BTBR and En2 (-/-) hippocampal DEGs included abnormal behavioral response and chemokine/MAP kinase signaling. Genes involved in abnormal function of the immune system and abnormal synaptic transmission/seizures were significantly represented among BTBR and En2 (-/-) DEGs, respectively. Interestingly, both BTBR and En2 (-/-) hippocampal DEGs showed a significant enrichment of ASD and schizophrenia (SCZ)-associated genes. Specific gene sets were enriched in the two models: microglial genes were significantly enriched among BTBR DEGs, whereas GABAergic/glutamatergic postsynaptic genes, FMRP-interacting genes and epilepsy-related genes were significantly enriched among En2 (-/-) DEGs. Weighted correlation network analysis (WGCNA) performed on BTBR and En2 (-/-) hippocampal transcriptomes together identified six modules significantly enriched in ASD-related genes. Each of these modules showed a specific enrichment profile in neuronal and glial genes, as well as in genes associated to ASD comorbidities such as epilepsy and SCZ. Our data reveal significant transcriptional similarities and differences between the BTBR and En2 (-/-) hippocampus, indicating that transcriptome analysis of ASD mouse models may contribute to identify novel molecular targets for pharmacological studies.

ANALYSIS OF ALZHEIMER'S DISEASE-RELATED SYNAPTIC ALTERATIONS USING MICROFLUIDIC MICROGLIA/NEURON CO-CULTURES

POSTER SESSION 06 - SECTION: GLIA AND DISORDERS OF THE NERVOUS SYSTEM

Dolores Siedlecki-Wullich, Anne-Marie Ayral, Jean-Charles Lambert, Devrim Kilinc
Institut Pasteur de Lille, Inserm U1167 - Université De Lille – Chu De Lille –labex Distalz, Lille, France

Aims Microglial cells are resident macrophages of the central nervous system. Genome-wide association studies identified numerous Alzheimer's disease (AD) risk genes highly or exclusively expressed in microglia, supporting their role as major players in AD pathogenesis. We aim to describe the effect of microglia activation on synaptic connectivity and its potential modulation by AD risk genes.
Methods We developed a microfluidic co-culture device where fluidically isolated, mature neuronal synapses are brought in contact with microglia, enabling exclusive genetic and pharmacological interventions to neurons and microglia. We cultured cortical neurons from WT embryonic mice in pre- and postsynaptic chambers for 7 days, after which primary microglia from 10-month-old WT and APP (hAPPJ20, PDGFAPPSw,Ind) mice were added into the synapse chamber. Microglia morphology and synaptic connectivity near microglia were analyzed via immunocytochemistry and confocal microscopy.
Results Exposure to lipopolysaccharide (LPS) activated microglia as evidenced by decreased surface area and increased circularity. Morphological changes were correlated with Interleukin-1 concentration in the medium, indicative of an inflammatory response. We observed a higher sensitivity to LPS in microglia from APP mice compared to WT mice. However, the level of neuronal network disruption near microglia was similar for WT and APP mice.
Conclusions Our microfluidic co-culture device enables specific modulation and high-content analysis of microglial activity and synaptic connectivity in physiological and AD pathological conditions. On-going work is focused on live-cell recordings with fluorescent microglia to characterize their dynamic response to amyloid-β and on harvesting microglia from mice carrying mutations for microglia-related AD risk genes.

ABSENCE OF FKBP51 IN MURINE MICROGLIA LEADS TO IMPAIRED RESPONSE TO NEUROINFLAMMATORY STIMULUS

POSTER SESSION 06 - SECTION: GLIA AND DISORDERS OF THE NERVOUS SYSTEM

Shiladitya Mitra
Max Planck Institute of Psychiatry, Neurobiology Of Stress Resilience, München, Germany

Microglia are one of the major types of glial cells that are essential for normal functioning of the brain. They have a range of functions that extend from protecting the neurons from external threats like infections, to pruning synapses for proper neuronal communications. Microglia can have both anti-inflammatory as well as pro-inflammatory responses, which can lead to neurodegeneration, depending upon the stimulus. Here we studied the role of the co-chaperone FKBP51, a protein closely associated with the stress response and a modulator of glucocorticoid receptor function, in microglia. Mice with microglia specific deletion of FKBP51 were analyzed for behavioral changes using paradigms like Open Field Test, Elevated Plus Maze Test, Social Interaction Test and Home Cage Locomotion Test. They were subsequently exposed to bacterial lipo-polysaccharide (LPS) known to elicit inflammatory response and investigated for behavioral, histopathological and molecular changes. Analysis revealed that the microglia specific deletion of FKBP51 led to reduced anxiety-like behavior along with attenuated response to LPS featured by morphological differences in *Fkbp5*$^{-/-}$ microglia as compared to controls in-vivo, which was concurrent with an in-vitro model. These results not only throw light on the microglia function and homeostasis, but add to our understanding of the role of microglia in stress response on the whole.

Background: Neuroinflammation plays a main role in inducing neurological impairment in many pathological situations including hyperammonemia and hepatic encephalopathy. Hyperammonemic rats show increased GABAergic neurotransmission and neuroinflammation in cerebellum and hippocampus which lead to motor incoordination and cognitive impairment. We proposed that reducing GABAergic neurotransmission may reduce neuroinflammation in many pathologies. Golexanolone (also known as GR3027) reduces the potentiation of $GABA_A$ receptors by neurosteroids such as allopregnanolone. **Aims:** to assess if reducing GABAergic neurotransmission in hyperammonemic rats using golexanolone reduces neuroinflammation in hippocampus and cerebellum and restores cognitive function and motor coordination. **Methods:** rats were made hyperammonemic by feeding them an ammonium containing diet. After one week of hyperammonemia, golexanolone was administered daily, using intra-gastric probes. Motor coordination and cognitive function were analyzed after 2-3 weeks of treatment with golexanolone and neuroinflammation at 4 weeks of treatment. **Results:** Hyperammonemic rats show microglia and astrocytes activation in cerebellum associated with impaired motor coordination as assessed in the motorater and CatWalk. They also show microglia and astrocytes activation in hippocampus, associated with impaired spatial memory in the novel object location test and short-term memory in a Y maze. Treatment of hyperammonemic rats with golexanolone reversed microglia and astrocytes activation in cerebellum and hippocampus and restored motor coordination and spatial and short-term memory. **Conclusions:** reducing $GABA_A$ receptors activation by treatment with golexanolone could reduce neuroinflammation and improve cognitive and motor function in patients with hepatic encephalopathy and, likely, in other pathologies associated with neuroinflammation.

Major depressive disorder (MDD) is a severe and debilitating mental illness with a very large socioeconomic impact worldwide. The neurobiology of this disease has been studied for a long time, focused on neuronal alterations; however, the underlying etiology is not yet fully understood. Astrocytes, a glial cell type, have been shown to play relevant roles in synaptic transmission and plasticity, with significant impact on behavioral responses. Evidence collected from human samples and animal models have shown that astrocytes shown particular alterations that might contribute to the pathophysiology of MDD. Here, we aim to investigate the role of astrocytes and their intracellular calcium signaling in this mental disease. Using a corticosterone treatment approach as depressive-like mouse model, we have evaluated the features of astrocyte Ca^{2+} signaling in medial prefrontal cortex (mPFC) from naïve and MDD mice, as well as the impact of astrocytic manipulations for animal behavior. Results: 1- *In vivo* spontaneous and behaviorally-related astrocyte Ca^{2+} signaling was altered in MDD mice. 2- Serotonin-evoked astrocyte Ca^{2+} dynamics were reduced in mPFC slices from MDD mice. 3- Selective chemogenetic activation of astrocytes by Gq-DREADDs in mPFC was able to restore the behavioral deficits shown by MDD mice. Although additional experiments are required, these results reveal the potential impact of astrocyte Ca^{2+} signaling in the pathophysiology of MDD.

Metabolic Changes in Brain Slices over Time: a Multiplatform Metabolomics Approach.
Brain slice preparations are widely used for research in neuroscience. However, a high-quality preparation is essential and there is no consensus regarding stable parameters that can be used to define the status of the brain slice preparation after its collection at different time points. Thus, it is critical to fully characterize the experimental conditions for ex vivo studies using brain slices for electrophysiological recording. In this study, we used a multiplatform (LC-MS and GC-MS) untargeted metabolomics-based approach to shed light on the metabolome and lipidome changes taking place at different time intervals during the brain slice preparation process. We have found significant modifications in the levels of 300 compounds, including several lipid classes and their derivatives, as well as metabolites involved in the GABAergic pathway and the TCA cycle. All these preparation-dependent changes in the brain biochemistry related to the time interval should be taken into consideration for future studies to facilitate non-biased interpretations of the experimental results.

Sex-dependent calcium hyperactivity due to lysosomal-related dysfunction in astrocytes from APOE4 versus APOE3 gene targeted replacement mice.
The apolipoprotein E (APOE) gene exists in three isoforms in humans: APOE2, APOE3 and APOE4. APOE4 causes structural and functional alterations in normal brains, and is the strongest genetic risk factor of the sporadic form of Alzheimer's disease (LOAD). Research on APOE4 has mainly focused on the neuronal damage caused by defective cholesterol transport and exacerbated amyloid-β and Tau pathology. The impact of APOE4 on non-neuronal cell functions has been overlooked. Astrocytes, the main producers of ApoE in the healthy brain, are building blocks of neural circuits, and Ca signaling is the basis of their excitability. Because APOE4 modifies membrane-lipid composition, and lipids regulate Ca channels, we determined whether APOE4 dysregulates Casignaling in astrocytes.

Melanopsin for Time-Controlling Activation of Astrocyte -Neuron Networks.
Melanopsin, a mammalian G-protein-coupled photopigment, is a novel optical tool which enables studying astrocyte-neuron

networks. Here, we describe the required guidelines to take advantage of this promising optical tool for functional neuron-glia studies. The selective expression of melanopsin in astrocytes allows triggering astrocytic Ca signaling, changes in synaptic transmission, and modifying behavioral responses.

Astrocyte-Neuron Networks: A Multilane Highway of Signaling for Homeostatic Brain Function.
Research on glial cells over the past 30 years has confirmed the critical role of astrocytes in pathophysiological brain states. However, most of our knowledge about astrocyte physiology and of the interactions between astrocytes and neurons is based on the premises that astrocytes constitute a homogeneous cell type, without considering the particular properties of the circuits or brain nuclei in which the astrocytes are located. Therefore, we argue that more-sophisticated experiments are required to elucidate the specific features of astrocytes in different brain regions, and even within different layers of a particular circuit. Thus, in addition to considering the diverse mechanisms used by astrocytes to communicate with neurons and synaptic partners, it is necessary to take into account the cellular heterogeneity that likely contributes to the outcomes of astrocyte-neuron signaling. In this review article, we briefly summarize the current data regarding the anatomical, molecular and functional properties of astrocyte-neuron communication, as well as the heterogeneity within this communication.

Aim. Chemotherapy-induced neuropathic pain is a clinically relevant adverse effect of several anticancer drugs leading to dose reduction or therapy discontinuation. The lack of knowledge about the mechanisms of neuropathy development and pain chronicization makes chemotherapy-induced neuropathic pain treatment an unmet medical need. In this context, the vascular endothelial growth factor A (VEGF-A) has emerged as a neurotoxicity biomarker in a model of chemotherapy-induced neuropathy, and its decrease has been related to pain relief. Aim was to clarify the VEGF-A-dependent pain signaling in the CNS for individuating new targeted therapeutic approaches. **Methods.** CD-1 male mice were used to investigate the role of VEGF-A/VEGFR-1 in pain signal using pharmacological and genetics tools. Models of neuropathy induced by anticancer drugs were used to study the pain relieving properties of the anti-VEGFR-1 mAb D16F7. **Results.** The intrathecal infusion of VEGF-A induced a dose-dependent noxious hypersensitivity mediated by the VEGF receptor 1 (VEGFR-1). In electrophysiological study, VEGF-A stimulated the spinal nociceptive neurons activity through VEGFR-1. In the spinal cord, VEGF-A increased in astrocytes of animals affected by neuropathy suggesting this cell population as a source of the potent pain mediator. Accordingly, the selective knockdown of astrocytic VEGF-A, by shRNAmir, blocked the development of oxaliplatin-induced neuropathic pain. Besides, D16F7 (previously described as anticancer) effectively relieved neuropathic pain induced by chemotherapeutic agents. **Conclusion.** Astrocyte-released VEGF-A is a new player in the complex neuron-glia network that oversees physiological and pathological pain and D16F7 mAb rises as a potent pain killer strategy.

Restorative and pain-relieving effects of fibroin in preclinical models of tendinopathy.
The term tendinopathy indicates a wide spectrum of conditions characterized by alterations in tendon tissue homeostatic response and damage to the extracellular matrix. The current pharmacological approach involves the use of nonsteroidal anti-inflammatory drugs and corticosteroids often with unsatisfactory results, making essential the identification of new treatments. In this study, the pro-regenerative and protective effects of an aqueous fibroin solution (0.5-500 μg/mL) against glucose oxidase (GOx)-induced damage in rat tenocytes were investigated. Then, fibroin anti-hyperalgesic and protective actions were evaluated in two models of tendinopathy induced in rats by collagenase or carrageenan injection, respectively. In vitro, 5-10 μg/mL fibroin per se increased cell viability and reverted the morphological alterations caused by GOx (0.1 U/mL). Fibroin 10 μg/mL evoked proliferative signaling upregulating the expression of decorin, scleraxin, tenomodulin ($p < 0.001$), FGF-2, and tenascin-C ($p < 0.01$) genes. Fibroin enhanced the basal FGF-2 and MMP-9 protein concentrations and prevented their GOx-mediated decrease. Furthermore, fibroin positively modulated the production of collagen type I. In vivo, the peri-tendinous injection of fibroin (5 mg) reduced the development of spontaneous pain and hypersensitivity ($p < 0.01$) induced by the intra-tendinous injection of collagenase; the efficacy was comparable to that of triamcinolone. The pain-relieving action of fibroin (peri-tendinous) was confirmed in the model of tendinopathy induced by carrageenan (intra-tendinous) where this fibrous protein was also able to improve tendon matrix organization, normalizing the orientation of collagen fibers. In conclusion, the use of fibroin in tendinopathies is suggested taking advantage of its excellent mechanical properties, pain-relieving effects, and ability to promote tissue regeneration processes.

The Histamine H Receptor Participates in the Anti-Neuropathic Effect of the Adenosine A Receptor Agonist IB-MECA: Role of CD4 T Cells.
A adenosine receptor (AAR) agonists have emerged as potent relievers of neuropathic pain by a T cell-mediated production of IL-10. The H histamine receptor (HR), also implicated in pain modulation, is expressed on T cells playing a preeminent role in its activation and release of IL-10. To improve the therapeutic opportunities, this study aimed to verify the hypothesis of a possible cross-talk between AAR and HR in the resolution of neuropathic pain. In the mouse model of Chronic Constriction Injury (CCI), the acute intraperitoneal co-administration of the AAR agonist IB-MECA (0.5 mg/kg) and the HR agonist VUF 8430 (10 mg/kg), were additive in counteracting mechano-allodynia increasing IL-10 plasma levels. In HR mice, IB-MECA activity was reduced, lower pain relief and lower modulation of plasma IL-1β, TNF-α, IL-6 and IL-10 were shown. The complete anti-allodynia effect of IB-MECA in HR mice was restored after intravenous administration of CD4 T cells obtained from naïve wild type mice. In conclusion, a role of the histaminergic system in the mechanism of AAR-mediated neuropathic pain relief was suggested highlighting the driving force evoked by CD4 T cells throughout IL-10 up-regulation.

VEGF-A/VEGFR-1 signalling and chemotherapy-induced neuropathic pain: therapeutic potential of a novel anti-VEGFR-1 monoclonal antibody.
Neuropathic pain is a clinically relevant adverse effect of several anticancer drugs that markedly impairs patients' quality of life and frequently leads to dose reduction or therapy discontinuation. The poor knowledge about the mechanisms involved in neuropathy development and pain chronicization, and the lack of effective therapies, make treatment of chemotherapy-induced neuropathic pain an unmet medical need. In this context, the vascular endothelial growth factor A (VEGF-A) has emerged as a candidate neuropathy hallmark and its decrease has been related to pain relief. In the present study, we have investigated the role of VEGF-A and its receptors, VEGFR-1 and VEGFR-2, in pain signalling and in chemotherapy-induced neuropathy establishment as well as the therapeutic potential of receptor blockade in the management of pain.

Pain Relieving and Neuroprotective Effects of Non-opioid Compound, DDD-028, in the Rat Model of Paclitaxel-Induced Neuropathy.
Chemotherapy-induced neuropathy (CIN) is a major dose-limiting side effect of anticancer therapy that can compel therapy discontinuation. Inadequate analgesic efficacy of current pharmacological approaches requires the identification of innovative therapeutics and, hence, the purpose of this study is to conduct a preclinical evaluation of the efficacy of DDD-028, a versatile pentacyclic pyridoindole derivative, against paclitaxel-induced neuropathic pain. In two separate experiments, DDD-028 was administered per os acutely (1-25 mg kg) or repeatedly (10 mg kg) in paclitaxel-treated rats. The response to mechanical noxious stimulus (paw pressure) as well as to non-noxious mechanical (von Frey) and thermal (cold plate) stimuli was investigated. Acute administration of DDD-028 induced a dose-dependent anti-neuropathic pain effect in all tests performed. Further, repeated daily treatment for 18 consecutive days (starting the first day of paclitaxel administration) significantly reduced the development of pain over time without the development of tolerance to the anti-hyperalgesic effect. Ex vivo analysis showed that DDD-028 was able to reduce oxidative damage of dorsal root ganglia as evidenced by the increase in the level of carbonylated proteins and the decrease in catalase activity. In the lumbar spinal cord, periaqueductal gray matter, thalamus, and somatosensory cortex 1, DDD-28 significantly prevented the activation of microglia and astrocytes. The pharmacodynamic study revealed that the pain-relieving effects of DDD-028 were fully blocked by both the non-selective nicotinic receptor (nAChR) antagonist mecamylamine and by the selective α7 nAChR antagonist methyllycaconitine. In conclusion, DDD-028 was active in reducing paclitaxel-induced neuropathic pain after single or repeated administrations without tolerance development and displaying a double symptomatic and neuroprotective profile. DDD-028 could represent a valuable candidate for the treatment of CIN.

Efficacy of Extract against Inflammatory Pain: In Vivo Studies in Mice.
(L.) Delile is traditionally used for its beneficial properties. Recently, promising antioxidant and anti-inflammatory biological properties emerged through studying the in vitro activity of the ethanolic leaves extract (POE). The present study aims to investigate the anti-inflammatory and analgesic role of POE in mice. Inflammatory pain was modeled in CD-1 mice by the intraplantar injection of carrageenan, interleukin IL-1β and formalin. Pain threshold was measured by von Frey and paw pressure tests. Nociceptive pain was studied by the hot-plate test. POE (10-100 mg kg) was administered per os. The paw

soft tissue of carrageenan-treated animals was analyzed to measure anti-inflammatory and antioxidant effects. POE exerted a dose-dependent, acute anti-inflammatory effect able to counteract carrageenan-induced pain and paw oedema. Similar anti-hyperalgesic and anti-allodynic results were obtained when inflammation was induced by IL-1β. In the formalin test, the pre-treatment with POE significantly reduced the nocifensive behavior. Moreover, POE was able to evoke an analgesic effect in naïve animals. Ex vivo, POE reduced the myeloperoxidase activity as well as TNF-α and IL-1β levels; further antioxidant properties were highlighted as a reduction in NO concentration. POE is the candidate for a new valid strategy against inflammation and pain.

The Use of the Selective Imidazoline I Receptor Agonist Carbophenyline as a Strategy for Neuropathic Pain Relief: Preclinical Evaluation in a Mouse Model of Oxaliplatin-Induced Neurotoxicity.
Anti-cancer therapy based on the repeated administration of oxaliplatin is limited by the development of a disabling neuropathic syndrome with detrimental effects on the patient's quality of life. The lack of effective pharmacological approaches calls for the identification of innovative therapeutic strategies based on new targets. We focused our attention on the imidazoline I receptor (I-R) and in particular on the selective I-R agonist 2-(1-([1,1'-biphenyl]-2-yl)propan-2-yl)-4,5-dihydro-1H-imidazole) (carbophenyline). The purpose of this work was the preclinical evaluation of the efficacy of carbophenyline on oxaliplatin-induced neuropathic pain in mice. Carbophenyline, acutely per os administered (0.1-10 mg kg), induced a dose-dependent anti-hyperalgesic effect that was completely blocked by the pre-treatment with the I-R antagonist 3 or the I/α receptor antagonist efaroxan, confirming the I-R-dependent mechanism. Conversely, pre-treatment with the I-R antagonist BU224 did not block the anti-nociceptive effect evoked by carbophenyline. Repeated oral administrations of carbophenyline (1 mg kg) for 14 days, starting from the first day of oxaliplatin injection, counteracted the development of neuropathic pain in all behavioral tests (cold plate, Von Frey, and paw pressure tests) carried out 24 h after the last carbophenyline treatment on days 7 and 14. In the dorsal horn of the spinal cord, carbophenyline significantly decreased the oxaliplatin-induced astrocyte activation detected by immunofluorescence staining by the specific labelling with GFAP antibody. In conclusion, carbophenyline showed anti-neuropathic properties both after acute and chronic treatment with preventive effect against oxaliplatin-induced astrocyte activation in the spinal cord. Therefore, I-R agonists emerge as a new class of candidates for the management of oxaliplatin-induced neuropathic pain.

Intranasal Low-Dose Naltrexone Against Opioid Side Effects: A Preclinical Study.
Opioids are broad spectrum analgesics that are an integral part of the therapeutic armamentarium to combat pain in the clinical practice. Unfortunately, together with analgesia, a number of adverse effects can occur such as nausea, vomiting, constipation, gastrointestinal alterations and cognitive impairments. Naltrexone is a competitive antagonist of opioid receptors commonly used to treat opioid addiction; its oral use against agonists side effects is limited by the decrease of opioids-therapeutic efficacy and own adverse effects. The intranasal delivery of naltrexone could offer a quick and effective achievement of CNS based on extracellular mechanisms including perineural and perivascular transport. The aim of the study was to test the efficacy of intranasal low-dose naltrexone in reducing intraperitoneal morphine and oxycodone side effects in rodents. In mice, 1 μg naltrexone intranasally administered 30 min before opioids reduced cognitive impairments and motor alteration induced by 10 mg kg morphine and 60 mg kg oxycodone in the Passive avoidance and Rota rod tests, respectively. Moreover, naltrexone rebalanced opioid-induced reduction of the intestinal transit and latency of feces expulsion as well as food intake inhibition. Importantly, 1 μg naltrexone instillation did not block analgesia as demonstrated by the Hot plate test. In rats, intranasal naltrexone counteracted the opioid-induced pica phenomenon related to emesis and increased water and palatable food intake. The effects were comparable to that achieved by metoclopramide used as reference drug. Treatments did not influence body weight. Lastly, the safety of the intranasal delivery has been checked by hematoxylin-eosin staining that did not show histological alterations of the nasal cavity. In conclusion, intranasal low-dose naltrexone counteracted morphine and oxycodone induced gastrointestinal and CNS side effects without impairing opioid analgesia. It is a candidate to be a valid clinical strategy deserving deep analysis.

Treatment of Non-Alcoholic Steatosis: Preclinical Study of a New Nutraceutical Multitarget Formulation.
Multifactorial pathogenesis of non-alcoholic steatohepatitis (NASH) disease, a wide-spread liver pathology associated with metabolic alterations triggered by hepatic steatosis, should be hit by multitarget therapeutics. We tested a multicomponent food supplement mixture (AP-NHm), whose components have anti-dislipidemic, antioxidant and anti-inflammatory effects, on in vitro and in vivo models of NASH. In vitro, hepatic cells cultures were treated for 24 h with 0.5 mM oleic acid (OA): in the

co-treatment set cells were co-treated with AP-NH mixtures (AP-NHm, 1:3:10 ratio) and in the post-injury set AP-NHm was added for 48 h after OA damage. In vivo, C57BL/6 mice were fed with high-fat diet (HFD) for 12 weeks, inducing NASH at 7th week, and treated with AP-NHm at two dosages (1:3 ratio) in co-treatment or post-injury protocols, while a control group was fed with a standard diet. In in vitro co-treatment protocol, alterations of redox balance, proinflammatory cytokines release and glucose uptake were restored in a dose-dependent manner, at highest dosages also in post-injury regimen. In both regimens, pathologic dyslipidemias were also ameliorated by AP-NHm. In vivo, high-dose-AP-NHm-co-treated-HFD mice dose-dependently gained less body weight, were protected from dyslipidemia, and showed a lower liver weight. Dose-dependently, AP-NHm treatment lowered hepatic LDL, HDL, triglycerides levels and oxidative damage; co-treatment regimen was anti-inflammatory, reducing TNF-α and IL-8 levels. Hepatic lipidic infiltration significantly decreased in co-treated and post-injury-AP-NHm-HFD animals. The multitarget approach with AP-NHm was effective in preventing and reducing NASH-related pathologic features, warranting for the clinical development of this compound.

Intra-Articular Route for the System of Molecules 14G1862 from : Pain Relieving and Protective Effects in a Rat Model of Osteoarthritis.
Current pharmacological therapies for the management of chronic articular diseases are far from being satisfactory, so new strategies need to be investigated. We tested the intra-articular pain relieving properties of a system of molecules from a characterized extract (14G1862) in a rat model of osteoarthritis induced by monoiodoacetate (MIA). 14G1862 (0.2-2 mg mL) was intra-articularly (i.a.) injected 7 days after MIA, behavioural and histological evaluations were performed 14, 30 and 60 days after treatments. Moreover, the effect of 14G1862 on nitrate production and iNOS expression in RAW 264.7 macrophages stimulated with LPS was assessed. , 14G1862 treatment attenuated LPS-induced NO production and iNOS expression in a comparable manner to celecoxib. , 14G1862 significantly reduced mechanical allodynia and hyperalgesia, spontaneous pain and motor alterations starting on day 14 up to day 60. The efficacy was higher or comparable to that evoked by triamcinolone acetonide (100 µg i.a.) used as reference drug. Histological evaluation highlighted the improvement of several morphological parameters in MIA + 14G1862-treated animals with particularly benefic effects on joint space and fibrin deposition. In conclusion, i.a. treatment with is a candidate to be a novel effective approach for osteoarthritis therapy.

L. Extract: Alpha-Amylase Inhibition against Metabolic Syndrome in Mice.
To examine the effects of the alpha-amylase inhibitor isoform 1 called phaseolamin, a standardized extract from white kidney beans (L) was tested against the hallmarks of metabolic syndrome. The efficacy of a repeated treatment with extract (500 mg/kg) was compared with metformin (100 mg/kg) and atorvastatin (10 mg/kg) in a model of metabolic syndrome evoked by prolonged high fat diet (HFD; week 1 to week 19) in C57BL/6 mice. Bean extract and compounds administration started after metabolic syndrome establishment (week 11). extract reduced the body weight overtime, as well as effectively lowered glycaemia, triglycerides, and cholesterol. On week 19, bean extract normalized the HFD-evoked tolerance to glucose and insulin. According to the phytochemical characterization, it inhibited the alpha-amylase activity. Animals treated with the extract were rescued from motor impairments and nociceptive threshold alterations induced by HFD. Specific organs analysis revealed that extract decreased hepatic steatosis and lipid peroxidation in liver. It protected the heart from HFD oxidative alterations increasing the expression of the detoxifying enzymes catalase and glutathione reductase, and normalizing NADH dehydrogenase level. The histological analysis of aorta showed a protection about the development of fatty streaks in the muscular layers. In conclusion, a prolonged treatment with the standardized extract of significantly reduced several pathological features related to a metabolic syndrome-like condition; a multifactorial approach that candidates this vegetal product as a possible therapeutic option against metabolic syndrome.

Introduction. Alzheimer's disease (AD) is notably characterized by the intraneuronal aggregation of tau proteins which play important roles in synaptic dysfunctions and memory decline. Studies have reported that chronic caffeine consumption reduces AD risk and cognitive deficits. These protective effects would be ascribed to the blockade of adenosine A_{2A} receptors (A_{2A}Rs) which are pathologically upregulated in the hippocampal astrocytes of AD patients and whose levels have been correlated with the development of cognitive deficits. However, the mechanisms underlying the link between astrocytic A_{2A} upregulation and cognitive deficits remain unknown. **Methods.** To uncover effects of astrocytic A_{2A}R upregulation, we intrahippocampally injected an AAV2/9 virus expressing A_{2A}R (AAV-A2A), or GFP as control (AAV-GFP), under a GFAabc1d astrocyte-specific promoter, in 2m-old C57Bl6/J mice. **Results/expected results.** Our data show that A_{2A}R overexpression in hippocampal astrocytes impairs short-term spatial memory (Y-Maze task) and long-term spatial learning (Barnes Maze task). At the network level, thanks to a DREADD approach, we observed an enhanced neuronal activability in the AAV-A2A hippocampus, compared to the control group, characterized by a higher immediate early gene expression. These changes were associated with altered astrocyte reactivity, morphology and transcriptome. **Conclusions.** Our results demonstrate that A_{2A}R upregulation in hippocampal astrocytes, as seen in the brain of AD patients, is sufficient to alter the astrocytic phenotype, neuronal response and memory. Further experiments in AD mouse models will determine how such A_{2A}R deregulation in astrocytes potentiate the development of AD lesions and their consequences, but also whether astrocytic A_{2A}R downregulation is sufficient to bring benefits.

DISCOVERING THE BIOLOGICAL BASIS OF NEURONAL-ACTIVITY INDUCED MYELIN REPAIR

POSTER SESSION 06 - SECTION: GLIA AND DISORDERS OF THE NERVOUS SYSTEM

Dorien Maas[1], Blandine Manot-Saillet[1], Philippe Bun[1], Chloé Habermacher[1], Corinne Poilbout[1], Filippo Rusconi[2], Maria Cecilia Angulo[1,3]

Enhanced neuronal activity in the healthy brain can induce oligodendrocyte differentiation and *de novo* myelination leading to behavioural changes. Accordingly, clinical studies have identified non-invasive brain stimulation as a therapeutic approach to ameliorate symptomatology in demyelinating diseases such as multiple sclerosis (MS). However, it is unknown whether the benefits of brain stimulation are due to improved myelin repair in this disease (Maas & Angulo, 2021, Front Cell Neurosci). Our lab has recently revealed that in lysolecithin demyelinated lesions in the mouse corpus callosum, optogenetic stimulation of demyelinated axons increases the number of differentiated oligodendrocytes and enhances the number of remyelinated axons (Ortiz et al., 2019, JCI Insight). Nevertheless, the exact manner in which neuronal activity instructs oligodendrocytes to differentiate and remyelinate these active axons remains unknown. To investigate this, we have performed calcium imaging in acute slices of demyelinated lesions in PDGFRαCreER +/- Gcamp6 lox/lox mice and found that at 7, 14 and 21 days post lysolecithin injection there was spontaneous calcium signaling in oligodendroglial cells in the lesion that was significantly enhanced after electrical stimulation of axons. We are presently dissecting the signaling pathways mediating neuron-oligodendroglia communication as well as testing whether these pathways are directly involved in activity-dependent remyelination *in vivo*. In the brain, polyamines play fundamental roles in neuron-astrocyte crosstalk. A transgenic mouse overexpressing the enzyme spermine oxidase (SMOX) in neocortical neurons, Dach-SMOX, was developed as model to study the effect of chronic activation of polyamine catabolism in the brain, generating evidence that these molecules are involved in vulnerability to excitotoxic and oxidative damages. **Aim**: This work aimed to investigate whether and how altered polyamine catabolism may impact synaptic transmission, focusing on neuronal and astrocytic counterparts. **Methods**: The effects of SMOX overexpression were evaluated in purified nerve terminals (synaptosomes) and astrocyte processes (gliosomes) from the neocortex of Dach-SMOX mice by assessing polyamine levels, ezrin and vimentin content, AMPA receptor activation, calcium influx, glutamate release, and catalase activity. **Results**: functional GluA2-lacking AMPA receptors are expressed on synaptosomes and gliosomes from Dach-SMOX, and in synaptosomes of control mice. A lower spermine content was observed in Dach-SMOX gliosomes, whereas in Dach-SMOX synaptosomes polyamine levels were unaffected, suggesting that astrocytes may play a pivotal role in maintaining neuronal polyamine levels. Moreover, the up-regulation of catalase, and the increased expression of vimentin and ezrin, suggest the presence of reactive astrocytosis in Dach-SMOX. This condition is correlated to neuronal suffering, characterized by a down-regulation of catalase in Dach-SMOX synaptosomes and impaired control of AMPA-evoked calcium response. **Conclusion**: Chronic activation of SMOX is responsible for crucial changes in astrocytes, including reduced spermine levels, AMPA-evoked calcium influx, and glutamate release. The consequent reactive astrocytosis leads to neuronal suffering and synaptic dysregulation, confirming polyamine involvement in healthy neuron-astrocyte communication.

ASTROCYTE ACTIVITY TRIGGERS ADAPTIVE MYELIN PLASTICITY AND INCREASED NEURONAL EXCITABILITY IN THE SOMATOSENSORY CORTEX FOLLOWING SENSORY DEPRIVATION

POSTER SESSION 06 - SECTION: GLIA AND DISORDERS OF THE NERVOUS SYSTEM

Claudia Miguel-Quesada[1], Alba Fernández-González[1], José Ángel Rodríguez-Alfaro[2], Elvira Brocca[1], Alonso Higuero[1], Marta Zaforas[1], Elena Alonso-Calviño[1], Elena Fernández-López[1], José Rodríguez-Abad[1], Juan Aguilar[1], Juliana M Rosa[1]

Recent data show that horizontal L2/3 axonal projections exhibit increased myelin segments elongation following monocular deprivation. Such adaptive myelin plasticity may improve synaptic efficacy of corticocortical connections with a possible role in cortical maps reorganization after sensory deprivation. Here, we explored the relationship between axonal myelination and cortical reorganization level in distinct layers of the somatosensory cortex following central sensory deprivation. Furthermore, we also investigated the ability of astrocytes, known to provide trophic factors for myelinating glia, to influence the adaptive myelin plasticity. Complete thoracic spinal cord was used to induce sensory deprivation of the cortical areas receiving information from hindlimbs. Fifteen-to-thirty days later, injured and control animals were subjected to electrophysiological recordings using a vertical array lowered into the hindlimb cortex to record evoked potentials in response to contralateral forelimb stimulation. Our experimental design aimed to determine the synaptic connectivity strength between the deprived and intact cortex. Our data showed that sensory deprivation enhanced L2/3 corticocortical connectivity observed as increased response magnitude and slope. Next, we explored whether the increased L2/3 synaptic efficacy was associated to myelin remodelling. While immunostaining against Olig2 showed no changes in deprived nor intact cortices, myelin basic protein staining showed increased intersections and horizontal myelination patterns, indicating increased myelination of corticocortical segments. These changes were not observed in $IP_3R2^{-/-}$ mice exhibiting deficient astrocyte activity, suggesting that astrocytes directly impact myelination. Overall, our data indicate a positive correlation among neuronal excitability and adaptive myelin plasticity that may mediate cortical reorganization through increased L2/3 corticocortical connectivity.

Cortical layer-specific modulation of neuronal activity after sensory deprivation due to spinal cord injury.
Cortical areas have the capacity of large-scale reorganization following sensory deafferentation. However, it remains unclear whether this phenomenon is a unique process that homogeneously affects the entire deprived cortical region or whether it is susceptible to changes depending on neuronal networks across distinct cortical layers. Here, we studied how the local circuitry within each layer of the deafferented cortex forms the basis for neuroplastic changes after immediate thoracic spinal cord injury (SCI) in anaesthetized rats. In vivo electrophysiological recordings from deafferented hindlimb somatosensory cortex showed that SCI induces layer-specific changes mediating evoked and spontaneous activity. In supragranular layer 2/3, SCI increased gamma oscillations and the ability of these neurons to initiate up-states during spontaneous activity, suggesting an altered corticocortical network and/or intrinsic properties that may serve to maintain the excitability of the cortical column after deafferentation. On the other hand, SCI enhanced the infragranular layers' ability to integrate evoked sensory inputs leading to increased and faster neuronal responses. Delayed evoked response onsets were also observed in layer 5/6, suggesting alterations in thalamocortical connectivity. Altogether, our data indicate that SCI immediately modifies the local circuitry within the deafferented cortex allowing supragranular layers to better integrate spontaneous corticocortical information, thus modifying column excitability, and infragranular layers to better integrate evoked sensory inputs to preserve subcortical outputs. These layer-specific neuronal changes may guide the long-term alterations in neuronal excitability and plasticity associated with the rearrangements of somatosensory networks and the appearance of central sensory pathologies usually associated with spinal cord injury. KEY POINTS: Sensory stimulation of forelimb produces cortical evoked responses in the somatosensory hindlimb cortex in a layer-dependent manner. Spinal cord injury favours the input statistics of corticocortical connections between intact and deafferented cortices. After spinal cord injury supragranular layers exhibit better integration of spontaneous corticocortical information while infragranular layers exhibit better integration of evoked

sensory stimulation. Cortical reorganization is a layer-specific phenomenon.

Despite tau major expression in neurons in physiological condition, abnormal forms of tau protein are also detected in astrocytes in diverse form of tauopathies. Here, we aimed to investigate the consequences of primary neuronal tau pathology on astrocytes morphology. We injected intravenously Thy-Tau22 transgenic mice, expressing a double mutant form of the human tau protein in neurons, with a PHP.eB AAV to express tdTomato fluorescent protein specifically in astrocytes. We used three-dimensional (3D) reconstruction to perform a detailed analysis of astrocytes complex morphology in the hippocampus combining confocal microscopy and Imaris software analyses. At 9 months of age, tau astrocytes' arborisation is simplified as compared to WT, whereas it is more ramified at 24 months with more branching points. On going 3D sholl analyses show that morphological changes associated to tauopathy are subregion-dependent, with subicular astrocytes being particularly affected. Principal component analysis indicates that the ramification index and number of branches are essential morphological parameters discriminating WT and tau astrocytes. Interestingly, perivascular astrocytic endfeet diameter significantly changed with age in the subiculum. We expect to unravel how tau pathology-induced morphological changes in astrocytes could affect their functions and interactions with neurons.

Tauopathy is characterized by neurofibrillary tangles composed of intraneuronal aggregates of hyperphosphorylated Tau protein. In Alzheimer's disease (AD), the spreading of tauopathy being highly correlated with the severity of cognitive symptoms, slowing or stopping it might be a valuable therapeutic strategy. To better understand the underlying mechanisms of Tau spreading, and the role of microglia in this phenomenon, focal models obtained by AAV gene transfer are highly relevant. Several models targeting different areas of the central nervous system already exist. However, due to their physical properties, AAV viral particles tend to efficiently diffuse in the cerebral parenchyma, preventing the discrimination between transduced neurons and secondarily affected ones. Here, we targeted retinal ganglion cells (RGCs) to study Tau spreading in the visual pathway, allowing detection of Tau transgene expression all along the RGCs' axons, up to their target in the dorso-lateral geniculate nucleus (dLGN) and superior colliculus (SC) of the thalamus. Tau was hyperphosphorylated in RGCs, as evidenced by positive staining of pSer422 and AT-8 phospho-specific epitopes. Furthermore, cell-counting showed a progressive degeneration of RGCs. To study the role of microglia in tauopathy, we applied this model to TREM2-deficient mice. RGCs death was reduced in these mice, showing that microglial activation is at least in part responsible for neurodegeneration. Despite tauopathy development in RGCs, we were not able to detect Tau spreading to their target neurons in dLGN or SC. Hence, this model will be useful to study the neuron selective vulnerability to Tau propagation due to their nature or environment.

CHRONIC POSTNATAL HM3DQ-DREADD-MEDIATED ACTIVATION OF CAMKIIα-POSITIVE FOREBRAIN EXCITATORY NEURONS MODULATES ADULT GLIAL FUNCTION AND METABOLISM

POSTER SESSION 06 - SECTION: GLIA AND DISORDERS OF THE NERVOUS SYSTEM

Early adversity increases vulnerability to developing adult psychopathology. Across multiple pre-clinical models of early adversity, glial dysfunction and disruption of amino acid neurotransmission systems have been implicated in contributing to the pathophysiology of mood disorders. Our recent study showed that enhancing Gq signaling in forebrain excitatory neurons during the postnatal window can profoundly impact the emergence of anxio-depressive behaviors, and perturb sensorimotor gating, accompanied by altered neuronal glutamate and GABA metabolism. Given prior evidence that glial dysfunction is associated with perturbed mood behaviors, we hypothesized that postnatally enhancing Gq signaling in the forebrain excitatory neurons may impact glial function in adulthood. To address this, we used a CaMKIIα-tTA::TetO-hM3Dq bigenic mouse line, wherein hM3Dq-DREADD is expressed in CaMKIIα-positive forebrain excitatory neurons, and administered clozapine-N-oxide or vehicle from postnatal day 2 to 14 to investigate the impact on glial metabolism and cytoarchitecture. We show that postnatal hM3Dq-mediated activation of forebrain excitatory neurons increases anxiety-like behavior. We also observe a significant decrease in glutamate and GABA metabolic fluxes in glia within the hippocampus and the neocortex using ^{1}H-[^{13}C]-NMR spectroscopy. Further, we are addressing the impact of enhanced postnatal Gq signaling in CaMKIIα-positive neurons on astrocyte cytoarchitecture and transcription of glia-associated genes. Our findings indicate that chemogenetically driving Gq signaling in the postnatal window in forebrain excitatory neurons results in enhanced anxiety-like behaviors in adulthood, correlated with disrupted glial glutamate and GABA metabolism, a feature that is implicated in pathogenesis of mood disorders.

Chronic hM4Di-DREADD-Mediated Chemogenetic Inhibition of Forebrain Excitatory Neurons in Postnatal or Juvenile Life Does Not Alter Adult Mood-Related Behavior.
G-protein-coupled receptors (GPCRs) coupled to G signaling, in particular downstream of monoaminergic neurotransmission, are posited to play a key role during developmental epochs (postnatal and juvenile) in shaping the emergence of adult anxiodepressive behaviors and sensorimotor gating. To address the role of G signaling in these developmental windows, we used a CaMKIIα-tTA::TRE hM4Di bigenic mouse line to express the hM4Di-DREADD (designer receptor exclusively activated by designer drugs) in forebrain excitatory neurons and enhanced G signaling via chronic administration of the DREADD agonist, clozapine--oxide (CNO) in the postnatal window (postnatal days 2-14) or the juvenile window (postnatal days 28-40). We confirmed that the expression of the HA-tagged hM4Di-DREADD was restricted to CaMKIIα-positive neurons in the forebrain, and that the administration of CNO in postnatal or juvenile windows evoked inhibition in forebrain circuits of the hippocampus and cortex, as indicated by a decline in expression of the neuronal activity marker c-Fos. hM4Di-DREADD-mediated inhibition of CaMKIIα-positive forebrain excitatory neurons in postnatal or juvenile life did not impact the weight profile of mouse pups, and also did not influence the normal ontogeny of sensory reflexes. Further, postnatal or juvenile hM4Di-DREADD-mediated inhibition of CaMKIIα-positive forebrain excitatory neurons did not alter anxiety- or despair-like behaviors in adulthood and did not impact sensorimotor gating. Collectively, these results indicate that chemogenetic induction of G signaling in CaMKIIα-positive forebrain excitatory neurons in postnatal and juvenile temporal windows does not appear to impinge on the programming of anxiodepressive behaviors in adulthood.

Exploring the role of framework mutations in enabling breadth of a cross-reactive antibody (CR3022) against the SARS-CoV-2 RBD and its variants of concern.

FENS Forum 2022
9-13 July 2022 | Paris, France

Cross-reactive and broadly neutralizing antibodies against surface proteins of diverse strains of rapidly evolving viral pathogens like SARS-CoV-2 can prevent infection and therefore are crucial for the development of effective universal vaccines. While antibodies typically incorporate mutations in their complementarity determining regions during affinity maturation, mutations in the framework regions have been reported as players in determining properties of broadly neutralizing antibodies against HIV and the Influenza virus. We propose an increase in the cross-reactive potential of CR3022 against the emerging SARS- CoV-2 variants of concern through enhanced conformational flexibility. In this study, we use molecular dynamics simulations, mutagenesis, structural modeling, and docking to explore the role of light chain FWR mutations in CR3022, a SARS-CoV anti-spike (S)-protein antibody cross-reactive to the S-protein receptor binding domain of SARS-CoV-2. Our study shows that single substitutions in the light chain framework region of CR3022 with conserved epitopes across SARS-CoV strains allow targeting of diverse antibody epitope footprints that align with the epitopes of recently-categorized neutralizing antibody classes while enabling binding to more than one strain of SARS-CoV-2. Our study has implications for rapid and evolution-based engineering of broadly neutralizing antibodies and reaffirms the role of framework mutations in effective change of antibody orientation and conformation via improved flexibility.Communicated by Ramaswamy H. Sarma.

Krabbe disease (KD; or Globoid cell leukodystrophy) is an autosomal recessive lysosomal storage disorder caused by deficiency of the galactosylceramidase (GALC) enzyme. No cure is currently available for KD. Clinical applied treatments are supportive only. Recently, we demonstrated that two differently acting autophagy inducers (Lithium and Rapamycin) can improve some KD hallmarks in-vitro, laying the foundation for their in-vivo pre-clinical testing. Here, we test Lithium carbonate in-vivo, in the spontaneous mouse model for KD, the Twitcher (TWI) mouse. The drug is administered ad libitum via drinking water (600 mg/L) starting from post natal day 20. We longitudinally monitor the mouse motor performance through the grip strength, the hanging wire and the rotarod tests, and a set of biochemical parameters related to the KD pathogenesis [i.e. GALC enzymatic activity, psychosine (PSY) accumulation and astrogliosis]. Additionally, we investigate the expression of some crucial markers related to the two pathways that could be altered by Lithium: the autophagy and the β-catenin-dependent pathways. Results demonstrate that Lithium has limited rescue effects on the TWI phenotype, mostly related to muscle strength and body weight. We also show that Lithium, with this administration protocol, is unable to stimulate autophagy in the TWI mice central nervous system, whereas it can restore the β-catenin activation status in the TWI sciatic nerve. Overall, these results give for the first time data about the effect of an autophagy inducer on the TWI mouse, providing intriguing inputs to be considered for possible use of Lithium treatment as supportive therapy for KD.

Brain-targeted enzyme-loaded nanoparticles: A breach through the blood-brain barrier for enzyme replacement therapy in Krabbe disease.
Lysosomal storage disorders (LSDs) result from an enzyme deficiency within lysosomes. The systemic administration of the missing enzyme, however, is not effective in the case of LSDs with central nervous system (CNS)-involvement. Here, an enzyme delivery system based on the encapsulation of cross-linked enzyme aggregates (CLEAs) into poly-(lactide-co-glycolide) (PLGA) nanoparticles (NPs) functionalized with brain targeting peptides (Ang2, g7 or Tf2) is demonstrated for Krabbe disease, a neurodegenerative LSD caused by galactosylceramidase (GALC) deficiency. We first synthesize and characterize Ang2-, g7- and Tf2-targeted GALC CLEA NPs. We study NP cell trafficking and capability to reinstate enzymatic activity in vitro. Then, we successfully test our formulations in the Twitcher mouse. We report enzymatic activity measurements in the nervous system and in accumulation districts upon intraperitoneal injections, demonstrating activity recovery in the brain up to the unaffected mice level. Together, these results open new therapeutic perspectives for all LSDs with major CNS-involvement.

Lithium improves cell viability in psychosine-treated MO3.13 human oligodendrocyte cell line via autophagy activation.
Globoid cell leukodystrophy (GLD) is a rare, rapidly progressing childhood leukodystrophy triggered by deficit of the lysosomal enzyme galactosylceramidase (GALC) and characterized by the accumulation of galactosylsphingosine (psychosine; PSY) in the nervous system. PSY is a cytotoxic sphingolipid, which leads to widespread degeneration of oligodendrocytes and Schwann cells, causing demyelination. Here we report on autophagy in the human oligodendrocyte cell line MO3.13 treated with PSY and exploitation of Li as an autophagy modulator to rescue cell viability. We demonstrate that PSY causes upregulation of the autophagic flux at the level of autophagosome and autolysosome formation and LC3-II expression. We show that pretreatment with Li, a drug clinically used to treat bipolar disorders, can further stimulate

autophagy, improving cell tolerance to PSY. This Li protective effect is found not to be linked to reduction of PSY-induced oxidative stress and might not stem from a reduction of PSY accumulation. These data provide novel information on the intracellular pathways activated during PSY-induced toxicity and suggest the autophagy pathway as a promising novel therapeutic target for ameliorating the GLD phenotype. © 2016 Wiley Periodicals, Inc.

Cross-Linked Enzyme Aggregates as Versatile Tool for Enzyme Delivery: Application to Polymeric Nanoparticles.
Polymeric nanoparticles (NPs) represent one of the most promising tools in nanomedicine and have been extensively studied for the delivery of water-insoluble drugs. However, the efficient loading of therapeutic enzymes and proteins in polymer-based nanostructures remains an open challenge. Here, we report a synthesis method for a new enzyme delivery system based on cross-linked enzyme aggregates (CLEAs) encapsulation into poly(lactide- co-glycolide) (PLGA) NPs. We tested the encapsulation strategy on four enzymes currently investigated for enzyme replacement therapy: palmitoyl protein thioesterase 1 (PPT1; defective in NCL1 disease), galactosylceramidase (GALC; defective in globoid cell leukodystrophy), alpha glucosidase (aGLU; defective in Pompe disease), and beta glucosidase (bGLU; defective in Gaucher's disease). We demonstrated that our system allows encapsulation of enzymes with excellent activity retention (usually around 60%), thus leading to functional and targeted nanostructures suitable for enzyme delivery. We then demonstrated that CLEA NPs efficiently deliver PPT1 in cultured cells, with almost complete enzyme release occurring in 48 h. Finally, we demonstrated that enzymatic activity is fully recovered in primary NCL1 fibroblasts upon treatment with PPT1 CLEA NPs.

Dysregulated autophagy as a new aspect of the molecular pathogenesis of Krabbe disease.
Krabbe disease (KD) is a childhood leukodystrophy with no cure currently available. KD is due to a deficiency of a lysosomal enzyme called galactosyl-ceramidase (GALC) and is characterized by the accumulation in the nervous system of the sphingolipid psychosine (PSY), whose cytotoxic molecular mechanism is not fully known yet. Here, we study the expression of some fundamental autophagy markers (LC3, p62, and Beclin-1) in a KD murine model [the twitcher (TWI) mouse] by immunohistochemistry and Western blot. Moreover, the autophagy molecular process is also shown in primary fibroblasts from TWI and WT mice, with and without PSY treatment. Data demonstrate that large p62 cytoplasmic aggregates are present in the brain of both early and late symptomatic TWI mice. p62 expression is also upregulated in TWI sciatic nerves compared to that measured for WT nerves. In vitro data suggest that this effect might not be fully PSY-driven. Finally, we investigate in vitro the capability of autophagy inducers (Rapamycin, RAP and Resveratrol, RESV) to reinstate the WT phenotype in TWI cells. We show that RAP administration can partially restore the autophagy markers levels, while RESV cannot, indicating a line along which new therapeutic approaches can be developed.

Visual System Impairment in a Mouse Model of Krabbe Disease: The Twitcher Mouse.
Krabbe disease (KD, or globoid cell leukodystrophy; OMIM #245200) is an inherited neurodegenerative condition belonging to the class of the lysosomal storage disorders. It is caused by genetic alterations in the gene encoding for the enzyme galactosylceramidase, which is responsible for cleaving the glycosydic linkage of galatosylsphingosine (psychosine or PSY), a highly cytotoxic molecule. Here, we describe morphological and functional alterations in the visual system of the Twitcher (TWI) mouse, the most used animal model of Krabbe disease. We report in vivo electrophysiological recordings showing defective basic functional properties of the TWI primary visual cortex. In particular, we demonstrate a reduced visual acuity and contrast sensitivity, and a delayed visual response. Specific neuropathological alterations are present in the TWI visual cortex, with reduced myelination, increased astrogliosis and microglia activation, and around the whole brain. Finally, we quantify PSY content in the brain and optic nerves by high-pressure liquid chromatography-mass spectrometry methods. An increasing PSY accumulation with time, the characteristic hallmark of KD, is found in both districts. These results represent the first complete characterization of the TWI visual system. Our data set a baseline for an easy testing of potential therapies for this district, which is also dramatically affected in KD patients.

Capturing Metabolism-Dependent Solvent Dynamics in the Lumen of a Trafficking Lysosome.
The eukaryotic cell compartmentalizes into spatially confined, membrane-enclosed, intracellular structures (e. g., organelles, endosomes, and vesicles). Here, peculiar physicochemical properties of the local environment occur and participate in the regulation of ongoing molecular processes. In spite of the huge amount of available environmental probes, experiments on subcellular structures are severely challenged by their three-dimensional (3D) movement. This bottleneck is tackled here by

focusing an excitation light beam in a periodic orbit around the structure of interest. The recorded signal is used as feedback to localize the structure position at high temporal resolution: microseconds along the orbit, milliseconds between orbits. The lysosome is selected as the intracellular target, together with 6-acetyl-2-dimethylaminonaphthalene (ACDAN) as probe of the physicochemical properties of the intralysosomal environment. Generalized polarization (GP) analysis of ACDAN emission is used to get a quantitative view on intralysosomal solvent dipolar relaxation. Thus, raster image correlation spectroscopy (RICS) analysis reveals that the ACDAN GP signal is fluctuating in the micro-to-millisecond time range during natural organelle 3D trafficking. We show that ACDAN GP fluctuations are characteristic of lysosomes in living cells, are selectively abolished by lysosomal basification, and depend on metabolic energy in the form of ATP. We argue that intralysosomal ACDAN GP fluctuates according to the ongoing organelle metabolism. Indeed, we report alterations in amplitude and timing of GP fluctuations in a cellular model of lysosomal storage disorder (LSD). The strategy proposed provides insight into the elusive local environment of a trafficking lysosome and supports similar molecular investigations at the subcellular level.

Direct imaging of APP proteolysis in living cells.
Alzheimer's disease is a multifactorial disorder caused by the interaction of genetic, epigenetic and environmental factors. The formation of cytotoxic oligomers consisting of A peptide is widely accepted as being one of the main key events triggering the development of Alzheimer's disease. A peptide production results from the specific proteolytic processing of the amyloid precursor protein (APP). Deciphering the factors governing the activity of the secretases responsible for the cleavage of APP is still a critical issue. Kits available commercially measure the enzymatic activity of the secretases from cells lysates, . By contrast, we have developed a prototypal rapid bioassay that provides visible information on the proteolytic processing of APP directly in living cells. APP was fused to a monomeric variant of the green fluorescent protein and a monomeric variant of the red fluorescent protein at the C-terminal and N-terminal (mChAPPmGFP), respectively. Changes in the proteolytic processing rate in transfected human neuroblastoma and rat neuronal cells were imaged with confocal microscopy as changes in the red/green fluorescence intensity ratio. The significant decrease in the mean red/green ratio observed in cells over-expressing the -secretase BACE1, or the -secretase ADAM10, fused to a monomeric blue fluorescent protein confirms that the proteolytic site is still accessible. Specific siRNA was used to evaluate the contribution of endogenous BACE1. Interestingly, we found that the degree of proteolytic processing of APP is not completely homogeneous within the same single cell, and that there is a high degree of variability between cells of the same type. We were also able to follow with a fluorescence spectrometer the changes in the red emission intensity of the extracellular medium when BACE1 was overexpressed. This represents a complementary approach to fluorescence microscopy for rapidly detecting changes in the proteolytic processing of APP in real time. In order to allow the discrimination between the - and the -secretase activity, we have created a variant of mChAPPmGFP with a mutation that inhibits the -secretase cleavage without perturbing the -secretase processing. Moreover, we obtained a quantitatively robust estimate of the changes in the red/green ratio for the above conditions by using a flow cytometer able to simultaneously excite and measure the red and green fluorescence. Our novel approach lay the foundation for a bioassay suitable to study the effect of drugs or particular conditions, to investigate in an unbiased way the the proteolytic processing of APP in single living cells in order, and to elucidate the causes of the variability and the factors driving the processing of APP.

Chronic lithium administration in a mouse model for Krabbe disease.
Krabbe disease (KD; or globoid cell leukodystrophy) is an autosomal recessive lysosomal storage disorder caused by deficiency of the galactosylceramidase (GALC) enzyme. No cure is currently available for KD. Clinical applied treatments are supportive only. Recently, we demonstrated that two differently acting autophagy inducers (lithium and rapamycin) can improve some KD hallmarks in-vitro, laying the foundation for their in-vivo pre-clinical testing. Here, we test lithium carbonate in-vivo, in the spontaneous mouse model for KD, the Twitcher (TWI) mouse. The drug is administered ad libitum via drinking water (600 mg/L) starting from post natal day 20. We longitudinally monitor the mouse motor performance through the grip strength, the hanging wire and the rotarod tests, and a set of biochemical parameters related to the KD pathogenesis [i.e., GALC enzymatic activity, psychosine (PSY) accumulation and astrogliosis]. Additionally, we investigate the expression of some crucial markers related to the two pathways that could be altered by lithium: the autophagy and the β-catenin-dependent pathways. Results demonstrate that lithium has not a significant rescue effect on the TWI phenotype, although it can slightly and transiently improves muscle strength. We also show that lithium, with this administration protocol, is unable to stimulate autophagy in the TWI mice central nervous system, whereas results suggest that it can restore the β-catenin activation status in the TWI sciatic nerve. Overall, these data provide intriguing inputs for further evaluations of lithium treatment in TWI mice.

Quantitative Microproteomics Based Characterization of the Central and Peripheral Nervous System of a Mouse Model of Krabbe Disease.
Krabbe disease is a rare, childhood lysosomal storage disorder caused by a deficiency of galactosylceramide beta-galactosidase (GALC). The major effect of GALC deficiency is the accumulation of psychosine in the nervous system and widespread degeneration of oligodendrocytes and Schwann cells, causing rapid demyelination. The molecular mechanisms of Krabbe disease are not yet fully elucidated and a definite cure is still missing. Here we report the first in-depth characterization of the proteome of the Twitcher mouse, a spontaneous mouse model of Krabbe disease, to investigate the proteome changes in the Central and Peripheral Nervous System. We applied a TMT-based workflow to compare the proteomes of the corpus callosum, motor cortex and sciatic nerves of littermate homozygous Twitcher and wild-type mice. More than 400 protein groups exhibited differences in expression and included proteins involved in pathways that can be linked to Krabbe disease, such as inflammatory and defense response, lysosomal proteins accumulation, demyelination, reduced nervous system development and cell adhesion. These findings provide new insights on the molecular mechanisms of Krabbe disease, representing a starting point for future functional experiments to study the molecular pathogenesis of Krabbe disease. Data are available via ProteomeXchange with identifier PXD010594.

Gene editing of DNAH11 restores normal cilia motility in primary ciliary dyskinesia.
Primary ciliary dyskinesia (PCD) is a rare autosomal recessive genetic disorder characterised by dysfunction of motile cilia. Ciliary dysmotility causes poor mucociliary clearance and leads to impairment of pulmonary function and severe respiratory infections. PCD has no specific therapy. With the aim to permanently restore gene function and normalise ciliary motility, we used gene editing to replace mutated with wild-type sequence in defective cells.

REACTIVE ASTROCYTES ACQUIRE BENEFICIAL ANTI-AGGREGATION PROPERTIES THROUGH THE JAK2-STAT3 PATHWAY IN HUNTINGTON'S DISEASE

POSTER SESSION 06 - SECTION: GLIA AND DISORDERS OF THE NERVOUS SYSTEM

María-Ángeles Carrillo-De Sauvage, Laurene Abjean, Miriam Riquelme-Pérez, Lucile Ben Haim, Pauline Gipchtein, Fanny Petit, Anne-Sophie Hérard, Martine Guillermier, Mylène Gaudin, Sueva Bernier, Cameron Héry, Noelle Dufour, Charlène Joséphine, Gilles Bonvento, Alexis Bemelmans, Philippe Hantraye, Julien Flament, Emmanuel Brouillet, Carole Escartin
Laboratoire des maladies neurodégénératives UMR 9199, CNRS, CEA, Université Paris Xi, Fontenay-aux-roses, France

Huntington's disease (HD) is an inherited neurodegenerative disease, characterized by the presence of intracellular aggregates of mutant huntingtin (mHtt). The degeneration of specific neuronal populations in the striatum and cortex is the main cause for clinical symptoms. However, astrocytes may also play a key role in HD. Astrocytes become reactive in response to virtually all pathological situations in the central nervous system. In the brain of HD patients, there is a progressive increase in reactive astrocytes and transcriptomics analysis reveals significant molecular changes in HD astrocytes. The JAK2-STAT3 pathway is a central cascade controlling the reactive response of astrocytes in the brain. We found STAT3 activation in astrocytes in the putamen of HD patients. To pinpoint the role of reactive astrocytes in HD, we generated viral vectors that infect astrocytes in the mouse striatum and activate or inhibit the JAK2-STAT3 pathway. We show that JAK2-STAT3-reactive astrocytes reduce the number and size of mHtt aggregates in striatal neurons in different mouse models of HD, and improved several HD pathological hallmarks. We found that the JAK2-STAT3 pathway controls the expression of proteolytic enzymes in HD astrocytes, enhances proteosomal and lysosomal activities and increase astrocyte capacity to clear mHtt. We also found that JAK2-STAT3-dependent reactive astrocytes produce chaperones, which can be transferred to neurons through exosomes to promote mHtt clearance. We show that astrocytes, through the JAK2-STAT3 pathway, with enhanced proteolysis capacity and anti-aggregation function, can engage in protective reactive responses that could be promoted for HD therapy.

Aims: Neuroinflammation leads to gradual neurodegeneration during pathological aging, contributing to disorders like Alzheimer's disease (AD). Basal forebrain cholinergic neuronal (BFCN) loss is associated with AD; however, the underlying mechanism is still unknown. This study investigated the effects of both aging and chronic neuroinflammation on the BFCN, focusing on the medial septum (MS). **Method:** Aged, 12- and 24-months WT and GFAP-IL6 mice (overexpressing IL-6 under the GFAP promoter) were used. Immunohistochemistry combined with unbiased stereology and 3D morphology analysis was performed to estimate the number and morphology of $Iba1^+$ microglia and $ChAT^+$ in the MS, combined with transcriptomic analysis using qPCR. **Results:** Stereological estimation of microglia number displayed a significant increase both at 12 and 24 months in GFAP-IL6 compared to WT. We found a significant, 28% and 38% decrease, in microglial 3D surface area, and volume between WT and GFAP-IL respectively at both 12 and 24 months, indicating increased glial reactivity. Meanwhile, BFCN in the MS displayed a significant, 31% and 30%, decrease in GFAP-IL6 compared to WT, respectively, at both 12 and 24 months. A significant 58% and 67% reduction in the 3D dendritic field surface area, and volume, respectively between WT and GFAP-IL at 12 months; and a significant 41% and 46% decrease between WT at 12 and 24 months respectively, revealing neuronal degeneration. **Conclusion:** We report evidence of the significant impact of both aging and chronic glial activation on the microglial and BFCN numbers and morphology in the MS, resulting in neurodegeneration, as seen in AD.

Cholinergic Modulation of Glial Function During Aging and Chronic Neuroinflammation.
Aging is a complex biological process that increases the risk of age-related cognitive degenerative diseases such as dementia, including Alzheimer's disease (AD), Lewy Body Dementia (LBD), and mild cognitive impairment (MCI). Even non-pathological aging of the brain can involve chronic oxidative and inflammatory stress, which disrupts the communication and balance between the brain and the immune system. There has been an increasingly strong connection found between chronic neuroinflammation and impaired memory, especially in AD. While microglia and astrocytes, the resident immune cells of the central nervous system (CNS), exerting beneficial effects during the acute inflammatory phase, during chronic neuroinflammation they can become more detrimental. Central cholinergic circuits are involved in maintaining normal cognitive function and regulating signaling within the entire cerebral cortex. While neuronal-glial cholinergic signaling is anti-inflammatory and anti-oxidative, central cholinergic neuronal degeneration is implicated in impaired learning, memory sleep regulation, and attention. Although there is evidence of cholinergic involvement in memory, fewer studies have linked the cholinergic anti-inflammatory and anti-oxidant pathways to memory processes during development, normal aging, and disease states. This review will summarize the current knowledge of cholinergic effects on microglia and astroglia, and their role in both anti-inflammatory and anti-oxidant mechanisms, concerning normal aging and chronic neuroinflammation. We provided details on how stimulation of α7 nicotinic acetylcholine (α7nACh) receptors can be neuroprotective by increasing amyloid-β phagocytosis, decreasing inflammation and reducing oxidative stress by promoting the nuclear factor erythroid 2-related factor 2 (Nrf2) pathways and decreasing the release of pro-inflammatory cytokines. There is also evidence for astroglial α7nACh receptor stimulation mediating anti-inflammatory and antioxidant effects by inhibiting the nuclear factor-κB (NF-κB) pathway and activating the Nrf2 pathway respectively. We conclude that targeting cholinergic glial interactions between neurons and glial cells α7nACh receptors could regulate neuroinflammation and oxidative stress, relevant to the treatment of several neurodegenerative diseases.

Spatial Memory and Microglia Activation in a Mouse Model of Chronic Neuroinflammation and the Anti-inflammatory Effects of Apigenin.
Chronic neuroinflammation characterized by microglia reactivity is one of the main underlying processes in the initiation and progression of neurodegenerative diseases such as Alzheimer's disease. This project characterized spatial memory during healthy aging and prolonged neuroinflammation in the chronic neuroinflammatory model, glial fibrillary acidic protein-interleukin 6 (GFAP-IL6). We investigated whether chronic treatment with the natural flavonoid, apigenin, could reduce microglia activation in the hippocampus and improve spatial memory. GFAP-IL6 transgenic and wild-type-like mice were fed with apigenin-enriched or control chow from 4 months of age and tested for spatial memory function at 6 and 22 months using the Barnes maze. Brain tissue was collected at 22 months to assess microgliosis and morphology using immunohistochemistry, stereology, and 3D single cell reconstruction. GFAP-IL6 mice showed age-dependent loss of spatial memory recall compared with wild-type-like mice. Chronic apigenin treatment decreased the number of Iba-1 microglia in the hippocampus of GFAP-IL6 mice and changed microglial morphology. Apigenin did not reverse spatial memory recall impairment in GFAP-IL6 mice at 22 months of age. GFAP-IL6 mice may represent a suitable model for age-related neurodegenerative disease. Chronic apigenin supplementation significantly reduced microglia activation, but this did not correspond with spatial memory improvement in the Barnes Maze.

The effect of aging and chronic microglia activation on the morphology and numbers of the cerebellar Purkinje cells.
Reduced cerebellar volume and motor dysfunction have previously been observed in the GFAP-IL6 murine model of chronic neuroinflammation. This study aims to extend these findings by investigating the effect of microglial activation and ageing on the total number of Purkinje cells and the morphology of their dendritic arborization. Through comparison of transgenic GFAP-IL6 mice and their wild-type counterparts at the ages of 12 and 24-months, we were able to investigate the effects of ageing and chronic microglial activation on Purkinje cells. Unbiased stereology was used to estimate the number of microglia in Iba1 stained tissue and Purkinje cells in calbindin stained tissue. Morphological analyses were made using 3D reconstructions of images acquired from the Golgi-stained cerebellar tissue. We found that the total number of microglia increased by approximately 5 times in the cerebellum of GFAP-IL6 mice compared to their WT littermates. The number of Purkinje cells decreased by as much as 50 % in aged wild type mice and 83 % in aged GFAP-IL6 mice. The remaining Purkinje cells in these cohorts were found to have significant reductions in their total dendritic length and number of branching points, indicating how the complexity of the Purkinje cell dendritic arbor reduces through age and inflammation. GFAP-IL6 mice, when compared to WT mice, had higher levels of microglial activation and more profound neurodegenerative changes in the cerebellum. The presence of constitutive IL6 production, driving chronic neuroinflammation, may account for these neurodegenerative changes in GFAP-IL6 mice.

The Effects of Modified Curcumin Preparations on Glial Morphology in Aging and Neuroinflammation.
Neuroinflammation is characterized by reactive microglia and astrocytes (collectively called gliosis) in the central nervous system and is considered as one of the main pathological hallmarks in different neurodegenerative diseases such as Alzheimer's disease, age-related dementia, and multiple sclerosis. Upon activation, glia undergoes structural and morphological changes such as the microglial cells swell in size and astrocytes become bushy, which play both beneficial and detrimental roles. Hence, they are unable to perform the normal physiological role in brain immunity. Curcumin, a cytokine suppressive anti-inflammatory drug, has a high proven pre-clinical potency and efficacy to reverse chronic neuroinflammation by attenuating the activation and morphological changes that occur in the microglia and astrocytes. This review will highlight the recent findings on the tree structure changes of microglia and astrocytes in neuroinflammation and the effects of curcumin against the activation and morphology of glial cells.

Abstract: Major Depressive Disorder (MDD) is a complex recurrent and debilitating psychiatric illness, representing one of the leading causes of disability worldwide. Despite the great economic and social burden of MDD, current pharmacotherapeutic strategies have limited efficiency, displaying partial or no response to the treatment. Although extensively studied, the etiopathogenesis of MDD is still not fully understood. Previous research has elucidated the roles of glial cells in brain processes and, among the three glial cell types, astrocytes are the most important determinant of glial pathology in MDD. Astrocytes are integral to synapse functioning and control many aspects of synapse activity, including the proper recognition, engulfment and degradation of redundant synapses through the multiple EGF-like domain protein 10 (MEGF10) pathway. Interestingly, mice astrocytes lacking MEGF10 show a halving of their relative engulfment ability. Moreover, synaptic communication and neuronal connectivity are disrupted in MDD suggesting a putative role for astrocytes in its pathogenesis. We have previously demonstrated that antidepressant drugs promote synaptic elimination in primary astrocyte-neuron co-cultures and in the adult rat prefrontal cortex. This elimination was accompanied by an increase of MEGF10 protein levels in astrocytes. These data point out that astrocytes not only may represent an additional target of antidepressant drugs, but also play an essential role in synaptic network refinement **Objective**: Our aim is to evaluate if a dysfunctional MEGF10 phagocytic pathway might underlie the neurobiology of depression, and whether this represents a potential novel candidate to develop alternative strategies for the treatment of MDD.

ALTERATION OF THE NEURON-GLIAL GABAERGIC CROSS-TALK IN THE SCIATIC NERVE OF DYSTROPHIC MDX MICE

POSTER SESSION 06 - SECTION: GLIA AND DISORDERS OF THE NERVOUS SYSTEM

Francesca Mastrostefano[1], Marzia Soligo[2], Veronica Bonalume[3], Silvia Di Nuzzo[1], Valentina Ferretti[1], Valerio Magnaghi[3], Maria Egle De Stefano[1]
[1]Sapienza Università di Roma, Dept. Biologia E Biotecnologie "charles Darwin", Roma, Italy, [2]National Research Council of Italy (CNR), Institute Of Translational Pharmacology, ROMA, Italy, [3]Università degli Studi di Milano, Dept. Scienze Farmacologiche E Biomolecolari, Milano, Italy

Duchenne muscular dystrophy (DMD) is a lethal X-linked muscular disease characterized by the lack of dystrophin, a cytoskeletal protein expressed in muscles and other cell types. Progressive muscle degeneration and impairment of neuromuscular junction stability are the main features of the disease, albeit nothing is known about the growth, integrity, and functional properties of peripheral nerves. These processes might be regulated by bidirectional signals that myelinating and non-myelinating Schwann cells (SCs) establish with both motor and sensory neuron axons. A re-known regulator of SC-neuron cross-talk is the neurotransmitter GABA. Therefore, the aim of the research was to investigate whether DMD would affect motor and sensory neuron physiology and their morpho-functional relationship with SCs. The studies, performed on the sciatic nerve of wild-type and dystrophic *mdx* mice, analyzed the expression and localization of proteins fundamental for myelin sheath integrity and SC-axon signaling. Real time RT-PCR demonstrated a significant reduction in mRNA levels of myelin proteins (e.g. MBP, P0, PMP22, MAG), and inotropic $GABA_A$ (α4, β3, δ) and metabotropic $GABA_B$-1b receptor subunits in *mdx* mice compared to controls. Reduction in protein levels was confirmed by Western immunoblot (e.g MBP, GABAβ3, GABAδ, GABABR1), and corresponded to a decrease in the mean immunofluorescence intensity following confocal microscope analysis. Further preliminary electrophysiological analyses identified a significant reduction in sensory Abeta fiber excitability. Altogether, our findings support the hypothesis of significant alterations of neuron-SC cross-talk in peripheral nerves of *mdx* mice, an intriguing factor that should be considered for the development of new DMD therapeutic strategies.

SYSTEMIC LIPOPOLYSACCHARIDE EXPOSURE TRIGGERS TLR4-DEPENDENT INFLAMMATORY RESPONSES IN THE MOUSE RETINA IN VIVO

POSTER SESSION 06 - SECTION: GLIA AND DISORDERS OF THE NERVOUS SYSTEM

Tsioti
Inselspital, University Hospital of Bern, Department Of Ophthalmology And Department For Biomedical Research, Bern, Switzerland

Aims: Systemic inflammation has been suggested to trigger activation of microglia cells in the retina. The aim of this study is to investigate the effect of systemic lipopolysaccharide (LPS) exposure on the inflammatory status of the mouse retina, *in vivo* and the involvement of Toll-like receptor 4 (Tlr4). Methods: B6(Cg)-Tlr4$^{tm1.2Karp}$ (Tlr4$^{-/-}$) and C57BL/6J mice were intravenously injected with LPS for four consecutive days. Immunohistochemical and flow cytometry analysis, using specific markers for microglia and monocyte-derived macrophages were performed. Electroretinography recordings (ERG) were utilized to investigate potential effects of LPS on retinal function. Transmission Electron Microscopy (TEM) was used to study the effect of LPS on outer plexiform layer organization (OPL). Results: LPS injections led to elevated numbers of microglia/macrophages and accumulation of these cells around retinal blood vessels in C57BL/6J but not in Tlr4$^{-/-}$ mice. Reactive microglia/macrophages were observed at day 4 in the inner and outer retina, while an intermediate activation phenotype was noticed in the outer retina at day 14 post LPS in C57BL/6J animals. In the Tlr4$^{-/-}$ mice reactive microglia was observed in the outer retina at day 14 after the first LPS challenge. ERG recordings, revealed reduced a- and b- wave amplitudes in scotopic conditions in LPS-challenged C57BL/6J mice. A delayed progression of LPS-induced retinal inflammation was observed in Tlr4$^{-/-}$ mice. TEM analysis, showed a disorganization of the OPL ultrastructure upon the LPS challenge, compared to the naïve C57BL/6J mice. Conclusions: Our results suggest that systemic LPS-induced inflammation perturbs retinal homeostasis in a *Tlr4*-dependent manner.

ASTROCYTE-NEURON INTERPLAY IS CRITICAL FOR ALZHEIMER'S DISEASE PATHOGENESIS AND IS RESCUED BY TRPA1 CHANNEL BLOCKADE

POSTER SESSION 06 - SECTION: GLIA AND DISORDERS OF THE NERVOUS SYSTEM

Adrien Paumier, Sylvie Boisseau, Jacquier-Sarlin Muriel, Karin Pernet-Gallay, Alain Buisson, Mireille Albrieux
Grenoble Institut Neurosciences, Neuropathologies And Synaptic Dysfunctions, Grenoble, France

The sequence of cellular dysfunctions in preclinical Alzheimer's disease must be understood if we are to plot new therapeutic routes. Hippocampal neuronal hyperactivity is one of the earliest events occurring during the preclinical stages of Alzheimer's disease in both humans and mouse models. The most common hypothesis describes amyloid β accumulation as the triggering factor of the disease but the effects of this accumulation and the cascade of events leading to cognitive decline remain unclear. In mice, we previously showed that amyloid β-dependent TRPA1 channel activation triggers hippocampal astrocyte hyperactivity, subsequently inducing hyperactivity in nearby neurons. In this work, we investigated the potential protection against Alzheimer's disease progression provided by early chronic pharmacological inhibition of TRPA1 channel. To do that, a specific inhibitor of TRPA1 channel (HC030031) was administered intraperitoneally from the onset of amyloid β overproduction in the APP/PS1-21 mouse model of Alzheimer's disease. Short-, medium-, and long-term effects of this chronic pharmacological TRPA1 blockade were characterized at functional (astrocytic and neuronal activity), structural, biochemical, and behavioural levels. Our results revealed that chronic TRPA1 blockade normalizes astrocytic activity, avoids perisynaptic astrocytic process withdrawal, prevents neuronal dysfunction and preserves structural synaptic integrity. These protective effects preserved spatial working-memory in this Alzheimer's disease mouse model. Therefore, the toxic effect of amyloid β on astrocytes triggered by TRPA1 channel activation is pivotal to Alzheimer's disease progression. TRPA1 blockade prevents irreversible neuronal dysfunction, making this channel a potential therapeutic target to promote neuroprotection.

Jena University Hospital, Hans Berger Department Of Neurology, Jena, Germany

Aims: We aim to establish an in vitro primary mouse 3D culture approach that incorporates key constituents of the CNS (neuron, astrocyte, microglia and ECM) for analyzing neuron-glia interactions under physiological and pathophysiological conditions. **Methods:** A collagen-based 3D-culture system was developed and optimized using spectrophotometry, immunofluorescence and western blotting analyses. A 2D murine neuron-astrocyte-microglia tri-culture system was developed and optimized by using different aged donor mice, seeding densities and supplementing with supporting factors (IL-34, TGF-β, cholesterol) for as long as 14 days in vitro. The 3D-tri-culture protocol was evaluated using Western blot and microscopy under inflammation and mechanical stimulation. **Results:** A collagen pre-gelation method was developed and efficiently improved to obtain an homogenous cell distribution without disturbing the dynamic of the gelation process. Slicing and staining protocols and microscopic analyses were established. Under co-culture conditions, the age of donor mice directly correlated with the glial cell density, and inversely with the density of neuronal processes. The highest number of microglia was observed in the high cell density group (1300cells/mm^2). Optimal concentration of supporting factors was determined by evaluating the neuronal network density and reaction to inflammatory stimulation. The collagen-based scaffold is able to sustain tri-culture of neural cells and allows for the development of extensive neuronal networks. **Conclusions:** Murine neurons, astrocytes and microglia can be co-cultured under specific conditions in the presence of selected growth and maintenance factors in both 2D and 3D conditions. The 3D-tri-culture system is suitable of reproducing the neural responses in neuroinflammation paradigms and mechanical injury.

Neurological Involvement in Primary Systemic Vasculitis.
Primary systemic vasculitis can affect every structure in both the central and peripheral nervous system, causing varied neurological manifestations of neurological dysfunction. Early recognition of the underlying causes of the neurological symptoms can facilitate timely treatment and improve the prognosis. This review highlights the clinical manifestations of primary systemic vasculitis in the nervous system.

Microglia P2X4 receptor contributes to central sensitization following recurrent nitroglycerin stimulation.
The mechanism underlying migraine chronification remains unclear. Central sensitization may account for this progression. The microglia P2X4 receptor (P2X4R) plays a pivotal role in the central sensitization of inflammatory and neuropathic pain, but there is no information about P2X4R in migraine. Therefore, the aim of this study was to identify the precise role of microglia P2X4R in chronic migraine (CM).

Microglial NLRP3 inflammasome activation mediates IL-1β release and contributes to central sensitization in a recurrent nitroglycerin-induced migraine model.
Central sensitization is an important mechanism of chronic migraine (CM) and is related to the inflammatory response of microglia. The NOD-like receptor protein 3 (NLRP3) inflammasome may regulate the inflammatory process of microglia in several neurological diseases, but its role in CM is largely unknown. Therefore, the aim of this study was to identify the precise role of microglial NLRP3 in CM.

Sphenopalatine Neuralgia: An Independent Neuralgia Entity. Pooled Analysis of a Case Series and Literature Review.

Structural damage or demyelization of the sphenopalatine ganglion may cause sphenopalatine neuralgia (SN). The current International Classification of Headache Disorders, third edition (ICHD-3) regards SN as a phenotype of cluster headache. Whether SN is an independent neuralgia entity has been debated for years.

Astrocytes play crucial roles in major homeostatic brain mechanisms and are key players in glia-neuron interactions in Parkinson's disease (PD), the second most common neurodegenerative disorder where both genetic and environmental factors contribute to selective degeneration of mesencephalic dopaminergic neurons (mDAns). Among genetic risks, the Leucine-Rich Repeat Kinase 2 (*LRRK2*) G2019S mutation is associated with both sporadic and familial PD. Besides the multiple functions that LRRK2 displays in several cellular processes involved in mDAns homeostasis, mounting evidence implicates LRRK2 in astrocyte's regulatory functions, but whether and how LRRK2 might modulate astrocyte-mDAns interactions is poorly understood. Here, we hypothesize that LRRK2-mediated perturbation of astrocyte-mDAns crosstalk during development might impact on mDAn growth and resistance to toxic insults. Using *in vitro* primary ventral midbrain (VM) astrocyte-mDAn cultures from wild type (WT) LRRK2 and transgenic (TG) G2019S-*LRRK2* mice, we identified G2019S astrocytes as key mediators of mDAn growth impairment and failure to exert neuroprotection against inflammation and oxidative stress-induced mDAn loss. Next, by integrating immunocytochemistry with gene expression and biochemical analyses, we found that G2019S astrocytes displayed exaggerated production of reactive oxygen (ROS) and nitrogen (RNS) species as well a significant up-regulation of proinflammatory cytokines upon low-dose LPS stimulation or moderate MPP^+ exposure. Furthermore, extracellular flux analysis showed significant changes of mitochondrial metabolism of G2019S astrocytes compared to WT-LRRK2 counterparts. Together, these findings provide insight into the role of LRRK2-G2019S in the regulation of astrocyte-mDAn communication as well as astroglia metabolic response to inflammatory stimuli.

Aims Astrocytes (AS) are key players in the regulation of dopaminergic neuron homeostasis both in health and disease, such as Parkinson's disease (PD). PD is a neurodegenerative disorder affecting neuronal cell bodies within ventral midbrain (VMB), and their terminals in striatum (STR), with consequent dopamine depletion. When AS are activated by the chemokine CCL3, they exert a robust neuroprotection both in cellular and pre-clinical PD models. We isolated extracellular vesicles (EVs) derived from VMB- and STR-AS, both in basal and CCL3 conditions, to evaluate their possible involvement in the complex cross-talk between AS and neurons. **Methods** EVs were isolated from AS supernatants via ultracentrifugation and characterized by different techniques: nanoparticle tracking analysis, immunogold-transmission electron microscopy and western blotting. The potential of AS-EV was evaluated on differentiated SH-SY5Y cells under neurodegenerative conditions using immunofluorescence and high resolution respirometry. **Results** We found that nigrostriatal AS produce small-EVs (~100 nm), which are positive for classical EV markers. In basal conditions VMB-AS release more EVs than STR-AS, and only VMB-AS respond to CCL3 by producing more EVs. Following internalization by SH-SY5Y cells, we tested AS-EV potential against oxidative stress and mitochondrial toxicity. We observed that both basal but mostly CCL3-AS-EVs fully counteract H_2O_2-induced caspase-3 activation. Furthermore, AS-EVs were able to recover mitochondrial complex I functionality on MPP^+-injured neurons, with only VMB-AS-EVs able to restore ATP production. **Conclusion** These results highlight a novel role for AS-EVs in the propagation of specific intercellular signaling - within the nigrostriatal system - with neuroprotective implications for PD.

Autosomal dominant leukodystrophy (ADLD) is a slowly, progressive, genetic, and fatal neurological disorder. The genetic cause of ADLD is Lamin B1 (LMNB1) overexpression due to coding duplications or noncoding deletions at the LMNB1 locus. Lamin B1 is a component of the inner nuclear membrane of cells and although LMNB1 is ubiquitously expressed, it appears that neurons and glial cells are particularly sensible to LMNB1 dosage. Currently, only symptomatic and palliative treatments are available for this fatal disease. Since its discovery, human induced pluripotent stem cell (hiPSC) technology has open to the generation of novel and pathological-relevant *in vitro* models for Central Nervous System human diseases, for which no appropriate model systems were available. In this work, we describe the reprogramming of peripheral blood mononuclear cell and fibroblast lines derived from ADLD patients carrying different genetic mutations into hiPSCs by Sendai Virus-based method. These hiPSC lines were characterized to assess their pluripotency state by means of qRT-PCR and immunofluorescence assay. Also, embryoid bodies formation assay was used to evaluate their functional pluripotency. In parallel, we set up a procedure for the controlled differentiation of hiPSCs into oligodendrocytes, neurons, and astrocytes. These mature cells were characterized to assess the expression of stage-specific markers by means of qRT-PCR and immunofluorescence assays. In conclusion, patient-derived ADLD hiPSC lines couple to the differentiation protocols that we report represent valuable tools for studies aiming to investigate ADLD-specific alterations at molecular and cellular levels and develop potential target specific drugs.

ROLE OF SHIP1 AS A MODULATOR OF MICROGLIAL FUNCTION

POSTER SESSION 06 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Alessandro Matera, Rosa Paolicelli
University of Lausanne, Department Of Biomedical Sciences, Lausanne, Switzerland

Microglia are the innate immune cells of the central nervous system (CNS). They play crucial roles in brain development, repair and plasticity, and are also critically involved in neurodegenerative processes. Genome wide associations studies (GWAS) reveal that hundreds of genetic variants associated with neurodegeneration are found in genes highly expressed in microglia. Nevertheless, the functions of most of these disease risk genes have been so far poorly studied. Here, we investigated how the SH-2 containing inositol 5' polyphosphatase 1 (SHIP1) influences key microglial properties. SHIP1, encoded by Inpp5d, is responsible for the dephosphorylation of phosphatidylinositol (3,4,5)-trisphosphate (PIP3) to PI(3,4)P2. It is predominantly expressed by microglia in the CNS, and its genetic variants have been associated with late-onset Alzheimer's disease. To investigate SHIP1 loss-of-function *in vitro*, we generated Inpp5d CRISPR/Cas9 single clones of the microglial BV2 cell line, and further validated the findings *ex vivo*, in primary microglia from SHIP1^{floxed} mice. Our results show that SHIP1 depletion in microglia significantly promotes the uptake and degradation of amyloid beta, while affecting synaptosome engulfment to a lesser degree. However, the efficient amyloid degradation is coupled to an impaired lysosomal profile, as indicated by a decrease both in the acidification of the endo/lysosomal compartment and in the levels of mRNAs of lysosomal enzymes. Furthermore, time-lapse imaging by light-sheet microscopy and wound healing assay revealed defective motility in cells lacking SHIP1. In conclusion, this study shows that SHIP1 plays an important role in modulating microglial properties, suggesting possible implications in the pathogenesis of neurodegeneration.

INVESTIGATING THE ANTI-INFLAMMATORY AND NEUROPROTECTIVE POTENTIAL OF A LESSER-EXPLORED PHYTOCANNABINOID COMPOUND IN ACUTE NEUROINFLAMMATORY MODELS.

POSTER SESSION 06 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Aoife Cosgrave[1], Derek Costello[1], Paola Pedarzani[2]
[1]UCD, School Of Biomolecular And Biomedical Sciences, Dublin, Ireland, [2]Neuroscience Physiology Pharmacology, Division Of Biosciences, WCE AE, United Kingdom

Phytocannabinoids derived from the *Cannabis sativa* plant, have been shown to act as modulators of neuroinflammation, a prominent example being Cannabidiol, which has demonstrated both anti-inflammatory and neuroprotective effects. Several other compounds have been identified from the plant but have been poorly investigated to date. This study examines the properties of a lesser-explored phytocannabinoid “GL4a” (identity of which has been blinded for research purposes) in Toll-like receptor (TLR)-mediated models of acute neuroinflammation. These receptors activate in response to pathogen- and damage-associated signals, which contributes to microglia activation and subsequent neuronal dysfunction. Subtypes TLR2 and 4 are known to play a primary role in the pathogenesis of disorders associated with neuroinflammation, therefore offering an attractive target for therapeutic intervention. We have determined that GL4a can attenuate pro-inflammatory responses in microglial BV2 cells exposed to the TLR2 agonist lipoteichoic acid (LTA). Moreover, we report that these effects extend to mitigation of TLR-mediated inflammatory responses in neuronal cell lines, evidenced by a significant reduction in the production of proinflammatory cytokines TNFα and IL-6 and also nitric oxide. We further assessed potential mechanisms of action by targeting specific signalling pathways, previously-reported to play a role in cannabinoid action. To assess the impact of GL4a on inflammatory-mediated neuronal integrity, we used whole-cell electrophysiology to examine TLR-induced inhibition of a specific potassium current in hippocampal slices as an *in vitro* model of neuronal dysfunction. This on-going, exploratory study reveals anti-inflammatory and neuroprotective effects of a novel, plant-based compound “GL4a”, and supports further interrogation of potential neurotherapeutic properties.

Characterising lipoteichoic acid as an in vitro model of acute neuroinflammation.
Toll-like receptor 2 (TLR2) is a primary sensor for pathogens, including those derived from gram-positive bacteria. It can also mediate the effects of endogenous inflammatory signals such as β-amyloid peptide (Aβ), thus promoting the microglial activation and subsequent neuronal dysfunction, characteristic of chronic neuroinflammatory conditions. More recently, a role for TLR2 has been proposed in the pathogenesis of disorders associated with acute inflammation, including anxiety and depression. The current study aims to characterise the acute effects of the TLR2 agonist lipoteichoic acid (LTA) on microglial activation and neuronal integrity, and to evaluate the influence of LTA exposure on sensitivity to the inflammation and neuronal dysfunction associated with Aβ. Using BV2 and N2a cells as an in vitro model, we highlight that acute exposure to LTA robustly promotes inflammatory cytokine and nitric oxide (NO) production in microglia but also in neurons, similar to that reported under longer-term and chronic inflammatory conditions. Moreover, we find that exposure to LTA can enhance sensitivity to subthreshold Aβ, promoting an 'M1'-like phenotype in microglia and provoking dysregulation of neuronal activity in acute hippocampal slices. Anti-inflammatory agents, including mimetics of brain-derived neurotrophic factor (BDNF), have proven effective at alleviating chronic neuroinflammatory complications. We further examined the effects of 7,8,3-trihydroxyflavone (7,8,3-THF), a small-molecule TrkB agonist, on LTA-induced microglial activation. We report that 7,8,3-THF can significantly ameliorate interleukin (IL)-6 and NO production in LTA-stimulated BV2 cells. Taken together, our findings offer support for exploration of TLR2 as a potential target for therapeutic intervention into acute neuroinflammatory conditions. Moreover we propose that exposure to gram-positive bacterial pathogens may promote sensitivity to the inflammatory changes characteristic of the aged brain.

ROLE OF HSP70 PROTEIN IN SH-SY5Y DIFFERENTIATION AND PROTECTION FROM OXIDATIVE STRESS-DEPENDENT CELL DAMAGE

POSTER SESSION 06 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Giulia Urone, Miriana Scordino, Monica Frinchi, Giuseppa Mudò, Valentina Di Liberto
University of Palermo, Department Of Biomedicine, Neuroscience And Advanced Diagnostic, Palermo, Italy

SH-SY5Y cells, a widely used model in *in vitro* neuroscience research, can be differentiated into mature human neurons through different mechanisms including serum deprivation and the use of retinoic acid. Undifferentiated SH-SY5Y cells rapidly proliferate and appear non-polarized, with very few, short processes. When differentiated, these cells extend long, branched processes, stop proliferating and polarize. By using MTT assay, we observed a different sensitivity to oxidative-stress induced cell death between differentiated and undifferentiated cells. Indeed, treatment of undifferentiated cells with hydrogen peroxide (H_2O_2) induces a dose-dependent decrease in cell viability, which is not detectable in differentiated cells. Since Heat shock proteins (HSPs) are key molecules involved in the correct folding of proteins and regulation of redox processes, we speculated their involvement in the modulation of cell survival against H_2O_2-induced cell death. By western blotting analysis, we observed that HSP70 protein was increasingly expressed in differentiated SH-SY5Y cells, in comparison to undifferentiated cells, and that inhibition of HSP70 expression by KNK437 during the process of differentiation induced an increase in differentiated cell sensitivity to H_2O_2-induced cell death and the failure of differentiation process, suggesting that HSP70 expression is necessary to overcome cell stress associated to the process of differentiation. Furthermore, when HSP70 expression was induced by treatment with Oxotremorine, a selective muscarinic acetylcholine receptor agonist, differentiated SH-SY5Y cells became more resistant to oxidative stress-induced cell death. In conclusion our data demonstrate that manipulation of HSP70 signal modulates the process of SH-SY5Y differentiation and survival to oxidative stress-dependent cell damage.

Oxidative stress and neuroinflammation are major mechanisms involved in neurological disorders. In the last years, therapeutic benefits of natural products in brain disorders have been intensively explored. Rich in Citrus flavonoids and terpenes and retaining the highly bioactive rhamnogalacturonan RG-I region, IntegroPectin is a new family of pectins recently extracted from citrus processing waste via hydrodynamic cavitation in water only. With the aim of characterizing beneficial effects of IntegroPectin in brain cells, we demonstrated, by MTT assay and morphological measurements, that lemon and grapefruit IntegroPectins rescued cell viability and cell morphology in SH-SY5Y neuronal-like cells treated with H_2O_2. Moreover, IntegroPectin treatment decreased reactive oxygen species (ROS) production (assessed by DCFH-DA assay), preserved mitochondrial membrane potential (evaluated by JC-1 dye) and morphology (analyzed by staining mitochondria with the MitoTracker Deep Red dye) severely impacted by H_2O_2 exposure. Similar results were also observed in microglia HMC3 cells. In addition, pilot experiments suggested that IntegroPectins may modulate inflammatory phenomena. Though preliminary, these results support experimentation of IntegroPectin on preclinical models of complex pathologies marked by extensive phenomena of oxidative stress and inflammation such as neurodegenerative diseases.

New Neuroprotective Effect of Lemon IntegroPectin on Neuronal Cellular Model.
Lemon IntegroPectin obtained via hydrodynamic cavitation of organic lemon processing waste in water shows significant neuroprotective activity in vitro, as first reported in this study investigating the effects of both lemon IntegroPectin and commercial citrus pectin on cell viability, cell morphology, reactive oxygen species (ROS) production, and mitochondria perturbation induced by treatment of neuronal SH-SY5Y human cells with HO. Mediated by ROS, including HO and its derivatives, oxidative stress alters numerous cellular processes, such as mitochondrial regulation and cell signaling, propagating cellular injury that leads to incurable neurodegenerative diseases. These results, and the absence of toxicity of this new pectic substance rich in adsorbed flavonoids and terpenes, suggest further studies to investigate its activity in preventing, retarding, or even curing neurological diseases.

Protective, Antioxidant and Antiproliferative Activity of Grapefruit IntegroPectin on SH-SY5Y Cells.
Tested in vitro on SH-SY5Y neuroblastoma cells, grapefruit IntegroPectin is a powerful protective, antioxidant and antiproliferative agent. The strong antioxidant properties of this new citrus pectin, and its ability to preserve mitochondrial membrane potential and morphology, severely impaired in neurodegenerative disorders, make it an attractive therapeutic and preventive agent for the treatment of oxidative stress-associated brain disorders. Similarly, the ability of this pectic polymer rich in RG-I regions, as well as in naringin, linalool, linalool oxide and limonene adsorbed at the outer surface, to inhibit cell proliferation or even kill, at high doses, neoplastic cells may have opened up new therapeutic strategies in cancer research. In order to take full advantage of its vast therapeutic and preventive potential, detailed studies of the molecular mechanism involved in the antiproliferative and neuroprotective of this IntegroPectin are urgently needed.

TLR-MEDIATED ACTIVATION OF MICROGLIA IS ATTENUATED BY THE TERPENE, ERGOLIDE, VIA NF-KB INHIBITION

POSTER SESSION 06 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Danielle Molly Galvin[1,2], Aoife Cosgrave[1,2], Derek Costello[1,2]
[1]Conway Institute, School Of Biomolecular And Biomedical Sciences, Dublin, Ireland, [2]UCD, School Of Biomolecular And Biomedical Sciences, Dublin, Ireland

Alzheimers Disease(AD) is the leading cause of dementia worldwide. Neuroinflammation is central to the pathology of most neurodegenerative conditions, including AD. Accumulation of the toxic β–Amyloid peptide(Aβ) promotes the chronic activation of microglia; resulting in the progressive loss in neuronal viability, a major characteristic of the disease. Microglial toll-like receptors(TLRs), in particular TLR2 and 4, are among the known receptors for Aβ. Their activation is widely-reported to mediate the inflammatory changes and neuronal dysfunction associated with AD, and has therefore become an interesting avenue of therapeutic investigation. For many years, naturally-occurring compounds have been exploited for their anti-oxidant and anti-inflammatory properties. Previously, ergolide has been reported to attenuate the pro-inflammatory activation of macrophages, following exposure to lipopolysaccharide(LPS) and interferon-ɣ. This study examines whether the anti-inflammatory effects of ergolide extend to the brain, and may offer therapeutic potential for neuroinflammatory disorders. Here we report that the activation of BV2 microglial cells, following exposure to the TLR2 and 4 agonists lipoteichoic acid and LPS respectively, is attenuated by ergolide. Incubation with ergolide significantly reduced the production of the cytokine IL-6, chemokine MCP-1 and nitric oxide from TLR-stimulated microglia. Using a combination of cellular fractionation and luciferase assays, we further demonstrate that ergolide likely exerts its anti-inflammatory effects in microglia via inhibition of NF-κB. Moreover, we evaluate its capacity to mitigate TLR-mediated cell death in a population of vulnerable hippocampal neurons. Taken together, our findings support the further exploration of ergolide as a promising therapeutic agent for neuroinflammatory conditions such as AD.

NFKB-MEDIATED TOLERANCE IN A CELLULAR MODEL OF NEUROINFLAMMATION: IMPLICATIONS FOR PARKINSON'S DISEASE DOPAMINERGIC NEURODEGENERATION

POSTER SESSION 06 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Irina Freitag, Maider Usandizaga, Meritxell Roig, Paula Martínez, Paola Casanova, Carlos Barcia
Institut de Neurociències - Universitat Autònoma de Barcelona, Biochemistry And Molecular Biology, Barcelona, Spain

Parkinson's disease (PD) is characterized by the degeneration of dopaminergic neurons in the substantia nigra *pars compacta* (SNpc). In this region, activation of resident immune cells, such as microglia, take part in the chronic neuroinflammatory scenario that contributes to the process of neuronal death. The main goal of this project is to evaluate the response of microglial cells after repetitive pro-inflammatory stimuli of LPS and IFN-g, in a scenario of PD-like neuroinflammation in vitro. Our hypothesis is that after pro-inflammatory pulses, microglia may change their phenotype and their characteristic reactive features. We performed a set of in vitro experiments applying different strategies of inflammatory treatment to microglia and presented dopaminergic cells. We evaluated features of microglial activation such as cell area, the release of nitrites, the number of cells or the nuclear colocalization of the transcription factor NF-kB, to characterize the phenotype of microglia. Our results show that after repetitive pro-inflammatory pulses, microglial cells seem to reduce the release of nitrites, decrease their cell size, and impede the effective elimination of dopaminergic cells, indicating the establishment of a tolerant state. Repetitive pro-inflammatory stimuli seem to hamper the characteristic translocation of NF-kB into the nucleus, suggesting the mechanistic signalling of the acquired tolerance. These results are critical for a better understanding of the microglial cells behavior after receiving neuroinflammatory stimuli and to know how it may affect the elimination of dopaminergic cells. Further investigation within this research line will be critical to understand the progression of the neurodegenerative process in PD.

INFLAMMATION ALTERS HUMAN MICROGLIAL NEUROSTEROIDOGENESIS WITH POSSIBLE IMPACT ON NEURAL STEM CELLS DIFFERENTIATION

POSTER SESSION 06 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Lorenzo Germelli, Chiara Tremolanti, Elisa Angeloni, Martina De Felice, Claudia Martini, Barbara Costa, Eleonora Da Pozzo
University Of Pisa, Department Of Pharmacy, Pisa, Italy

Dysregulated microglial activation underlies the insurgence of chronic neuroinflammation and neurodegeneration. The Translocator Protein (TSPO), involved in *de novo* production of neurosteroids, is upregulated in activated microglia and is emerging as an interesting target to control neuroinflammation. **Aims:** Given the anti-inflammatory/neuroprotective properties of neurosteroids, our study aims to evaluate whether inflammation could affect human microglial neurosteroidogenesis. First, the ability of TSPO ligands to restore homeostatic neurosteroid levels was assessed. Furthermore, the effects of microglial conditioned medium (MCM) on human neural stem cell line (ReN cells) differentiation were also evaluated. **Methods:** Microglia were activated by IL-1β administration, and the expression of TSPO and CYP11A1, the enzyme of neurosteroidogenesis rate-limiting step, was evaluated. MCM derived from activated microglia pre-treated with 1μM of XBD-173 and PIGA1138 TSPO ligands or not, was analysed by LC-MS to measure neurosteroid levels. ReN cells were differentiated in presence of MCM for 3 days and immunostained for βIII-Tubulin and GFAP, neuronal and astrocytic markers respectively. **Results:** IL-1β treatment increased TSPO and CYP11A1 expression. LC-MS analysis of IL-1β-stimulated MCM evidenced a reduction in the levels of progesterone, testosterone, and estradiol, while TSPO ligands administration restored their levels. IL-1β-stimulated MCM impaired ReN differentiation into neurons by promoting astrocytogenesis, whereas TSPO ligand/IL-1β MCM rescued neuritic density and reduced GFAP fluorescence intensity. **Conclusions:** Activated microglia reduces the production of anti-inflammatory neurosteroids contributing to the maintenance of a pro-inflammatory microenvironment. TSPO pharmacological stimulation could represent a promising strategy to restore altered neurosteroid levels in order to counteract the negative effects of neuroinflammatory processes.

De novo Neurosteroidogenesis in Human Microglia: Involvement of the 18 kDa Translocator Protein.
Neuroactive steroids are potent modulators of microglial functions and are capable of counteracting their excessive reactivity. This action has mainly been ascribed to neuroactive steroids released from other sources, as microglia have been defined unable to produce neurosteroids de novo. Unexpectedly, immortalized murine microglia recently exhibited this de novo biosynthesis; herein, de novo neurosteroidogenesis was characterized in immortalized human microglia. The results demonstrated that C20 and HMC3 microglial cells constitutively express members of the neurosteroidogenesis multiprotein machinery-in particular, the transduceosome members StAR and TSPO, and the enzyme CYP11A1. Moreover, both cell lines produce pregnenolone and transcriptionally express the enzymes involved in neurosteroidogenesis. The high TSPO expression levels observed in microglia prompted us to assess its role in de novo neurosteroidogenesis. TSPO siRNA and TSPO synthetic ligand treatments were used to reduce and prompt TSPO function, respectively. The TSPO expression downregulation compromised the de novo neurosteroidogenesis and led to an increase in StAR expression, probably as a compensatory mechanism. The pharmacological TSPO stimulation the de novo neurosteroidogenesis improved in turn the neurosteroid-mediated release of Brain-Derived Neurotrophic Factor. In conclusion, these results demonstrated that de novo neurosteroidogenesis occurs in human microglia, unravelling a new mechanism potentially useful for future therapeutic purposes.

Translocator Protein Ligand PIGA1138 Reduces Disease Symptoms and Severity in Experimental Autoimmune Encephalomyelitis Model of Primary Progressive Multiple Sclerosis.
Multiple sclerosis (MS) is an autoimmune and demyelinating disease of the central nervous system (CNS) caused by CNS

infiltration of peripheral immune cells, immune-mediated attack of the myelin sheath, neuroinflammation, and/or axonal/neuronal dysfunctions. Some drugs are available to cope with relapsing-remitting MS (RRMS) but there is no therapy for the primary progressive MS (PPMS). Because growing evidence supports a regulatory role of the translocator protein (TSPO) in neuroinflammatory, demyelinating, and neurodegenerative processes, we investigated the therapeutic potential of phenylindolyilglyoxylamydes (PIGAs) TSPO ligands in myelin oligodendrocyte glycoprotein (MOG)-induced experimental autoimmune encephalomyelitis (EAE) mice mimicking the human PPMS. MOG-EAE C57Bl/6-mice were treated by TSPO ligands PIGA839, PIGA1138, or the vehicle. Several methods were combined to evaluate PIGAs-TSPO ligand effects on MOG-EAE symptoms, CNS infiltration by immune cells, demyelination, and axonal damages. PIGA1138 (15 mg/kg) drastically reduced MOG-EAE mice clinical scores, ameliorated motor dysfunctions assessed with the Catwalk device, and counteracted MOG-EAE-induced demyelination by preserving Myelin basic protein (MBP) expression in the CNS. Furthermore, PIGA1138-treatment prevented EAE-evoked decreased neurofilament-200 expression in spinal and cerebellar axons. Moreover, PIGA1138 inhibited peripheral immune-CD45 + cell infiltration in the CNS, suggesting that it may control inflammatory mechanisms involved in PPMS. Concordantly, PIGA1138 enhanced anti-inflammatory interleukin-10 serum level in MOG-EAE mice. PIGA1138-treatment, which increased neurosteroid allopregnanolone production, ameliorated all pathological biomarkers, while PIGA839, unable to activate neurosteroidogenesis in vivo, exerted only moderate/partial effects in MOG-EAE mice. Altogether, our results suggest that PIGA1138-based treatment may represent an interesting possibility to be explored for the innovation of effective therapies against PPMS.

Antitumoral effects of attenuated Listeria monocytogenes in a genetically engineered mouse model of melanoma.
Attenuated Listeria monocytogenes (Lm-LLO) represents a valuable anticancer vaccine and drug delivery platform. Here we show that in vitro Lm-LLO causes ROS production and, in turn, apoptotic killing of a wide variety of melanoma cells, irrespectively of their stage, mutational status, sensitivity to BRAF inhibitors or degree of stemness. We also show that, when administered in the therapeutic setting to Braf/Pten genetically engineered mice, Lm-LLO causes a strong decrease in the size and volume of primary melanoma tumors, as well as a reduction of the metastatic burden. At the molecular level, we confirm that the anti-melanoma activity exerted in vivo by Lm-LLO depends also on its ability to potentiate the immune response of the organism against the infected tumor. Our data pave the way to the preclinical testing of listeria-based immunotherapeutic strategies against metastatic melanoma, using a genetically engineered mouse rather than xenograft models.

Carbonic anhydrase activation profile of indole-based derivatives.
Carbonic Anhydrase Activators (CAAs) could represent a novel approach for the treatment of Alzheimer's disease, ageing, and other conditions that require remedial achievement of spatial learning and memory therapy. Within a research project aimed at developing novel CAAs selective for certain isoforms, three series of indole-based derivatives were investigated. Enzyme activation assay on human CA I, II, VA, and VII isoforms revealed several effective micromolar activators, with promising selectivity profiles towards the brain-associated cytosolic isoform hCA VII. Molecular modelling studies suggested a theoretical model of the complex between hCA VII and the new activators and provide a possible explanation for their modulating as well as selectivity properties. Preliminary biological evaluations demonstrated that one of the most potent CAA is not cytotoxic and is able to increase the release of the brain-derived neurotrophic factor (BDNF) from human microglial cells, highlighting its possible application in the treatment of CNS-related disorders.

CROSSTALK BETWEEN GLIAL CELLS AND C-KIT+ MAST CELLS IN THE ALS DEGENERATING SPINAL CORD

POSTER SESSION 06 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Mariangeles Kovacs[1], Catalina Alamon[1], Sofia Ibarburu[1], Valentina Varela[1], Lucas Tarrago[1], Cecilia Maciel[1], Olivier Hermine[2], Peter King[3,4], Ying Si[3,4], Yuri Kwon[3]

Background. Amyotrophic lateral sclerosis (ALS) is characterized by degeneration of motor neurons, reactive gliosis and immune cell infiltration into the CNS, resulting in a degenerative cell microenvironment. We have recently reported that mast cells (MC) expressing c-Kit receptor can enter the damaged parenchyma as precursors (Kovacs *et al,* 2021). MCs spatially interact with astrocytes expressing the c-Kit ligand, Stem Cell Factor (SCF), suggesting a mechanism for local MC differentiation and activation. MCs have the potential to degranulate and induce inflammation through the release of mediators such as cytokines, histamine, and proteases. MC-tryptase is a MC-restricted protease that can interact with glial cells through the activation of proteinase activated receptors, representing a major neuroinflammatory mediator. However, the pathogenic significance and interaction between MC-tryptase and glial cells in ALS remain unclear. **Methods.** The expression of MC-tryptase was analyzed in autopsied spinal cords from ALS subjects and controls as well as in the CNS of $SOD1^{G93A}$ mice. Murine tissues were analyzed by flow cytometry and PAGE-western blotting. Crosstalk between MC-tryptase and glial cells was analyzed in primary cultures of glial cells. **Results.** We have identified that MC-tryptase is strongly upregulated in the ALS spinal cord, correlating with the degree of MC infiltration, microgliosis, and defective microvasculature. Downregulation of MC-infiltration with the tyrosine-kinase inhibitor, Masitinib which targets SCF/c-Kit signaling, decreased the MC-tryptase levels. In cell cultures, MC-tryptase was sufficient to modulate the phenotype of microglia and astrocytes. **Conclusions.** Our results suggest a pathogenic mechanism triggered by MC-tryptase that leads to glial activation in ALS, which can be targeted therapeutically.

STUDY OF THE PHARMACOLOGICAL INHIBITION OF RPTP β/ζ AS A NOVEL STRATEGY TO MODULATE THE LPS-INDUCED LOSS OF NEURONAL PROGENITORS IN THE DENTATE GYRUS

POSTER SESSION 06 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Universidad CEU San Pablo, Pharmacology, Madrid, Spain

Neuroinflammation plays an essential role in the response mechanisms to brain damage. However, prolonged neuroinflammation exert harmful effects on the Central Nervous System. Pleiotrophin (PTN) is a cytokine that modulates neuroinflammation in different contexts by binding to receptor Protein Tyrosine Phosphatase (RPTP) β/ζ. **AIMS:** To test the implication of RPTP β/ζ signalling pathway in lipopolysaccharide (LPS)-induced neuroinflammation and to evaluate the long-term effects of an LPS acute exposure. **METHODS:** Adult male C57BL/6J mice were administered MY10 (60 mg/kg i.g., inhibitor of RPTP β/ζ) or vehicle 1 h before a single injection of LPS (7.5 mg/kg i.p.) or saline 16 h prior to sacrifice. To study the long-term influence of neuroinflammation, another cohort of mice were sacrificed 10 months after a single LPS (5 mg/kg i.p.) or saline administration. In immunohistochemistry assays, we studied changes in ionized calcium-binding adaptor molecule 1 (Iba1, microglial marker) and doublecourtin (DCx, neuronal progenitor marker) expression in dentate gyrus (DG). **RESULTS:** Acute LPS significantly decreases DCx positive cells in the DG. Interestingly, data suggest that treatment with MY10 could prevent this deleterious effect of LPS on hippocampal neurogenesis. However, microglial changes in DG were not modulated by MY10 administration. Regarding long-term LPS effects, no significant differences in Iba1 neither DCx were found. **CONCLUSION:** PRPTP β/ζ appears to be a promising druggable target to modulate the loss of neuronal progenitors induced by LPS acute damage. Further studies are needed to clarify the molecular mechanisms mediating hippoccampal neuroinflammation and the role of the PTN/ RPTP β/ζ signalling pathway.

Chronic neuroinflammatory states are associated with the development of several neurodegenerative diseases. The PI3K/Akt signalling pathway has been implicated in these disease processes and holds therapeutic promise as a target to modulate neuroinflammatory responses. Here we demonstrate a robust *in vitro* assay to assess dynamic Akt Kinase activity in real-time. To monitor Akt activity we used astrocytic and immune cell lines stably expressing the Incucyte® Kinase Akt Green/Red Lentivirus Reagent, a genetically-encoded fluorescent kinase translocation reporter whose subcellular localization is phosphorylation dependent. Images were acquired using the Incucyte® Live-Cell Analysis System and Akt activity was quantified using integrated software. To validate inhibition, cells were treated with the allosteric Akt inhibitor MK-2206. Quantification revealed concentration-dependent inhibition of Akt activity across all cell types over 24h, with increased potency for HMC3 microglia, compared to T98G or U87 astrocytes (IC_{50} values of 0.17, 0.73, and 1.29 µM, respectively). Additionally, T98G astrocytes were treated with inhibitors targeting both upstream PI3K and downstream mTOR. Results show concentration-dependent inhibition of Akt activity for all compounds with varying kinetic profiles. Subsequent experiments investigated the effects of immunocompetent cell activation on Akt using inflammatory insults. Lipopolysaccharide (LPS) showed a rapid concentration-dependent increase in Akt activity reaching maximal response by 6h, which was suppressed in the presence of MK-2206, suggestive of the Akt pathway playing an important role in LPS-induced activation. These data exemplify the Incucyte® Kinase Akt Assay as a powerful live-cell approach for assessing Akt activity in neuroinflammatory models and its amenability to screening of therapeutic candidates.

NEUROINFLAMM-AGING OF THE MICROENVIRONMENT DURING GLIOBLASTOMA PROGRESSION.

POSTER SESSION 06 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Assunta Virtuoso[1,2], Ciro De Luca[1], Giovanni Cirillo[1], Roberto Giovannoni[3], Marialuisa Lavitrano[2], Michele Papa[1]
[1]University of Campania Luigi Vanvitelli, Neuronal Morphology Network And System Biology Lab, Department Of Mental And Physical Health And Preventive Medicine, Naples, Italy, [2]University of Bicocca, School Of Medicine And Surgery, Monza, Italy, [3]University of Pisa, Dept Of Biology, Pisa, Italy

Glioblastoma (GBM) is a lethal brain tumor, supported by a unique microenvironment. By secreting modulating factors, GBM converts innate immune cells activation away from a pro-inflammatory state. Such modulations engage immune cells into a tissue repair mode, promoting tumor growth and invasion. The inflammation status of the microenvironment temporally plays a pivotal role in cancer development. Therefore, studying the inflamm-aging may help to understand the molecular sequence through which GBM affects the brain microenvironment. GL261 glioma cells were injected in the right striatum of immuno-competent C57Bl6J mice and animals were sacrificed after 7, 14, and 21 days (7D, 14D, 21D). The tumor development was assessed through 3D reconstruction of tomographic imaging and brains were processed by immunohistochemistry, immunofluorescence, and western blotting. In the initiation stage, the proliferating tumor (ki67+) triggered astrocytes (GFAP+) reaction and induced the extracellular matrix remodeling (MMP-9, FIB-2). Microglia (TMEM119+; Iba1+) and macrophages (Iba1+) were scarcely represented, and the chemokine-CCL-2- dependent recruitment of inflammatory monocytes appeared to be reduced. The 14D stage showed an evident tumor bulk and the peak of tenascin C (TnC) protein levels, allowing the migration of the tumor cells. At 21D, CD133+ glioma stem cells were out of the primary bulk, which appeared inflamed, necrotic, and infiltrated by macrophages. The contralateral hemisphere was engaged with a secondary tumor mass, showing cyclic pro and anti-tumor features of inflammation. The present study emphasizes the role of inflammation in the microenvironment during the GBM progression, fostering time-dependent therapies in an experimental model similar to human disease.

The Spinal Extracellular Matrix Modulates a Multi-level Protein Net and Epigenetic Inducers Following Peripheral Nerve Injury.
The extracellular matrix (ECM) of the central nervous system (CNS) plays a pivotal role in the pathogenesis of several neurodegenerative and neuroinflammatory disorders. Among the major factors, matrix metalloproteinases (MMPs) are actively involved in ECM remodeling and directly affect neuro-glial interactions. Since disease-related functional alterations mostly rely on the proteome, modulation of MMPs activity may be a strategy to correct mechanisms behind neurological disorders. We here investigated modifications of signaling components related to the central pathways in spinal maladaptive plasticity following spared nerve injury (SNI) of the sciatic nerve, and after treatment with the MMPs inhibitor GM6001 for 3 or 8 days. We found that GM6001 reduced the massive astrocytic and microglial activation indicative of reactive gliosis. Functional activity of GM6001 was paralleled by its significant effect on expression levels of the purinergic P2X4 receptor (P2X4R), the transcription factors NFκB and RPBJ, as well as levels of the nerve growth factor (NGF) receptor TrkA. Moreover, we showed that histone deacetylases 1 and 2 (HDAC1, HDAC2) were differentially modulated after SNI and GM6001 treatments for 3 or 8 days. Our data suggest a multi-level network of interactions across ECM and the neuroglial network involving MMPs, the neurotrophin system, intracellular signaling, and epigenetic modifications.

THE LINK BETWEEN ENVIRONMENTAL MYCOTOXIN, OCHRATOXIN A, AND NEURODEGENERATIVE DISEASES

POSTER SESSION 06 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Sean Gettings, Riddhi Sharma, Gareth Hazel, Nora Bourbia
UKHSA, Radiation Effects, Didcot, United Kingdom

Aim: Ochratoxin A (OTA) is a common contaminant of crops, foods and drinks. OTA is a known neurotoxin, readily crossing the blood brain barrier yet the role of OTA in neurodegenerative diseases is not understood. This investigation sought to determine whether OTA may act as an environmental hazard linked to neurodegenerative diseases. **Methods**: Undifferentiated SH-SY5Y cells were used as a model to investigate the effect of OTA on MAPT, BAX, P53, BDNF and TPPP gene expression. SH-SY5Y cells were exposed to 1µM or 1nM OTA for 1-2 days or 2pM OTA for 2, 5 or 11 days. Cells were then harvested and pelleted for RNA extraction, followed by cDNA conversion and rt-qPCR to quantify gene expression. **Results**: Exposing cells to 1µM OTA reduced P53, MAPT, and BAX expression at days 1 and 2. The expression of BDNF and TPPP were significantly reduced at day 1 yet significantly increase at day 2 relative to controls. SH-SY5Y cells exposed to a 1nM OTA were observed to have a significant reduction in BAX and P53 only. After 11 days no change in gene expression was observed following a dose of 2pM OTA. **Conclusion**: Gene expression was not altered by 2pM OTA suggesting that low doses of OTA may not trigger neurodegenerative diseases. Downregulation of pro-apoptotic BAX and P53 and upregulation pro-survival BDNF suggest 1µM OTA supresses apoptotic signals and encourages cell survival after just one day. Interestingly, 1µM OTA reduced Alzheimer's disease marker, MAPT expression, while increasing TPPP expression, marker of Parkinson's disease.

White matter capillaries in vascular and neurodegenerative dementias.
Previous studies suggest white matter (WM) integrity is vulnerable to chronic hypoperfusion during brain ageing. We assessed ~ 0.7 million capillary profiles in the frontal lobe WM across several dementias comprising Alzheimer's disease, dementia with Lewy bodies, Parkinson's disease with dementia, vascular dementia, mixed dementias, post-stroke dementia as well as post-stroke no dementia and similar age ageing and young controls without significant brain pathology. Standard histopathological methods were used to determine microvascular pathology and capillary width and densities in 153 subjects using markers of the basement membrane (collagen IV; COL4) and endothelium (glucose transporter-1; GLUT-1). Variable microvascular pathology including coiled, tortuous, collapsed and degenerated capillaries as well as occasional microaneurysms was present in all dementias. As expected, WM microvascular densities were 20-49% lower than in the overlying cortex. This differential in density between WM and cortex was clearly demonstrated by COL4, which was highly correlated with GLUT-1 densities (Spearman's rho = 0.79, P = 0.000). WM COL4 immunopositive microvascular densities were decreased by ~ 18% across the neurodegenerative dementias. However, we found WM COL4 densities were increased by ~ 57% in post-stroke dementia versus ageing and young controls and other dementias. Using three different methods to measure capillary diameters, we found WM capillaries to be significantly wider by 19-45% compared to those in overlying neocortex apparent with both COL4 and GLUT-1. Remarkably, WM capillary widths were increased by ~ 20% across all dementias compared to ageing and young controls (P < 0.01). We also noted mean WM pathology scores incorporating myelin loss, arteriolosclerosis and perivascular spacing were correlated with COL4 immunopositive capillary widths (Pearson's r = 0.71, P = 0.032). Our key finding indicates that WM capillaries are wider compared to those in the overlying neocortex in controls but they dilate further during dementia pathogenesis. We suggest capillaries undergo restructuring in the deep WM in different dementias. This reflects compensatory changes to retain WM perfusion and integrity during hypoperfusive states in ageing-related dementias.

Two Functional Epithelial Sodium Channel Isoforms Are Present in Rodents despite Pronounced Evolutionary Pseudogenization and Exon Fusion.

FENS Forum 2022
9-13 July 2022 | Paris, France

The epithelial sodium channel (ENaC) plays a key role in salt and water homeostasis in tetrapod vertebrates. There are four ENaC subunits (α, β, γ, δ), forming heterotrimeric αβγ- or δβγ-ENaCs. Although the physiology of αβγ-ENaC is well understood, for decades the field has stalled with respect to δβγ-ENaC due to the lack of mammalian model organisms. The SCNN1D gene coding for δ-ENaC was previously believed to be absent in rodents, hindering studies using standard laboratory animals. We analyzed all currently available rodent genomes and discovered that SCNN1D is present in rodents but was independently lost in five rodent lineages, including the Muridae (mice and rats). The independent loss of SCNN1D in rodent lineages may be constrained by phylogeny and taxon-specific adaptation to dry habitats, however habitat aridity does not provide a selection pressure for maintenance of SCNN1D across Rodentia. A fusion of two exons coding for a structurally flexible region in the extracellular domain of δ-ENaC appeared in the Hystricognathi (a group that includes guinea pigs). This conserved pattern evolved at least 41 Ma and represents a new autapomorphic feature for this clade. Exon fusion does not impair functionality of guinea pig (Cavia porcellus) δβγ-ENaC expressed in Xenopus oocytes. Electrophysiological characterization at the whole-cell and single-channel level revealed conserved biophysical features and mechanisms controlling guinea pig αβγ- and δβγ-ENaC function as compared with human orthologs. Guinea pigs therefore represent commercially available mammalian model animals that will help shed light on the physiological function of δ-ENaC.

Methylmercury (MeHg) is an environmental contaminant that especially affects the central nervous system, causing neurological alterations. In response to disturbed microenvironment homeostasis, microglial cells mount an innate immune response contributing to neurodegenerative and neuroinflammatory conditions, a process potentially affected by MeHg exposure. This work aimed to clarify the acute toxic effects of MeHg exposure in microglial cells and associated cell death pathways. BV-2 mouse microglial cells were incubated with MeHg at different concentrations (0.01; 0.1; 1 and 10µM) for 1 hour prior to Lipopolysaccharide (LPS 0.5 µg/mL) exposure for 6 or 24 hours. After cell exposure, the supernatants were harvested and IL-6 and TNF-alpha production and release, ROS production, NO release, iNOS expression, metabolic activity and Propidium Iodide (PI) uptake were assessed. MeHg 10 µM induced a reduction in the production and secretion of pro-inflammatory proteins IL-6, TNF-alpha, iNOS immunoreactivity, release of NO, and ROS formation in BV-2 cells. Furthermore, MeHg 10 µM, with and without LPS stimulation, decreased metabolic activity of BV-2 and increased the number of PI-positive cells (necrotic cell death) when compared to the respective control groups. The short-term effects of a high concentration of MeHg on BV-2 microglial cells lead to impaired production of several pro-inflammatory mediators, as well as a higher microglial cell death via necrosis, compromising their neuroinflammatory response. Clarifying the mechanisms underlying MeHg-induced neurotoxicity and neurodegeneration in brain cells is relevant to better understand acute and long-term chronic neuroinflammatory responses due to MeHg exposure. **Funded by FCT-FUNCAP POCTI-FEDER-02/SAICT/2017/31699**

Gut microbiota has been associated with several neurobehavioural alterations. Some studies highlighted that it can modulates brain inflammation. The aim of the study is to dissect how some gut-derived metabolites can affect brain inflammation and brain functioning. To do so, we explored the effect of these molecules on primary microglia cultures.The first step of the project was to select gut-derived metabolites that are associated with behavioural alterations in patients suffering mood disturbances. Then, we took advantage of an innovative model of primary microglia cells. Quickly, microglia were harvested from adult C57 mice and then a cocktail of molecules was added to the medium in order to make cells acquiring either a quiescent or activated phenotype. Then several gut-derived metabolites were tested in presence or absence of a concomitant LPS stimulation. Several gut-derived metabolites displayed an ability to modulate microglia phenotype in absence of any inflammatory challenge. After LPS stimulation, some metabolites attenuate inflammatory response (i.e cytokines release) and switch in phenotype.Our results revealed that gut microbiota derived metabolites can efficiently modulate microglia phenotype and its response toward inflammatory stimuli *in vitro*.

Amyloid- β 1-42 peptides accumulation and aggregation are the principal hallmarks for Alzheimer Disease (AD) and it triggers to neuroinflammation onset activating Microglia M1 state stimulating pro-inflammatory cytokines. For its properties and enzymatic activites, Transglutaminase 2 (TG2) could be taken in consideration as druggable marker of AD-associated neuroinflammation. Many evidences show a TG2 role during AD-associated neuroinflammation in activated microglia, in association with M1 markers production. To evaluate TG2 inhibition as possible therapeutic approach for AD neuroinflammation, we tested two Endocannabinoids, PEA and its oxazolinic derivative PEA-OXA, with documented anti-inflammatory activity. We analyze TG2 and M1-M2 microglial markers expression to evaluate inflammatory state and define PEA and PEA-OXA neuroprotective activity. Methods : Mouse BV2 microglial cells were treated with fibrillated Aβ1-42 peptides in presence of PEA or PEA-OXA. PEA-OXA effects were studied also in a soluble Amyloid- β mouse model. Real Time PCR and Western Blot analyses were performed to evaluate TG2 expression and M1-M2 microglial markers. Results : TG2 is up-regulated in presence of fibrillated Aβ 1-42 peptide, both at protein and mRNA levels. In presence of PEA and PEA-OXA, TG2 protein and mRNA expression decreases considerably, as M1 markers choosen for the study. Endocannabinoids are able to up-regulate M2 markers Arginase-1 and TREM2 expression. Conclusions : Added to evidences in literature, these data confirm the possibility to consider TG2 as a marker of neuroinflammation. PEA and PEA-OXA have confirmed their anti-inflammatory role suggesting a possible use to block AD patients brain inflammation down-regulating TG2 expression and promoting microglial neuroprotective M2 state.

Aims: Microglia are the resident immune cells of the brain. They have been studied in the context of Alzheimer's disease (AD) since are able to take up amyloid-beta (Aβ) fibrils which form plaques, the main hallmark of AD. Nevertheless, microglia play a dual role in this affection: in the beginning they regulate Aβ; but later they become detrimentally activated causing neuroinflammation. Therefore, we sought for a novel way of regulating AD pathogenesis through microglia. Galectin-3, a key protein for microglial activation, has been described to be involved in AD and to interact with Aβ. Herein, we want to characterize the microglial phenotype *in vitro* related to Aβ due to Galectin-3 regulation. **Methods**: We use the BV-2 cell line, a model of murine microglia in combination with recombinant Galectin-3 and Aβ proteins. Different forms of aggregation were characterized through Thioflavin T assay and added to the cells at different timepoints and concentrations. Moreover, we work with Galectin-3 inhibitors and Galectin-3 knockout BV-2 cells. We follow Aβ internalization with live-cell imaging. We also quantify the inflammatory cytokines release through ELISA Mesoscale and identifying the key microglial gene transcripts through quantitative reverse transcription PCR. **Results**: Preliminary results include an increase in the Aβ fibrils internalization and TNFα levels increased in the medium when cells were pretreated with Galectin-3. We expect to identify a phenotype beneficial for the pathogenesis when Galectin-3 is inhibited or knocked out. **Conclusions**: We expect to successfully find a way of maintaining a beneficial activation of microglia throughout AD pathology.

Aims: Alzheimer's disease (AD) is a progressive neurodegenerative disorder with memory loss, cognitive and mobility decline. Central nervous system (CNS) glia, particularly astrocytes and oligodendrocytes are linked to the pathogenesis of Alzheimer's. Glial cells are coupled through gap junctions (GJ) assembled by two hemichannels consisting of six connexin (Cx) proteins on each opposed cell. Recent studies support that brain oligodendrocytic Cx47 might play a pathological role in Alzheimer's progression. The project aim is to investigate oligodendroglial pathology in the spinal cord of the 5xFAD mouse model. Methods: Western blot experiments were performed for the quantification of Cx47 in 5xFAD and non-transgenic mice groups (3 and 12 months). Fluorescence immunohistochemistry (IHC) in 3rd-4th cervical and 2nd-3rd lumbar frozen spinal sections was carried out for Cx47, CC1, Olig2, GFAP, and Iba1 markers. Results: 12-month-old 5xFAD mice showed a time-dependent increased immunoreactivity for GFAP+ astrocytes and Iba1+ microglia in the spinal cord compared to 3-month-old mice. In addition, older 5xFAD mice exhibited increased immunoreactivity for Cx47 in the grey matter of the abovementioned spinal levels and increased protein levels. Lastly, 12M 5xFAD expressed significantly higher levels of both mature and precursor oligodendrocyte populations in the gray matter of the spinal cord in comparison to the younger transgenic mice. Conclusions: We detected severe astrogliosis and increased expression levels of Cx47, which may contribute to Alzheimer's pathogenesis. Future studies will be focused on the investigation of connexins' contribution to the overall glia pathology resulting in motor deficiencies observed in 5xFAD mice.

Endocannabinoids (eCBs) show pleiotropic and pro-homeostatic activities, including changes of inflammatory response within CNS and the ability to drive microglial polarization towards an anti-inflammatory phenotype. The anandamide (AEA) hydrolase fatty-acid-amide-hydrolase (FAAH) was found to be up-regulated in patients with Alzheimer's disease (AD), where the reduced levels of AEA are considered responsible for defective autophagy that leads to increased accumulation of β-amyloid (Aβ). **Aims** By the use of the selective FAAH inhibitor URB597, we have recently shown a shift towards an antiinflammatory phenotype in Aβ-treated BV2 murine microglia cells. Here, we aimed at investigating the possibility that *in vitro* and *in vivo* URB597 treatment can restore autophagy machinery in Aβ-treated microglial cells. **Methods** mRNAs of autophagy marker proteins (ATG-7, Beclin1, LC3, p62), and of the nuclear factor erythroid 2-related factor 2 (Nrf2) were obtained from URB597-treated BV-2 cells with or without Aβ, and were analyzed by real-time PCR. Protein expression was assessed by immunohistochemistry of brain sections (cortex-hippocampus) of URB597-administered transgenic Tg2576 mice, and the results confirmed by Western blot or immunofluorescence. **Results** FAAH inhibition increased the mRNA-expression of ATG-7, Beclin1, LC3, p62 as well as Nrf2 in BV-2 cells. The expression of ATG-7, Beclin1 and LC3 was also increased in BV2 cells and in the brain of URB597-administered transgenic Tg2576 mice, where a decrease of the total number/whole area of Aβ plaques was demonstrated. **Conclusions** The enhancement of eCB tone, and of AEA-mediated signaling, may improve autophagy in ADlike neuropathology.

Fatty Acid Amide Hydrolase (FAAH) Inhibition Modulates Amyloid-Beta-Induced Microglia Polarization.
The ability of endocannabinoid (eCB) to change functional microglial phenotype can be explored as a possible target for therapeutic intervention. Since the inhibition of fatty acid amide hydrolase (FAAH), the main catabolic enzyme of anandamide (AEA), may provide beneficial effects in mice model of Alzheimer's disease (AD)-like pathology, we aimed at determining whether the FAAH inhibitor URB597 might target microglia polarization and alter the cytoskeleton reorganization induced by the amyloid-β peptide (Aβ). The morphological evaluation showed that Aβ treatment increased the surface area of BV-2 cells, which acquired a flat and polygonal morphology. URB597 treatment partially rescued the control phenotype of BV-2 cells when co-incubated with Aβ. Moreover, URB597 reduced both the increase of Rho protein activation in Aβ-treated BV-2 cells and the Aβ-induced migration of BV-2 cells, while an increase of Cdc42 protein activation was observed in all samples. URB597 also increased the number of BV-2 cells involved in phagocytosis. URB597 treatment induced the polarization of microglial cells towards an anti-inflammatory phenotype, as demonstrated by the decreased expression of iNOS and pro-inflammatory cytokines along with the parallel increase of Arg-1 and anti-inflammatory cytokines. Taken together, these data suggest that FAAH inhibition promotes cytoskeleton reorganization, regulates phagocytosis and cell migration processes, thus driving microglial polarization towards an anti-inflammatory phenotype.

Mediterranean Diet and Neurodegenerative Diseases: The Neglected Role of Nutrition in the Modulation of the Endocannabinoid System.
Neurodegenerative disorders are a widespread cause of morbidity and mortality worldwide, characterized by neuroinflammation, oxidative stress and neuronal depletion. The broad-spectrum neuroprotective activity of the

Mediterranean diet is widely documented, but it is not yet known whether its nutritional and caloric balance can induce a modulation of the endocannabinoid system. In recent decades, many studies have shown how endocannabinoid tone enhancement may be a promising new therapeutic strategy to counteract the main hallmarks of neurodegeneration. From a phylogenetic point of view, the human co-evolution between the endocannabinoid system and dietary habits could play a key role in the pro-homeostatic activity of the Mediterranean lifestyle: this adaptive balance among our ancestors has been compromised by the modern Western diet, resulting in a "clinical endocannabinoid deficiency syndrome". This review aims to evaluate the evidence accumulated in the literature on the neuroprotective, immunomodulatory and antioxidant properties of the Mediterranean diet related to the modulation of the endocannabinoid system, suggesting new prospects for research and clinical interventions against neurodegenerative diseases in light of a nutraceutical paradigm.

Immunohistochemical detection of IL-17 and IL-23 improves the identification of patients with a possible diagnosis of Sjogren's syndrome.
The diagnosis of primary Sjogren's syndrome (pSS) continues to be difficult and several patients keep symptomatic for years with different diagnoses before confirmation of pSS. Since the IL-23-IL-17 axis is involved in the etiopathogenesis of pSS we evaluated by immunohistochemistry and morphometric methods the presence of IL-17 as well as IL-23 within minor salivary glands (MSG) obtained from patients with uncertain diagnosis of pSS.

Nutraceuticals as potential therapeutics for vesicant-induced pulmonary fibrosis.
Exposure to vesicants, including sulfur mustard and nitrogen mustard, causes damage to the epithelia of the respiratory tract and the lung. With time, this progresses to chronic disease, most notably, pulmonary fibrosis. The pathogenic process involves persistent inflammation and the release of cytotoxic oxidants, cytokines, chemokines, and profibrotic growth factors, which leads to the collapse of lung architecture, with fibrotic involution of the lung parenchyma. At present, there are no effective treatments available to combat this pathological process. Recently, much interest has focused on nutraceuticals, substances derived from plants, herbs, and fruits, that exert pleiotropic effects on inflammatory cells and parenchymal cells that may be useful in reducing fibrogenesis. Some promising results have been obtained with nutraceuticals in experimental animal models of inflammation-driven fibrosis. This review summarizes the current knowledge on the putative preventive/therapeutic efficacy of nutraceuticals in progressive pulmonary fibrosis, with a focus on their activity against inflammatory reactions and profibrotic cell differentiation.

Blueberry Counteracts BV-2 Microglia Morphological and Functional Switch after LPS Challenge.
Microglia, the innate immune cells of the CNS, respond to brain injury by activating and modifying their morphology. Our study arises from the great interest that has been focused on blueberry (BB) for the antioxidant and pharmacological properties displayed by its components. We analyzed the influence of hydroalcoholic BB extract in resting or lipopolysaccharide (LPS)-stimulated microglia BV-2 cells. BB exerted a protective effect against LPS-induced cytotoxicity, as indicated by cell viability. BB was also able to influence the actin cytoskeleton organization, to recover the control phenotype after LPS insult, and also to reduce LPS-driven migration. We evaluated the activity of Rho and Rac1 GTPases, which regulate both actin cytoskeletal organization and migratory capacity. LPS caused an increase in Rac1 activity, which was counteracted by BB extract. Furthermore, we demonstrated that, in the presence of BB, mRNA expression of pro-inflammatory cytokines IL-1β, IL-6 and TNF-α decreased, as did the immunofluorescence signal of iNOS, whereas that of Arg-1 was increased. Taken together, our results show that, during the inflammatory response, BB extract shifts the M1 polarization towards the M2 phenotype through an actin cytoskeletal rearrangement. Based on that, we might consider BB as a nutraceutical with anti-inflammatory activities.

Relationship between proinflammatory cytokines (Il-1beta, Il-18) and leukocyte telomere length in mild cognitive impairment and Alzheimer's disease.
Inflammation plays a crucial role in Alzheimer's disease (AD). AD neurodegeneration and concurrent involvement of the peripheral immune system may promote leukocyte division and telomere shortening. We examined genotypes and plasma levels of two proinflammatory cytokines, IL-1beta and IL-18, and leukocyte telomere length (LTL) in patients with mild cognitive impairment (MCI) and AD. We wanted to determine whether changes in plasma IL-1beta and IL-18 levels, together

with LTL shortening, could be diagnostic for disease progression from MCI to AD. Median plasma IL-1beta levels were in the order MCI patients (2.2 pg/ml) < AD patients (4.0 pg/ml), both of which differed significantly from the controls (0.0 pg/ml). In the AD patients, the lowest IL-1beta levels were associated with the presence of the C allele of IL-1beta rs16944 SNP. Median plasma IL-18 levels were in the order MCI patients (116.3 pg/ml) > AD patients (85.8 pg/ml), both of which were significantly higher than in the controls (17.6 pg/ml). Analysis of LTL showed a progressive reduction in the order controls > MCI > AD patients ($p < 0.0001$). Overall LTL reduction was correlated with increased plasma IL-1beta levels, substantiating the hypothesis that inflammatory processes secondary to neuroinflammation may trigger telomere attrition. Changes in plasma IL-1beta and Il-18 levels, and LTL seem to reflect shifts in AD stage; they may have potential use as blood biomarkers to monitor disease onset and progression from MCI to AD.

- Aims: Adenosine binds 4 different mammalian receptors: A_1, A_{2A}, A_{2B} and A_3. These receptors couple two different heterotrimeric G proteins, while A_1 and A_3 couple Gi, A_{2A} and A_{2B} couple Gs/Golf. GPCRs can interact forming heteromeric complexes and acquiring new structural and functional properties. Accordingly, the aim of this study was to look for expression and function of the A_{2A}/A_3 receptor heteromer ($A_{2A}A_3$Het) in HEK-transfected cells, neurons and microglia. **- Methods:** Transfected HEK-293T cells, neuronal and glial primary cultures were characterized by cAMP accumulation and MAPK activation, analyzing A_{2A} and A_3 receptors function. Using in situ proximity ligation assay (PLA) $A_{2A}A_3$Het expression was characterized in primary neurons and microglia of $APP_{Sw,Ind}$ mice model of Alzheimer's disease. **- Results:** The heteromeric context led to a marked decrease of the signaling originating at A_3 receptors. Interestingly from a therapeutic point of view, A_{2A} receptor antagonists overrode the blockade, thus allowing A_3 receptor-mediated signaling. $A_{2A}A_3$Het expression was markedly higher in striatal than in cortical and hippocampal neurons and the expression of the heteromer was markedly enhanced in microglia from the $APP_{Sw,Ind}$ model of Alzheimer's disease. **- Conclusion:** Within this study, we demonstrate that A_{2A}-A_3 can interact forming heteromeric complexes and the receptor heteromer can be an important target for neuroprotection by using A_{2A}R antagonists in order to potentiate the action of A_3R and avoid the blockade by the A_{2A} pro-inflammatory receptor.

Microglial Adenosine Receptors: From Preconditioning to Modulating the M1/M2 Balance in Activated Cells.
Neuronal survival depends on the glia, that is, on the astroglial and microglial support. Neurons die and microglia are activated not only in neurodegenerative diseases but also in physiological aging. Activated microglia, once considered harmful, express two main phenotypes: the pro-inflammatory or M1, and the neuroprotective or M2. When neuroinflammation, i.e., microglial activation occurs, it is important to achieve a good M1/M2 balance, i.e., at some point M1 microglia must be skewed into M2 cells to impede chronic inflammation and to afford neuronal survival. G protein-coupled receptors in general and adenosine receptors in particular are potential targets for increasing the number of M2 cells. This article describes the mechanisms underlying microglial activation and analyzes whether these cells exposed to a first damaging event may be ready to be preconditioned to better react to exposure to more damaging events. Adenosine receptors are relevant due to their participation in preconditioning. They can also be overexpressed in activated microglial cells. The potential of adenosine receptors and complexes formed by adenosine receptors and cannabinoids as therapeutic targets to provide microglia-mediated neuroprotection is here discussed.

Methamphetamine Blocks Adenosine A Receptor Activation via Sigma 1 and Cannabinoid CB Receptors.
Methamphetamine is, worldwide, one of the most consumed drugs of abuse. One important side effect is neurodegeneration leading to a decrease in life expectancy. The aim of this paper was to check whether the drug affects one of the receptors involved in neurodegeneration/neuroprotection events, namely the adenosine A receptor (AR). First, we noticed that methamphetamine does not affect A functionality if the receptor is expressed in a heterologous system. However, AR becomes sensitive to the drug upon complexes formation with the cannabinoid CB receptor (CBR) and the sigma 1 receptor (σR). Signaling via both adenosine AR and cannabinoid CBR was affected by methamphetamine in cells co-expressing the two receptors. In striatal primary cultures, the AR-CBR heteromer complex was detected and methamphetamine not only altered its expression but completely blocked the AR- and the CBR-mediated activation of the mitogen activated protein kinase (MAPK) pathway. In conclusion, methamphetamine, with the participation of σR, alters the expression and function of

two interacting receptors, AR, which is a therapeutic target for neuroprotection, and CBR, which is the most abundant G protein-coupled receptor (GPCR) in the brain.

Similarities and differences upon binding of naturally occurring Δ-tetrahydrocannabinol-derivatives to cannabinoid CB and CB receptors.
We have here assessed, using Δ-tetrahydrocannabinol (Δ-THC) for comparison, the effect of Δ-tetrahydrocannabinolic acid (Δ-THCA) and of Δ-tetrahydrocannabivarin (Δ9-THCV) that is mediated by human versions of CB, CB, and CB-CB receptor functional units, expressed in a heterologous system. Binding to the CB and CB receptors was addressed in living cells by means of a homogeneous assay. A biphasic competition curve for the binding to the CB receptor, was obtained for Δ-THCV in cells expressing the two receptors. Signaling studies included cAMP level determination, activation of the mitogen-activated protein kinase pathway and ß-arrestin recruitment were performed. The signaling triggered by Δ-THCA and Δ-THCV via individual receptors or receptor heteromers disclosed differential bias, i.e. the bias observed using a given phytocannabinoid depended on the receptor (CB, CB or CB-CB) and on the compound used as reference to calculate the bias factor (Δ-THC, a selective agonist or a non-selective agonist). These results are consistent with different binding modes leading to differential functional selectivity depending on the agonist structure, and the state (monomeric or heteromeric) of the cannabinoid receptor. In addition, on studying Gi-coupling we showed that Δ-THCV and Δ-THCA and Δ-THCV were able to revert the effect of a selective CB receptor agonist, but only Δ9-THCV, and not Δ9-THCA, reverted the effect of arachidonyl-2'-chloroethylamide (ACEA 100 nM) a selective agonist of the CB receptor. Overall, these results indicate that cannabinoids may have a variety of binding modes that results in qualitatively different effects depending on the signaling pathway that is engaged upon cannabinoid receptor activation.

Discovery of a macromolecular complex mediating the hunger suppressive actions of cocaine: Structural and functional properties.
Cocaine not only increases brain dopamine levels but also activates the sigma receptor (σ R) that in turn regulates orexigenic receptor function. Identification of interactions involving dopamine D (D R), ghrelin (GHS-R), and σ receptors have been addressed by biophysical techniques and a complementation approach using interfering peptides. The effect of cocaine on receptor functionality was assayed by measuring second messenger, cAMP and Ca , levels. The effect of acute or chronic cocaine administration on receptor complex expression was assayed by in situ proximity ligation assay. In silico procedures were used for molecular model building. σ R KO mice were used for confirming involvement of this receptor. Upon identification of protomer interaction and receptor functionality, a unique structural model for the macromolecular complex formed by σ R, D R, and GHS-R is proposed. The functionality of the complex, able to couple to both Gs and Gq proteins, is affected by cocaine binding to the σ R, as confirmed using samples from σ R mice. The expression of the macromolecular complex was differentially affected upon acute and chronic cocaine administration to rats. The constructed 3D model is consistent with biochemical, biophysical, and available structural data. The σ R, D R, and GHS-R complex constitutes a functional unit that is altered upon cocaine binding to the σ R. Remarkably, the heteromer can simultaneously couple to two G proteins, thus allowing dopamine to signal via Ca and ghrelin via cAMP. The anorexic action of cocaine is mediated by such complex whose expression is higher after acute than after chronic administration regimens.

Potentiation of cannabinoid signaling in microglia by adenosine A receptor antagonists.
Neuroprotective M2-skewed microglia appear as promising to alter the course of neurodegenerative diseases and G protein-coupled receptors (GPCRs) are potential targets to achieve such microglial polarization. A common feature of adenosine A (A R) and cannabinoid CB (CB R) GPCRs in microglia is that their expression is upregulated in Alzheimer's disease (AD). On the one hand, CB R seems a target for neuroprotection, delaying neurodegenerative processes like those associated to AD or Parkinson's diseases. A R antagonists reduce amyloid burden and improve cognitive performance and memory in AD animal models. We here show a close interrelationship between these two receptors in microglia; they are able to physically interact and affect the signaling of each other, likely due to conformational changes within the A -CB receptor heteromer (A -CB Het). Particularly relevant is the upregulation of A -CB Het expression in samples from the APP , AD transgenic mice model. The most relevant finding, confirmed in both heterologous cells and in primary cultures of microglia, was that blockade of A receptors results in increased CB R-mediated signaling. This heteromer-specific feature suggests that A R antagonists

would potentiate, via microglia, the neuroprotective action of endocannabinoids with implications for AD therapy.

Identification of the Ghrelin and Cannabinoid CB Receptor Heteromer Functionality and Marked Upregulation in Striatal Neurons from Offspring of Mice under a High-Fat Diet.
Cannabinoids have been reported as orexigenic, i.e., as promoting food intake that, among others, is controlled by the so-called "hunger" hormone, ghrelin. The aim of this paper was to look for functional and/or molecular interactions between ghrelin GHSR1a and cannabinoid CB receptors at the central nervous system (CNS) level. In a heterologous system we identified CB-GHSR1a receptor complexes with a particular heteromer print consisting of impairment of CB receptor/G-mediated signaling. The blockade was due to allosteric interactions within the heteromeric complex as it was reverted by antagonists of the GHSR1a receptor. Cannabinoids acting on the CB receptor did not affect cytosolic increases of calcium ions induced by ghrelin acting on the GHSR1a receptor. In situ proximity ligation imaging assays confirmed the expression of CB-GHSR1a receptor complexes in both heterologous cells and primary striatal neurons. We tested heteromer expression in neurons from offspring of high-fat-diet mouse mothers as they have more risk to be obese. Interestingly, there was a marked upregulation of those complexes in striatal neurons from siblings of pregnant female mice under a high-fat diet.

N-Methyl-D-aspartate (NMDA) and cannabinoid CB receptors form functional complexes in cells of the central nervous system: insights into the therapeutic potential of neuronal and microglial NMDA receptors.
The cannabinoid CB receptor (CBR), which is a target to afford neuroprotection, and N-methyl-D-aspartate (NMDA) ionotropic glutamate receptors, which are key in mediating excitatory neurotransmission, are expressed in both neurons and glia. As NMDA receptors are the target of current medication in Alzheimer's disease patients and with the aim of finding neuromodulators of their actions that could provide benefits in dementia, we hypothesized that cannabinoids could modulate NMDA function.

Ghrelin and Cannabinoid Functional Interactions Mediated by Ghrelin/CB Receptor Heteromers That Are Upregulated in the Striatum From Offspring of Mice Under a High-Fat Diet.
There is evidence of ghrelinergic-cannabinoidergic interactions in the central nervous system (CNS) that may impact on the plasticity of reward circuits. The aim of this article was to look for molecular and/or functional interactions between cannabinoid CB and ghrelin GHS-R1a receptors. In a heterologous system and using the bioluminescence resonance energy transfer technique we show that human versions of cannabinoid CB and ghrelin GHS-R1a receptors may form macromolecular complexes. Such receptor heteromers have particular properties in terms of CB/G-mediated signaling and in terms of GHS-R1a-G-mediated signaling. On the one hand, just co-expression of CBR and GHS-R1a led to impairment of cannabinoid signaling. On the other hand, cannabinoids led to an increase in ghrelin-derived calcium mobilization that was stronger at low concentrations of the CB receptor agonist, arachidonyl-2'-chloroethylamide (ACEA). The expression of CB-GHS-R1a receptor complexes in striatal neurons was confirmed by proximity ligation imaging assays. Upregulation of CB-GHS-R1a- receptor complexes was found in striatal neurons from siblings of pregnant female mice on a high-fat diet. Surprisingly, the expression was upregulated after treatment of neurons with ghrelin (200 nM) or with ACEA (100 nM). These results help to better understand the complexities underlying the functional interactions of neuromodulators in the reward areas of the brain.

Adenosine A Receptor Antagonists Affects NMDA Glutamate Receptor Function. Potential to Address Neurodegeneration in Alzheimer's Disease.
(1) Background. -methyl d-aspartate (NMDA) ionotropic glutamate receptor (NMDAR), which is one of the main targets to combat Alzheimer's disease (AD), is expressed in both neurons and glial cells. The aim of this paper was to assess whether the adenosine A receptor (AR), which is a target in neurodegeneration, may affect NMDAR functionality. (2) Methods. Immuno-histo/cytochemical, biophysical, biochemical and signaling assays were performed in a heterologous cell expression system and in primary cultures of neurons and microglia (resting and activated) from control and the APP transgenic mice. (3) Results. On the one hand, NMDA and A receptors were able to physically interact forming complexes, mainly in microglia. Furthermore, the amount of complexes was markedly enhanced in activated microglia. On the other hand, the interaction resulted in a novel functional entity that displayed a cross-antagonism, that could be useful to prevent the exacerbation of NMDAR function by using AR antagonists. Interestingly, the amount of complexes was markedly higher in the hippocampal cells from the APP than from the control mice. In neurons, the number of complexes was lesser, probably due to NMDAR not

interacting with the AR. However, the activation of the AR receptors resulted in higher NMDAR functionality in neurons, probably by indirect mechanisms. (4) Conclusions. AR antagonists such as istradefylline, which is already approved for Parkinson's disease (Nouriast in Japan and Nourianz in the US), have potential to afford neuroprotection in AD in a synergistic-like fashion. i.e., via both neurons and microglia.

Adenosine A and A Receptors Are Able to Interact with Each Other. A Further Piece in the Puzzle of Adenosine Receptor-Mediated Signaling.
The aim of this paper was to check the possible interaction of two of the four purinergic P1 receptors, the A and the A. Discovery of the A-A receptor complex was achieved by means of immunocytochemistry and of bioluminescence resonance energy transfer. The functional properties and heteromer print identification were addressed by combining binding and signaling assays. The physiological role of the novel heteromer is to provide a differential signaling depending on the pre-coupling to signal transduction components and/or on the concentration of the endogenous agonist. The main feature was that the heteromeric context led to a marked decrease of the signaling originating at A receptors. Interestingly from a therapeutic point of view, A receptor antagonists overrode the blockade, thus allowing A receptor-mediated signaling. The A-A receptor heteromer print was detected in primary cortical neurons. These and previous results suggest that all four adenosine receptors may interact with each other. Therefore, each adenosine receptor could form heteromers with distinct properties, expanding the signaling outputs derived from the binding of adenosine to its cognate receptors.

Alzheimer's disease (AD) is the most common form of dementia. Microglia are the main immune cells of the brain and play key roles in triggering and maintaining neuroinflammation, a fundamental feature of AD. Additionally, Human genome wide association studies have recently demonstrated that most of the AD risk genes were strongly or exclusively expressed by microglia, supporting their critical involvement in AD pathogenesis. However, whether their contribution is detrimental or beneficial is not yet well understood. Several studies suggested the coexistence of different subpopulations of microglia with various phenotypes, which could be responsible for the different and ambivalent responses observed. It is therefore crucial to decipher human microglia heterogeneity. To achieve this goal, we took advantages of recent advances in human induced Pluripotent Stem Cells (hiPSCs) cultures that pave the way for the development of innovative cellular models containing human microglia. To start, we set-up a complex iPSC-derived 3D-full-Networks composed of neural networks supplemented with microglia. We validating that microglial precursors co-cultured with 3D neural networks differentiated into fully functional microglia. We then generated 3D-full-Networks from both healthy donors, AD-patients iPSCs carrying either autosomic dominant or sporadic forms of the disease, and isogenic controls of the AD-lines (generated through CRISPR Cas9 technology). In these different models, we are characterizing the occurrence of several AD-related hallmarks: Ab and Phospho-Tau accumulation, neuroinflammation, neuronal defects, and more specifically microglial alterations. Our final objective will be to characterize the molecular heterogeneity of human microglia through single-cell RNA sequencing and functional genomic analysis.

EFFECT OF IMPAIRED ENDO-LYSOSOMAL DEGRADATION ON MICROGLIA IN A MOUSE MODEL OF ALZHEIMER´S DISEASE

POSTER SESSION 06 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Kristin Oberländer[1], Beate Koch[1], Tarek Elmzzahi[2], Marc Beyer[2], Anja Schneider[1]

Microglia activation and associated neuroinflammation are regarded as key players in Alzheimer´s disease (AD) initiation and progression. Several risk loci for developing sporadic AD were identified in genes involved in microglia phagocytosis and endolysosomal processes. Since old age is still the biggest risk factor for AD, senescent microglia which show reduced degradative capacity are speculated to exaggerate AD pathology. However, the exact role of microglia degradation in AD is still controversial. To answer the question how impaired microglial endolysosomal degradation affects AD pathology, we combined a murine model of familial AD, 5xFAD, with a microglia specific conditional knockout of Rab7 (Rab7ΔMG). Rab7 is involved in the maturation of the late endo-lysosome and it was previously shown that Rab7ΔMG causes reduced lysosomal degradation in aged mice. We confirmed impaired lysosomal function in Rab7ΔMGx5FAD microglia which caused lysosomal accumulation of amyloid beta and reduced amyloid phagocytosis. Since it is well known that subsets of microglia contribute differently to AD pathology we performed single cell sequencing (scSeq) after FACS to investigate the impact of impaired degradation on different microglia clusters. On top we combined this scSeq results with the expression profile of phagocytic active (MX04+) and inactive (MX04-) microglia.

Dysregulation of and expression and an altered excitation-inhibition balance are associated with cognitive deficits in DBA/2 mice.
Differences in the learning associated transcriptional profiles between mouse strains with distinct learning abilities could provide insight into the molecular basis of learning and memory. The inbred mouse strain DBA/2 shows deficits in hippocampus-dependent memory, yet the transcriptional responses to learning and the underlying mechanisms of the impairments are unknown. Comparing DBA/2J mice with the reference standard C57BL/6N mouse strain we verify an enhanced susceptibility to kainic acid induced seizures, confirm impairments in hippocampus-dependent spatial memory tasks and uncover additional behavioral abnormalities including deficits in hippocampus-independent learning. Surprisingly, we found no broad dysfunction of the DBA/2J strain in immediate early gene (IEG) activation but instead report brain region-specific and gene-specific alterations. The learning-associated IEGs , -, and showed no DBA/2J deficits in basal or synaptic activity induced gene expression in hippocampal or cortical primary neuronal cultures or in the CA1, CA3, or retrosplenial cortex following spatial object recognition (SOR) training in vivo. However, the parietal cortex showed reduced and the dentate gyrus showed enhanced SOR-evoked induction of most IEGs. All DBA/2J hippocampal regions exhibited elevated basal expression of inhibin β A () and a learning-associated superinduction of the transcription factor neuronal Per-Arnt-Sim domain protein 4 () known to regulate the synaptic excitation-inhibition balance. In line with this, CA1 pyramidal neurons of DBA/2J mice showed fewer inhibitory and more excitatory miniature postsynaptic currents but no alteration in most other electrophysiological properties or gross dendritic morphology. The dysregulation of and expression and synaptic connectivity may underlie the cognitive deficits and increased susceptibility to seizures of DBA/2J mice.

One nuclear calcium transient induced by a single burst of action potentials represents the minimum signal strength in activity-dependent transcription in hippocampal neurons.
Neurons undergo dramatic changes in their gene expression profiles in response to synaptic stimulation. The coupling of neuronal excitation to gene transcription is well studied and is mediated by signaling pathways activated by cytoplasmic and nuclear calcium transients. Despite this, the minimum synaptic activity required to induce gene expression remains unknown. To address this, we used cultured hippocampal neurons and cellular compartment analysis of temporal activity by

fluorescence in situ hybridization (catFISH) that allows detection of nascent transcripts in the cell nucleus. We found that a single burst of action potentials, consisting of 24.4±5.1 action potentials during a 6.7±1.9s depolarization of 19.5±2.0mV causing a 9.3±0.9s somatic calcium transient, is sufficient to activate transcription of the immediate early gene arc (also known as Arg3.1). The total arc mRNA yield produced after a single burst-induced nuclear calcium transient was very small and, compared to unstimulated control neurons, did not lead to a significant increase in arc mRNA levels measured using quantitative reverse transcriptase PCR (qRT-PCR) of cell lysates. Significantly increased arc mRNA levels became detectable in hippocampal neurons that had undergone 5-8 consecutive burst-induced nuclear calcium transients at 0.05-0.15Hz. These results indicate that a single burst-induced nuclear calcium transient can activate gene expression and that transcription is rapidly shut off after synaptic stimulation has ceased.

To understand the role of microglia degradation in Aß-pathology, neuroinflammation and neurotoxicity, we generated 5xFAD transgenic AD mice with microglia-specific knockout of Rab7 GTPase (Rab7ΔMG x 5xFAD), which is responsible for the fusion of late endosomes and autophagosomes with the lysosome, and thereby promotes lysosomal degradation. We confirmed impaired lysosomal function in Rab7ΔMG x 5xFAD microglia, which also caused lysosomal accumulation of amyloid beta and reduced amyloid phagocytosis. With our single cell sequencing data (presented by Dr. Kristin Oberlander), we obtained detailed information of microglia subclusters. Since previous studies showed that microglia affect Aß-plaque properties, we investigated the effect of Rab7ΔMG x 5xFAD on Aß-plaque number, compaction and morphology. We also examined the effect of the microglial Rab7 depletion on neuronal health status in our mouse model and evaluated neuronal and synaptic markers by immunohistochemistry and western blot.

Label-free chemiluminescent ATP aptasensor based on graphene oxide and an instantaneous derivatization of guanine bases.
In this work, a novel label-free chemiluminescent (CL) aptasensor has been developed for rapid and facile detection of adenosine triphosphate (ATP, as model analyte) using graphene oxide (GO) nano-platform. The strategy relies on the preferential binding of GO to single-stranded DNA (ssDNA) over rigid double-stranded DNA (dsDNA) or aptamer-target complexes, and the instantaneous derivative reaction between phenylglyoxal (PGO), a special CL reagent as the signaling molecule, and guanine nucleobases (G) of aptamer strands adsorbed on the surface of GO. In the absence of ATP, the aptamers adsorbed onto the surface of GO leading to a strong background CL signal. Conversely, in the presence of ATP, the aptamers formed the aptamer-ATP complexes which had weak binding ability to GO resulting in a significant CL signal decrease. The CL intensity was adversely related to the ATP concentration in the assay solution. The biosensor's signal decreased linearly with the logarithm of the concentration of ATP from 2 to 80 nmol with a detection limit of 1.4 nmol. The aptasensor also showed high selectivity against cytosine triphosphate (CTP), guanosine triphosphate (GTP), and uridine triphosphate (UTP). The method presented here holds the advantages of being label-free, cost effective, rapid, sensitive and selective, which would shows great promise for clinical application.

CYP4Z1 - A Human Cytochrome P450 Enzyme that Might Hold the Key to Curing Breast Cancer.
The human cytochrome P450 (CYP) enzyme CYP4Z1 is a fatty acid hydroxylase which among human CYPs is unique for being much stronger expressed in the mammary gland than in all other tissues. Moreover, it is strongly overexpressed in all subtypes of breast cancer, and some overexpression has also been found in other types of malignancies, such as ovarian, lung, and prostate cancers, respectively. Due to its unique expression pattern it is conceivable that this enzymes' activity might be exploited for a new therapeutic approach. However, the main challenge for a CYP4Z1-based prodrug strategy (CBPS) for the treatment of breast cancer (and possibly other CYP4Z1-positive malignancies) is the identification of candidate prodrugs that can be activated by this enzyme. In this mini-review we summarize the current knowledge about the enzymatic properties of the CYP4Z1 enzyme as well as on the expression pattern of the CYP4Z1 gene in both normal and cancer cells. Moreover, we present the first homology model of this enzyme and give an outlook on its potential use in cancer treatment strategies.

UNVEILING THE ASTROCYTIC-DRIVEN INFLAMMATORY RESPONSE IN ALZHEIMER'S DISEASE – INSIGHTS INTO INFLAMMASOME PATHWAYS

POSTER SESSION 06 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Mariana Van Zeller[1,2], Ana M. Sebastião[1,2], Cláudia A. Valente[1,2]
[1]Instituto de Farmacologia e Neurociências, Faculdade De Medicina, Universidade De Lisboa, Lisboa, Portugal, [2]Instituto de Medicina Molecular João Lobo Antunes, Faculdade De Medicina, Universidade De Lisboa, Lisboa, Portugal

Alzheimer's disease (AD) is a neurodegenerative disease that has been associated with the activation of multiprotein cytoplasmic complexes, the inflammasomes, which lead to the processing of Caspase-1, culminating in the maturation of Interleukin (IL)-1β and cleavage of Gasdermin D, the effector protein of pyroptosis, an inflammatory type of cell death. Microglia's contribution to the neuroinflammatory environment observed in AD via inflammasome pathways is highly explored. In astrocytes, less is known about inflammasome activation, being believed in the past that these complexes did not assemble in this cell type. However, evidence arose for inflammasome activation in astrocytes, generating controversy regarding this matter. Thus, this project aims to unravel the inflammatory response of astrocytes, under an AD context, focusing on the NLRP3 inflammasome cascade. For this, primary cultures of astrocytes were stimulated with $A\beta_{25-35}$, microglia derived-factors (F), and both stimuli concomitantly for 24h. Expression of NLRP3 components, their assembly in astrocytes, and IL-1β release were analyzed through Western Blot, Immunocytochemistry, and ELISA. Preliminary results showed that F, but not $A\beta_{25-35}$ alone, promoted an increase in NLRP3 domains and in IL-1β release, and this increase was more significant when the two stimuli were applied together. This was coincident with an increase in C3 and PTX3 expression, markers for reactive astrocytes. Altogether, we show that in the presence of F, which mimics microglia presence promoting astrocytic reactivity, $A\beta_{25-35}$ can activate NLRP3 pathway in astrocytes. Future work will explore other inflammasomes, such as NLRP1 and NLRP2, to unveil which pathway contributes most to astrocytic responsiveness.

Alzheimer's Disease (AD) is the most common form of dementia. It is characterized by behavioral deficits and histological features. Neuroinflammation is another important disease's hallmark, for which microglia are playing key roles. Of note, almost all AD risk genes are highly expressed in microglia, highlighting their crucial role in AD pathogenesis. Whether microglia play beneficial and/or detrimental roles to the disease progression remains heavily debated. In addition, their role in the initiation of the pathology is still poorly understood. The present study was designed to investigate microglial reaction at early stage of AD. The main objectives were to: 1) characterize whether microglial reaction occurs prior to plaques seeding; 2) identify genes and pathways dysregulated at this phase; and 3) determine whether deregulated genes may represent potential early biomarkers. Using the $APP^{swe}/PS1^{dE9}$:$CX3CR1^{+/eGFP}$ AD mice model, we isolated plaque-distant microglia at an early phase of the disease. RNA sequencing revealed significant remodeling of the microglial transcriptome and led to the identification of early markers of the pathology. In particular, we focused on two genes representing potential early biomarkers and investigated their expression in brain tissue from early stage AD mice. Using in-situ hybridization and immunohistochemical approaches, we demonstrate their upregulation in discrete microglial subpopulations. In parallel, we demonstrate that, at this disease's stage, synaptic modifications, microglial phenotypic reactivity and subtle cognitive alterations occur. Our data thus support an early contribution of microglia to AD progression and point to two specific genes that may represent potential early biomarkers and/or therapeutic targets.

University of Barcelona, Biochemistry And Physiology, Barcelona, Spain

N -methyl d -aspartate (NMDA) ionotropic glutamate receptor (NMDAR), which is one of the main targets to combat Alzheimer's disease (AD), is expressed in both neurons and glial cells. The aim of this paper was to assess whether the adenosine A2A receptor (A2A R), which is a target in neurodegeneration, may affect NMDAR functionality. Methods. Immuno-histo/ cytochemical, biophysical, biochemical and signaling assays were performed in a heterologous cell expression system and in primary cultures of neurons and microglia (resting and activated) from control and the APPSw,Ind transgenic mice. Results: On the one hand, NMDA and A2A receptors were able to physically interact forming complexes, mainly in microglia. Furthermore, the amount of complexes was markedly enhanced in activated microglia. On the other hand, the interaction resulted in a novel functional entity that displayed a cross-antagonism, that could be useful to prevent the exacerbation of NMDAR function by using A2A R antagonists. Interestingly, the amount of complexes was markedly higher in the hippocampal cells from the APPSw,Ind than from the control mice. In neurons, the number of complexes was lesser, probably due to NMDAR not interacting with the A2A R. However, the activation of the A2A R receptors resulted in higher NMDAR functionality in neurons, probably by indirect mechanisms. A2A R antagonists such as istradefylline, which is already approved for Parkinson's disease (Nouriast® in Japan and Nourianz® in the US), have potential to afford neuroprotection in AD in a synergistic-like fashion. i.e., via both neurons and microglia.

METABOLIC REGULATION OF AMYLOID-BETA CLEARANCE VIA MICROGLIA: IMPLICATIONS FOR ALZHEIMER'S DISEASE THERAPEUTICS

POSTER SESSION 06 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Izabela Lepiarz-Raba, Ali Jawaid
Nencki Institute of Experimental Biology PAS, Braincity: Nencki-embl Center Of Excellence For Neural Plasticity And Brain Disorders, Warsaw, Poland

Background: Alzheimer's disease (AD) is the most common cause of dementia and is characterized by pathological deposition of amyloid-β (Aβ) along with neuronal aggregation of hyperphosphorylated tau protein. Abnormal accumulation of Aβ deposits in AD is a critical early event that precedes neurodegeneration and involves an imbalance between the level of Aβ production and clearance. Aβ clearance is primarily a function of microglia, the brain-resident immune cells that are increasingly being implicated in several neuropsychiatric disorders. Microglia are highly sensitive to environmental factors and emerging evidence suggests that microglial functions are controlled by metabolic manipulations. Therefore, the aim of this project is to identify metabolic conditions that could selectively modulate microglial Aβ phagocytosis without substantially harming healthy neurons.
Methods: Human microglia-like (HMC3) cells were incubated with a variety of metabolic nutrients followed by exposure to 488-labelled Aβ (1-42) and fluorescent detection of Aβ uptake by cells. Relative gene expression of proteins involved in uptake and degradation of Aβ was assessed using RT-PCR.
Results: HMC3 cells incubated with lipid-depleted serum significantly upregulated Aβ phagocytosis when compared to lipid-containing serum. Moreover, pre-treatment of cells with HDL and LDL significantly reduced Aβ uptake. RT-PCR indicated that scavenger and lipoprotein receptors, as well as lipid metabolism-related proteins, might be responsible for observed effects. Further molecular underpinnings of the modulation of phagocytosis and its selectivity are the subjects of ongoing investigations.
Conclusions: Preliminary results involving high-throughput metabolic manipulations of HMC3 microglia indicate a role for lipoproteins and lipoprotein receptors in the modulation of microglial phagocytosis.

Garcinia kola and garcinoic acid suppress SARS-CoV-2 spike glycoprotein S1-induced hyper-inflammation in human PBMCs through inhibition of NF-κB activation.
Symptoms and complications associated with severe SARS-CoV-2 infection such as acute respiratory distress syndrome (ARDS) and organ damage have been linked to SARS-CoV-2 spike protein S1-induced increased production of pro-inflammatory cytokines by immune cells. In this study, the effects of an extract of Garcinia kola seeds and garcinoic acid were investigated in SARS-CoV-2 spike protein S1-stimulated human PBMCs. Results of ELISA experiments revealed that Garcinia kola extract (6.25, 12.5, and 25 µg/ml) and garcinoic acid (1.25, 2.5, and 5 µM) significantly reduced SARS-CoV-2 spike protein S1-induced secretion of TNFα, IL-6, IL-1β, and IL-8 in PBMCs. In-cell western assays showed that pre-treatment with Garcinia kola extract and garcinoic acid reduced expressions of both phospho-p65 and phospho-IκBα proteins, as well as NF-κB DNA binding capacity and NF-κB-driven luciferase expression following stimulation of PBMCs with spike protein S1. Furthermore, pre-treatment of PBMCs with Garcinia kola extract prior to stimulation with SARS-CoV-2 spike protein S1 resulted in reduced damage to adjacent A549 lung epithelial cells. These results suggest that the seed of Garcinia kola and garcinoic acid are natural products which may possess pharmacological/therapeutic benefits in reducing cytokine storm in severe SARS-CoV-2 and other coronavirus infections.

Methyl 3,4,5-trimethoxycinnamate suppresses inflammation in RAW264.7 macrophages and blocks macrophage-adipocyte interaction.
Methyl 3,4,5-trimethoxycinnamate (MTC) is a bioactive natural phenylpropanoid. We evaluated anti-inflammatory effects of synthetic MTC in RAW264.7 macrophages and RAW264.7-3T3-L1 adipocytes co-culture. Levels of cytokines and

chemokines, as well as NO and PGE in cell supernatants were analysed using ELISAs, Griess assay and enzyme immunoassays, respectively. In-cell cytoblot was used to assess levels of proteins; while DNA binding and reporter gene assays were used to measure transcription factor DNA binding and transcriptional activities, respectively. Glucose uptake in adipocytes was evaluated with 2-deoxy-2-[(7-nitro-2, 1, 3-benzoxadiazol-4-yl) amino]-D-glucose uptake. MTC (5-20 μM) suppressed LPS + IFNγ-induced release of TNFα, IL-6 and IL-1β, as well as NO/iNOS and PGE/COX-2 levels in RAW264.7 cells. Furthermore, there was a reduction in phospho-IκB and phospho-p65 proteins, accompanied by a reduction in total IκB in RAW264.7 cells. Further studies showed that MTC also produced a reduction in NF-κB DNA binding and luciferase activity. Treatment of RAW264.7 cells with MTC (5-20 μM) resulted in enhanced DNA binding of Nrf2 and an increase in ARE-luciferase activity. In a macrophage-adipocyte co-culture, the compound reduced the release of TNFα, IL-6, IL-1β, MCP-1 and RANTES, while enhancing glucose uptake and activation of AMPKα. Our results suggest that MTC produced anti-inflammatory and antioxidant activities in macrophages. MTC also prevented inflammation in macrophage-adipocyte co-culture. The effect of MTC on glucose uptake in adipocytes is proposed to be linked to activation of AMPK.

Induction of Exaggerated Cytokine Production in Human Peripheral Blood Mononuclear Cells by a Recombinant SARS-CoV-2 Spike Glycoprotein S1 and Its Inhibition by Dexamethasone.
An understanding of the pathological inflammatory mechanisms involved in SARS-CoV-2 virus infection is necessary in order to discover new molecular pharmacological targets for SARS-CoV-2 cytokine storm. In this study, the effects of a recombinant SARS-CoV-2 spike glycoprotein S1 was investigated in human peripheral blood mononuclear cells (PBMCs). Stimulation of PBMCs with spike glycoprotein S1 (100 ng/mL) resulted in significant elevation in the production of TNFα, IL-6, IL-1β and IL-8. However, pre-treatment with dexamethasone (100 nM) caused significant reduction in the release of these cytokines. Further experiments revealed that S1 stimulation of PBMCs increased phosphorylation of NF-κB p65 and IκBα, and IκBα degradation. DNA binding of NF-κB p65 was also significantly increased following stimulation with spike glycoprotein S1. Treatment of PBMCs with dexamethasone (100 nM) or BAY11-7082 (1 μM) resulted in inhibition of spike glycoprotein S1-induced NF-κB activation. Activation of p38 MAPK by S1 was blocked in the presence of dexamethasone and SKF 86002. CRID3, but not dexamethasone pre-treatment, produced significant inhibition of S1-induced activation of NLRP3/caspase-1. Further experiments revealed that S1-induced increase in the production of TNFα, IL-6, IL-1β and IL-8 was reduced in the presence of BAY11-7082 and SKF 86002, while CRID3 pre-treatment resulted in the reduction of IL-1β production. These results suggest that SARS-CoV-2 spike glycoprotein S1 stimulated PBMCs to release pro-inflammatory cytokines through mechanisms involving activation of NF-κB, p38 MAPK and NLRP3 inflammasome. It is proposed that the clinical benefits of dexamethasone in COVID-19 are possibly due to its anti-inflammatory activity in reducing SARS-CoV-2 cytokine storm.

The tiliroside derivative, 3-O-[(E)-(2-oxo-4-(p-tolyl) but-3-en-1-yl] kaempferol produced inhibition of neuroinflammation and activation of AMPK and Nrf2/HO-1 pathways in BV-2 microglia.
Neuroinflammation is now widely accepted as an important pathophysiological mechanism in neurodegenerative disorders, thus providing a critical target for novel compounds. In this study, 3-O-[(E)-(2-oxo-4-(p-tolyl)but-3-en-1-yl] kaempferol (OTBK) prevented the production of pro-inflammatory mediators TNFα, IL-6, PGE and nitrite from BV-2 microglia activated with LPS and IFNγ. These effects were accompanied by reduction in the levels of pro-inflammatory proteins COX-2 and iNOS. Involvement of NF-κB in the anti-inflammatory activity of OTBK was evaluated in experiments showing that the compound prevented phosphorylation, nuclear accumulation and DNA binding of p65 sub-unit induced by stimulation of BV-2 microglia with LPS and IFNγ. Exposure of mouse hippocampal HT22 neurons to conditioned media from LPS + IFNγ-stimulated BV-2 cells resulted in reduced cell viability and generation of cellular reactive oxygen species. Interestingly, conditioned media from LPS/IFNγ-stimulated BV-2 cells which were treated with OTBK did not induce neuronal damage or oxidative stress. OTBK was shown to increase protein levels of phospho-AMPKα, Nrf2 and HO-1 in BV-2 microglia. It was further revealed that OTBK treatment increased Nrf2 DNA binding in BV-2 microglia. The actions of the compound on AMPKα and Nrf2 were shown to contribute to its anti-inflammatory activity as demonstrated by diminished activity in the presence of the AMPK

antagonist dorsomorphin and Nrf2 inhibitor trigonelline. These results suggest that OTBK inhibits neuroinflammation through mechanisms that may involve activation of AMPKα and Nrf2 in BV-2 microglia.

Inhibition of neuroinflammation by thymoquinone requires activation of Nrf2/ARE signalling.
Thymoquinone is an antioxidant phytochemical that has been shown to inhibit neuroinflammation. However, little is known about the potential roles of intracellular antioxidant signalling pathways in its anti-inflammatory activity. The objective of this study was to elucidate the roles played by activation of the Nrf2/ARE antioxidant mechanisms in the anti-inflammatory activity of this compound. Thymoquinone inhibited lipopolysaccharide (LPS)-induced neuroinflammation through interference with NF-κB signalling in BV2 microglia. Thymoquinone also activated Nrf2/ARE signalling by increasing nuclear localisation, DNA binding and transcriptional activity of Nrf2, as well as increasing protein levels of HO-1 and NQO1. Suppression of Nrf2 activity through siRNA or with the use of trigonelline resulted in the loss of anti-inflammatory activity by thymoquinone. Taken together, our studies show that thymoquinone inhibits NF-κB-dependent neuroinflammation in BV2 microglia, by targeting antioxidant pathway involving activation of both Nrf2/ARE. We propose that activation of Nrf2/ARE signalling pathway by thymoquinone probably results in inhibition of NF-κB-mediated neuroinflammation.

AMPK and SIRT1 activation contribute to inhibition of neuroinflammation by thymoquinone in BV2 microglia.
Thymoquinone is a known inhibitor of neuroinflammation. However, the mechanism(s) involved in its action remain largely unknown. In this study, we investigated the roles of cellular reactive oxygen species (ROS), 5' AMP-activated protein kinase (AMPK) and sirtuin 1 (SIRT1) in the anti-neuroinflammatory activity of thymoquinone. We investigated effects of the compound on ROS generation in LPS-activated microglia using the fluorescent 2',7'-dichlorofluorescin diacetate (DCFDA)-cellular ROS detection. Immunoblotting was used to detect protein levels of p40, gp91, AMPK, LKB1 and SIRT1. Additionally, ELISA and immunofluorescence were used to detect nuclear accumulation of SIRT1. NAD/NADH assay was also performed. The roles of AMPK and SIRT1 in anti-inflammatory activity of thymoquinone were investigated using RNAi and pharmacological inhibition. Our results show that thymoquinone reduced cellular ROS generation, possibly through inhibition of p40 and gp91 protein. Treatment of BV2 microglia with thymoquinone also resulted in elevation in the levels of LKB1 and phospho-AMPK proteins. We further observed that thymoquinone reduced cytoplasmic levels and increased nuclear accumulation of SIRT1 protein and increased levels of NAD. Results also show that the anti-inflammatory activity of thymoquinone was abolished when the expressions of AMPK and SIRT1 were suppressed by RNAi or pharmacological antagonists. Pharmacological antagonism of AMPK reversed thymoquinone-induced increase in SIRT1. Taken together, we propose that thymoquinone inhibits cellular ROS generation in LPS-activated BV2 microglia. It is also suggested that activation of both AMPK and NAD/SIRT1 may contribute to the anti-inflammatory, but not antioxidant activity of the compound in BV2 microglia.

MICROGLIAL RESPONSE IS A PATHOGENIC DRIVING MECHANISM IN THE NDUFS4 KO MOUSE MODEL OF LEIGH SYNDROME

POSTER SESSION 06 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Kevin Aguilar[1,2], Gemma Comes[1,2], Carla Canal[1,2], Albert Quintana[1,2], Elisenda Sanz[1,2], Juan Hidalgo[1,2]

Leigh syndrome is a mitochondrial disease that is typically accompanied by a progressive neurodegenerative disorder. Mice lacking the complex I subunit NDUFS4 (*Ndufs4* KO) develop fatal progressive encephalopathy resembling Leigh syndrome. As the disease progresses, neurodegeneration and neuroinflammation increase and are responsible for the neurological symptoms, which include: sever motor decline, respiratory alterations and epilepsy. However, despite the magnitude of the neuroinflammation associated to brain lesions the role of its main cellular components have barely been addressed in the context of *Ndufs4* KO mouse pathology. Therefore, we aim to elucidate the role of microglia, the specialized immune cell of the CNS, on the pathology of the *Ndufs4* KO mice. For that purpose, we have depleted microglia by using PLX3397, an antagonist of the colony-stimulating factor 1 receptor (CSF1R), since CSF-1 is essential for the maintenance of these cells. We daily injected intraperitoneally PLX3397 both control and Ndufs4 KO mice and evaluated the progression of the disease by using the open field and the rotarod test. We also measured the onset of clasping behavior and the respiratory pattern. Moreover, we addressed brain neuroinflammation using IBA-1 and GFAP staining. Our results show that microglial depletion extends survival, delays the onset of the motor phenotype and alleviates brain pathology. We conclude that microglial response contributes to the progression of the pathology, suggesting a causative role of neuroinflammation in the disease in Ndufs4 KO mice and potentially in Leigh patients.

A new mouse model to study restoration of interleukin-6 (IL-6) expression in a Cre-dependent manner: microglial IL-6 regulation of experimental autoimmune encephalomyelitis.
Interleukin-6 (IL-6) is a pleiotropic cytokine that controls numerous physiological processes both in basal and neuroinflammatory conditions, including the inflammatory response to experimental autoimmune encephalomyelitis (EAE). IL-6 is produced by multiple peripheral and central cells, and until now, the putative roles of IL-6 from different cell types have been evaluated through conditional cell-specific IL-6 knockout mice. Nevertheless, these mice probably undergo compensatory responses of IL-6 from other cells, which makes it difficult to assess the role of each source of IL-6.

Multiple sclerosis (MS) is a neurodegenerative autoimmune disease characterized by demyelination and manifested by various motor, somatosensory and cognitive symptoms. Demyelinating lesions are accompanied by neuroinflammation and increased blood-brain barrier (BBB) permeability. Advanced imaging techniques as magnetic resonance imaging (MRI) have contributed to detect lesions (and permeability) of the BBB. In addition, the use of magnetic ultra-small particles of iron oxide (USPIO) as contrast agents has been confirmed to improve MRI observations. From a repertoire of peptides detected under neuroinflammation, we previously identified that peptide-88 (P88) has high affinity to laminin-511, an extracellular matrix protein present in the BBB. Laminin has been reported to change its expression and function under neuroinflammation, including MS. This proposal aims to validate the peptide-receptor pair (P88/laminin511) vectorized on USPIO nanoprobes, in order to explore BBB molecular alterations occurring during neuroinflammation as potential tools for use in MRI analysis.We have designed USPIO-P88 nanoprobes and tested cytotoxicity, observing no cell death at concentrations < 4 mM. In addition, we validated the nanoprobes with P88 as a biomarker, under inflammatory conditions, in an *in vitro* model of BBB conformed by brain endothelial cells, astrocytes and pericytes. We have also performed biocompatibility and pharmacokinetic studies *in vivo*, in rats, and additionally tested the marking of the nanoprobe-P88 under induced neuroinflammation. Affinity between P88 and laminin, may provide insight into the role laminin plays in BBB disruption under neuroinflammation, thus laminin (as a target of P88) may be considered a potential biomarker in MS.

AMYLOID CLEARANCE BY OLIGODENDROCYTE-MEDIATED MICROGLIAL ACTIVATION

POSTER SESSION 06 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Soonbong Baek, Seungeun Yeo, Hyun Jin Jung, Jae Myung Jang, Jong-Pil Kim, Youngshik Choe*
Korea brain research institute, Developmental Disorders & Rare Diseases Research Group, daegu, Korea, Republic of

In Alzheimer diseases (AD), microglia, the brain-resident immune cells, protect neural connections against amyloid accumulation and dystrophic neurites. However, the cellular mechanism of microglial activation and recruitment to amyloid plaques is still unclear. In this presentation, we provide evidence that the interaction of amyloid plaque and oligodendrocytes (OLs), a guardian of neural circuits, initiates activation of microglial cells and clearance of the neurotic plaques. Expression of OL-specific immune factor (OSIF) was induced by beta-amyloid, which subsequently promoted the phagocytic activity of microglia. Conditional inhibition of OSIF expression in 5xFAD transgenic background (OSIF-cKO-Tg) increased the spreading of amyloid plaques along with diminished plaque-associated microglia in the cortex. Interestingly, transcriptome analysis showed a Trem2/CD68-positive microglial subtype was reduced in the cortex of OSIF-cKO-Tg mice which is phenotypically similar to microglia-specific *Trem2* knockout in AD model mice. Our presentation illustrates that the OSIF is an important initiator of Trem2-dependent microglial condensation of amyloid plaques to protect neurite damages in AD.

Introduction: Neuroinflammation is one of the most important components related to neurodegenerative processes and can be triggered by various stimuli that lead to the activation of innate immunity receptors and consequently to neurons death. Among the inflammatory pathways studied in neurodegenerative diseases, the pathway mediated by the HMGB1 protein has been shown to be fundamental. HMGB1 released by neurons and microglia into the extracellular space can activate RAGE and TLR4 receptors, which, in turn, activate inflammatory pathways mediated by the gene transcription factor NF-κB, leading to the production of proteins such as IL-6 and TNF-α. Aims: The main objective of this work was to study the effect of Parthenolide on LPS-induced microglial neuroinflammation and its effect on HGMB1 gene expression. Parthenolide is a sesquiterpene lactone of the germacranolide class which occurs naturally in *Tanacetum parthenium* with recognized anti-inflammatory action via NF-κB inhibition. Methods: To evaluate the effects of Parthenolide, murine microglial cells (BV2) were treated with Parthenolide for 30 minutes and then the cells were stimulated with LPS in presence of IFNγ for 24h. Results: Our results shown a decrease of Nitric Oxide and TNF-α production by cells treated with Parthenolide and stimulated with LPS plus IFN-γ when compared with the positive control. Also, preliminary data showed that Parthenolide treatment decreases the *hmgb1*, *tlr4* and *rage* gene expression on cells stimulated with LPS plus IFN-γ. Conclusions: Together, these results contribute to understand the neuroinflammatory scenario and may help the development of new therapeutic strategies related with neuroinflammatory process.

MOLECULAR LOGIC OF MICROGLIAL ACTIVATION IN ALZHEIMER'S DISEASE

POSTER SESSION 06 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Marcos Costa[1,2]
[1]Institut Pasteur de Lille, Umr1167, Lille, France, [2]Federal University of Rio Grande do Norte, Brain Institute, Natal, France

Genomic-wide association studies (GWAS) and whole exome sequencing (WES) in large cohorts of human subjects have underlined a conspicuous role for microglial cells in the susceptibility to Alzheimer's disease (AD) (Bellenguez et al., 2022). However, the contribution of different microglial states to pathophysiological processes remains elusive. Recent work using single-cell RNA-sequencing (scRNA-seq) or single-nucleus RNA-sequencing (snRNA-seq) has started to unravel the molecular signatures of microglial states in the human AD brain (Mathys et al., 2019; Olah et al., 2020; Srinivasan et al., 2020; Zhou et al., 2020; Morabito et al., 2021). Despite the different classifications used in these studies, they consistently showed that diverse microglial subpopulations can be distinguished in the healthy and diseased adult human brain using molecular profiles revealed by sc/snRNA-seq. However, these studies found remarkably little overlap between microglial gene-expression signatures in human Alzheimer's with those previously identified in mouse models, including disease-associated microglia (DAM, Keren-Shaul et al., 2017). In this work, we took advantage of CellID (Cortal et al., 2021) to identify DAM and homeostatic microglia gene signatures at single cell resolution in three different sc/snRNA-seq datasets generated from healthy and AD brain samples. We also used pseudotime to identify relationships among microglial subsets and SCENIC (Aibar et al., 2018) to study gene regulatory networks and identify master regulatory transcription factors associated with different microglial phenotypes. Our results provide a comprehensive molecular characterization of microglial subtypes in the AD brain and pinpoints potential regulators of microglial states in this pathology.

Alzheimer's disease (AD) is a progressive neurodegenerative disease and the most common form of dementia worldwide. Neuroinflammation is an important feature of AD pathology, but the precise contribution of neuroinflammation on disease progression is poorly understood. Microglia, the brain's resident macrophages, are likely to play an important role in initiating and maintaining neuroinflammatory responses that contribute directly or indirectly to AD etiology. Several genome-wide association studies in human AD patients identified genes enriched or uniquely expressed in microglia. Moreover, single-cell RNA sequencing (scRNA-seq) studies identified multiple microglia-enriched genes that are upregulated in the context of disease, both in human AD tissue as well as mouse models of AD. Development of tools to these specific genes or gene products can be used to identify disease-associated microglial states and further our understanding of the specific neuroinflammatory responses that contribute to disease. We have developed and validated a cohort of rabbit monoclonal antibodies that can be used to detect these microglial gene products. We used multiplexing techniques to establish microglial enrichment of these targets, including ASC/TMS1, GPNMB, TMEM119, and Galectin-3, in both mouse brain tissue and mouse models of AD. Within this cohort, we highlight Cathepsin D, a lysosomal aspartyl protease involved in protein degradation that is enriched in microglia, particularly in the context of disease. We continue to develop a comprehensive portfolio of monoclonal antibodies to further characterize microglia cellular processes and activation states to understand the role of microglia in neurodegenerative diseases.

Despite the accumulating evidence implying activated microglia in the synaptic loss, the sequence of events preceding synaptic phagocytosis or spine retraction remains elusive. Therefore, we performed two-photon time-lapse study of light-directed microglia-synapse interactions in two acute models of neuroinflammation induced in adult mice by bacterial lipopolysaccharide (LPS) administration or by inoculation of Tau/Ab-enriched sarkosyl-insoluble fraction derived from AD patient brain. Both treatments induced activation of microglia, which manifested as characteristic morphological changes and upregulated expression of phagosomal markers, CD68, C3 and C3R, particularly in the model of AD. These changes were associated with decreased surveillance of synapses under baseline condition and establishment of long-lasting contacts between microglia and synapses after single-synapse photoablation. The duration of contacts and expression levels of phagosomal proteins correlated with elevated spine/bouton turnover, generation of synaptic filopodia, and elimination of spines. Several scenarios of spine loss were observed: (i) rapid retraction of spines after their interaction with microglia; (ii) engulfment of spines, followed by endocytosis; and, most surprisingly, (iii) spine engulfment followed by pullout of a spine head filopodia, its stretching during microglia retraction and spine elimination. Our findings highlight multiple common features of synaptic remodeling by microglia in the context of systemic inflammation and AD, and gain a direct insight into the cellular mechanisms of synaptic stripping in these conditions.

Aims: Extracellular vesicles (EVs) released by human induced pluripotent stem cell-derived neural stem cells (hiPSC-NSCs) are enriched with miRNAs and proteins capable of mediating anti-inflammatory activity (Upadhya et al., J. Extracell Vesicles, 9:1809064, 2020). The lack of tumorigenic and immunogenic properties and ability to permeate the entire brain to incorporate into neurons and microglia following intranasal (IN) administrations makes them an attractive biologic for mediating neuroprotection and curtailing chronic neuroinflammation in neurodegenerative disorders. We tested the hypothesis that intranasal administrations of hiPSC-NSC-EVs can alleviate chronic neuroinflammation and cognitive impairments induced by systemic lipopolysaccharide (LPS) challenge. **Methods:** Adult male C57BL/6J mice received intraperitoneal injections of LPS (0.75 mg/Kg) for seven consecutive days. Then, the mice received either vehicle (VEH) or hiPSC-NSC-EVs (~66 x 10^9 EVs/administration, thrice over 7 days). A month later, mice in all groups were investigated for cognitive function with a battery of behavioral tests and euthanized for histological and biochemical studies. **Results:** Mice receiving VEH after LPS displayed impairments in object location memory, spatial recognition memory, and pattern separation function. Such impairments were associated with an increased incidence of activated microglia presenting NLRP3 inflammasomes and an increased concentration of proinflammatory cytokines in the hippocampus. In contrast, in all behavioral tests, mice receiving hiPSC-NSC-EVs after LPS exhibited better cognitive function than mice receiving VEH after LPS. Importantly, these mice exhibited diminished microglial activation with reduced NLRP3 inflammasomes and proinflammatory cytokines. **Conclusion:** Thus, intranasal administrations of hiPSC-NSC-EVs are an efficacious approach to reducing chronic neuroinflammation-associated cognitive impairments.

IGF-1 EFFECT IN LPS-DERIVED NEUROINFLAMMATION IS MEDIATED BY P110α SUBUNIT OF PI3K AND SHOWS SEXUAL DIFFERENCES.

POSTER SESSION 06 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Daniel Pinto[1,2], Angeles Arévalo[1,2], Carmen Paradela[1]
[1]Instituto Cajal, Neurobiología Funcional Y De Sistemas, Madrid, Spain, [2]Instituto de Salud Carlos III, Ciberfes, Madrid, Spain

Insulin-like growth factor-1 (IGF-1) has been characterized as one of the main neuroprotective molecules. It also actively participates in processes such as synaptic pruning and clearance of harmful aggregates present in most neurodegenerative diseases. However, those functions have been evaluated using male or non-sexed animals.
Systemic bacterial lipopolysaccharide (LPS)-treatment increased in both sexes the expression of GFAP, a reactive astrocyte marker, in the cortex of mice and was blocked by IGF-1 only in males. In primary astrocytes, LPS enhanced the mRNA expression of Toll-like receptors 2 and 4, and proinflammatory factors such as iNOS, IP-10 and cytokines IL-1β, IL-6 and IL-10 in male and female. However, treatment with IGF-1 counteracted cytokines expression in males. Furthermore, reactive astrocyte phagocytosis was modulated by IGF-1 in male astrocytes exclusively. By Western Blot, we observed that IGF-1 was also able to increase AKT-phosphorylation only in male astrocytes, and was reduced using PI3K inhibitors, AG66, TGX-221 and CAL-101, with selectivity towards catalytic p110α, p110β and p110δ isoforms respectively. Although all isoforms interact physically with IGF-1-receptor in both sexes, the expression of p110α is higher in males while the expression of IGF-1-receptor is similar among sexes. AG66 suppressed the IGF-1 effect on cytokine expression and counteracted the IGF-1-produced phagocytosis decrease in male reactive astrocytes.
Taken together, our results suggest that sex differences could be due to a lower expression of the p110α subunit in female and that IGF-1-effects on the inflammatory response and phagocytosis of male reactive astrocytes are mediated by p110α/PI3K subunit.

BALANCE IS BLISS: EXPLORING THE ROLE OF KYNURENINE 3-MONOOXYGENASE (KMO) IN IMMUNE CHALLENGED MICROGLIA

POSTER SESSION 06 - SECTION: MICROGLIA AND NEUROINFLAMMATION

Martina Esposito Soccoio[1], Robert Mason[2], Flaviano Giorgini[1]
[1]University of Leicester, Department Of Genetics And Genome Biology, Leicester, United Kingdom, [2]University of Leicester, Department Of Genetics And Genome Biology, leicester, United Kingdom

Aims: Kynurenine 3-monooxygenase (KMO) is a key enzyme in the kynurenine pathway (KP) of tryptophan degradation, which contains several neuromodulatory metabolites. KMO lies at a critical branch point in the KP and thereby regulates the balance between neuroprotective and neurotoxic kynurenine-derived metabolites associated with the pathogenesis of several neurodegenerative and psychotic disorders. In the central nervous system, KMO is highly expressed in microglial cells, which serve as the primary active immune defence system of the brain. As it has been proposed that KMO plays a central role in regulating neuroinflammation, here we sought to better understand the cellular function of KMO in microglia during inflammation. **Methods:** C20 human microglial cells were challenged for 24 hours with pro-inflammatory cytokines (TNF-α, IL-1β, IFN-γ) or bacterial LPS. *Kmo* expression was then measured by RT-qPCR and excreted cytokines quantified using MSD multi-spot assays. **Results:** We found that immune challenged cells dramatically upregulated release of several pro-inflammatory cytokines as compared to untreated cells. Notably, this correlated to a significant increase in *Kmo* expression. Supplementation of microglia with dexamethasone, a synthetic glucocorticoid (GC), was sufficient to dampen the effect of this immune stimulation - yielding a robust decrease in both *Kmo* mRNA and cytokine levels. In contrast, pre-treatment with the KMO inhibitor Ro 61-8048 did not alter cytokine release, suggesting altered *Kmo* expression occurs downstream of immune stimulation. **Conclusions:** Our data suggest that the use of GCs could be a possible therapeutic strategy for diseases associated with neuroinflammation, particularly those with altered KP metabolism.

A NOVEL KNOCK-IN MODEL RECAPITULATES EARLY EVENTS OF ALZHEIMER'S DISEASE.

POSTER SESSION 06 - SECTION: ALZHEIMER'S AND TAUOPATHIES

Sarra Kraiem, Hamza Benderradji, Sabiha Eddarkaoui, Sarah Leclercq, Kevin Carvalho, Emilie Faivre, Nicolas Sergeant, Luc Buée, David Blum, Valerie Buee Scherrer
Inserm UMRS1172, Lille University, Lille Neuroscience & Cognition, LILLE, France

Aims: Alzheimer's disease (AD), primary cause of dementia in the elderly, is characterized at the neuropathological level by extracellular accumulation of amyloid peptide and intraneuronal aggregation of abnormally and hyperphosphorylated Tau proteins. Tau aggregation causes neuronal death and leads to cognitive impairment. Many animal models that try to mimic AD pathology have been obtained by overexpressing both proteins. This study focuses on a new AD mouse model that should develop concomitant pathologies linked to the co-expression of the two humanized proteins, without overexpression. Methods: We have generated this mouse model by crossing a Knock-In humanized mouse model for amyloid peptide (kindly provided by Pr TC Saido) with a Knock-In mouse model for human mutated 1N4R Tau isoform. Double mutant mice (APPxTau) were analyzed at 6 months and compared to single mutants APP or Tau and wild-type littermates. Metabolic, behavior, molecular and biochemical analyses were undertaken in this study. Results: APPxTau mice do not display any particular metabolic and behavior phenotype. Transgenes are expressed at a level similar to endogenous corresponding proteins. An increase in Tau phosphorylation is observed as well as an increasing number of amyloid plaques. Finally, using q-PCR, neuroinflammation markers likely related to amyloid pathology are increased in these APPxTau mice. Conclusion: Although amyloid pathology and Tau hyperphosphorylation are increased in these mice, neuronal degeneration could not be observed. Further investigation is currently done on 12-month-old mice to explore any cognitive impairment as well as neurodegeneration. Therefore, this model likely displays early events of AD.

CX-DHED EFFICIENTLY REDUCES AMYLOID BETA PRODUCTION AND MEMORY DEFICITS MORE THAN DHED IN A MOUSE MODEL OF ALZHEIMER'S DISEASE BY ADDITIONAL REGULATION ON ALPHA-SECRETASE ACTIVITY

POSTER SESSION 06 - SECTION: ALZHEIMER'S AND TAUOPATHIES

Su-Jin Noh[1,2], Jakyung Yoo[3], Ki Young Shin[4], Cheol Hyung Park[1], Jinyeong Yoo[2], Hyun-Ju Park[3], Wonhyuk Suh[5], Yoo-Hun Suh[6]
[1]College of Medicine Seoul National University, Pharmacology, Seoul, Korea, Republic of, [2]Pohang University of Science and Technology, Life Science, Pohang, Korea, Republic of, [3]Sungkyunkwan University, School Of Pharmacy, Suwon, Korea, Republic of, [4]Seoul National University, Bio-max Institute, Seoul, Korea, Republic of, [5]University of New Hampshire, Department Of Life Sciences, Manchester, United States of America, [6]Gachon University, Neuroscience Research Institute, Incheon, Korea, Republic of

We have recently demonstrated that DHED can reduce the generation of amyloid beta peptide by inhibiting beta-secretase (BACE-1) activity. In this study, carboxylated DHED (cx-DHED), a more effective analogue of DHED on APP processing was developed and its mechanism was investigated. Administration of cx-DHED (1mg/kg) for 4 months resulted in more significant lowering of brain amyloid beta peptide than that of DHED in Tg2576 mice. In addition, cx-DHED ameliorates memory impairments and hippocampal cell death in Tg2576 mice. 10mg/kg injection of cx-DHED for 1 month also decreases amyloid beta and cognitive deficits in Tg2576 mice. Treatment of 10 uM cx-DHED impedes amyloid beta peptide production in Tg2576 primary neuronal cells. Furthermore, cx-DHED significantly reducesd beta-secretase activity and increasesd alpha-secretase activity in an enzymatic activity test. These results strongly suggest that cx-DHED may reduce the biosynthesis of amyloid beta peptide by inhibiting BACE-1 and activating alpha-secretase concurrently. These findings arewere confirmed through an induced-fit docking study; both DHED and cx-DHED to beta-secretase showsed similar binding modes, but only cx-DHED to alpha-secretase displayed binding potential. Combined with previous findings of direct inhibition of BACE-1 by DHED, this work indicates that our carboxylating strategy on beta-secretase inhibitors may have the potential to provide new insights into designing novel drugs that target aberrant multiple steps of aberrant APP processing to treat Alzheimer's disease.

ALZHEIMER'S DISEASE PATHOGENESIS IS INFLUENCED BY SELECTIVE BRAIN IL-6 OVEREXPRESSION

POSTER SESSION 06 - SECTION: ALZHEIMER'S AND TAUOPATHIES

Carla Canal[1,2], Gemma Comes[1,2], Kevin Aguilar[1,2], Iain L. Campbell[3], Juan Hidalgo[1,2]
[1]Autonomous University of Barcelona, Department Of Cell Biology, Physiology And Immunology, Animal Physiology Unit, Bellaterra, Spain, [2]Autonomous University of Barcelona, Institut De Neurociències, Bellaterra, Spain, [3]The University of Sydney, Charles Perkins Centre And Sydney Institute For Infectious Diseases, Sydney, Australia

Increasing evidence suggests that neuroinflammation has a strong contribution in Alzheimer's disease (AD) pathogenesis. Understanding and controlling the mechanisms underlying the interaction between the immune system and the nervous system might be key at the therapeutic level. Interleukin-6 (IL-6), a pleiotropic and multifunctional cytokine, is involved in numerous physiological functions, as it plays a critical role in the homeostasis of the neural tissue and in the pathogenesis of inflammatory disorders including AD. We have examined the role of cerebral IL-6 overexpression in a mouse model of AD, the Tg2576, which courses with progressive loss of brain functions and strong inflammatory processes that accompany the neuropathology of the disease. The effects of IL-6 overexpression on the progression of AD were examined at different levels, including physiology, behavior, and neuropathology. Aged Tg2576 mice showed enhanced locomotor activity and exploration, decreased anxiety-like behavior, and impaired working memory. Overexpression of IL-6 had sex-dependent changes at the behavioral level, affecting locomotion, anxiety-like behavior, and working memory. When assessing the effect of chronic neuroinflammation on motor performance, vertical pole test revealed deteriorated motor function in IL-6-overexpressing mice. Neuropathological analysis revealed extensive plaque-associated chronic glial activation, which has been hypothesized to further promote b-amyloid accumulation and neuroinflammation. IL-6-induced neuroinflammation in AD may promote neurodegeneration, but the evidence suggests that could also play a neuroprotective role by decreasing the amyloid load. Collectively, our results reveal the behavioral and neuropathological impact of brain IL-6 overexpression and suggest that regulating this cytokine may be relevant for the pathogenesis of AD.

Microglial activation elicits a negative affective state through prostaglandin-mediated modulation of striatal neurons.
Microglia are activated in many neurological diseases and have been suggested to play an important role in the development of affective disorders including major depression. To investigate how microglial signaling regulates mood, we used bidirectional chemogenetic manipulations of microglial activity in mice. Activation of microglia in the dorsal striatum induced local cytokine expression and a negative affective state characterized by anhedonia and aversion, whereas inactivation of microglia blocked aversion induced by systemic inflammation. Interleukin-6 signaling and cyclooxygenase-1 mediated prostaglandin synthesis in the microglia were critical for the inflammation-induced aversion. Correspondingly, microglial activation led to a prostaglandin-dependent reduction of the excitability of striatal neurons. These findings demonstrate a mechanism by which microglial activation causes negative affect through prostaglandin-dependent modulation of striatal neurons and indicate that interference with this mechanism could milden the depressive symptoms in somatic and psychiatric diseases involving microglial activation.

Microglial cell-derived interleukin-6 influences behavior and inflammatory response in the brain following traumatic brain injury.
Traumatic brain injury (TBI) is a major health problem with high rates of mortality and morbidity worldwide. The response of the brain to TBI is orchestrated by a number of cytokines, including interleukin-6 (IL-6). IL-6 is a major cytokine in the central nervous system and it is produced by different cells, such as neurons, glial cells, and endothelial cells. Since glial cells are one of the most important sources and targets of IL-6, we have examined the role of microglia-derived IL-6 in normal conditions and following a model of TBI, cryolesion of the somatosensorial cortex. To this end, tamoxifen-inducible microglial IL-6-deficient (Il6 , using Cx3cr1 model) mice and control (Il6) mice were used. In normal conditions, microglial IL-6

deficiency reduced deambulation and exploratory behavior and decreased anxiety in a sex-dependent manner. The transcriptome profile following cryolesion was dramatically altered 1 day post-lesion in Il6 compared with Il6 mice. However, the phenotype of Il6 mice was less compromised in the following days, suggesting that compensatory mechanisms are at play.

Pain, Anxiety, Depression, and Quality of Life in Patients with Vulvodynia.
The term vulvodynia refers to vulvar pain of unknown origin lasting at least 3 months. Psychiatric comorbidities are a common feature and, along with pain, may severely affect patients' wellbeing. We aimed to determine the characteristics of pain in vulvodynia, to correlate characteristics with symptoms of anxiety and depression, and to analyse the impact of these factors on patients' quality of life.

IL-6 trans-signaling in the brain influences the behavioral and physio-pathological phenotype of the Tg2576 and 3xTgAD mouse models of Alzheimer's disease.
Alzheimer's disease (AD) is the most commonly diagnosed dementia but its underlying pathological mechanisms still unclear. Neuroinflammation and secretion of cytokines such as interleukin-6 (IL-6) accompany the main hallmarks of the disease: amyloid plaques and neurofibrillary tangles. In this study, we analyzed the role of IL-6 trans-signaling in two mouse models of AD, Tg2576 and 3xTg-AD mice. The inhibition of IL-6 trans-signaling partially rescued the AD-induced mortality in females of both models. Before amyloid plaques deposition, it reversed AD-induced changes in exploration and anxiety (but did not affect locomotion) in Tg2576 female mice. However, after plaque deposition the only behavioral trait affected by the inhibition of IL-6 trans-signaling was locomotion. Results in the Morris water maze suggest that cognitive flexibility was reduced by the blocking of the IL-6 trans-signaling in young and old Tg2576 female mice. The inhibition of IL-6 trans-signaling also decreased amyloid plaque burden in cortex and hippocampus, and Aβ and Aβ levels in the cortex, of Tg2576 female mice. The aforementioned changes might be correlated with changes in blood vessels and matrix structure and organization rather than changes in neuroinflammation. 3xTgAD mice showed a very mild phenotype regarding amyloid cascade, but results were in accordance with those of Tg2576 mice. These results strongly suggest that the inhibition of the IL-6 trans-signaling could represent a powerful therapeutic target in AD.

Introduction More than 50 mutations have been identified in the amyloid precursor protein (APP) gene that lead to amyloid-β (Aβ) proteins in humans. Mutated Aβ are mostly toxic leading to Alzheimer's disease (AD). Some mutated Aβ can be protective. Our study evaluated the consequences of the transmission of toxic Osaka (E22D, Aβosa) or protective Icelandic (A2T, Aβice) mutations in Aβ plaque-bearing transgenic rodents with high Aβ production. **Methods** Two-month-old $APP_{swe}/PS1_{dE9}$ mice were inoculated in the dentate gyrus (n=10/group) with Aβ variants bearing Osaka or Icelandic mutations. *In vivo* longitudinal follow-up of functional impairments by resting-state functional MRI and behavioral tests (novel object recognition task and water maze test) were performed 4 months post-inoculation (mpi). Then, biochemical (western blot, 6E10) and histological (BAM10) analyses of Aβ were performed in the brain of inoculated mice. **Results** Intracerebral infusion of Aβosa induced memory impairment at 4 mpi (Fig. 1a) and altered functional connectivity in the hippocampus of inoculated animals (Fig. 1b). It increased Aβ plaque load (Fig. 2a) and changed Aβ oligomer patterns (Fig. 2b) at 4 mpi, as compared to mice inoculated with PBS. Interestingly, the protective Aβice reduced significantly cognitive decline and did not alter either brain connectivity (Fig. 1) or Aβ metabolism (Fig. 2). **Conclusion** The inoculation of “good and bad” variants of Aβ to Aβ plaque-bearing mouse models is sufficient to regulate functional impairments, Aβ forms occurrence and Aβ plaque load. The ability to modulate AD pathologies by Aβ species is a promising result for future innovative anti-amyloid therapies.

ALZHEIMER DISEASE: FUNCTIONAL CHARACTERIZATION OF KLVFF ACTIVITY ON NATIVE NICOTINIC RECEPTORS

POSTER SESSION 06 - SECTION: ALZHEIMER'S AND TAUOPATHIES

Hanna Trebesova, Guendalina Olivero, Mario Marchi, Massimo Grilli
University of Genova, Department Of Pharmacy, Genoa, Italy

Aims: In recent years, the inhibition of beta-amyloid (Aβ) aggregation became a potential strategy for Alzheimer's disease. KLVFF, a small peptide corresponding to the aminoacidic sequence 16-20 of Aβ, reduces dose-dependently Aβ fibrillation. Consequently, the toxic and functional characterization of its brain activity is fundamental for clarifying its potential therapeutic role. Methods: Accordingly, we studied the modulatory role of KLVFF on the cholinergic receptors regulating dopamine and noradrenaline release in rats synaptosomes. Moreover, we evaluated the direct toxicity of KLVFF on synaptic terminals using flow cytometry. Results: In the nucleus accumbens the nicotinic receptors on dopaminergic nerve terminals are inhibited by KLVFF, that closely resembles the full-length Aβ1-40. Moreover, KLVFF entrapped in synaptosomes does not modify the nicotinic receptor's function, suggesting that the external binding to the receptor is required for its activity. Furthermore, the cholinergic agents desformylflustrabromine and galantamine counteracted the KLVFF effect. Remarkably, muscarinic receptors on dopaminergic terminals and nicotinic receptors regulating noradrenaline release in the hippocampus are completely insensitive to KLVFF. Based on our findings, KVLFF mimics Aβ1-40 as a negative modulator of specific nicotinic receptor subtypes affecting dopamine transmission in the rat's brain. In addition, KLVFF does not modify the viability of incubated nor entrapped synaptosomes. The viability was assessed through calcein-AM and annexin-V labelling followed by flow cytometric analysis. Conclusions: The anti-aggregative peptide KLVFF modulates specific nicotinic receptors subtypes without evident toxic effects on the synaptic terminals. Further investigation should be carried out to evaluate the impact of this activity on Alzheimer disease patients.

ROLE OF AMYLOID PRECURSOR PROTEIN IN ASTROCYTES IN ALZHEIMER´S DISEASE

POSTER SESSION 06 - SECTION: ALZHEIMER'S AND TAUOPATHIES

Gretsen Velezmoro
International Clinical Research Center (FNUSA-ICRC) St. Anne's University Hospital, Center For Translational Medicine (ctm), Brno, Czech Republic

Aims: Astrocytes are specialized glial cells that when exposed to inflammatory factors go through a process known as reactive astrogliosis. Reactive astrocytes are a neuropathological feature of Alzheimer's disease (AD). The etiology of AD is often explained by the accumulation of β-amyloid peptides, a proteolytic product of the amyloid precursor protein (APP). However, inflammation also plays a prominent role in the development of AD. How reactive astrocytes participate in the pathogenesis of AD remains poorly understood. Consequently, our goal is to understand how APP affects Astrocytes in AD. **Methods:** To elucidate the role of astrocytes in the pathogenesis of AD we exploited different *in vitro* and *in vivo* models to investigate the role of APP in setting the immune response of astrocytes, measured by biochemical and molecular techniques. **Results:** Our results show that overexpression of APP in human cortical astrocytes induces reactive phenotype, similar to astrocytes found in brains of AD patients. These reactive astrocytes produce significantly increased levels of interferon gamma (INF-γ) in comparison with control astrocytes. Similar positive correlation between APP levels and INF-γ is found also in astrocytes from AD transgenic and traumatic brain injury (TBI) mice models. **Conclusions:** Our data indicate that astrocytes are activated by high levels of APP, which promotes production and secretion of interferons and recapitulates salient features of astrocytes in AD.

INVISIBLE KILLER: INTRACELLULAR Aβ ACCUMULATION LEADS TO ENDOSOMAL/LYSOSOMAL LEAKAGE IN HIPPOCAMPAL NEURONS

POSTER SESSION 06 - SECTION: ALZHEIMER'S AND TAUOPATHIES

Yang Gao, Bengt Winblad, Sophia Schedin Weiss, Lars Tjernberg
Karolinska Institutet, Department Of Neurobiology, Care Sciences And Society (nvs), Solna, Sweden

Aims Alzheimer disease (AD) is characterized by amyloid-β (Aβ) plaques and intracellular neurofibrillary tangles. Besides extracellular Aβ plaques, intracellular Aβ was also shown to correlate with AD neuropathology. As an important source of intracellular Aβ, extracellular Aβ can be internalized and accumulate in endocytic vesicles. Previously we treated hippocampal neurons with Aβ42 monomers and detected Aβ42 oligomerization in the late endosomes/lysosomes by Förster resonance energy transfer live cell imaging. However, it is still unclear if those Aβ aggregates can cause vesicle membrane leakage. Here we investigate whether low extracellular concentration of Aβ could be endocytosed and accumulate in late endosomes/lysosomes to high levels and cause endosomal/lysosomal membrane permeabilization in primary neurons. Methods Hippocampal neurons were isolated from the E16-17 C57/BL6 mice embryo brains and cultured for 21 days in vitro. Neurons were treated with Aβ42 with or without fluorescent label at different concentrations for different time periods in an acute or chronic model. Aβ42 concentrations in neuronal vesicles were determined by live cell imaging using confocal microscopy. Immunocytochemistry and Airyscan microscopy were used to detect the loss of endosomal/lysosomal integrity in neurons. Results Treatment with 1 nM Aβ42 for 20 days caused three orders of magnitude higher concentrations in neuronal vesicles than in cell culture medium. Accumulated Aβ42 induced endosomal/lysosomal leakage in hippocampal neurons when Aβ42 concentration reached submillimolar level in those vehicles. Conclusions These data agreed with our model in which extracellular Aβ42 gradually accumulates in neurons and damages the vesicle integrity, and further initiates cellular pathogenesis in AD.

Live Cell FRET Imaging Reveals Amyloid β-Peptide Oligomerization in Hippocampal Neurons.
Amyloid β-peptide (Aβ) oligomerization is believed to contribute to the neuronal dysfunction in Alzheimer disease (AD). Despite decades of research, many details of Aβ oligomerization in neurons still need to be revealed. Förster resonance energy transfer (FRET) is a simple but effective way to study molecular interactions. Here, we used a confocal microscope with a sensitive Airyscan detector for FRET detection. By live cell FRET imaging, we detected Aβ42 oligomerization in primary neurons. The neurons were incubated with fluorescently labeled Aβ42 in the cell culture medium for 24 h. Aβ42 were internalized and oligomerized in the lysosomes/late endosomes in a concentration-dependent manner. Both the cellular uptake and intracellular oligomerization of Aβ42 were significantly higher than for Aβ40. These findings provide a better understanding of Aβ42 oligomerization in neurons.

Serum Folate Correlates with Severity of Guillain-Barré Syndrome and Predicts Disease Progression.
The aim of this study was to determine the associations between serum folate level and the clinical course and severity of Guillain-Barré syndrome (GBS). We retrospectively enrolled 112 pairs of GBS patients and age- and sex-matched healthy controls with measured serum folate levels. On admission, 21 (18.9%) GBS patients had folate deficiency, of which only two were female patients. Patients with normal folate levels had a shorter disease progression than those with folate deficiency (median progression duration: 6 versus 13 days, < 0.001). Serum folate levels on admission were correlated with progression

duration and Medical Research Council (MRC) sum score in the upper limbs at nadir (r = -0.261, = 0.005; r = -0.208, = 0.03) but not with the duration of hospital stay or GBS disability score (> 0.05). Logistic regression analysis revealed that normal folate levels on admission were an independent predictor of faster GBS progression, along with younger age, intact deep sensation, and a lower MRC sum score on admission. These results show that serum folate levels are correlated with the progression duration and severity of GBS. Further studies are required to confirm the potential of folate level as a biomarker for GBS prognosis.

INTERACTIONS BETWEEN Aβ OLIGOMERS AND PIRB RECEPTOR AT THE SINGLE-MOLECULE LEVEL

POSTER SESSION 06 - SECTION: ALZHEIMER'S AND TAUOPATHIES

Sybille Marchese[1], Suman De[2], Juan Varela[3]
[1]University of St. Andrews, School Of Biology, St Andrews, United Kingdom, [2]University of Sheffield, Sheffield Institute For Translational Neuroscience (sitran), Sheffield, United Kingdom, [3]University of St. Andrews, School Of Physics And Astronomy, St. Andrews, United Kingdom

Amyloid beta (Aβ) oligomers have been shown to induce a variety of toxic effects in neurons, including pore formation in the plasma membrane and a range of deleterious interactions with cellular receptors. Among these receptors, it has been shown that the Paired-Immunoglobulin-like receptor B (PirB) has a high affinity for Aβ oligomers, and their interaction leads to an impairment in synaptic plasticity in mice models. The surprising divergence of toxicity pathways of Aβ oligomers reported in the literature is likely due to the high structural heterogeneity of these oligomers. Early Aβ oligomers have been shown to preferentially induce membrane damage, while later oligomers of the same aggregation reaction are less prone to create pores while being more inflammatory. Conventional biophysical methods fail to account for these heterogeneous properties of oligomers due to their nanoscale dimensions, low abundance and short lifetime. Using single-molecule and super-resolution imaging techniques, we characterized Aβ populations at the single-oligomer level, allowing us to take structural features into consideration in our biological experiments. We subsequently studied their effect on the trafficking and distribution of individual PirB receptors in primary hippocampal and cortical neurons also by means of single-molecule imaging techniques in living neurons. Our results show that oligomers form at different stages of an aggregation reaction affect the mobility of receptors and their localization in different ways. This approach will help dissecting the conformation-specific toxicity pathway induced by Aβ oligomers, and contribute to assess the relevance of the multiple toxicity pathways associated with Alzheimer’s disease pathogenesis.

Oxidative stress (OS) is a self-propagating phenomenon caused by an imbalance between oxidant and antioxidant systems, namely an overproduction of reactive oxygen species, which overwhelms the intrinsic antioxidant defenses. In Alzheimer's disease (AD), there is growing evidence supporting the link between ROS-mediated damage and mitochondrial dysfunction, with endoplasmic reticulum stress and proteostasis imbalance. Our previous work demonstrated the protective role of ubiquinol (Ub), the reduced form of coenzyme Q10, in the 3xTg-AD mice model, preventing hypoxia and amyloid-β peptide deposition in hippocampal and neocortical areas at onset (6 months) and advanced (12 months) stages of disease. Aims: to assay the effect of Ub-supplementation on brain proteostasis in the 3xTg-AD model and to discover new biomarkers of disease recovery after Ub treatment. Methodology: 2-month-old wild-type and 3xTg-AD mice were fed during 10 months with standard or Ub-supplemented diet. After performing behavioural tests and euthanasia, brains were processed for MALDI-Imaging. Protein identification was inferred from significantly altered m/z peaks using MaTisse database and clustered using bioinformatics tools (Metaboanalyst 5.0, STRING, Cytoscape and Metascape) and subsequently validated by confocal microscopy. Results: Behavioral tests showed an Ub-dependent rescue in the AD-associated cognitive decline. MALDI-Imaging analysis revealed differential protein signatures in the 3xTg-AD model vs. WT mice in hippocampal and cortex areas. These protein profiles were reset to WT levels upon Ub supplementation. Therefore, several inferred proteins such as CAII and RPL23, closely involved in OS regulation and protein translation respectively, could be potentially used as biomarkers of a mild recovery of the disease.

Pubmed:
32063825: Llanos-González E, Henares-Chavarino ÁA, Pedrero-Prieto CM, García-Carpintero S, Frontiñán-Rubio J, Sancho-Bielsa FJ, Alcain FJ, Peinado JR, Rabanal-Ruíz Y, Durán-Prado M
Interplay Between Mitochondrial Oxidative Disorders and Proteostasis in Alzheimer's Disease.
Although the basis of Alzheimer's disease (AD) etiology remains unknown, oxidative stress (OS) has been recognized as a prodromal factor associated to its progression. OS refers to an imbalance between oxidant and antioxidant systems, which usually consist in an overproduction of reactive oxygen species (ROS) and reactive nitrogen species (RNS) which overwhelms the intrinsic antioxidant defenses. Due to this increased production of ROS and RNS, several biological functions such as glucose metabolism or synaptic activity are impaired. In AD, growing evidence links the ROS-mediated damages with molecular targets including mitochondrial dynamics and function, protein quality control system, and autophagic pathways, affecting the proteostasis balance. In this scenario, OS should be considered as not only a major feature in the pathophysiology of AD but also a potential target to combat the progression of the disease. In this review, we will discuss the role of OS in mitochondrial dysfunction, protein quality control systems, and autophagy associated to AD and suggest innovative therapeutic strategies based on a better understanding of the role of OS and proteostasis.

EARLY IMPAIRMENT OF REFERENCE MEMORY AT THREE MONTHS OF AGE IN THE 5XFAD MOUSE MODEL OF ALZHEIMER'S DISEASE USING THE HELICO MAZE.

POSTER SESSION 06 - SECTION: ALZHEIMER'S AND TAUOPATHIES

INP Institut de Neurophysiopathologie, Umr 7051 Cnrs - Aix-marseille Université Neurobiologie Des Processus Mnésiques Aix-marseille Université – Faculté De Médecine/campus Timone –, Marseille Cedex, France

Background: The 5XFAD model of Alzheimer's disease bearing five familial mutations of Alzheimer's disease on human *AbPP* and *PSEN1* transgenes shows deposits of beta amyloid peptide (Ab) as early as 2 months. Given that detecting early dysfunctions in Alzheimer's disease prior to overt pathology is of major interest in the field, we sought to detect memory deficits at earlier stages of the disease in 3-month old 5XFAD male mice. Methods: The Helico Maze a new behavioral task, recently developed and patented, allowing deeper analysis of learning and sub-categories of hippocampal-dependent long-term memory using olfactory cues, was used. Results: Eight 5XFAD and 6 wild-type (WT) male mice at 3 months of age were tested in the Helico Maze. The results demonstrated, for the first time, a starting deficit of pure reference long-term memory. Interestingly, memory impairment was clearly correlated with the amount of Ab deposits in the hippocampus. While we also found significant differences regarding astrogliosis between 5XFAD and WT mice, this was not correlated with memory abilities. Conclusion: These results underlined the efficiency of this new olfactory-dependent behavioral task, easy to use, with a small cohort of mice. Using the Helico Maze may open new avenues to validate efficacy of treatments that target early events related with the amyloid-dependent pathway of the disease and AD progression. M. Migliorati and C. Manrique: Equal contribution

Abstract text: Alzheimer's Disease is a neurodegenerative proteinopathy in which recent evidence indicates that Aβ can misfold and aggregate into seeds that structurally corrupt native proteins, mimicking a prion-like process of template protein corruption or seeding. In fact, studies show that Aβ deposition can be induced by the intracerebral infusion of seed-containing brain homogenates, and that the characteristics of both the seeding agent and the host, influence the pathologic signature of the Aβ seeds. However, it is still unknown which Aβ-misfolded species are most efficient in triggering the aggregation process and which is the effect of amyloid seeds on different AD models. Methods: Amyloid seeds from AD patients (stage C for amyloid) from the Alzheimer's Disease Research Center (ADRC) at UCI were administered into 7-8-month-old hAβ-KI mice and 3xTg-AD mice. Next, we intracerebrally injected brain homogenates from the human AD patient and 25mo-3xTg-AD mice into the hippocampus of 7-month-old 3xTg-AD mice, which were analyzed at 18 months of age. Results: Our findings demonstrated that amyloid deposition differentially occurs in 3xTg-AD and hAβ-KI mice, and the Aβ aggregates are developed earlier in the familial model. Moreover, the amyloid seeds from the human patient induce more aggressive amyloid pathology compared to seeds from aged 3xTg-AD mice. Conclusion: These results suggest that multiple factors such as the seed, recipient model and time are critical factors that can modulate the amyloid pathology onset and progression. Thus, more profound understanding of these factors will provide key insight on how amyloid pathology progresses in AD.

SYNAPTIC ACTIVITY PROMOTES AMYLOIDOGENIC CLEAVAGE OF APP AND SUBSEQUENTLY THE PRODUCTION OF Aβ

POSTER SESSION 06 - SECTION: ALZHEIMER'S AND TAUOPATHIES

Karina Vargas-Baron, Rebecca Powell, Quentin Rodriguez, Muriel Jaquier-Sarlin, Sylvie Boisseau, Eve Borel, Alain Buisson

Aim: Accumulation of Aβ peptides is a key player in the development of Alzheimer's disease (AD) physiopathology. Aβ peptides are produced by the sequential cleavage of transmembrane protein APP by proteases BACE-1 and γ-secretase, respectively. Resent findings show increased production of Aβ is driven by synaptic activity. Thus, this study aims at identifying the conditions by which synaptic activity affect Aβ peptides production and APP processing. Methods: For this purpose, we design a plasmid containing human APP695 with and without the Swedish mutation (swe) tagged with mCherry at the c-terminus followed by transfection of this plasmid in murine primary cortical neurons (DIV14). By measuring the fluorescence, we monitored APP processing in live neurons exposed to chemical long-term potentiation (cLTP) protocols (bicuculline [50 mM] and 4-aminopyridine [2.5 mM]) in the presence of BACE inhibitor [5mM]. APP processing was also characterized by Western blotting on murine primary neuronal cultures exposed to cLTP treatment. Results: We showed that exposure to cLTP induced a reduction of APP fluorescence in both APP695. The swe APP displays a 2 folds increase in the reduction of APP fluorescence. Pharmacological inhibition of BACE by B-IV is blocking APP processing driven by synaptic activity in neurons. Conclusions: Our findings suggest that APP processing by amyloidogenic pathway can be monitored in live neurons by measuring the fluorescence of APP-tagged proteins. We showed that synaptic activity promotes BACE-1 cleavage of APP leading to the production of Aβ. These finding highlight the role of synaptic activity in the physiopathology of AD.

Neurovascular abnormalities are considered to be the major feature of Alzheimer's disease (AD) and preclinical AD models. Few studies, however, have questioned the traditional view by showing the absence of vascular dysfunction in animal models of AD. Here, we aimed to characterize two major functions of brain vasculature: neurovascular coupling (NVC) and blood-brain barrier (BBB) in 5xFAD mouse model of AD. This model reproduces deposition of amyloid-beta in the brain, but not the neurofibrillary tangles. We used two-photon microscopy in anesthetized 6-9-month-old 5xFAD mice and WT littermate controls. We quantified the NVC by measuring dilation of penetrating arterioles upon whisker-pad stimulation; and the BBB leakage was quantified by measuring the accumulation of small fluorescent tracer the in brain parenchyma. We showed that the baseline diameter of penetrating arterioles (PAs) was similar between WT and 5xFAD mice. We detected no effect of amyloid-beta deposition on the NVC and the BBB: the fraction of dilating PAs, dilation of the PAs, and the BBB leakage were non-significantly different between 5xFAD and WT mice. We concluded that amyloid deposition alone in the 5xFAD model might not be enough to trigger cerebrovascular abnormalities.

Cost of auditory sharpness: Model-Based estimate of energy use by auditory brainstem "octopus" neurons.
Octopus cells (OCs) of the mammalian auditory brainstem precisely encode timing of fast transient sounds and tone onsets. Sharp temporal fidelity of OCs relies on low resting membrane resistance, which suggests high energy expenditure on maintaining ion gradients across plasma membrane. We provide a model-based estimate of energy consumption in resting and spiking OCs. Our results predict that a resting OC consumes up to 2.6 × 10 ATP molecules (ATPs) per second which remarkably exceeds energy consumption of other CNS neurons. Glucose usage by all OCs in the rat is nevertheless low due to their low number. Major part of the OCs energy use results from the ion mechanisms providing for the low membrane resistance: hyperpolarization-activated mixed cation conductance and low-voltage activated K-conductance. Spatially ordered synapses-a feature of the OCs allowing them to compensate for asynchrony of the synaptic input-brings only a 12% energy saving to OCs excitability cost. Only 13% of total OC energy used for an AP generation (1.5 × 10 ATPs) is associated with the AP generation in the axon initial segment, 64%-with synaptic currents processing and 23%-with keeping resting potential.

Aim: Rare variants of the Triggering receptor expressed on myeloid cells 2 (TREM2) are associated with increased risk for Alzheimer's disease (AD). The AD-associated TREM2 variants not only affect the binding to Amyloid-β (Aβ) but also alter its deposition in AD brain. Here, we wanted to investigate the binding of TREM2 to aggregation prone Aβ phosphorylated at serine 8 (pSer8-Aβ) and the functional relevance for the deposition in the brains of transgenic mouse models and human AD cases. **Methods:** Interaction with TREM2 was analyzed by BLI, co-immunoprecipitation, and dot blot overlay assays. The deposition characteristics were assessed by immunohistochemistry using generic and phosphorylation-state specific monoclonal antibodies for Aβ with brain sections from APP/PS1 and 5xFAD transgenic TREM2 wildtype and TREM2 knockout mice, and human AD cases with the common and rare variants of TREM2. **Results:** We show the highest affinity interaction of TREM2 to pSer8-Aβ compared to non-phosphorylated Aβ. Also, this modification decreases the TREM2 dependent phagocytosis by primary microglia and in APP transgenic mouse models. Furthermore, we demonstrate characteristic spatio-temporal deposition of pSer8-Aβ in extracellular plaques, vessels and as intraneuronal deposits in brains of transgenic mice and human AD cases with rare TREM2 variants. **Conclusions:** The increased interaction of TREM2 with pSer8-Aβ species is associated with altered deposition in distinct lesions, including extracellular plaques, cerebral amyloid angiopathy, and intraneuronal aggregates. Thus, differential sensing of modified Aβ variants in distinct aggregation states by TREM2 could contribute to the deposition of toxic Aβ species during AD pathogenesis.

Sex differences in the effect of chronic mild stress on mouse prefrontal cortical BDNF levels: A role of major ovarian hormones.
Depression induced by stress is affected by sex, age and hormonal status of the animal and also by duration and type of the stressors. Moreover, higher prevalence of depression and comorbidities in women than men implies the need to include the sex variable in studies on animal models of depression. The present study was therefore initiated to evaluate the effect of sex and ovarian hormones on depression-like phenotypes in mice exposed to a 21-day Chronic Variable Mild Stress (CVMS) paradigm. Adult male, intact female and, ovariectomized (OVX) female mice exposed to CVMS displayed despair behavior, a depression-like phenotype, in all the groups. However, intact females alone, but not males and OVX females, showed anhedonia, another depression-like phenotype. At the molecular level, the expression of Brain-Derived Neurotrophic Factor (BDNF), a neuropeptide associated with depression, and few other stress-specific genes CRH, NR3C1, CART, and NPY

were measured in the Prefrontal Cortex (PFC) region of the reward circuitry. There was a significant decrease in the BDNF protein expression along with an increase in the mRNA expression of CRH, NR3C1, CART, and NPY in intact females, but not in the other two groups of mice. OVX females resembled males in behavioral and molecular responses to CVMS. 17β-Estradiol (E2) administration, not Progesterone (P4), to OVX female stress mice, mitigated despair and enhanced hedonic capacity with an increased expression of BDNF in PFC. This study strengthens the evidence for the beneficial effects of E2 administration in stress condition.

Transient global cerebral ischemia differentially affects cortex, striatum and hippocampus in Bilateral Common Carotid Arterial occlusion (BCCAo) mouse model.
Despite the advancements in medical sciences in last few decades, we are yet to develop promising therapeutics for stroke, which is one of the current global non-communicative disease concerns. The occurrence of stroke is likely to increase further due to the transition in our lifestyles. Inadequate knowledge of the sequential region-specific pathological events induced by cerebral ischemia is one of the underlying reasons. Hence to address this, we have used Bilateral Common Carotid Arterial occlusion (BCCAo) model that mimics human cardiac arrest condition. After ischemic insult, motor coordination and cognitive functions were analysed through series of behavioral tasks. Animals were sacrificed and brain regions viz. cortex, striatum and hippocampus, were isolated further for histopathology and molecular investigations. All the molecular studies were performed at 1d and 7d post-ischemia and reperfusion by immunohistochemistry, RT-qPCR and western blot analysis, for hypoxic, inflammatory and apoptotic markers. Our study indicates that unlike cortex and striatum, hippocampus was found to be consistently late ischemic susceptible at a behavioral and molecular level which might be regulated by c-Jun N-terminal kinases (JNK) and AKT signaling mechanism with associative changes in NMDA receptors. This study shows a region-specific temporal molecular response to global ischemia in the brain, which is important to get better insight into the pathophysiology since each region consists of different subsets of neurons that are having different susceptibility and tolerance pattern/level. This insight into a temporally different ischemic response and the underlying molecular basis might help in strategizing the effective therapeutics against stroke.

A 2-oxa-spiro[5.4]decane scaffold displays neurotrophic, neurogenic and anti-neuroinflammatory activities with high potential for development as a versatile CNS therapeutic.
Following our recent discovery of a new scaffold exhibiting significant neurotrophic and neurogenic activities, a structurally tweaked analogue, embodying a 2-oxa-spiro [5.4]decane framework, has been conceptualised and found to be more potent and versatile. It exhibits enhanced neurotrophic and neurogenic action in in vitro, ex vivo and in vivo models and also shows robust neuroprotection in mouse acute cerebral stroke model. The observed attributes are traceable to the predominant activation of the TrkB-PI3K-AKT-CREB pathway. In addition, it also exhibits remarkable anti-neuroinflammatory activity by concurrently down-regulating pro-inflammatory cytokines IL-1α and IL-6, thereby providing a unique molecule with a trinity of neuroactivities, i.e. neurotrophic, neurogenic and anti-inflammatory. The new chemical entity disclosed here has the potential to be advanced as a versatile therapeutic molecule to treat stroke, depression, and possibly other neuropsychiatric disorders associated with attenuated neurotrophic/ neurogenic activity, together with heightened neuroinflammation.

Synthesis and biological evaluation of longanlactone analogues as neurotrophic agents.
Longanlactone analogues were synthesized using a route featuring Friedel-Crafts acylation, Sonogashira coupling and 1,3-dipolar cycloaddition reactions. Structure-activity relationships were investigated for neurotrophic activity. Compound 6 was found to have the most potent neurotrophic activity among all the synthesized analogues in Neuro2a cells as evidenced by a battery of in vitro/cell based assays for assessment of neurogenic and potential neurotrophic activity including neurite outgrowth assay and real time PCR for popular markers of augmented neurotrophic activity. Compound 6 might serve as a template for further development of highly effective neurotrophic molecules.

Novel Phosphorylation-State Specific Antibodies Reveal Differential Deposition of Ser26 Phosphorylated Aβ Species in a Mouse Model of Alzheimer's Disease.
Aggregation and deposition of amyloid-β (Aβ) peptides in extracellular plaques and in the cerebral vasculature are prominent neuropathological features of Alzheimer's disease (AD) and closely associated with the pathogenesis of AD. Amyloid plaques

in the brains of most AD patients and transgenic mouse models exhibit heterogeneity in the composition of Aβ deposits, due to the occurrence of elongated, truncated, and post-translationally modified Aβ peptides. Importantly, changes in the deposition of these different Aβ variants are associated with the clinical disease progression and considered to mark sequential phases of plaque and cerebral amyloid angiopathy (CAA) maturation at distinct stages of AD. We recently showed that Aβ phosphorylated at serine residue 26 (pSer26Aβ) has peculiar characteristics in aggregation, deposition, and neurotoxicity. In the current study, we developed and thoroughly validated novel monoclonal and polyclonal antibodies that recognize Aβ depending on the phosphorylation-state of Ser26. Our results demonstrate that selected phosphorylation state-specific antibodies were able to recognize Ser26 phosphorylated and non-phosphorylated Aβ with high specificity in enzyme-linked immunosorbent assay (ELISA) and Western Blotting (WB) assays. Furthermore, immunofluorescence analyses with these antibodies demonstrated the occurrence of pSer26Aβ in transgenic mouse brains that show differential deposition as compared to non-phosphorylated Aβ (npAβ) or other modified Aβ species. Notably, pSer26Aβ species were faintly detected in extracellular Aβ plaques but most prominently found intraneuronally and in cerebral blood vessels. In conclusion, we developed new antibodies to specifically differentiate Aβ peptides depending on the phosphorylation state of Ser26, which are applicable in ELISA, WB, and immunofluorescence staining of mouse brain tissues. These site- and phosphorylation state-specific Aβ antibodies represent novel tools to examine phosphorylated Aβ species to further understand and dissect the complexity in the age-related and spatio-temporal deposition of different Aβ variants in transgenic mouse models and human AD brains.

Differential interaction with TREM2 modulates microglial uptake of modified Aβ species.
Rare coding variants of the microglial triggering receptor expressed on myeloid cells 2 (TREM2) confer an increased risk for Alzheimer's disease (AD) characterized by the progressive accumulation of aggregated forms of amyloid β peptides (Aβ). Aβ peptides are generated by proteolytic processing of the amyloid precursor protein (APP). Heterogeneity in proteolytic cleavages and additional post-translational modifications result in the production of several distinct Aβ variants that could differ in their aggregation behavior and toxic properties. Here, we sought to assess whether post-translational modifications of Aβ affect the interaction with TREM2. Biophysical and biochemical methods revealed that TREM2 preferentially interacts with oligomeric Aβ, and that phosphorylation of Aβ increases this interaction. Phosphorylation of Aβ also affected the TREM2 dependent interaction and phagocytosis by primary microglia and in APP transgenic mouse models. Thus, TREM2 function is important for sensing phosphorylated Aβ variants in distinct aggregation states and reduces the accumulation and deposition of these toxic Aβ species in preclinical models of Alzheimer's disease.

TREM2 modulates differential deposition of modified and non-modified Aβ species in extracellular plaques and intraneuronal deposits.
Progressive accumulation of Amyloid-β (Aβ) deposits in the brain is a characteristic neuropathological hallmark of Alzheimer's disease (AD). During disease progression, extracellular Aβ plaques undergo specific changes in their composition by the sequential deposition of different modified Aβ species. Microglia are implicated in the restriction of amyloid deposits and play a major role in internalization and degradation of Aβ. Recent studies showed that rare variants of the Triggering Receptor Expressed on Myeloid cells 2 (TREM2) are associated with an increased risk for AD. Post-translational modifications of Aβ could modulate the interaction with TREM2, and the uptake by microglia. Here, we demonstrate that genetic deletion of TREM2 or expression of a disease associated TREM2 variant in mice lead to differential accumulation of modified and non-modified Aβ species in extracellular plaques and intraneuronal deposits. Human brains with rare TREM2 AD risk variants also showed altered deposition of modified Aβ species in the different brain lesions as compared to cases with the common variant of TREM2. These findings indicate that TREM2 plays a critical role in the development and the composition of Aβ deposits, not only in extracellular plaques, but also intraneuronally, that both could contribute to the pathogenesis of AD.

Amyloid beta (Aβ), is a neurotoxic protein associated with Alzheimer's disease that rapidly aggregates into amyloid oligomers, protofibrils and well-defined fibrils. Indeed, some familial early-onset forms of AD are associated with single amino acid Aβ mutations, such as the most toxic Aβ42 mutation Arctic. Based on previous computational predictions of aggregation propensity and a rational mutagenesis study on Aβ peptides, several variants were identified with distinct effects on survival in a *Drosophila* model: E3R Aβ40, E22G Aβ42 (Arctic), I31E/E22G Aβ42 and F19S/L34P Aβ42. Here we have characterized the amyloidogenic cascade of these variants from the monomer, the oligomers and the fibrils using single-molecule force spectroscopy, Thioflavin T binding assay, immunoassay methods and electron microscopy. We found that the Arctic mutation increases the frequency of mechanostable conformers, including hypermechanostable ones, which correlates with an increased aggregation, fibrillogenesis and toxicity associated to SH-SY5Y cell lines. In contrast, I31E/E22G and F19S/L34P mutations in Aβ42 and E3R mutation in Aβ40 caused a decrease in mechanostable conformers and showed lower *in vitro* aggregation as expected, although they exerted similar or even higher cytotoxicity in SH-SY5Y cells. These effects can be attributed to their capacity to form deleterious protofibrillar aggregates instead of well-defined fibrils, which might result in higher toxicity. Deciphering the molecular bases of Aβ pathogenicity, directly linked to its intrinsic properties, should allow us a deeper understand of the complex pathogenic events that are involved in developing Alzheimer's disease in different *in vivo* models (*i.e.*, *Drosophila* constitutive expression vs. human cell lines).

Conversion of the OmpF Porin into a Device to Gather Amyloids on the Outer Membrane.
Protein amyloids are ubiquitous in natural environments. They typically originate from microbial secretions or spillages from mammals infected by prions, currently raising concerns about their infectivity and toxicity in contexts such as gut microbiota or soils. Exploiting the self-assembly potential of amyloids for their scavenging, here, we report the insertion of an amyloidogenic sequence stretch from a bacterial prion-like protein (RepA-WH1) in one of the extracellular loops (L5) of the abundant outer membrane porin OmpF. The expression of this grafted porin enables bacterial cells to trap on their envelopes the same amyloidogenic sequence when provided as an extracellular free peptide. Conversely, when immobilized on a surface as bait, the full-length prion-like protein including the amyloidogenic peptide can catch bacteria displaying the L5-grafted OmpF. Polyphenolic molecules known to inhibit amyloid assembly interfere with peptide recognition by the engineered OmpF, indicating that this is compatible with the kind of homotypic interactions expected for amyloid assembly. Our study suggests that synthetic porins may provide suitable scaffolds for engineering biosensor and clearance devices to tackle the threat posed by pathogenic amyloids.

Alzheimer's Disease (AD) is a progressive neurodegenerative disorder. The main factor that has been involved on AD physiopathology is the aberrant aggregation of Amyloid beta peptide (Aβ), that induce Ca^{2+} dyshomeostasis and disruption of mitochondria-associated membranes (MAMs) . Here, we postulate that transglutaminase type 2 (TG2) is a potential target in several steps of the amyloid cascade. Using Hippocampal neuron treated with oligomeric forms of Aβ peptide and aged J20 brain slices, we observed an increase in TG2 transamidating activity and total levels (159 %). Using different molecular techniques we characterize the biochemical features of Aβ aggregates induced by TG2. We observed that TG2-Aβ interaction is energetically favorable with TG2 in open conformation (ΔG $A\beta_{mon}$: -10.9, $A\beta_{dim}$: -9.4, $A\beta_{trim}$: -6.4). We find that TG2 can induce a toxic Aβ assemblies size of ~28 and 55 kDa. Thioflavin T measures showed that TG2 incubation was able to promote Aβ aggregation, increasing lag phase, and maximum peak of fluorescence in stationary phase. We observe an increase in synaptic transmission induced by TG2-Aβ assemblies, that was blockage by inhibitor of TG2. Using PLA technology and Rhod-2 measurements we examine the effect of these aggregates on mitochondrial function in APP/PS1 CAD cells. We observed that after acute exposure to Aβ aggregates in the presence of TG2 a significant two-fold increase in the number of ER-mitochondria contact points and mitochondrial Ca2+ transference (220%). Our results contribute to explaining the key TG2 involvement on sinaptotoxicity and its potentiality as pharmacological target to treat AD.

PrP as a Transducer of Physiological and Pathological Signals.
After the discovery of prion phenomenon, the physiological role of the cellular prion protein (PrP) remained elusive. In the past decades, molecular and cellular analysis has shed some light regarding interactions and functions of PrP in health and disease. PrP , which is located mainly at the plasma membrane of neuronal cells attached by a glycosylphosphatidylinositol (GPI) anchor, can act as a receptor or transducer from external signaling. Although the precise role of PrP remains elusive, a variety of functions have been proposed for this protein, namely, neuronal excitability and viability. Although many issues must be solved to clearly define the role of PrP , its connection to the central nervous system (CNS) and to several misfolding-associated diseases makes PrP an interesting pharmacological target. In a physiological context, several reports have proposed that PrP modulates synaptic transmission, interacting with various proteins, namely, ion pumps, channels, and metabotropic receptors. PrP has also been implicated in the pathophysiological cell signaling induced by β-amyloid peptide that leads to synaptic dysfunction in the context of Alzheimer's disease (AD), as a mediator of Aβ-induced cell toxicity. Additionally, it has been implicated in other proteinopathies as well. In this review, we aimed to analyze the role of PrP as a transducer of physiological and pathological signaling.

Deciphering the role of PGC-1α in neurological disorders: from mitochondrial dysfunction to synaptic failure.
The onset and mechanisms underlying neurodegenerative diseases remain uncertain. The main features of neurodegenerative diseases have been related with cellular and molecular events like neuronal loss, mitochondrial dysfunction and aberrant accumulation of misfolded proteins or peptides in specific areas of the brain. The most prevalent neurodegenerative diseases belonging to age-related pathologies are Alzheimer's disease, Huntington's disease, Parkinson's disease and amyotrophic lateral sclerosis. Interestingly, mitochondrial dysfunction has been observed to occur during the early onset of several neuropathological events associated to neurodegenerative diseases. The master regulator of mitochondrial quality control and energetic metabolism is the transcriptional coactivator peroxisome proliferator-activated

receptor gamma coactivator 1-alpha (PGC-1α). Additionally, it has been observed that PGC-1α appears to be a key factor in maintaining neuronal survival and synaptic transmission. In fact, PGC-1α downregulation in different brain areas (hippocampus, substantia nigra, cortex, striatum and spinal cord) that occurs in function of neurological damage including oxidative stress, neuronal loss, and motor disorders has been seen in several animal and cellular models of neurodegenerative diseases. Current evidence indicates that PGC-1α upregulation may serve as a potent therapeutic approach against development and progression of neuronal damage. Remarkably, increasing evidence shows that PGC-1α deficient mice have neurodegenerative diseases-like features, as well as neurological abnormalities. Finally, we discuss recent studies showing novel specific PGC-1α isoforms in the central nervous system that appear to exert a key role in the age of onset of neurodegenerative diseases and have a neuroprotective function in the central nervous system, thus opening a new molecular strategy for treatment of neurodegenerative diseases. The purpose of this review is to provide an up-to-date overview of the PGC-1α role in the physiopathology of neurodegenerative diseases, as well as establish the importance of PGC-1α function in synaptic transmission and neuronal survival.

Changes in PGC-1α/SIRT1 Signaling Impact on Mitochondrial Homeostasis in Amyloid-Beta Peptide Toxicity Model.
Alzheimer's disease (AD) is a neurodegenerative disorder characterized by cognitive impairment that increasingly afflicts the elderly population. Soluble oligomers (AβOs) has been implicated in AD pathogenesis: however, the molecular events underlying a role for Aβ are not well understood. We studied the effects of AβOs on mitochondrial function and on key proteins that regulate mitochondrial dynamics and biogenesis in hippocampal neurons and PC-12 cells. We find that AβOs treatment caused a reduction in total Mfn1 after a 2 h exposure (42 ± 11%); while DRP1 increased at 1 and 2 h (205 ± 22% and 198 ± 27%, respectively), correlating to changes in mitochondrial morphology. We also observed that SIRT1 levels were reduced after acute and chronic AβOs treatment (68 ± 7% and 77 ± 6%, respectively); while PGC-1α levels were reduced with the same time treatments (68 ± 8% and 67 ± 7%, respectively). Interestingly, we found that chronic treatment with AβOs increased the levels of pSIRT1 (24 h: 157 ± 18%), and we observed changes in the PGC-1α and p-SIRT1 nucleus/cytosol ratio and SIRT1-PGC-1α interaction pattern after chronic exposure to AβOs. Our data suggest that AβOs induce important changes in the level and localization of mitochondrial proteins related with the loss of mitochondrial function that are mediated by a fast and sustained SIRT1/PGC-1α complex disruption promoting a "non-return point" to an irreversible synaptic failure and neuronal network disconnection.

Data on SVCT2 transporter expression and localization in cancer cell lines and tissues.
The data presented in this article are related to the research paper entitled "Increased expression of mitochondrial sodium-coupled ascorbic acid transporter-2 (mitSVCT2) as a central feature in breast cancer", available in Free Radical Biology and Medicine Journal [1]. In this article, we examined the SVCT2 transporter expression in various breast cancer cell lines using RT-PCR and Western blot assays. In addition, we analyzed the subcellular localization of SVCT2 by immunofluorescence colocalization assays and cellular fractionation experiments. Finally, an analysis of different cancer tissue microarrays immunostained for SVCT2 and imaged by The Human Protein Atlas (https://www.proteinatlas.org) is presented.

Increased expression of mitochondrial sodium-coupled ascorbic acid transporter-2 (mitSVCT2) as a central feature in breast cancer.
The potential role of vitamin C in cancer prevention and treatment remains controversial. While normal human cells obtain vitamin C as ascorbic acid, the prevalent form of vitamin C in vivo, the uptake mechanisms by which cancer cells acquire vitamin C has remained unclear. The aim of this study is to characterize how breast cancer cells acquire vitamin C. For this, we determined the expression of vitamin C transporters in normal and breast cancer tissue samples, and in ZR-75, MCF-7, MDA-231 and MDA-468 breast cancer cell lines. At the same time, reduced (AA) and oxidized (DHA) forms of vitamin C uptake experiments were performed in all cell lines. We show here that human breast cancer tissues differentially express a form of SVCT2 transporter, that is systematically absent in normal breast tissues and it is increased in breast tumors. In fact, estrogen receptor negative breast cancer tissue, exhibit the most elevated SVCT2 expression levels. Despite this, our analysis in breast cancer cell lines showed that these cells are not able to uptake ascorbic acid and depend on glucose

transporter for the acquisition of vitamin C by a bystander effect. This is consistent with our observations that this form of SVCT2 is completely absent from the plasma membrane and is overexpressed in mitochondria of breast cancer cells, where it mediates ascorbic acid transport. This work shows that breast cancer cells acquire vitamin C in its oxidized form and are capable of accumulated high concentrations of the reduced form. Augmented expression of an SVCT2 mitochondrial form appears to be a common hallmark across all human cancers and might have implications in cancer cells survival capacity against pro-oxidant environments.

P2X receptor overexpression induced by soluble oligomers of amyloid beta peptide potentiates synaptic failure and neuronal dyshomeostasis in cellular models of Alzheimer's disease.
The most common cause of dementia is Alzheimer's disease. The etiology of the disease is unknown, although considerable evidence suggests a critical role for the soluble oligomers of amyloid beta peptide (Aβ). Because Aβ increases the expression of purinergic receptors (P2XRs) in vitro and in vivo, we studied the functional correlation between long-term exposure to Aβ and the ability of P2XRs to modulate network synaptic tone. We used electrophysiological recordings and Ca microfluorimetry to assess the effects of chronic exposure (24 h) to Aβ oligomers (0.5 μM) together with known inhibitors of P2XRs, such as PPADS and apyrase on synaptic function. Changes in the expression of P2XR were quantified using RT-qPCR. We observed changes in the expression of P2X1R, P2X7R and an increase in P2X2R; and also in protein levels in PC12 cells (143%) and hippocampal neurons (120%) with Aβ. In parallel, the reduction on the frequency and amplitude of mEPSCs (72% and 35%, respectively) were prevented by P2XR inhibition using a low PPADS concentration. Additionally, the current amplitude and intracellular Ca signals evoked by extracellular ATP were increased (70% and 75%, respectively), suggesting an over activation of purinergic neurotransmission in cells pre-treated with Aβ. Taken together, our findings suggest that Aβ disrupts the main components of synaptic transmission at both pre- and post-synaptic sites, and induces changes in the expression of key P2XRs, especially P2X2R; changing the neuromodulator function of the purinergic tone that could involve the P2X2R as a key factor for cytotoxic mechanisms. These results identify novel targets for the treatment of dementia and other diseases characterized by increased purinergic transmission.

Alzheimer's disease (AD) is the most common neurodegenerative disorder characterized by a progressive deficit in memory leading to dementia. Insoluble amyloid beta peptide (Aβ) deposits in the brain are a pathological hallmark of the disease, but soluble Aβ oligomers (Aβo) are considered as the most toxic form for neurons and synapses. Indeed, Aβo induce synapse loss and impair a cellular basis of learning and memory, the long-term potentiation (LTP). In AD patients, Aβ accumulates in the brain decades before disease onset. Therefore, targeting toxic Aβo at early stages appears as a promising strategy to delay disease progression. Thus, we designed a new peptide tool which binds Aβo with high affinity. Using ThT assay, TEM and Western blotting, we showed that this peptide strongly alters Aβ aggregation and reduces Aβo formation. To investigate the potential toxicity of Aβo formed with the peptide, we performed synaptic targeting experiments on neuronal cultures using immunocytochemistry and confocal imaging. Our findings demonstrate that these Aβo are no longer able to bind synapses. Finally, we investigated the functional impact of this peptide on LTP, using electrophysiological experiments on hippocampal slices in the APP/PS1 mouse model of AD. Our results reveal that this blocking peptide rescues LTP in APP/PS1 slices. Altogether, these results indicate that the peptide is a promising candidate for alleviating synaptic defects in AD preclinical models. Further in vivo explorations will help determining the benefits of this blocking strategy on synaptotoxicity, learning and memory alterations in the APP/PS1 mouse model of AD.

Aims. Gαo is an alpha subunit of heterotrimeric G proteins, and a highly expressed protein in the nervous system. Long ago, Gαo was reported to interact with the amyloid precursor protein (APP), central to the Alzheimer's pathology. When triggered by an unknown cue, APP prolongs Gαo activation, either by behaving as a guanine nucleotide exchange factor (GEF) or by decreasing Gαo's GTPase-activating protein (GAP) activity. This interaction of unknown function may open new perspectives to the physiological role of APP in the brain. Methods. Gαo interacts with the APP C-terminus at His657-Lys676, in a hydrophobic pocket immediately downstream the APP 653YTSI656 sorting motif. Using SH-SY5Y neuroblastoma cells and rat primary neurons expressing APP S655 phosphomutants, and CB1R-Gαo activating cannabinoids, we have explored APP-Gαo functional interaction in neuritogenesis, and how APP phosphorylation at S655 impacts the physical and functional APP-Gαo interaction. Results. S655 phosphorylation increases/prolongs APP binding to Gαo and Gαo activation. It is also determinant for APP/Gαo-induced neuritogenesis, fine-tuning between the formation and the elongation of cellular pre-neurites in SH-SY5Y cells. In neurons, APP-Gαo co-promote dendritic branching. Two signaling cascades, the Src-STAT3 and ERK1/2 signaling pathways, may be involved, with APP S655 phosphorylation increasing Gαo-induced ERK1/2 activation at 24h. Conclusions. The characterization of the dual neuritogenic effects and signaling activation of the APP-Gαo complex, and the role of APP phosphorylation on its modulation, not only sheds new light on the mechanisms of neuronal differentiation and APP physiology, but might also provide new groundwork to advance the knowledge on AD pathogenesis.

Myelin degeneration and white matter loss are early events in Alzheimer's disease (AD) that lead to cognitive deficits. One of the hallmarks of AD is the presence of extracellular aggregates of amyloid beta peptide (Aβ), and Aβ oligomers (Abo) have been proposed to induce changes in oligodendrocytes and myelin. However, the underlying molecular mechanisms remain unknown. We found that Aβo alter the translation of MBP and MOBP, one of the major and essential proteins of CNS. Here, we characterized how Aβo control and deregulate the metabolism of *Mbp* and *Mobp* mRNA and its local translation in cultured oligodendrocytes. First, we observed that Aβo increase mRNA and protein levels of MBP and MOBP, as well as of ribonucleoprotein A2 (hnRNPA2), which binds to their 3'UTR. Interestingly, immunofluorescence analysis along with RNA-immunoprecipitation showed an increase in total transport granule number and active granules, together with a higher association between *Mbp* and *Mobp* mRNA and hnRNPA2. Additionally, activation of Fyn with an upregulation in phosphorylation levels of tyrosine residues of hnRNPA2 and direct visualization of newly synthesized proteins by Puro-PLA confirmed that Abo increase the local translation in oligodendrocytes. Consistent with these results, we observed an upregulation of hnRNPA2, MOBP and MBP in the hippocampus of 3xTg-AD mice. Likewise, RNA-seq analysis from oligodendrocytes isolated from 3xTg-AD mice brains revealed changes in genes related to translation and myelination. Taken together, these results suggest that Aβo could be altering the proteostasis, influencing the dynamics of oligodendroglial maturation and myelin, with potential consequences in axonal conduction.

Tauopathies are a group of neurodegenerative disorders characterized by cerebral atrophy, hyperphosphorylation, abnormal aggregation of tau filaments into intracellular neurofibrillary tangles and chronic neuroinflammation. A role of lipid metabolism dysregulation in aging and neurodegeneration is well established, however still poorly understood. To investigate the impact of tau pathology on lipid metabolism, we have performed a thorough targeted lipidomic and metabolomic analysis of brain tissue, cerebrospinal fluid (CSF) and plasma of transgenic rats expressing human truncated tau. Specific biofluid markers of tau pathology (total-tau and neurofilament-light-chain) and tau hyperphosphorylated and aggregated forms in brain tissue were measured to examine the effect of tau pathology on metabolic profiles. Presence of neurofibrillary pathology resulted in substantially dysregulated lipid metabolism in brain tissue and even more in the CSF. The most profound change was in phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, lysophosphatidylcholine and sphingomyelin subclasses. However, neither of the changes in CSF nor brain lipidome were reflected in the plasma. Further analysis showed that lipid changes correlate with the tau pathology in brain tissue. Moreover, we found that tau pathology induces formation of lipid droplets *in vitro* and *in vivo* . Our results results highlight the importance of lipid metabolism in tau pathology alone, but also main hallmarks of neurodegenerative disesases such as neuroinflammation, glial activation and hyperphoshorylation.

Novel Blood-Brain Barrier Shuttle Peptides Discovered through the Phage Display Method.
Delivery of therapeutic agents into the brain is a major challenge in central nervous system drug development. The blood-brain barrier (BBB) prevents access of biotherapeutics to their targets in the central nervous system and, therefore, prohibits the effective treatment of many neurological disorders. To find blood-brain barrier shuttle peptides that could target therapeutics to the brain, we applied a phage display technology on a primary endothelial rat cellular model. Two identified peptides from a 12 mer phage library, GLHTSATNLYLH and VAARTGEIYVPW, were selected and their permeability was validated using the in vitro BBB model. The permeability of peptides through the BBB was measured by ultra-performance liquid chromatography-tandem mass spectrometry coupled to a triple-quadrupole mass spectrometer (UHPLC-MS/MS). We showed higher permeability for both peptides compared to N-C reversed-sequence peptides through in vitro BBB: for peptide GLHTSATNLYLH 3.3 × 10 cm/s and for peptide VAARTGEIYVPW 1.5 × 10 cm/s. The results indicate that the peptides identified by the in vitro phage display technology could serve as transporters for the administration of biopharmaceuticals into the brain. Our results also demonstrated the importance of proper BBB model for the discovery of shuttle peptides through phage display libraries.

GM3 Ganglioside Linked to Neurofibrillary Pathology in a Transgenic Rat Model for Tauopathy.
Glycosphingolipids (GSLs) are amphipathic lipids composed of a sphingoid base and a fatty acyl attached to a saccharide moiety. GSLs play an important role in signal transduction, directing proteins within the membrane, cell recognition, and modulation of cell adhesion. Gangliosides and sulfatides belong to a group of acidic GSLs, and numerous studies report their involvement in neurodevelopment, aging, and neurodegeneration. In this study, we used an approach based on hydrophilic interaction liquid chromatography (HILIC) coupled to high-resolution tandem mass spectrometry (HRMS/MS) to characterize the glycosphingolipid profile in rat brain tissue. Then, we screened characterized lipids aiming to identify changes in glycosphingolipid profiles in the normal aging process and tau pathology. Thorough screening of acidic glycosphingolipids in rat brain tissue revealed 117 ganglioside and 36 sulfatide species. Moreover, we found two ganglioside subclasses that were not previously characterized-GT1b-Ac2 and GQ1b-Ac2. The semi-targeted screening revealed significant changes in the

levels of sulfatides and GM1a gangliosides during the aging process. In the transgenic SHR24 rat model for tauopathies, we found elevated levels of GM3 gangliosides which may indicate a higher rate of apoptotic processes.

A Novel UHPLC-MS Method Targeting Urinary Metabolomic Markers for Autism Spectrum Disorder.
Autism spectrum disorder is a heterogeneous neurodevelopmental disease. Currently, no biomarker of this disease is known. Diagnosis is performed through observation, standardized behavioral scales, and interviews with parents. In practice, diagnosis is often delayed to the average age of four years or even more which adversely affects a child's perspective. A laboratory method allowing to detect the disorder at earlier stages is of a great need, as this could help the patients to start with treatment at a younger age, even prior to the clinical diagnosis. Recent evidence indicates that metabolomic markers should be considered as diagnostic markers, also serving for further differentiation and characterization of different subgroups of the autism spectrum. In this study, we developed an ultra-high performance liquid chromatography-tandem triple quadrupole mass spectrometry method for the simultaneous determination of six metabolites in human urine. These metabolites, namely methylguanidine, N-acetyl arginine, inosine, indole-3-acetic acid, indoxyl sulfate and xanthurenic acid were selected as potential biomarkers according to prior metabolomic studies. The analysis was carried out by means of reversed-phase liquid chromatography with gradient elution. Separation of the metabolites was performed on a Phenomenex Luna Omega Polar C18 (100 × 1.0 mm, 1.6 µm) column at a flow rate of 0.15 mL/min with acetonitrile/water 0.1% formic acid aqueous as the mobile phase. The analysis was performed on a group of children with autism spectrum disorder and age-matched controls. In school children, we have detected disturbances in the levels of oxidative stress markers connected to arginine and purine metabolism, namely methylguanidine and N-acetylargine. Also, products of gut bacteria metabolism, namely indoxyl sulfate and indole-3-acetic acid, were found to be elevated in the patients' group. We can conclude that this newly developed method is fast, sensitive, reliable, and well suited for the quantification of proposed markers.

Determination of immunogenic proteins in biopharmaceuticals by UHPLC-MS amino acid analysis.
Nowadays, there is a growing interest in innovative and more efficient therapeutics-biopharmaceuticals, based on peptides or proteins. There are increased demands on quality control of such therapeutics. One of the methods usually used for characterization and quantification of biopharmaceuticals is amino acid analysis. In this work, a modern advanced analytical method based on precolumn derivatization and reversed-phase ultra high-performance liquid chromatography in combination with single quadrupole mass spectrometer was developed for amino acid analysis in different protein samples-model sample of bovine serum albumin, sample of strong immunogenic protein keyhole limpet hemocyanin, and sample of drug etanercept present in commercially available biopharmaceutical Enbrel. The method used isotopically labeled internal standards and was validated according to the International Council for Harmonisation guideline. The developed method was characterized by favorable performance and validation parameters, such as time of analysis (6 min), specificity, linearity ($r \geq 0.99$), limit of detection (0.009-0.822 µM), limit of quantification (1-2.5 µM), accuracy (recovery in the range 90-102.8%), intra-day (RSD in the range 0.25-11.97%) and inter-day precision (RSD in the range 1.67-11.57%), or stability ($RE \leq 12\%$). According to these findings, the developed amino acid analysis approach is suitable for routine use in areas of peptide/protein quantification, such as quality control laboratories of biopharmaceutical companies.

Determination of Branched-Chain Amino Acids in Food Supplements and Human Plasma by a CE-MS/MS Method with Enhanced Resolution.
In the presented study, a capillary electrophoresis-mass spectrometry method combining high separation efficiency and sensitive detection has been developed and validated, for the first time, to quantify branched chain amino acids (valine, isoleucine, leucine) in commercial food and sport supplement samples and human plasma samples. The separations were performed in a bare fused silica capillary. The background electrolyte was composed of 500 mM formic acid with pH 2.0. The plasma sample pretreatment was realized by simple protein precipitation with acetonitrile. Injection of a short zone of highly basic electrolyte before the sample injection and application of the negative pressure on the separation were accompanied by enhanced resolution of the isobaric amino acids-isoleucine and leucine. The developed method was characterized by favorable validation parameters, such as linearity ($r > 0.99$), accuracy and precision, the limit of detection, lower limit of quantification, or robustness. These parameters were more than sufficient for the quantification of branched chain amino acids in various samples. The determined concentrations of branched chain amino acids in food and sports supplements were in very good agreement with the content declared by the manufacturer. The investigated concentrations of branched chain amino acids were in the range 294.68-359.24 µM for valine, 91.76-95.67 µM for isoleucine, and 196.78-251.24 µM for leucine. These concentrations fall within the physiological limits. The developed CE-MS/MS method represents a suitable

alternative to traditional approaches used in branched chain amino acid quality control and bioanalysis.

Fast and Sensitive Screening of Oxandrolone and Its Major Metabolite 17-Epi-Oxandrolone in Human Urine by UHPLC-MS/MS with On-Line SPE Sample Pretreatment.
Oxandrolone, a synthetic testosterone analog, is used for the treatment of several diseases associated with weight loss. Unfortunately, oxandrolone is abused by many athletes and bodybuilders due to its strong anabolic effect. We have developed and validated a highly sensitive and rapid on-line SPE-UHPLC-MS/MS method for the determination of oxandrolone and simultaneous identification of its major metabolite 17-epi-oxandrolone in urine matrices. Enrichment of the analytes via an integrated solid-phase extraction was achieved using an Acquity UPLC BEH C18 Column. Subsequently, the chromatographic separation of the on-line preconcentrated sample fraction was achieved using an Acquity HSS T3 C18 Column. For the structural identification of these analytes, a high-resolution mass spectrometer Synapt-G2Si coupled to the Acquity M-class nano-LC system with ionKey source was used. A highly sensitive determination of oxandrolone was achieved using a tandem quadrupole mass spectrometer XEVO TQD. The method was successfully validated in the linear range of oxandrolone from 81.63 pg·mL (limit of quantification, LOQ) to 5000 pg·mL in the human urine matrix. It was applied to the analysis of real urine samples obtained from a healthy volunteer after the oral administration of one dose (10 mg) of oxandrolone. Concentration vs. time dependence was tested in the time interval of 4 h-12 days (after oral administration) to demonstrate the ability of the method to detect the renal elimination of oxandrolone from the human body. Favorable performance parameters along with successful application indicate the usefulness of the proposed method for its routine use in antidoping control labs.

Profiling of Amino Acids in Urine Samples of Patients Suffering from Inflammatory Bowel Disease by Capillary Electrophoresis-Mass Spectrometry.
Urine represents a convenient biofluid for metabolomic studies due to its noninvasive collection and richness in metabolites. Here, amino acids are valuable biomarkers for their ability to reflect imbalances of different biochemical pathways. An impact of amino acids on pathology, prognosis and therapy of various diseases, including inflammatory bowel disease (IBD), is therefore the subject of current clinical research. This work is aimed to develop a capillary electrophoresis-tandem mass spectrometry (CE-MS/MS) method for the quantification of the 20 proteinogenic amino acids in human urine samples obtained from patients suffering from IBD and treated with thiopurines. The optimized CE-MS/MS method, with minimum sample preparation (just "dilute and shoot"), exhibited excellent linearity for all the analytes (coefficients of determination were higher than 0.99), with inter-day and intra-day precision yielding relative standard deviations in the range of 0.91-15.12% and with accuracy yielding relative errors in the range of 85.47-112.46%. Total analysis time, an important parameter for the sample throughput demanded in routine practice, was shorter in ca. 17% when compared to established CE-MS methods. Favorable performance of the proposed CE-MS/MS method was also confirmed by the comparison with corresponding ultra-high performance liquid chromatography-mass spectrometry (UHPLC-MS) method. Consistent data for the investigated amino acid metabolome were obtained using both methods. For the first time, the amino acid profiling by CE-MS approach was applied on the clinical IBD samples. Here, significant differences observed in the concentration levels of some amino acids between IBD patients undergoing thiopurine treatment and healthy volunteers could result from the simultaneous action of the disease and the corresponding therapy. These findings indicate that amino acids analysis could be a valuable tool for the study of mechanism of the IBD treatment by thiopurines.

Tau protein aggregates are a key element in the development of certain neurodegenerative diseases, defined as tauopathies. Pathological Tau accumulates in the brain and disrupts synaptic communication through different mechanisms, ultimately inducing neurodegeneration. The aim of this project is to understand how tauopathies, and the associated accumulation of pathological tau-protein aggregates, affect the functional connectivity of neuronal networks.
Due to the sheer size of the brain, and the difficulty to monitor tauopathies at a cellular scale, an interesting approach is to use in vitro neuronal circuits. We prepare neuronal cultures derived from mouse cortical tissue and introduce pathological tau protein extracted from different sources. We record the spontaneous activity through fluorescence calcium imaging and apply complex networks analysis to reveal the functional connectivity of the cultures. With this information we can establish aspects such as collective dynamics, the existence of functional modules, and the emergence of synchrony between neurons and their loss upon damage.
Experiments showed a remarkable change in the fluorescence traces between control and tau-treated conditions: cultures treated with pathological tau presented a higher fluorescence intensity as well as a higher number of spikes within bursts. We associate these results to the damage or loss of activity-regulatory mechanisms in the neuronal circuits due to the presence of pathological tau.
The project leading to these results has received funding from “la Caixa” Foundation (ID 100010434) under the agreement LCF/PR/HR19/52160007.

Alzheimer diseases and tauopathies are mostly characterized by histological features such as retinal ganglion cell loss along amyloid deposits and phosphorylated Tau. We have here investigated the functional alterations of vision in the P301S murine model of tauopathy. Visual impairments were demonstrated by a reduced visual acuity already at 6 months, the pathology onset. Visual signals at the cortical and retinal levels were delayed at 6 and 9 months, respectively. Surprisingly, the retinal output signal was advanced on the OFF pathway but delayed on the ON pathway at 6 months. This antagonistic effect, which relies on a dysfunction of the cone photoreceptor synapse, was associated to changes in the expression of the vesicular glutamate transporter and a microglial reaction. This dysfunction of the retinal glutamatergic synapses provides a novel explanation for visual deficits in tauopathies reinforcing the interest for the retinal model in Alzheimer diseases for diagnostic and therapeutic assessment of treatments.

REBOXETINE TREATMENT REDUCES NEUROINFLAMMATION AND GLIAL ACTIVATION IN THE P301S MOUSE MODEL OF TAUOPATHY

POSTER SESSION 06 - SECTION: ALZHEIMER'S AND TAUOPATHIES

Irene López Gutiérrez, Borja García Bueno, Javier Caso, José Luis Muñoz Madrigal, Juan Carlos Leza
UNIVERSIDAD COMPLUTENSE DE MADRID, Farmacología Y Toxicología, MADRID, Spain

Introduction Noradrenaline (NA) is a major modulatory neurotransmitter of the central nervous system (CNS) and besides its actions as a neurotransmitter, it presents a potent anti-inflammatory and neuroprotective effect mainly due to its ability to reduce the activation of glial cells. The main source of NA in the CNS is the Locus Coeruleus (LC), which is the brain region where neurofibrillary tangles of tau first start to accumulate in Alzheimer's disease (AD) patients, being this the earliest detectable AD-like neuropathology. These toxic tau aggregates lead to the death of noradrenergic neurons and a subsequent decrease in NA levels that facilitates the progression of AD. Therefore, treatments to increase NA levels could slow down the progression of AD. Based on this, our main aim was to analyze the effects of a NA elevating drug in a mouse model of tauopathy. **Methods** We treated WT and P301S mice with vehicle or reboxetine, a NA reuptake inhibitor, with mini-osmotic pumps during 28 days. After the treatment we collected brain samples for biochemical analysis. **Results** Our data indicate that reboxetine treatment is able to reduce the neuroinflammation present in the hippocampus of P301S mice through the reduction of astrocytes and microglia activation. **Conclusions** Reboxetine and other NA-elevating drugs could be an interesting therapeutic approach to reduce the neuroinflammation and glial cells over-activation that contribute to the progression of tauopathies such as AD.

Microglial CX3CR1 production increases in Alzheimer's disease and is regulated by noradrenaline.
The loss of noradrenergic neurons and subsequent reduction of brain noradrenaline (NA) levels are associated with the progression of Alzheimer's disease (AD). This seems to be due mainly to the ability of NA to reduce the activation of microglial cells. We previously observed that NA induces the production of the chemokine Fractalkine/CX3CL1 in neurons. The activation of microglial CX3CR1, sole receptor for CX3CL1, reduces the activation of microglia, which is known to largely contribute to the neuronal damage characteristic of AD. Therefore, alterations of CX3CR1 production in microglia could translate into the enhancement or inhibition of CX3CL1 anti-inflammatory effects. In order to determine if microglial CX3CR1 production is altered in AD and if NA can control it, CX3CR1 expression and synthesis were analyzed in 5xFAD mice and human AD brain samples. In addition, the effects of NA and its reuptake inhibitor reboxetine were analyzed in microglial cultures and mice respectively. Our results indicate that in AD CX3CR1 production is increased in the brain cortex and that reboxetine administration further increases it and enhances microglial reactivity toward amyloid beta plaques. However, direct administration of NA to primary rat microglia or human HMC3 cells inhibits CX3CR1 production, suggesting that microglia responses to NA may be altered in the absence of CX3CL1-producing neurons or other nonmicroglial external factors.

Reboxetine Treatment Reduces Neuroinflammation and Neurodegeneration in the 5xFAD Mouse Model of Alzheimer's Disease: Role of CCL2.
The reduction of brain noradrenaline levels is associated to the initiation of Alzheimer's disease and contributes to its progression. This seems to be due mainly to the anti-neuroinflammatory actions of noradrenaline. The analysis of noradrenaline effects on brain cells demonstrates that it also regulates the production of the chemokine CCL2. In the present study, we analyzed the effect of the selective noradrenaline reuptake inhibitor, reboxetine, on the inflammatory and neurodegenerative alterations present in 5xFAD mice, and how the genetic removal of CCL2 affects reboxetine actions. We observed that the removal of CCL2 reduced the memory impairments in 5xFAD mice as well as the neuroinflammatory response, the accumulation of amyloid beta plaques, and the degeneration of neurons in the brain cortex. The administration of reboxetine with osmotic pumps for 28 days also resulted in anti-inflammatory and neuroprotective changes in 5xFAD mice,

even in the absence of CCL2. Yet, 6-month-old CCL2KO mice presented a significant degree of neuroinflammation and neuronal damage. These findings indicate that reboxetine treatment prevents the brain alterations caused by prolonged overproduction of amyloid beta, being these effects independent of CCL2, which is a mediator of the damage caused by amyloid beta in the brain cortex, but necessary for the prevention of the development of neurodegeneration in normal healthy conditions.

Alternative Method to Detect Neuronal Degeneration and Amyloid β Accumulation in Free-Floating Brain Sections With Fluoro-Jade.
Fluoro-Jade is a fluorescein-derived fluorochrome which specifically binds to damaged neurons. Due to this characteristic, it is commonly used for the histochemical detection and quantification of neurodegeneration in mounted brain sections. Here, we describe an alternative and simpler histochemistry protocol based on the use of free-floating brain sections. For this purpose, we have used brain slices from wild-type and 5xFAD mice as well as from mice that received an intracerebral injection of oligomeric amyloid beta peptides. We observed that our histochemistry staining procedure allows for a well-defined labeling of degenerating neurons providing a better signal-to-noise ratio staining than the commonly used one. In addition, our modified protocol demonstrates the ability of Fluoro-Jade C to also fluorescently label amyloid beta plaques.

CCL2 Induces the Production of β2 Adrenergic Receptors and Modifies Astrocytic Responses to Noradrenaline.
The decline in brain noradrenaline levels is associated with the progression of certain neurodegenerative diseases. This seems to be due, at least in part, to the ability of noradrenaline to limit glial activation and to reduce the damage associated with it. Our previous studies of the mechanisms involved in this process indicate that noradrenaline induces the production of the chemokine CCL2 in astrocytes. While CCL2 can protect neurons against certain injuries, its overproduction has also proven to be harmful and to prevent noradrenaline neuroprotective effects. Therefore, in this study, we analyze if the modifications caused to astrocytes by an excessive production of CCL2 may alter their response to noradrenaline. Using primary cultures of rat cortical astrocytes, we observed that CCL2 enhances the production of beta 2 adrenergic receptors in these cells. While this potentiates noradrenaline signaling through cAMP, the activation of the transcription factor CREB is inhibited by CCL2. Furthermore, although CCL2 potentiates noradrenaline induction of glycogenolysis, this does not translate into an augmented release of lactate, one of the processes through which astrocytes help support neurons. Additionally, other neuroprotective actions of noradrenaline, such as the production of brain derived neurotrophic factor and the inhibition of the inducible nitric oxide synthase in astrocytes were modified by CCL2. These data suggest that some of the central nervous system alterations related to CCL2 could be due to its effects on adrenergic receptors and its interference with noradrenaline signaling.

Noradrenaline induces CX3CL1 production and release by neurons.
CX3CL1 is a chemokine for which neurons constitute its primary source within the brain. Besides acting as a chemokine, CX3CL1 regulates multiple processes and is known to inhibit microglial activation. Because of this, CX3CL1 is considered as a messenger used by neurons to communicate with microglia. Similarly, the neurotransmitter noradrenaline reduces microglial activation and production of neurotoxic agents. Based on this, the regulation of neuronal CX3CXL1 by noradrenaline was analyzed. In primary cortical neurons, noradrenaline induced the accumulation of CX3CL1 protein and mRNA. Noradrenaline also increased CX3CL1 in its soluble form despite the inhibition of the activity and synthesis of ADAM10 and ADAM17, the main proteases known to cleave CX3CL1 from the neuronal membrane. Noradrenaline-treated neurons displayed a higher degree of dendritic arborization and a characteristic accumulation of CX3CL1 in the dendritic bifurcation zones. The soluble CX3CL1 produced by neurons after noradrenaline treatment, reduced the accumulation of nitrites in microglia. These findings indicate that NA anti-inflammatory actions are mediated by neuronal CX3CL1. In addition, CX3CL1 seems to be involved in the development of neuronal processes stimulated by noradrenaline.

POST-TRANSLATIONAL MODIFICATIONS OF TAU PROTEIN IN NEURONAL CELLS EXPOSED TO SATURATED FATTY ACIDS: IMPLICATIONS FOR ALZHEIMER´S DISEASE

POSTER SESSION 06 - SECTION: ALZHEIMER'S AND TAUOPATHIES

Valeria Melissa García Cruz, Patricia Ferrera, Clorinda Arias
Universidad Nacional Autónoma de México, Instituto De Investigaciones Biomédicas, Ciudad de México, Mexico

Elevated levels of circulating saturated free fatty acids such as palmitic acid (PA) are associated with obesity and insulin resistance. These metabolic alterations are considered risk factors for developing Alzheimer's disease (AD), as demonstrated by numerous epidemiological studies. Previously, we have found that neuronal exposure to PA induces insulin resistance, increments the intracellular calcium and ROS production, and diminishes the NAD^+/NADH ratio, resulting in decreasing content and activity of Sirtuin1 (Sirt1) deacetylase. However, the precise mechanism triggered after elevated PA on neurons and their association with metabolic disturbances leading to the expression of AD pathological markers, such as post-translational modifications (PTMs) of tau protein have not been elucidated. Therefore, the aim of the present study was to analyze the relationships between the effects of PA metabolism in neuronal cells, differentiated from human neuroblatoma MSN, on protein kinases activation, Sirt1 dysfunction and its consequences in tau phosphorylation and acetylation at AD-related epitopes such as p-S199/202, p-S214, p-S396 and AC-K280. So far, we have observed increased levels of tau phosphorylation and acetylation at specific epitopes such as those mentioned above after 1h or 24 h of PA incubation. These PTMs were mainly associated with activation of GSK3-β and other classical PKCs, and by reduction of Sirt1 activity. Present results provide evidence of how saturated fatty acids metabolism contributes to biochemical alterations in tau protein that resemble some changes found in AD. This work was supported by CONACYT A1-S9559.

Tauopathies, such as Alzheimer's Disease and Frontotemporal dementia, are characterized by several MAPT mutations which lead to the hyperphosphorylation and accumulation of the microtubule-associated protein TAU, leading to a synaptic and neuronal loss, together with a prominent neuroinflammatory state. Considering the genetically inheritance of these mutations and the late onset of the symptoms, we proposed to investigate the role of the IVS10+16 TAU mutation during neurodevelopment and maturation exploiting patterned cortical organoids generated using both commercial-available hIPSC line that carries that mutation and its isogenic control. We took advantages from different experimental approaches aimed to decipher either gene and protein expression as well as neuronal functionality during both early and late stages of brain development. Gene expression analysis revealed that Tau mutation deeply affects neuronal, astrocytic and synaptic maturation. Moreover, we assessed, through confocal analysis that neurons which carry TAU mutation displayed strong cytoskeleton alterations, characterized by small fragments with lower volume compared to control neurons. Functional analysis of Ca^{2+} oscillations of whole cortical-organoids and 2D neuronal cultures have shown that TAU mutation impairs neuronal activity, in terms of reduced frequency, synchronicity and active neurons. These results suggest that inherited intronic TAU mutation deeply affects neuronal and glial maturation already during neurodevelopment, highlighting the pathophysiological role of TAU in the developing brain and paving the road for the identification of new therapeutical targets.

Antibiotics Treatment Modulates Microglia-Synapses Interaction.
'Dysbiosis' of the adult gut microbiota, in response to challenges such as infection, altered diet, stress, and antibiotics treatment has been recently linked to pathological alteration of brain function and behavior. Moreover, gut microbiota composition constantly controls microglia maturation, as revealed by morphological observations and gene expression analysis. However, it is unclear whether microglia functional properties and crosstalk with neurons, known to shape and modulate synaptic development and function, are influenced by the gut microbiota. Here, we investigated how antibiotic-mediated alteration of the gut microbiota influences microglial and neuronal functions in adult mice hippocampus. Hippocampal microglia from adult mice treated with oral antibiotics exhibited increased microglia density, altered basal patrolling activity, and impaired process rearrangement in response to damage. Patch clamp recordings at CA3-CA1 synapses revealed that antibiotics treatment alters neuronal functions, reducing spontaneous postsynaptic glutamatergic currents and decreasing synaptic connectivity, without reducing dendritic spines density. Antibiotics treatment was unable to modulate synaptic function in CX3CR1-deficient mice, pointing to an involvement of microglia-neuron crosstalk through the CX3CL1/CX3CR1 axis in the effect of dysbiosis on neuronal functions. Together, our findings show that antibiotic alteration of gut microbiota impairs synaptic efficacy, suggesting that CX3CL1/CX3CR1 signaling supporting microglia is a major player in in the gut-brain axis, and in particular in the gut microbiota-to-neuron communication pathway.

Novel fragile X syndrome 2D and 3D brain models based on human isogenic FMRP-KO iPSCs.
Fragile X syndrome (FXS) is a neurodevelopmental disorder, characterized by intellectual disability and sensory deficits, caused by epigenetic silencing of the FMR1 gene and subsequent loss of its protein product, fragile X mental retardation

protein (FMRP). Delays in synaptic and neuronal development in the cortex have been reported in FXS mouse models; however, the main goal of translating lab research into pharmacological treatments in clinical trials has been so far largely unsuccessful, leaving FXS a still incurable disease. Here, we generated 2D and 3D in vitro human FXS model systems based on isogenic FMR1 knock-out mutant and wild-type human induced pluripotent stem cell (hiPSC) lines. Phenotypical and functional characterization of cortical neurons derived from FMRP-deficient hiPSCs display altered gene expression and impaired differentiation when compared with the healthy counterpart. FXS cortical cultures show an increased number of GFAP positive cells, likely astrocytes, increased spontaneous network activity, and depolarizing GABAergic transmission. Cortical brain organoid models show an increased number of glial cells, and bigger organoid size. Our findings demonstrate that FMRP is required to correctly support neuronal and glial cell proliferation, and to set the correct excitation/inhibition ratio in human brain development.

Systemic delivery of a specific antibody targeting the pathological N-terminal truncated tau peptide reduces retinal degeneration in a mouse model of Alzheimer's Disease.
Retina and optic nerve are sites of extra-cerebral manifestations of Alzheimer's Disease (AD). Amyloid-β (Aβ) plaques and neurofibrillary tangles of hyperphosphorylated tau protein are detected in eyes from AD patients and transgenic animals in correlation with inflammation, reduction of synapses, visual deficits, loss of retinal cells and nerve fiber. However, neither the pathological relevance of other post-translational tau modifications-such as truncation with generation of toxic fragments-nor the potential neuroprotective action induced by their in vivo clearance have been investigated in the context of AD retinal degeneration. We have recently developed a monoclonal tau antibody (12A12mAb) which selectively targets the neurotoxic 20-22 kDa NH-derived peptide generated from pathological truncation at the N-terminal domain of tau without cross-reacting with its full-length normal protein. Previous studies have shown that 12A12mAb, when intravenously (i.v.)-injected into 6-month-old Tg2576 animals, markedly improves their AD-like, behavioural and neuropathological syndrome. By taking advantage of this well-established tau-directed immunization regimen, we found that 12A12mAb administration also exerts a beneficial action on biochemical, morphological and metabolic parameters (i.e. APP/Aβ processing, tau hyperphosphorylation, neuroinflammation, synaptic proteins, microtubule stability, mitochondria-based energy production, neuronal death) associated with ocular injury in the AD phenotype. These findings prospect translational implications in the AD field by: (1) showing for the first time that cleavage of tau takes part in several pathological changes occurring in vivo in affected retinas and vitreous bodies and that its deleterious effects are successfully antagonized by administration of the specific 12A12mAb; (2) shedding further insights on the tight connections between neurosensory retina and brain, in particular following tau-based immunotherapy. In our view, the parallel response we detected in this preclinical animal model, both in the eye and in the hippocampus, following i.v. 12A12mAb injection opens novel diagnostic and therapeutic avenues for the clinical management of cerebral and extracerebral AD signs in human beings.

Retinal and Brain Organoids: Bridging the Gap Between Physiology and Micro-Physiology for the Study of Alzheimer's Diseases.
Recent progress in tissue engineering has led to increasingly complex approaches to investigate human neurodegenerative diseases , such as Alzheimer's disease, aiming to provide more functional and physiological models for the study of their pathogenesis, and possibly the identification of novel diagnostic biomarkers and therapeutic targets. Induced pluripotent stem cell-derived cortical and retinal organoids represent a novel class of three-dimensional models capable to recapitulate with a high similarity the structure and the complexity of the native brain and retinal tissues, thus providing a framework for better mimicking in a dish the patient's disease features. This review aims to discuss progress made over the years in the field of three-dimensional cell culture systems, and the benefits and disadvantages related to a possible application of organoids for the study of neurodegeneration associated with Alzheimer's disease, providing a promising breakthrough toward a personalized medicine approach and the reduction in the use of humanized animal models.

SPREADING OF P301S AGGREGATED TAU INVESTIGATED IN ORGANOTYPIC MOUSE BRAIN SLICES

POSTER SESSION 06 - SECTION: ALZHEIMER'S AND TAUOPATHIES

Dhwani Korde, Christian Humpel
Psychiatry I, Medical University of Innsbruck, Psychiatry Lab For Experimental Alzheimer‘s Research, Dept. For Psychiatry, Psychotherapy, Psychosomatics, And Medical Psychology, Innsbruck, Austria

Neurofibrillary tangles composed of hyperphosphorylated tau protein aggregates are a key neuropathological feature of Alzheimer’s disease (AD). Tau pathology is reported to spread throughout the brain in a prion-like fashion through connected brain regions. However, the details of the underlying mechanisms are incompletely understood. The present study aims to examine the spreading of tau proteins using organotypic brain slice cultures. Coronal hippocampal slices (170 µm) were prepared from postnatal (day 8-10) C57BL6 wild-type mice. Collagen hydrogels loaded with different tau proteins (full-length tau, K18 PHF tau, Δ306-311 tau, and P301S aggregated tau) were applied to slices and the spread of tau was assessed by immunohistochemistry after 8 weeks. Collagen hydrogels are an effective protein delivery system subject to natural degradation in 14 days and release tau proteins up to 8 weeks. Only P301S aggregated tau loaded in collagen hydrogels was detectable by Western blotting. Slices with collagen hydrogels loaded with un- and hyperphosphorylated P301S aggregated tau demonstrate significant spreading to the ventral parts of the hippocampal slices compared to empty collagen hydrogels after 8 weeks. Moreover, the spread of P301S aggregated tau occurs in a time-dependent manner. We illustrate that tau spreading can be investigated in organotypic slice cultures using collagen hydrogels to locally and slowly apply tau proteins. P301S aggregated tau significantly spreads to the ventral areas of the slices, suggesting that the disease-relevant aggregated tau form possesses more spreading potential compared to the other tau proteins. Thus, the results offer a novel insight on tau spreading in AD.

USING VIRAL VECTORS TO STUDY THE SYNERGISTIC DEVELOPMENTAL EFFECTS OF TAU, ALPHA-SYNUCLEIN AND AMYLOID-BETA

POSTER SESSION 06 - SECTION: ALZHEIMER'S AND TAUOPATHIES

Elise Thompson[1], Guro Vatne[1], Ali Telet[1], Torkel Hafting[2], Marianne Fyhn[1]
[1]University in Oslo, Biosciences, oslo, Norway, [2]University of Oslo, Institute For Basic Medical Research, Oslo, Norway

We want to expand our knowledge on how to study dementia in the mice brain using viral vectors in lieu of transgenic animals. Our research includes tau protein, amyloid-beta and alpha-synuclein and our goal is to understand their synergistic development in dementia pathology. Adeno-associated viruses (AAVs) are modified in-house to carry a gene of interest and are then injected locally. Post mortem analysis shows negligible spread from the injection site. This is important because we wish to study pathology in a limited brain area and have minimal impact on the animal's well-being. In our initial experiments we looked at the tau protein mutation P301S. The goal of the experiment was to evaluate how the mutation impacted transfected cells and the mice in general over a period of 16 weeks. We observed no impact on the mice's general health, locomotion, anxiety or nesting abilities. The AAV-P301S injection causes overexpression of human tau in transfected cells, this was confirmed using immunohistochemistry and western blot. A substantial amount of the tau proteins were hyperphosphorylated (p-tau), this is an early sign of protein malfunction. Tau protein was mainly observed in the neuron cell bodies, while p-tau was also found in dendrites. The mislocation of p-tau to dendritic spines contribute to synaptic loss in Alzheimer's disease. Future experiments will involve other proteins linked to dementia pathology, namely amyloid-beta and alpha-synuclein. Moreover, we will use two-photon imaging to study neuronal activity by imaging Ca2+ transients, and look at the morphology of transfected cells over time.

Removal of perineuronal nets disrupts recall of a remote fear memory.
Throughout life animals learn to recognize cues that signal danger and instantaneously initiate an adequate threat response. Memories of such associations may last a lifetime and far outlast the intracellular molecules currently found to be important for memory processing. The memory engram may be supported by other more stable molecular components, such as the extracellular matrix structure of perineuronal nets (PNNs). Here, we show that recall of remote, but not recent, visual fear memories in rats depend on intact PNNs in the secondary visual cortex (V2L). Supporting our behavioral findings, increased synchronized theta oscillations between V2L and basolateral amygdala, a physiological correlate of successful recall, was absent in rats with degraded PNNs in V2L. Together, our findings suggest a role for PNNs in remote memory processing by stabilizing the neural network of the engram.

Tauopathies are a group of neurodegenerative diseases (e.g., Alzheimer's disease (AD)) characterized by the accumulation and deposition of the Tau protein into amyloid structures. The progression of Tau pathology in AD follows a predictable, hierarchical, and stereotyped pattern between anatomically connected areas of the brain. Thus, it is thought that pathological Tau (pTau) protein engages in a self-amplification process known as "seeding" followed by a trans-cellular "spreading" of the disease. However, the precise molecular mechanisms involved remain elusive.
Recently, the cellular prion protein (PrP^c) has been proposed to mediate Aβ-amyloid progression in AD and α-synuclein in Pakinson's disease, yet less is known about its role in the induction and progression of Tau pathology. In this regard, we inoculated in the parietal cortex and corpus callosum of wild-type, Tau knock-out (KO), PrP^c KO (Zürich III), and PrP^c anchorless (Tg44) mice with samples from AD patients. All mice models, except for the Tau KO, revealed similar amounts of pTau aggregates and spreading at 3 and 6 months post-inoculation. Using immunohistochemical techniques, we have determined that such aggregates mainly contain murine endogenous Tau being positives for histopathological pTau markers such as AT8 and PHF-1. Thereby, our preliminary findings suggest that PrP^c does not seem to have a crucial role in the initialization and/or progression of Tau pathology in our tested models, and other mechanisms might run in parallel. Current experiments are directed to determine these alternative processes and whether they are linked to PrP^c.

SCREENING TYROSINE KINASES FOR THEIR INVOLVEMENT IN SYNAPTOTOXICITY INDUCED BY TAU MICROTUBULE-BINDING REGION FIBRILS

POSTER SESSION 06 - SECTION: ALZHEIMER'S AND TAUOPATHIES

Kelly Hodonou, Dolores Siedlecki-Wullich, Anaïs-Camille Vreulx, Jean-Charles Lambert, Devrim Kilinc
Institut Pasteur de Lille, Inserm U1167 - Université De Lille – Chu De Lille –labex Distalz, Lille, France

Aims: Synapse loss is an early event in Alzheimer's disease (AD); yet, mechanisms of synaptotoxicity induced by amyloid-β and tau –hallmarks of AD pathology – remain unclear. We have recently developed a lab-ona-chip device that fluidically isolates synapses of primary neurons from their cell bodies, thereby enabling us to exclusively access synaptic, as well as pre- and postsynaptic regions. Our aim is to identify molecular mechanisms of synaptotoxicity related to AD. **Methods:** Using the said in vitro model, we assessed the impact of exogenously applied monomeric and fibrillar forms of tau microtubule-binding region (tau-MTBR) as well as of full-length tau isoforms on the connectivity of isolated synapses, quantified through distance-based assignment of postsynaptic puncta to presynaptic puncta. After confirming that the fibrillar form of tau-MTBR induces a detrimental effect on mature synapses, we conducted a medium-throughput compound screening, in which we tested small molecule inhibitors of 25 tyrosine kinases for their capacity to block tau-MTBR-induced synaptotoxicity. **Results:** Four compounds that did not impact synapses in the absence of tau-MTBR, but protected them from the detrimental effect were considered potentially protective and subjected to dose-response analysis. Experiments to validate the observed toxic and protective effects using electrophysiological recordings –via microfluidic devices integrated to microelectrode arrays– are under way. **Conclusions:** Deciphering downstream signaling mechanisms in tau-induced synaptotoxicity will help us gain a better understanding of AD pathogenesis and identify potential therapeutic targets.

Aims: Tauopathies are neurodegenerative diseases characterized by intraneuronal accumulation of hyperphosphorilated Tau protein, leading to neuronal dysfunction and neurodegeneration. Recent evidence suggests selective vulnerability of specific brain nuclei to initiate Tau pathology, from where pathological Tau propagates to other areas. Several experimental approaches pointed Tau reduction as a promising therapeutic strategy for tauopathies. Yet, global Tau elimination might affect endogenous physiological functions. Therefore, we aimed to validate a novel strategy for local Tau knock-down into specific brain nuclei in a mouse model of tauopathy. Methods: We analyzed the hTau mouse model of tauopathy, which primarily accumulates hyperphosphorylated Tau in the prefrontal cortex (PFC) and develops cognitive impairments and cortical-pyramidal neuronal firing deficits from 6 months-old. Artificial microRNAs designed to target the *MAPT* transcript were delivered into the PFC of hTau mice by lentiviral vectors, either before (3 months-old) or after (6 months-old) phenotypic onset. Mice were analyzed in behavioral tasks (cognitive and motor) and biochemical, electrophysiological and microPET imaging studies. Tau reduction was determined by RT-qPCR and western blot. Results: microRNAs efficiently reduced endogenous Tau *in vivo* by 50% in the PFC. Tau knock-down from 3 months-old prevented Tau pathology and cognitive impairments. Phenotypic rescue was also observed when microRNAs were administered at mid-stage (6 months-old) of Tau pathology onset. No adverse effects were observed neither in hTau nor wild type mice after microRNAs administration. Conclusions: Our results provide proof of concept for the potential use of microRNAs to locally reduce pathological Tau accumulation as a therapeutic approach for tauopathies.

Tau mis-splicing correlates with motor impairments and striatal dysfunction in a model of tauopathy.
Tauopathies are neurodegenerative diseases caused by the abnormal metabolism of the microtubule associated protein tau (MAPT), which is highly expressed in neurons and critically involved in microtubule dynamics. In the adult human brain, the alternative splicing of exon 10 in MAPT pre-mRNA produces equal amounts of protein isoforms with either three (3R) or four (4R) microtubule binding domains. Imbalance in the 3R:4R tau ratio is associated with primary tauopathies that develop atypical parkinsonism, such as progressive supranuclear palsy and corticobasal degeneration. Yet, the development of effective therapies for those pathologies is an unmet goal. Here we report motor coordination impairments in the htau mouse model of tauopathy which harbour abnormal 3R:4R tau isoforms content, and in contrast to TauKO mice, are unresponsive to l-DOPA. Preclinical-PET imaging, array tomography and electrophysiological analyses indicated the dorsal striatum as the candidate structure mediating such phenotypes. Indeed, local modulation of tau isoforms by RNA trans-splicing in the striata of adult htau mice, prevented motor coordination deficits and restored basal neuronal firing. Together, these results suggest that abnormal striatal tau isoform content might lead to parkinsonian-like phenotypes and demonstrate a proof of concept that modulation of tau mis-splicing is a plausible disease-modifying therapy for some primary tauopathies.

Dissociation of hyper-phosphorylated Tau from neuronal microtubules and its pathological aggregates, are hallmarks in the etiology of tauopathies. The Tau-microtubule interface is subject to polyglutamylation, a reversible posttranslational modification, increasing negative charge at tubulin tails. Here, we asked whether tubulin polyglutamylation may contribute to Tau pathology *in vivo*. Since polyglutamylases modify various proteins other than tubulin, we generated a knock-in mouse carrying gene mutations to abolish Tuba4a polyglutamylation in a substrate-specific manner. We found that Tuba4a lacking polyglutamylation prevents the binding of Tau and MAP2a/b and GSK3 kinase to neuronal microtubules, thereby strongly reducing phospho-Tau levels. Notably, crossbreeding of mutant mice with a tauopathy model, expressing a human Tau transgene, reversed the oligomerization of hyper-phosphorylated Tau and normalized microglia activation in brain. Our data highlight tubulin polyglutamylation as a novel molecular parameter to develop treatment strategies in fighting tauopathies.

DEFINING SPECIFIC FINGERPRINTS OF NEURODEGENERATIVE DISEASES IN THE RETINA

POSTER SESSION 06 - SECTION: ALZHEIMER'S AND TAUOPATHIES

Silvia Di Angelantonio, Natalia Pediconi, Ylenia Gigante, Silvia Ghirga
Istituto Italiano Di Tecnologia, Cln2s, Roma, Italy

The eye offers a natural window to the brain, as the retina is considered part of the central nervous system. AD, PD and ALS-associated neurodegenerative changes in the brain are accompanied by structural and possible functional changes in the neuroretina and the ocular vasculature. Aim: The present project aimed to define and provide a panel of retinal biomarkers specific to AD and ALS as a tool for monitoring disease progression. Methods: The identification of specific cellular and molecular alterations in human AD and ALS retina were evaluated by immunofluorescence approaches in autoptic human retinal slices from patients versus healthy controls. Images were acquired with a confocal microscope. Results: Our results indicated the presence of TDP43 protein aggregated in the cytoplasm of retinal ganglion bipolar cells of ALS patients, nuclear retinal TDP43 staining was found also in control slices. We could also show an increase of SQSTM1/p62 aggregates in the retina of ALS patients as compared to healthy control. Both TDP43 and SQSTM1/p62 are described as pathological hallmark lesions in the spinal cord and brain of most ALS patients, without clear signs of glial activation. By contrast in AD patients, retinal sections displayed beta-amyloid and tau protein aggregates together with DAM microglia and A1 astrocytes activation, paving the road to the definition of a disease-specific biomarker panel. Conclusions: Retinal biomarkers may be used in vivo as an additional and specific early diagnostic tool, offering the opportunity to longitudinally monitor individuals and therapies over time in a non-invasive and cost-effective way.

Background: In regards of tau involvement in tauopathies and the protective effect of tau ablation in epilepsy, understanding tau functions in brain networks is paramount. However, tau functions are difficult to highlight as *tau*^{KO} (*Mapt*$^{-/-}$) neural networks exhibit only elusive phenotypes. **Objectives:** To explore further the physiological role of tau in brain networks, the impact of tau ablation has been investigated during the network remodelling occurring in hippocampal/entorhinal slice co-cultures. **Methods:** We recorded spontaneous extracellular neuronal activity over two weeks from single slice cultures and slice co-cultures established from *wild-type* and *tau*^{KO} animals. We compared bursting activity features and applied concepts and analytical tools intended for the study of network synchrony and connectivity. **Results:** Tau ablation resulted in an anti-synchrony effect on hippocampal/entorhinal slice co-cultures, in line with literature. By focusing on the changes between single culture and co-culture paradigms, we demonstrated that tau ablation led to differential, even opposite, effects at the sub-network scale. Tau ablation induced throughout the duration of the co-culture an anti-synchrony effect within the hippocampal slice likely due to an excitation/inhibition ratio reduction. Conversely, tau ablation led to increased synchrony within the entorhinal slice likely due to homogenization of the connectivity distribution at early stages of the co-culture. **Conclusions:** Our new and powerful methodology to study the role played by a gene/protein in brain networks has confirmed a role of tau in the remodelling of complex neural networks and, for the first time, demonstrate this role is multifaceted and dependent of the sub-network nature.

LEPTIN PREVENTS AMYLOID-BETA-INDUCED ABERRANT TARGETING OF PHOSPHORYLATED TAU VIA PI 3 KINASE SIGNALLING

POSTER SESSION 06 - SECTION: ALZHEIMER'S AND TAUOPATHIES

Kirsty Hamilton, Kate Morrow, Jenni Harvey
University of Dundee, School of Medicine, Cellular And Systems Medicine, Dundee, United Kingdom

Accumulation of amyloid-β (Aβ) and hyperphosphorylated tau are hallmarks of Alzheimer's disease (AD). Recent studies show that Aβ promotes tau phosphorylation causing migration of tau from axons to dendritic spines and synapses, resulting in synaptic impairment. Aberrant leptin production and signalling has been observed in AD patients. Various studies have identified neuroprotective properties of leptin in models of Aβ-related toxicity. However, the effects of leptin on tau-related synaptic dysfunction are unclear. Here, we show that $A\beta_{1-42}$ treatment (1μM, 1hr) to primary hippocampal neurons causes a significant increase in dendritic p-tau compared to control (167 ± 9%, $p<0.001$, n=36 dendrites), and a significant increase in % colocalisation of p-tau and PSD-95 (synaptic marker) from 43 ± 1.4% to 57 ± 1.4% ($p<0.001$, n=36 dendrites). Treatment with leptin prevents this aberrant targeting of p-tau to dendrites and synapses as dendritic p-tau levels and % colocalisation are not significantly different from control in leptin+$A\beta_{1-42}$ treated neurons ($p>0.05$, n=36 dendrites). PI 3 kinase activation and GSK-3β inhibition were identified as the likely signalling mechanisms underlying the protective effects of leptin. Wortmannin treatment (PI3K inhibitor, 50nM, 1hr) ablated the protective effects of leptin, resulting in a significant increase in dendritic p-tau in wortmannin+$A\beta_{1-42}$+leptin treated neurons (150 ± 6% of control, $p<0.001$, n=36). TCS2002 treatment (GSK-3β inhibitor, 100nM, 1hr) mimicked and occluded the protective effects of leptin, resulting in no significant difference in dendritic p-tau in TCS2002+$A\beta_{1-42}$ and TCS2002+$A\beta_{1-42}$+leptin treated neurons ($p>0.05$, n=36 dendrites). These data further validate the leptin system as a therapeutic target in AD.

Background: The metabolic syndrome (MetS) is a common pathology in western societies which is characterized by synaptic insulin resistance (IR), high body weight, and high levels of cholesterol. It has been proposed the MetS together with a high amyloid load and low-level neuroinflammation is an important risk factor for Alzheimer's disease (AD). **Aims and methods**: We investigated the biological mechanism behind this interplay establishing an *in vitro* model with the use of primary neurons to induce synaptic insulin resistance. We move then to a mouse model of high-risk aging that includes a high amyloid load, diet induced-obesity, and neuroinflammation. **Results**: We found that neddylation of Cullin 7 induces proteasomal degradation of the Insulin receptor substrate1 (IRS1) inducing synaptic insulin resistance. Moreover, the neddylation activating enzyme inhibitor MLN-4924 restores synaptic IR and cognitive related impairments found in mice with high amyloid load and fed with high-fat diet. **Conclusions:** Our data suggest that neddylation-dependent degradation of IRS1 is the nodal point that might explain the link between synaptic IR, amyloid load and neuroinflammation. Inhibition of neddylation is a molecular entry point to treat cognitive deficits associated with MetS and might be useful to reduce the risk of AD.

A group of more than 20 progressive neurodegenerative diseases are pathologically defined by Tau dysfunction; also referred to as Tauopathies, which are characterised by synapse dysfunction and neurodegeneration. The underlying mechanism is unclear. The aim of this study is to elucidate how Tau dysfunction leads to synapse loss. Pathological Tau translocates to the pre-synapse and binds to synaptic vesicles. Binding of Tau to synaptic vesicles is physically mediated by Synaptogyrin-3. In this study, we determined the role of pathogenic Tau at presynaptic terminals by lowering Synaptogyrin-3 levels in mice with Tau pathology. We assessed structural, functional and behavioural effects. We found that heterozygous knockout of Synaptogyrin-3 strongly rescues mutant Tau-induced synaptic defects as well as memory loss. Interestingly, both pre- and postsynapse can be rescued in TauPS19 mice with Synaptogyrin-3 heterozygous knockout. These findings show that reducing Synaptogyrin-3 expression rescues Tau-induced synapse loss and cognitive decline. Together, these findings point to Synaptogyrin-3 as a highly interesting therapeutic candidate to target Tauopathies.

Sporadic and familial Alzheimer´s disease (AD) are characterized by a progressive neurodegeneration mainly in memory-related areas such as the entorhinal cortex and hippocampus. The epsilon4 allele of gene encoding apolipoprotein E (APOE) is the strongest genetic risk factor for late-onset AD whereas mutations in PSEN1 gene cause early-onset AD. Increasing evidence shows that APOE4 is associated with diverse aspects of AD pathogenesis, but the impact of APOE alleles on neuronal differentiation, maturation and function remains to be fully elucidated. Furthermore, the effect of G206D-PSEN1 mutation on human neurons has been little explored. To clarify these questions, we obtained induced pluripotent stem cells (iPSCs) from fibroblasts of AD patients carrying the epsilon3 and epsilon4 alleles (in homozygosis) or having G206D-PSEN1 mutation, and from healthy patients. We also used gene-edited iPSC lines homozygous for APOE variants and an APOE knock-out line. Both cortical and hippocampal neurons were generated from human iPSCs by establishing differentiation protocols through the addition of small molecules and growth factors, and their cellular, molecular, functional and neuropathological characterisation was performed. iPSCs-derived neurons expressed cortical and hippocampal markers and showed a functional profile determined by glutamate release, electrical activity and synapse formation visualized by electron microscopy. In addition, release of amyloid-beta 42/40, total Tau and phosphorylated Tau to the culture medium, as well as the presence of amyloid-beta plaques and p-Tau181 aggregates are being analysed. Overall, our results point to specific actions of APOE polymorphism and G206D-PSEN1 mutation affecting neuronal differentiation, dysfunction and neurodegeneration.

Alzheimer's disease (AD) is a slow-growing neurodegenerative disease that remains irreversible and incurable today. Early in the disease, both histopathological hallmarks, amyloid plaques and neurofibrillary tangles, affect brain structures involved in memory processes such as the median temporal lobe and the prefrontal cortex. The diagnosis of AD is often late as several years elapse between the beginning of the pathology and the onset of the first cognitive deficits. It is therefore crucial to better understand the earliest stages of AD. We are studying a doubly humanized *App*$^{NL-F}$*/MAPT* double knock-in (dKI) model expressing a humanized App gene with two familiar Alzheimer's disease mutations (*App*$^{NL-F}$) and a humanized tau gene (*MAPT*) (Saito *et al*., 2014 and 2019). This dKI mouse show increased amyloidogenic processing of APP and the six normal human Tau protein isoforms instead of the three murine isoforms. Using a series of sensitive object exploration tasks, we showed that dKI mice displayed a deficit in object-place association memory as soon as 4 months of age, that was associated to molecular alterations related to initial steps of AD. Indeed, western blot studies notably revealed an increase of β-amyloid peptides (pre-plaques stage) in the median temporal lobe whereas an increase of phosphotau proteins was restricted to the perirhinal-entorhinal region and prefrontal cortex, sparing the hippocampus. The similarity between our findings and those reported in the earliest stages of AD suggests that the *App*$^{NL-F}$*/MAPT* dKI model has a high potential to better understand the initial stage of the disease.

Alzheimer's disease (AD) involves severe impairment of cognitive and executive functions.Neuropathologically,it is characterized by the deposition of beta-amyloid peptide in extracellular neuritic plaques and the formation of intraneuronal neurofibrillary tangles,which elimination has been the unsuccessful goal of different therapies.However,little is known about the progressing neuroinflammatory process,characterized by an increase in the number and morphological changes of microglial cells at different stages of the disease.The aim of this study is to characterize the morphological differences and tau-relationship of microglial cells in the hippocampus of an aged AD murine model to elucidate whether, associated with age and tau and beta amyloid deposits,there is an active proinflammatory phenotype different from the physiological pattern and how it is related to the formation of tau neurofibrillary tangles. First,we characterized microglial morphology.Twelve female mice (healthy controls and 3xTgAD, n = 6 per group) between 19 and 22 months were used.Ten cells from each animal were randomly analysed using the AnalyzeSkeleton and FracLac extensions of the Image-J program.No significant differences were found between both groups. Secondly,we studied microglial relationship with tau accumulation at different stages (9, 12 and 15 months, n=6).Our results show an increase in both the number of microglia cells and intracellular tau tangles associated with age,as well as a strong positive correlation between both variables. In sum,we must consider the age variable to understand the role of microglial cells in AD neurodegeneration process.Understanding their morphological heterogeneity may be one of the keys of this neurodegenerative disorder. Alzheimer´s disease (AD) is the most common form of dementia. A wealth of evidence supports the hypothesis that a major factor in AD is dysregulation of Abeta-homeostasis, which leads to an increased cleavage of amyloid precursor protein by the enzyme beta-site of APP cleaving enzyme 1 (BACE1). Apart from its important role in AD, we recently reported BACE1 as a salient interaction-partner of neuronal and cardiac Kv7-channels independent of proteolysis. We investigated the physiological functions of BACE1 by developing specific, tag- and antibody-free labelling tools. All new compounds are conjugates of BACE1-inhibitor IV linked to different fluorescent dyes. We show here that these fluorescent small molecules bind specifically to the protease with a 1:1 labeling stoichiometry at their catalytic moiety, a crucial property especially for single-molecule and super-resolution microscopy. Using such microscopy, we characterized its biophysical properties and labelling capabilities in over-expressing cell systems, native and fixed neuronal tissue. In addition, the capability to label endogenous and over-expressed BACE1 with high specificity allowed us to perform Acceptor-Photobleaching FRET (Förster resonance energy transfer) assay to evaluate BACE1/Kv7-interactions. Hence, our novel fluorescent inhibitors make it possible to investigate protein-protein interactions and diffusion behavior of BACE1 from the tissue setting down to single molecule level.

DYRK1A INHIBITION AS A THERAPEUTIC APPROACH FOR ALZHEIMER'S DISEASE

POSTER SESSION 06 - SECTION: ALZHEIMER'S AND TAUOPATHIES

Travis Dunckley[1], Ramon Velazquez[2], Aranea Dunckley[1], Bessie Meechoovet[3], Christopher Hulme[4]
[1]Arizona State University, Neurodegenerative Disease Research Center, Tempe, United States of America, [2]Arizona State University, Ndrc, Tempe, United States of America, [3]Translational Genomics Research Institute, Neurogenomics Division, Phoenix, United States of America, [4]University of Arizona, College Of Pharmacy, Tucson, United States of America

There is a critical need for new treatment approaches that can slow or prevent the progression of Alzheimer's disease (AD). Targets that act on multiple relevant pathways could have significant therapeutic potential. Dual-specificity tyrosine phosphorylation-regulated kinase 1A (Dyrk1a) phosphorylates both amyloid precursor protein (APP) and tau. Dyrk1a is upregulated in post-mortem brains of AD patients and elevated expression is associated with cognitive deficits. We previously demonstrated that inhibition of Dyrk1 is well-tolerated and reduces amyloid plaques and pathological forms of tau in 3xTg-AD mice if administered after formation of these pathologies. However, while insoluble forms of hyperphosphorylated tau were reduced by Dyrk1 inhibition, overt neurofibrillary tangle (NFT) pathology remained unchanged. Herein, we specifically test the hypothesis that inhibition of Dyrk1 prior to NFT formation will delay the onset of pathology. 3xTg-AD mice were treated chronically, beginning at 6 months of age, prior to NFT pathology. Mice were dosed daily for either 3 or 6 months and amyloid and tau pathology were assessed. We show that chronic Dyrk1 inhibition reduces insoluble forms of amyloid beta peptides (Aβ) and hyper-phosphorylated tau long-term and that these reductions are associated with dramatic delay in the onset of both amyloid plaques and NFTs. In addition, we show that DYR219, a potent and selective small molecule Dyrk1 inhibitor, induces degradation of Dyrk1a protein, likely contributing to its in vivo efficacy. Collectively, these results suggest that therapeutic strategies targeting tau phosphorylation will show the greatest effect if administered very early in the pathogenesis of AD.

A COMBINED TDP43-TAU CELLULAR MODEL FOR THE UNDERSTANDING OF LATE-NC PROTEINOPATHY

POSTER SESSION 06 - SECTION: ALZHEIMER'S AND TAUOPATHIES

Saray López-Benito, Patricia Villacé Lozano, Rosa Mella Lopez, Meritxell Roura, Clarisa Salado
Innoprot, Cell Biology Laboratory, Derio, Spain

TDP-43 protein is known as the major disease protein in amyotrophic lateral sclerosis (ALS) and in the most common variant of frontotemporal lobar degeneration (FTLD). Recently, TDP-43 proteinopathy has been related with a newly recognized type of dementia, limbic-predominant agerelated TDP-43 encephalopathy (LATE-NC). Several studies have shown that almost 50% of patients with LATE-NC also present TDP-43 protein deposits in their brain cells. Although the true role of TDP-43 in LATE-NC and its relationship with pathological forms of Tau is currently unknown, in recent years it has been revealed that they may coexist in exacerbated forms of the disease. The development of a cellular assay aimed to study the behavior of the TDP43-TAR protein in combination with hyperphosphorylated Tau protein may allow us to elucidate new pathways of molecular signaling in LATE disease, as well as to screen compounds that may intercede in the pathological synergy between these two targets. Using this HCS assay in 96 well format, we performed the screening of a small synthetic chemical library of 1,200 compounds. The Z′ factor of the assay was over 0.5 demonstrating the robust performance of the assay. After the screening campaign, the positive compounds were chosen for further testing, based on the strength of the initial response and the lack of cytotoxicity.

Age-dependent protein aggregation is a conserved phenomenon that is associated with many neurodegenerative diseases, including Alzheimer's disease (AD). AD is characterized by aggregation of Tau, a microtubule-binding protein that is normally soluble and mainly localized to neuronal axons, but can form oligomers and higher-order amyloid-like aggregates that accumulate in soma and dendrites and eventually lead to neuronal death. Although the main risk factor for the onset of AD is aging, the exact causes of Tau protein aggregation are largely unclear. To investigate factors that influence Tau protein aggregation, we expressed human Tau protein fused with fluorescent proteins in yeast *Saccharomyces cerevisiae*. We examined intracellular localization of Tau in young and aged cells, and in cells under different stress conditions, such as glucose starvation, elevated temperature, hyperosmotic and proteotoxic stress caused by toxic amino acid analogue. Furthermore, to study factors affecting Tau oligomerization, we used luminescent reporter NanoBiT in which protein-protein interaction results in the complementation of the luciferase NanoLuc. Results show basal levels of Tau-NanoBiT reporter signal in logarithmically growing wild-type cells, suggesting that Tau oligomerization doesn't occur under normal growth conditions. *Cofinanced by the Research Cooperability Program of the Croatian Science Foundation funded by the EU from the European Social Fund under the Operational Program Efficient Human Resources 2014-2020 (PZS-2019-02-3610); Croatian Science Foundation grants IP-2019-04-3584 and DOK-2018-01-9299, DOK-2021-02-2505; Scientific Centre of Excellence for Basic, Clinical and Translational Neuroscience ("Experimental and clinical research of hypoxic-ischemic damage in perinatal and adult brain"; GA KK01.1.1.01.0007 funded by the EU through the European Regional Development Fund).*

Aims: In this study, we aimed to get better insights into mechanisms underlying α-Synuclein (αS) aggregation and neurodegeneration in Parkinson disease (PD). **Methods:** For that, we established primary cultures of mouse dopamine (DA) neurons and chronically exposed them to fibrils 91 (F91) generated from recombinant human αS. We used astrocyte-conditionned medium to enable long-term cultures. **Results:** We established that F91 have an exquisite propensity to seed aggregation of endogenous αS in DA neurons (somas + neurites) through a process that is unrelated to DA metabolism. Until two weeks post-exposure to F91 somal aggregation in DA neurons increased with F91 concentrations and time elapsed since initiation of seeding. There was, however, no evidence of DA cell loss under such treatment conditions. In the same experimental context, neither toxin-induced mitochondrial deficits nor genetically-induced loss of mitochondrial quality control mechanisms promoted F91-mediated αS aggregation or neurodegeneration. Yet, a significant loss of DA neurons (~30%) was detectable three weeks after exposure to F91 (0.5 µM), i.e., at a time point where somal aggregation reaches a plateau phase. This loss was preceded by early deficits in DA uptake, a sensitive marker of DA cell function. Unlike αS aggregation, the loss of DA neurons was prevented by treatment with GDNF suggesting that αS aggregation in DA neurons induces a form of cell death mimicking a state of trophic factor deprivation. **Conclusions:** Overall, we suggest that this model system might be useful to explore PD-related pathomechanisms and test molecules of therapeutic interest for this disorder.

The Excitatory Amino Acid Transporter 2 (EAAT2) accounts for the 80% of brain glutamate clearance and it is mainly expressed in astrocytic perisynaptic processes. Noteworthy, deficits in EAAT2 have been associated with neurodegenerative diseases including Parkinson's disease (PD). **AIM**- The aim of this study was to investigate the link between EAAT2 impairment and PD starting from human *post-mortem* samples. **METHODS**- We employed biochemical and imaging techniques to analyze EAAT2 expression in human as well as mouse brains. Purified astrocytic terminals, primary astrocytes and brain organotypic cultures were also applied to study the molecular mechanisms behind EAAT2 dysfunction. **RESULTS**- EAAT2 protein levels are clearly decreased and match with elevated gliosis in PD patients harboring the LRRK2 G2019S mutation, a common cause of familiar PD, and the deficits are less pronounced in the idiopathic PD forms. The decreased expression of the transporter correlates with its reduced functionality in mouse LRRK2 G2019S purified astrocytic terminals. In LRRK2 G2019S knockin mouse brain, the correct surface localization of the endogenous transporter is impaired, resulting in its interaction with a plethora of endo-vesicular proteins. Mechanistically, we report that pathogenic LRRK2 kinase activity delays the recycling of the transporter to the plasma membrane *via* Rabs inactivation, causing its intracellular relocalization and degradation. **CONCLUSIONS**- Our results demonstrate that a molecular and functional connection between EAAT2 and pathogenic LRRK2. Specifically, LRRK2 G2019S interferes with the recycling of EAAT2, pointing to extracellular glutamate overload as a possible contributor to neurodegeneration in PD.

33629273: Streubel-Gallasch L, Giusti V, Sandre M, Tessari I, Plotegher N, Giusto E, Masato A, Iovino L, Battisti I, Arrigoni G, Shimshek D, Greggio E, Tremblay ME, Bubacco L, Erlandsson A, Civiero L
Parkinson's Disease-Associated LRRK2 Interferes with Astrocyte-Mediated Alpha-Synuclein Clearance.
Parkinson's disease (PD) is a neurodegenerative, progressive disease without a cure. To prevent PD onset or at least limit neurodegeneration, a better understanding of the underlying cellular and molecular disease mechanisms is crucial. Mutations in the leucine-rich repeat kinase 2 (LRRK2) gene represent one of the most common causes of familial PD. In addition, LRRK2 variants are risk factors for sporadic PD, making LRRK2 an attractive therapeutic target. Mutations in LRRK2 have been linked to impaired alpha-synuclein (α-syn) degradation in neurons. However, in which way pathogenic LRRK2 affects α-syn clearance by astrocytes, the major glial cell type of the brain, remains unclear. The impact of astrocytes on PD progression has received more attention and recent data indicate that astrocytes play a key role in α-syn-mediated pathology. In the present study, we aimed to compare the capacity of wild-type astrocytes and astrocytes carrying the PD-linked G2019S mutation in Lrrk2 to ingest and degrade fibrillary α-syn. For this purpose, we used two different astrocyte culture systems that were exposed to sonicated α-syn for 24 h and analyzed directly after the α-syn pulse or 6 days later. To elucidate the impact of LRRK2 on α-syn clearance, we performed various analyses, including complementary imaging, transmission electron microscopy, and proteomic approaches. Our results show that astrocytes carrying the G2019S mutation in Lrrk2 exhibit a

decreased capacity to internalize and degrade fibrillar α-syn via the endo-lysosomal pathway. In addition, we demonstrate that the reduction of α-syn internalization in the Lrrk2 G2019S astrocytes is linked to annexin A2 (AnxA2) loss of function. Together, our findings reveal that astrocytic LRRK2 contributes to the clearance of extracellular α-syn aggregates through an AnxA2-dependent mechanism.

Microglia-Derived Small Extracellular Vesicles Reduce Glioma Growth by Modifying Tumor Cell Metabolism and Enhancing Glutamate Clearance through miR-124.
Brain homeostasis needs continuous exchange of intercellular information among neurons, glial cells, and immune cells, namely microglial cells. Extracellular vesicles (EVs) are active players of this process. All the cells of the body, including the brain, release at least two subtypes of EVs, the medium/large EVs (m/lEVs) and small EVs (sEVs). sEVs released by microglia play an important role in brain patrolling in physio-pathological processes. One of the most common and malignant forms of brain cancer is glioblastoma. Altered intercellular communications constitute a base for the onset and the development of the disease. In this work, we used microglia-derived sEVs to assay their effects in vitro on murine glioma cells and in vivo in a glioma model on C57BL6/N mice. Our findings indicated that sEVs carry messages to cancer cells that modify glioma cell metabolism, reducing lactate, nitric oxide (NO), and glutamate (Glu) release. sEVs affect Glu homeostasis, increasing the expression of Glu transporter Glt-1 on astrocytes. We demonstrated that these effects are mediated by miR-124 contained in microglia-released sEVs. The in vivo benefit of microglia-derived sEVs results in a significantly reduced tumor mass and an increased survival of glioma-bearing mice, depending on miR-124.

Dexpramipexole enhances hippocampal synaptic plasticity and memory in the rat.
Even though pharmacological approaches able to counteract age-dependent cognitive impairment have been highly investigated, drugs improving cognition and memory are still an unmet need. It has been hypothesized that sustaining energy dynamics within the aged hippocampus can boost memory storage by sustaining synaptic functioning and long term potentiation (LTP). Dexpramipexole (DEX) is the first-in-class compound able to sustain neuronal bioenergetics by interacting with mitochondrial F1Fo-ATP synthase. In the present study, for the first time we evaluated the effects of DEX on synaptic fatigue, LTP induction, learning and memory retention. We report that DEX improved LTP maintenance in CA1 neurons of acute hippocampal slices from aged but not young rats. However, we found no evidence that DEX counteracted two classic parameters of synaptic fatigue such as fEPSP reduction or the train area during the high frequency stimulation adopted to induce LTP. Interestingly, patch-clamp recordings in rat hippocampal neurons revealed that DEX dose-dependently inhibited (IC 814 nM) the I current, a rapidly-inactivating K current that negatively regulates neuronal excitability as well as cognition and memory processes. In keeping with this, DEX counteracted both scopolamine-induced spatial memory loss in rats challenged in Morris Water Maze test and memory retention in rats undergoing Novel Object Recognition. Overall, the present study discloses the ability of DEX to boost hippocampal synaptic plasticity, learning and memory. In light of the good safety profile of DEX in humans, our findings may have a realistic translational potential to treatment of cognitive disorders.

Breathing stimulation mediated by 5-HT and 5-HT receptors within the preBötzinger complex of the adult rabbit.
Serotonin (5-HT) has been reported to play excitatory effects on respiration by acting on preBötzinger complex (preBötC) neurons in neonatal or juvenile rodents. However, whether its action is circumscribed to the preBötC and present in other animal species, particularly in adult preparations, is unknown. We investigated the respiratory role of 5-HT within the preBötC and neighbouring respiration-related regions. Experiments were performed on α-chloralose-urethane anesthetized, vagotomized, paralyzed and artificially ventilated rabbits making use of bilateral microinjections (30-50 nl). 5-HT caused excitatory effects on respiratory activity only when applied to the preBötC. These effects were mediated by 5-HT and 5-HT receptors as shown by microinjections of specific agonists of the different types of 5-HT receptors. Unexpectedly, the blockade of 5-HT receptors by methysergide or the specific antagonist (S)-WAY 100135 induced excitatory respiratory effects. Microinjections of the 5-HT receptor antagonist ondansetron did not influence respiration, but prevented (S)-WAY 100135-induced responses. The blockade of GABA receptors by bicuculline within the preBötC prevented the effects of the 5-HT receptor agonist 8-OH-DPAT. The involvement of GABAergic inhibition and 5-HT receptor-mediated disinhibition is also corroborated by immunohistochemical data. The results show for the first time in an adult animal preparation that 5-HT plays a pivotal role in the modulation of the preBötC activity probably via both presynaptic and postsynaptic mechanisms and highlight the importance of disinhibition phenomena. Present findings may be relevant to some respiratory disorders in which

an impairment of central 5-HT mechanisms has been reported, such as sleep apnoea and sudden infant death syndrome.

Key role of 5-HT receptors in the modulation of the neuronal network underlying the respiratory rhythm generation in lampreys.
In mammals, 5-HTexcitatory respiratory effects imply 5-HT receptor-mediated disinhibition of pre-Bötzinger complex neurons. In the lamprey, 5-HT receptors are involved in the neural control of locomotion, but their role in the respiratory regulation, particularly at the level of the putative respiratory rhythm generator, the paratrigeminal respiratory group (pTRG), is not known. We here investigate the respiratory function of inhibitory 5-HT receptors within the pTRG of the isolated brainstem of the adult lamprey. The 5-HT receptor agonists either bath applied or microinjected into the pTRG did not cause significant effects. However, the selective 5-HT receptor antagonist (S)-WAY 100135 bath applied or microinjected into the pTRG induced depressing respiratory effects or even apnoea, thus revealing that 5-HT exerts a 5-HT receptor-mediated potent tonic influence on respiration and contributes to maintain baseline levels of respiratory activity. Microinjections of strychnine or bicuculline, either alone or in combination, into the pTRG prevented (S)-WAY 100135-induced apnoea. In addition, immunohistochemical studies corroborate the present findings suggesting that 5-HT receptors are widely expressed in close apposition to the soma of glycine-immunoreactive cells located within the pTRG region. The results show that in the lamprey respiratory network, 5-HT exerts a tonic influence on respiration by a potent inhibitory control on both GABAergic and glycinergic mechanisms. The observed disinhibitory effects resemble the excitatory respiratory modulation exerted by 5-HT receptor-mediated inhibition of glycinergic and/or GABAergic neurons present in mammals, supporting the notion that some features of the neuronal network subserving respiratory rhythm generation are highly conserved throughout phylogeny.

Inhibitory modulation of the cough reflex by acetylcholine in the caudal nucleus tractus solitarii of the rabbit.
A cholinergic system has been described in the nucleus tractus solitarii (NTS). However, no information is available on the role played by acetylcholine (ACh) in the modulation of the cough reflex within the caudal NTS that has an important function in cough regulation. We addressed this issue making use of bilateral microinjections (30-50 nl) of 10 mM ACh combined with 5 mM physostigmine as well as of 10 mM mecamylamine or 10 mM scopolamine into the caudal NTS of pentobarbital sodium-anesthetized, spontaneously breathing rabbits. Microinjections of ACh/physostigmine caused depressant effects on the cough reflex induced by mechanical and chemical stimulation of the tracheobronchial tree. They also elicited transient increases in respiratory frequency and decreases in abdominal activity. These effects were prevented by scopolamine, but not by mecamylamine. The results show for the first time that ACh exerts an inhibitory modulation of the cough reflex through muscarinic receptors within the caudal NTS. They also may provide hints for novel antitussive approaches.

The neuron-astrocyte-microglia triad involvement in neuroinflammaging mechanisms in the CA3 hippocampus of memory-impaired aged rats.
We examined the effects of inflammaging on memory encoding, and qualitative and quantitative modifications on proinflammatory proteins, apoptosis, neurodegeneration and morphological changes of neuron-astrocyte-microglia triads in CA3 Stratum Pyramidale (SP), Stratum Lucidum (SL) and Stratum Radiatum (SR) of young (3months) and aged rats (20months). Aged rats showed short-term memory impairments in the inhibitory avoidance task, increased expression of iNOS and activation of p38MAPK in SP, increase of apoptotic neurons in SP and of ectopic neurons in SL, and decrease of CA3 pyramidal neurons. The number of astrocytes and their branches length decreased in the three CA3 subregions of aged rats, with morphological signs of clasmatodendrosis. Total and activated microglia increased in the three CA3 subregions of aged rats. In aged rats CA3, astrocytes surrounded ectopic degenerating neurons forming "micro scars" around them. Astrocyte branches infiltrated the neuronal cell body, and, together with activated microglia formed "triads". In the triads, significantly more numerous in CA3 SL and SR of aged rats, astrocytes and microglia cooperated in fragmentation and phagocytosis of ectopic neurons. Inflammaging-induced modifications of astrocytes and microglia in CA3 of aged rats may help clearing neuronal debris derived from low-grade inflammation and apoptosis. These events might be common mechanisms underlying many neurodegenerative processes. The frequency to which they appear might depend upon, or might be the cause of, the burden and severity of neurodegeneration. Targeting the triads may represent a therapeutic strategy which may control inflammatory processes and spread of further cellular damage to neighboring cells.

GABAA- and glycine-mediated inhibitory modulation of the cough reflex in the caudal nucleus tractus solitarii of the rabbit.
Cough-related sensory inputs from rapidly adapting receptors (RARs) and C fibers are processed by second-order neurons

mainly located in the caudal nucleus tractus solitarii (NTS). Both GABAA and glycine receptors have been proven to be involved in the inhibitory control of second-order cells receiving RAR projections. We investigated the role of these receptors within the caudal NTS in the modulation of the cough reflex induced by either mechanical or chemical stimulation of the tracheobronchial tree in pentobarbital sodium-anesthetized, spontaneously breathing rabbits. Bilateral microinjections (30-50 nl) of the receptor antagonists bicuculline and strychnine as well as of the receptor agonists muscimol and glycine were performed. Bicuculline (0.1 mM) and strychnine (1 mM) caused decreases in peak abdominal activity and marked increases in respiratory frequency due to decreases in both inspiratory time (Ti) and expiratory time (Te), without concomitant changes in arterial blood pressure. Noticeably, these microinjections induced potentiation of the cough reflex consisting of increases in the cough number associated with decreases either in cough-related Ti after bicuculline or in both cough-related Ti and Te after strychnine. The effects caused by muscimol (0.1 mM) and glycine (10 mM) were in the opposite direction to those produced by the corresponding antagonists. The results show that both GABAA and glycine receptors within the caudal NTS mediate a potent inhibitory modulation of the pattern of breathing and cough reflex responses. They strongly suggest that disinhibition is one important mechanism underlying cough regulation and possibly provide new hints for novel effective antitussive strategies.

Glutamate-induced excitotoxicity in Parkinson's disease: The role of glial cells.
Glutamate is the major excitatory neurotransmitter in the central nervous system. Glutamate transmission efficiency depends on the correct functionality and expression of a plethora of receptors and transporters, located both on neurons and glial cells. Of note, glutamate reuptake by dedicated transporters prevents its accumulation at the synapse as well as non-physiological spillover. Indeed, extracellular glutamate increase causes aberrant synaptic signaling leading to neuronal excitotoxicity and death. Moreover, extrasynaptic glutamate diffusion is strongly associated with glia reaction and neuroinflammation. Glutamate-induced excitotoxicity is mainly linked to an impaired ability of glial cells to reuptake and respond to glutamate, then this is considered a common hallmark in many neurodegenerative diseases, including Parkinson's disease (PD). In this review, we discuss the function of astrocytes and microglia in glutamate homeostasis, focusing on how glial dysfunction causes glutamate-induced excitotoxicity leading to neurodegeneration in PD.

ATP and astrocytes play a prominent role in the control of the respiratory pattern generator in the lamprey.
The paratrigeminal respiratory group (pTRG) is responsible for the respiratory pattern generation in the lamprey. The role of ATP and astrocytes, known to control respiratory activity in mammals, was investigated in the lamprey respiratory network. ATP microinjected into the pTRG induces a biphasic response consisting of marked increases in respiratory frequency mediated by P2X receptors followed by a decrease in the respiratory motor output due to the ATP metabolite adenosine. We provide evidence that astrocytes are involved in the genesis of the normal respiratory pattern, ATP-induced responses and acidification-induced increases of the respiratory activity. The function of astrocytes in rhythmic networks appears to be phylogenetically conserved.

INTERPLAY BETWEEN LEWY PATHOLOGY AND MACROAUTOPHAGY IN MIDBRAIN DOPAMINERGIC NEURONS IN VIVO

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Camille Loiseau[1], Natalie Doig[1], Lisa Conyers[1], David Bergin[1], Benjamin Vallin[2], Richard Wade-Martins[2], Peter Magill[1]

Aims. The cardinal motor symptoms of Parkinson's disease (PD) arise from the degeneration of midbrain dopaminergic neurons (DANs) of the substantia nigra pars compacta (SNc). This degenerative process correlates with the presence of Lewy pathology (LP). DANs of the ventral tegmental area (VTA) are less affected in PD. Here, we aim to elucidate the relationship between LP and macroautophagy, a major degradative pathway that should oppose the emergence of LP, in vulnerable and resistant DANs *in vivo*. **Methods.** To characterise the macroautophagic machinery engaged in DANs in response to LP, and investigate the importance of macroautophagy in influencing LP, we compared phenotypes of wildtype and macroautophagy-deficient mice. We induced the development of LP in either SNc or VTA DANs using intracranial injections of Pre-Formed Fibrils (PFFs) of α-synuclein. 1-3 months after PFF injections, we used immunofluorescence, high-resolution microscopy and CellProfiler analyses to localise and quantify LP and macroautophagy-related molecules in DANs. **Results**. Our data in WT mice showed that LAMP1+ puncta cluster at Lewy-like aggregates in DANs, and that clustered puncta are larger than those not associated with aggregates. Both of these phenomena were more pronounced in SNc DANs than VTA DANs. In macroautophagy-deficient mice, LAMP1+ puncta did not cluster at Lewy-like aggregates and were not enlarged. **Conclusions.** Observations in wildtype mice suggest that the induction of LP perturbs macroautophagic machinery in DANs *in vivo*. Comparative observations in macroautophagy-deficient mice suggest that macroautophagy is important for DANs to handle LP and its sequalae.

ROLE OF TGF-BETA SIGNALLING PATHWAY AGAINST ALPHA SYNUCLEIN-INDUCED TOXICITY IN A PARKINSON'S DISEASE CELL MODEL

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Oscar Wing Ho Chua, Matthias Höllerhage, Günter Höglinger
Hannover Medical School, Clinic For Neurology, Hannover, Germany

Parkinson's disease (PD) is histopathologically defined by the presence of intracellular proteinaceous inclusions known as Lewy bodies (LB). Alpha-synclein (aSyn) has been identified as the main component of LBs. It is generally believed that small intermediates between monomers and large aggregates of aSyn found in LBs are toxic and can lead to the death of dopaminergic neurons in the substantia nigra, resulting in the motor symptoms present in PD. Our group established a cell culture model in which post-mitotic human dopaminergic neurons die in the course of six days upon moderate overexpression of wild-type aSyn. Based on this model, we performed a genome-wide siRNA screening in order to identify genes, which upon their knockdown, can reduce aSyn-induced cytotoxicity. Ultimately, 12 top-hits were identified, whose knockdown protected against aSyn-induced cytotoxicity. 4 of these genes were associated with TGF-beta signalling pathway. Hence, we hypothesized that the knock-down/reduction of the TGF-beta pathway could reduce aSyn-induced cytotoxicity. We aimed at investigating the genes involved in TGF-beta signalling and the mechanism of protectiveness. First, the knockdown efficacy and protectiveness were both further confirmed. Next, we separately knockdown different branches of the pathway to verify if the knockdown/reduction of TGF-beta pathway protected against aSyn-induced cytotoxicity. Our results suggest that the knockdown of TGF-beta pathway can indeed rescue dopaminergic neurons from aSyn-induced toxicity and such effect is aSyn-specific. Altogether, we have identified a potential therapeutic role of TGF-beta signalling pathway against aSyn-induced toxicity. These findings can provide insights that can be used for the development of novel strategies and drugs against synucleinopathies.

Role of nuclear factor of activated T-cells 5 in regulating hypertonic-mediated secretin receptor expression in kidney collecting duct cells.
A growing body of evidence suggests that secretin (SCT) is an important element in the osmoregulatory pathway. It is interesting to note that both SCT and its receptor (SCTR) gene are activated upon hyperosmolality in the kidney. However, the precise molecular mechanisms underlying the induction of the SCTR gene expression in response to changes in osmolality have yet to be clarified. Detailed DNA sequence analysis of the promoter regions of the SCTR gene reveals the presence of multiple osmotic response elements (ORE). The ORE is the binding site of a key osmosensitive transactivator, namely, the nuclear factor of activated T-cells 5 (NFAT5). SCTR and NFAT5 are co-expressed in the kidney cortex and medulla collecting duct cells. We therefore hypothesize that NFAT5 is responsible for modulating SCTR expression in hypertonic environments. In this study, we found hypertonicity stimulates the promoter activities and endogenous gene expression of SCTR in mouse kidney cortex collecting duct cells (M1) and inner medulla collecting duct cells (mIMCD3). The overexpression and silencing of NFAT5 further confirmed it to be responsible for the up-regulation of the SCTR gene under hypertonic conditions. A significant increase in the interaction between NFAT5 and the SCTR promoter was also observed following chromatin immunoprecipitation assay. In vivo, osmotic stress up-regulates the SCTR gene in the kidney cortex and medulla of wild-type mice, but does not do so in NFAT5(+/-) animals. Hence, this study provides comprehensive information on how NFAT5 regulates SCTR expression in different osmotic environments.

5-HT receptor-mediated attenuation of synaptic transmission in rat medial vestibular nucleus impacts on vestibular-related motor function.
Chemogenetic activation of medial vestibular nucleus-projecting 5-HT neurons resulted in deficits in vestibular-mediated tasks, including negative geotaxis, balance beam and rota-rod tests. The 5-HT receptor mediates the vestibular-related behavioural effects of 5-HT in the vestibular nucleus. 5-HT receptor activation attenuated evoked excitatory postsynaptic

currents and evoked inhibitory postsynaptic currents via a presynaptic mechanism in the vestibular nucleus.

Parkinson's disease (PD) is a neurodegenerative disease characterized by a selective loss of dopaminergic (DA) neurons and accumulation of α-synuclein in the substantia nigra. It is considered that gene mutations, environmental factors and aging are causative factors of PD. Understanding the mechanisms involved in neurodegeneration is the key to identifying potential therapeutic strategies for PD. Neurotoxins, such as rotenone and 6-hydroxidopamine are widely used to induce *in vivo* and *in vitro* model of PD. These neurotoxins induce mitochondrial dysfunction and increase oxidative stress, which leads to neuronal degeneration and cell death by apoptosis. Neurosteroids, dehydroepiandrosterone (DHEA) and its sulfate (DHEAS), are the most abundant steroid hormones and can be synthesized *de novo* in the brain. Levels of DHEA(S) decrease with age and play an important role in brain aging and neurodegeneration. Neurotrophin, brain-derived neurotrophic factor (BDNF) is also involved in neuroprotection and neuroregeneration, while decreased levels of BDNF were observed in the aging process and in neurodegenerative diseases such as PD. In this study we have investigated potential neuroprotective effects of DHEA(S) and BDNF in four different cell models: primary mouse neurons, SH-SY5Y neuroblastoma cells, PC12 and N27 cells. These cells were injured with rotenone or 6-hydroxidopamine to induce an *in vitro* model of PD. In addition, cells were treated with DHEA(S) and BDNF separately and combined to investigate their interactions and neuroprotective potential. The obtained results suggest that DHEA(S) and BDNF may play important role in prevention and treatment of PD.

INVESTIGATING THE FUNCTION AND THE POTENTIAL NEUROPROTECTIVE ROLE OF NATO3 IN DOPAMINERGIC NEURONS.

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Eva Paulina Valencia-Alarcon, Federico Miozzo, Emi Nagoshi
University of Geneva, Genetics And Evolution, Geneva, Switzerland

Parkinson's disease (PD) is the second most prevalent neurodegenerative disorder. PD manifests progressive loss of dopaminergic (DA) neurons in the substantia nigra (SN) pars compacta in the midbrain, leading to a wide array of motor and non-motor disabilities.The high prevalence of the disease and the limited therapeutic options make the discovery of novel targets for PD treatments an urgent need. Accumulating evidence shows that many developmental transcription factors that remain expressed throughout life are implicated in DA neurodegeneration. *Nato3* (*Ferd3l*) encodes a transcription factor required for midbrain DA neuron development and continues to be expressed during adulthood; however, its role in adulthood remains poorly understood. To investigate the post-developmental role of *Nato3* in midbrain DA neurons, we generated a mouse strain that conditionally ablates *Nato3* in differentiated DA neurons (*Nato3* cKO). Employing immunohistochemistry, electron microscopy, and behavioural assays, we found that *Nato3* cKO mice recapitulate two hallmarks of PD: progressive locomotor decline and mitochondrial pathology. These results indicate the critical roles of *Nato3* in the lifelong maintenance of mitochondrial integrity and functioning of midbrain DA neurons. Furthermore, using a combination of RNA-seq analysis and *in vitro* studies in midbrain DA neurons differentiated from induced pluripotent stem cells (iPSCs) derived from PD patients, we are exploring the molecular mechanisms underlying the role of *Nato3* and its neuroprotective potential. Overall, our investigations contribute to identify the transcriptional programmes that maintain DA neurons in the adult brain and will help better understand DA neurodegeneration and how to prevent it.

Application of Airy beam light sheet microscopy to examine early neurodevelopmental structures in 3D hiPSC-derived human cortical spheroids.
The inability to observe relevant biological processes in vivo significantly restricts human neurodevelopmental research. Advances in appropriate in vitro model systems, including patient-specific human brain organoids and human cortical spheroids (hCSs), offer a pragmatic solution to this issue. In particular, hCSs are an accessible method for generating homogenous organoids of dorsal telencephalic fate, which recapitulate key aspects of human corticogenesis, including the formation of neural rosettes-in vitro correlates of the neural tube. These neurogenic niches give rise to neural progenitors that subsequently differentiate into neurons. Studies differentiating induced pluripotent stem cells (hiPSCs) in 2D have linked atypical formation of neural rosettes with neurodevelopmental disorders such as autism spectrum conditions. Thus far, however, conventional methods of tissue preparation in this field limit the ability to image these structures in three-dimensions within intact hCS or other 3D preparations. To overcome this limitation, we have sought to optimise a methodological approach to process hCSs to maximise the utility of a novel Airy-beam light sheet microscope (ALSM) to acquire high resolution volumetric images of internal structures within hCS representative of early developmental time points.

Atypical Neurogenesis in Induced Pluripotent Stem Cells From Autistic Individuals.
Autism is a heterogeneous collection of disorders with a complex molecular underpinning. Evidence from postmortem brain studies have indicated that early prenatal development may be altered in autism. Induced pluripotent stem cells (iPSCs) generated from individuals with autism with macrocephaly also indicate prenatal development as a critical period for this condition. But little is known about early altered cellular events during prenatal stages in autism.

Adenosine is an endogenous autacoid purine nucleoside involved in several physiological functions. In the brain, it modulates neurotransmission through inhibitory adenosine A_1 receptors (A_1Rs) and stimulatory A_{2A} receptors (A_{2A}Rs). These G protein-coupled ARs are involved in motor function and related to neurodegenerative diseases such as Parkinson's disease (PD). In line with this, a recent study associated a new autosomal recessive mutation (G279S) within the A_1R gene to the development of early onset PD. Here, we aimed at investigating the impact of this mutation on receptors' structure and function. Our results revealed that the G279S A_1R mutation does not alter receptor's ligand binding, constitutive activity or coupling to transducer proteins (i.e., $G_{\alpha i}$ and $G_{\alpha q}$) in transfected cells. However, G279S mutation reduced A_1R-A_{2A}R heteromer formation and abolished the heteromer-dependent ligand-independent modulation that A_1R exerts over the constitutive and agonist-induced activation of the A_{2A}R. Interestingly, computational studies supported that the G279S A_1R mutation could have a negative effect on the heterodimer interface stability. Overall, our results indicate that G279S mutation does not modify A_1R canonical signalling, whereas it reduces the ability of A_1R to act as a negative allosteric modulator of A_{2A}R function

Solid Lipid Nanoparticles Surface Modification Modulates Cell Internalization and Improves Chemotoxic Treatment in an Oral Carcinoma Cell Line.
Solid lipid nanoparticles (SLN) present low toxicity, versatility to incorporate both lipophilic and hydrophilic drugs, controlled drug release and they are easy to scale-up. It is well known that the endocytosis pathway by which SLN are taken up and the subsequent subcellular distribution are crucial for the biological effect of the incorporated drug. In addition, interactions between SLN and cells depend on many factors, such as, the composition of nanoparticle surface. In this work different amounts of phosphatidylethanolamine polyethylene glycol (PE^-PEG) were added to SLN composed of stearic acid, Epikuron 200 and sodium taurodeoxycholate. Characterization of obtained nanoparticle suspensions were performed by the analysis of particle size, polydispersity index, ζ-potential, cell toxicity and cell internalization pathway. We have observed that the presence of PE^-PEG improves active cell internalization of the nanoparticles in an oral adenocarcinoma cell line, reducing non-specific internalization mechanisms. Finally, we have tested the effect of surface coating on the efficiency of incorporated drugs using all-trans retinoic acid as a model drug. We have observed that delivery of this drug into PE^-PEG coated SLN increases its chemotoxic effect compared to non-coated SLN. Therefore, it can be concluded that surface modification with PE^-PEG improves the efficiency and the specificity of the SLN-loaded drug.

RABPHILIN-3A AS NOVEL TARGET TO RESCUE ALPHA-SYNUCLEIN INDUCED SYNAPTIC LOSS IN PARKINSON'S DISEASE

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Elena Ferrari, Elisa Zianni, Chiara Parravicini, Diego Scheggia, Marta Brumana, Monica Di Luca, Ivano Eberini, Fabrizio Gardoni
University of Milan, Department Of Pharmacological And Biomolecular Sciences, Milan, Italy

Toxic aggregates of the protein alpha-synuclein (αsyn) are considered a key driver of Parkinson's disease (PD) pathology. αsyn mediates synaptic dysfunction at early phases of PD through several mechanisms. αsyn modulates NMDA-type glutamate receptors' (NMDARs) surface levels and activity at the postsynaptic compartment of corticostriatal synapses and our group previously showed that NMDARs retention at postsynaptic sites is strictly correlated with the binding to Rph3A. Moreover, a direct αsyn/Rph3A interaction has been put forward. **Aims**. This work aims at characterizing Rph3A/αsyn interaction and its role in early PD to identify pharmacological approaches able to block αsyn-induced synaptic toxicity. **Methods**. Imaging, biochemical and *in silico* approaches were exploited to investigate Rph3A/αsyn interaction and its role in PD. Experiments were mainly performed using an *in vivo* mouse model of αsyn-induced PD based on striatal injections of αsyn preformed fibrils (PFF) to perform molecular, morphological and motor behavioral evaluation of the early disease phases. **Results**. Firstly, we showed that Rph3A is a novel αsyn interactor at synaptic sites. Then, using the *in vivo* PD model we found that αsyn-PFF in the striatum impaired Rph3A postsynaptic levels, its binding to NMDARs and the overall molecular composition of the postsynaptic compartment. Besides, αsyn-mice showed striatal dendritic spine loss and motor alterations. Interestingly, modulation of Rph3A in the striatum was able to prevent dendritic spine loss and motor defects in αsyn-PFF mice. **Conclusions**. Results indicate that approaches aimed at restoring Rph3A striatal functions represent a strategy to slow-down early detrimental effects of αsyn in PD.

Dopamine-dependent early synaptic and motor dysfunctions induced by α-synuclein in the nigrostriatal circuit.
Misfolding and aggregation of α-synuclein are specific features of Parkinson's disease and other neurodegenerative diseases defined as synucleinopathies. Parkinson's disease progression has been correlated with the formation and extracellular release of α-synuclein aggregates, as well as with their spread from neuron to neuron. Therapeutic interventions in the initial stages of Parkinson's disease require a clear understanding of the mechanisms by which α-synuclein disrupts the physiological synaptic and plastic activity of the basal ganglia. For this reason, we identified two early time points to clarify how the intrastriatal injection of α-synuclein-preformed fibrils in rodents via retrograde transmission induces time-dependent electrophysiological and behavioural alterations. We found that intrastriatal α-synuclein-preformed fibrils perturb the firing rate of dopaminergic neurons in the substantia nigra pars compacta, while the discharge of putative GABAergic cells of the substantia nigra pars reticulata is unchanged. The α-synuclein-induced dysregulation of nigrostriatal function also impairs, in a time-dependent manner, the two main forms of striatal synaptic plasticity, long-term potentiation and long-term depression. We also observed an increased glutamatergic transmission measured as an augmented frequency of spontaneous excitatory synaptic currents. These changes in neuronal function in the substantia nigra pars compacta and striatum were observed before overt neuronal death occurred. In an additional set of experiments, we were able to rescue α-synuclein-induced alterations of motor function, striatal synaptic plasticity and increased spontaneous excitatory synaptic currents by subchronic treatment with l-DOPA, a precursor of dopamine widely used in the therapy of Parkinson's disease, clearly demonstrating that a dysfunctional dopamine system plays a critical role in the early phases of the disease.

From cell lines to pluripotent stem cells for modelling Parkinson's Disease.
Parkinson's disease (PD) is the second most common neurodegenerative disorder characterized by loss of dopaminergic (DAergic) neurons in the substantia nigra (SN) that contributes to the main motor symptoms of the disease. At present, even

if several advancements have been done in the last decades, the molecular and cellular mechanisms involved in the pathogenesis are far to be fully understood. Accordingly, the establishment of reliable in vitro experimental models to investigate the early events of the pathogenesis represents a key issue in the field. However, to mimic and reproduce in vitro the complex neuronal circuitry involved in PD-associated degeneration of DAergic neurons still remains a highly challenging issue. Here we will review the in vitro PD models used in the last 25 years of research, ranging from cell lines, primary rat or mice neuronal cultures to the more recent use of human induced pluripotent stem cells (hiPSCs) and, finally, the development of 3D midbrain organoids.

Protease-activated receptor 1 (PAR1) inhibits synaptic NMDARs in mouse nigral dopaminergic neurons.
Protease-activated receptor 1 (PAR1) is a G protein-coupled receptor (GPCR), whose activation requires a proteolytic cleavage in the extracellular domain exposing a tethered ligand, which binds to the same receptor thus stimulating Gα-, Gα- and Gα proteins. PAR1, activated by serine proteases and matrix metalloproteases, plays multifaceted roles in neuroinflammation and neurodegeneration, in stroke, brain trauma, Alzheimer's diseases, and Parkinson's disease (PD). Substantia nigra pars compacta (SNpc) is among areas with highest PAR1 expression, but current evidence on its roles herein is restricted to mechanisms controlling dopaminergic (DAergic) neurons survival, with controversial data showing PAR1 either fostering or counteracting degeneration in PD models. Since PAR1 functions on SNpc DAergic neurons activity are unknown, we investigated if PAR1 affects glutamatergic transmission in this neuronal population. We analyzed PAR1's effects on NMDARs and AMPARs by patch-clamp recordings from DAergic neurons from mouse midbrain slices. Then, we explored subunit composition of PAR1-sensitive NMDARs, with selective antagonists, and mechanisms underlying PAR1-induced NMDARs modulation, by quantifying NMDARs surface expression. PAR1 activation inhibits synaptic NMDARs in SNpc DAergic neurons, without affecting AMPARs. PAR1-sensitive NMDARs contain GluN2B/GluN2D subunits. Moreover, PAR1-mediated NMDARs hypofunction is reliant on NMDARs internalization, as PAR1 stimulation increases NMDARs intracellular levels and pharmacological limitation of NMDARs endocytosis prevents PAR1-induced NMDARs inhibition. We reveal that PAR1 regulates glutamatergic transmission in midbrain DAergic cells. This might have implications in brain's DA-dependent functions and in neurological/psychiatric diseases linked to DAergic dysfunctions.

GluA3-containing AMPA receptors: From physiology to synaptic dysfunction in brain disorders.
In the mammalian brain, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)-type glutamate receptors (AMPARs) play a fundamental role in the activation of excitatory synaptic transmission and the induction of different forms of synaptic plasticity. The modulation of the AMPAR tetramer subunit composition at synapses defines the functional properties of the receptor. During the last twenty years, several studies have evaluated the roles played by each subunit, from GluA1 to GluA4, in both physiological and pathological conditions. Here, we have focused our attention on GluA3-containing AMPARs, addressing their functional role in synaptic transmission and synaptic plasticity and their involvement in a variety of brain disorders. Although several aspects remain to be fully understood, GluA3 is a widely expressed and functionally relevant subunit in AMPARs involved in several brain circuits, and its pharmacological modulation could represent a novel approach for the rescue of altered glutamatergic synapses associated with neurodegenerative and neurodevelopmental disorders.

NEUROTOXIC EFFECTS OF BETA-SYNUCLEIN AND ITS MUTANTS, P123H AND V70M

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Sofia Guerin, Sebastian Kügler
Universitätsmedizin Göttingen, Neurology, Göttingen, Germany

The synuclein protein family is composed of three proteins, alpha-, beta- and gamma-Synuclein (αSyn, βSyn and γSyn). Whereas much work has been put on studying αSyn (due to its apparent toxic role in Synucleinopathies), less attention has been paid to βSyn. In fact, two mutations of this protein, V70M and P123H, have been linked to Dementia with Lewy bodies. Recently, our group showed that these βSyn mutants lead to neurotoxic effects comparable to αSyn's at the level of the mitochondria (V70M) and the synapse (P123H) when overexpressed. In order to understand the mechanisms by which these mutations exert such effects, we study the differential affinity of these proteins for biological membranes. Using techniques such as TEM or DLS, we want to understand how this interaction is regulated and the downstream consequences that these affinities may have on the functioning and trafficking of certain cellular organelles.

Aims: Dysfunction of medium spiny neurons (MSNs) are implicated in motor impairments in Parkinson's Disease (PD). However, most research on MSN pathology in PD has relied on animal models of toxin-induced PD which fail to recapitulate the human nature, genetics and temporal aspects of PD pathogenesis. By developing an all induced pluripotent stem cells (iPSCs)-derived cortico-striato-nigral mini-circuit, we recapitulate the complex connectivity received by MSNs and examine temporal changes of human striatal electrophysiology due to DaNs habouring PD-relevant mutations. Methods: Healthy control iPSC-derived cortical neurons and MSNs, together with dopaminergic neurons (DaNs) derived from either healthy controls or patients carrying GBA N370S mutation were sequentially seeded onto custom 3-chamber microfluidics. Connectivity of different neuronal populations was validated with immunocytochemistry and pairwise chemical stimulation and optical recording. We then performed whole-cell patch clamp with post-hoc labelling to investigate electrophysiological properties of MSNs cocultured with either healthy or GBA N370S DaNs. Results: MSNs cocultured with GBA N370S DaNs exhibited significantly increased intrinsic excitability and reduced current densities of both sodium and potassium conductance. Such changes were observed in 40-45 days *in vitro* (div) MSNs but absent in aged MSNs of up to 75div. Preliminary data suggested alterations in channel-specific kinetics, including recovery time from inactivation and inactivation properties, in aged MSNs. Conclusions: Our results highlight the utility of modelling neurons in a highly physiological manner preserving their endogenous connectivity. They also suggest early electrophysiological dysfunctions in human MSNs induced by surviving GBA N370S DaNs, providing insights into early pathology of MSNs in PD.

Transgenic Strategies for Sparse but Strong Expression of Genetically Encoded Voltage and Calcium Indicators.
Rapidly progressing development of optogenetic tools, particularly genetically encoded optical indicators, enables monitoring activities of neuronal circuits of identified cell populations in longitudinal in vivo studies. Recently developed advanced transgenic approaches achieve high levels of indicator expression. However, targeting non-sparse cell populations leads to dense expression patterns such that optical signals from neuronal processes cannot be allocated to individual neurons. This issue is particularly pertinent for the use of genetically encoded voltage indicators whose membrane-delimited signals arise largely from the neuropil where dendritic and axonal membranes of many cells intermingle. Here we address this need for sparse but strong expression of genetically encoded optical indicators using a titratable recombination-activated transgene transcription to achieve a Golgi staining-type indicator expression pattern in vivo. Using different transgenic strategies, we also illustrate that co-expression of genetically encoded voltage and calcium indicators can be achieved in vivo for studying neuronal circuit input-output relationships.

EXTRACELLULAR CALCIUM RELEASE MEDIATES POLARIZED MOTILITY AND DISPLACEMENT OF MICROGLIAL CELLS IN A SCENARIO OF PARKINSONIAN NEURODEGENERATION

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Meritxell Roig-Martínez, Paola Casanova, Elena Saavedra, Irina Freitag, Paula Martínez, Roser Masgrau, Carlos Barcia
Institut de Neurociències UAB, Department Of Biochemistry, Barcelona, Spain

Parkinson's disease (PD) is a neurodegenerative disorder in which the loss of dopaminergic neurons, specifically in the Substantia Nigra, causes characteristic motor symptoms and deterioration. The cause of this neuronal loss is still unknown but increasing evidences point to microglial-mediated neuroinflammation as a contributing factor. We propose that dying neurons release Ca^{2+} to the extracellular space that may contribute to the neuroimmune response, particularly provoking changes in microglial cells, which may signal their polarization and motility. Our *in vitro* experiments revealed that microglia internalize and bind extracellular calcium – potentially binding the specific molecule Iba-1 – modifying their shape, and increasing motility. Then, experiments performed *in vivo* showed similar changes. We administered Ca^{2+} to the brain parenchyma to determine the changes in microglial dynamics. We observed slight morphological changes of microglial cells in Ca^{2+}-injected animals. However, when we measured the polarization of microglial cells branches with 3D high-resolution confocal imaging, we found clear differences when compared to saline injections. Knowing that Iba-1 is a Ca^{2+} binding protein specific for microglia and macrophages, we quantified Iba-1 expression after Ca^{2+} administration, and we observed a clear increase that correlates with morphological changes. These results indicate that Iba-1 may be a crucial factor leading these polarizing changes occurred when microglia sense Ca^{2+} changes in their surroundings. These evidences suggest a novel interplay between dying dopaminergic neurons and neighboring microglial cells in which specific Ca^{2+}-dependent responses may contribute to the specific inflammatory response in areas of parkinsonian neurodegeneration.

The MTOC/Golgi Complex at the T-Cell Immunological Synapse.
T cells effectively explore the tissue in search for antigens. When activated, they dedicate a big amount of energy and resources to arrange a complex structure called immunological synapse (IS), containing a particular distribution of molecules defined as supramolecular activation clusters (SMACs), and become polarized toward the target cell in a manner that channels the information specifically. This arrangement is symmetrical and requires the polarization of the MTOC and the Golgi to be operational, especially for the proper delivery of lytic granules and the recycling of molecules three dimensionally segregated at the clustered interface. Alternatively, after the productive encounter, T cells need to rearrange again to newly navigate through the tissue, changing back to a motile state called immunological kinapse (IK). In this IK state, the MTOC and the Golgi apparatus are repositioned and recruited at the back of the T cell to facilitate motility, while the established symmetry of the elements of the SMACs is broken and distributed in a different pattern. Both states, IS and IK, are interchangeable and are mainly orchestrated by the MTOC/Golgi complex, being critical for an effective immune response. Results Probl Cell Differ, 2019; 67

Three-dimensional vascular microenvironment landscape in human glioblastoma.
The cellular complexity of glioblastoma microenvironments is still poorly understood. In-depth, cell-resolution tissue analyses of human material are rare but highly necessary to understand the biology of this deadly tumor. Here we present a unique 3D visualization revealing the cellular composition of human GBM in detail and considering its critical association with the neo-vascular niche. Our images show a complex vascular map of human 3D biopsies with increased vascular heterogeneity and altered spatial relationship with astrocytes or glioma-cell counterparts. High-resolution analysis of the structural layers of the blood brain barrier showed a multilayered fenestration of endothelium and basement membrane. Careful examination of T cell position and migration relative to vascular walls revealed increased infiltration corresponding with tumor proliferation. In addition, the analysis of the myeloid landscape not only showed a volumetric increase in glioma-associated microglia and macrophages relative to GBM proliferation but also revealed distinct phenotypes in tumor nest and stroma. Images and data

sets are available on demand as a resource for public access.

Phagocytic glioblastoma-associated microglia and macrophages populate invading pseudopalisades.
Hypoxic pseudopalisades are a pathological hallmark of human glioblastoma, which is linked to tumour malignancy and aggressiveness. Yet, their function and role in the tumour development have scarcely been explored. It is thought that pseudopalisades are formed by malignant cells escaping from the hypoxic environment, although evidence of the immune component of pseudopalisades has been elusive. In the present work, we analyse the immunological constituent of hypoxic pseudopalisades using high-resolution three-dimensional confocal imaging in tissue blocks from excised tumours of glioblastoma patients and mimic the hypoxic gradient in microfluidic platforms to understand the cellular motility. We visualize that glioblastoma-associated microglia and macrophages abundantly populate pseudopalisades, displaying an elongated kinetic morphology across the pseudopalisades, and are oriented towards the necrotic focus. experiments demonstrate that under hypoxic gradient, microglia show a particular motile behaviour characterized by the increase of cellular persistence in contrast with glioma cells. Importantly, we show that glioblastoma-associated microglia and macrophages utilize fibres of glioma cells as a haptotactic cue to navigate along the anisotropic structure of the pseudopalisades and display a high phagocytic activity at the necrotic border of the pseudopalisades. In this study, we demonstrate that glioblastoma-associated microglia and macrophages are the main immune cells of pseudopalisades in glioblastoma, travelling to necrotic areas to clear the resulting components of the prothrombotic milieu, suggesting that the scavenging features of glioblastoma-associated microglia and macrophages at the pseudopalisades serve as an essential counterpart for glioma cell invasion.

Gossypol Treatment Restores Insufficient Apoptotic Function of DFF40/CAD in Human Glioblastoma Cells.
Glioblastoma (GBM) is a highly aggressive brain tumor and almost all patients die because of relapses. GBM-derived cells undergo cell death without nuclear fragmentation upon treatment with different apoptotic agents. Nuclear dismantling determines the point-of-no-return in the apoptotic process. DFF40/CAD is the main endonuclease implicated in apoptotic nuclear disassembly. To be properly activated, DFF40/CAD should reside in the cytosol. However, the endonuclease is poorly expressed in the cytosol and remains cumulated in the nucleus of GBM cells. Here, by employing commercial and non-commercial patient-derived GBM cells, we demonstrate that the natural terpenoid aldehyde gossypol prompts DFF40/CAD-dependent nuclear fragmentation. A comparative analysis between gossypol- and staurosporine-treated cells evidenced that levels of neither caspase activation nor DNA damage were correlated with the ability of each compound to induce nuclear fragmentation. Deconvoluted confocal images revealed that DFF40/CAD was almost completely excluded from the nucleus early after the staurosporine challenge. However, gossypol-treated cells maintained DFF40/CAD in the nucleus for longer times, shaping a ribbon-like structure piercing the nuclear fragments and building a network of bridged masses of compacted chromatin. Therefore, GBM cells can fragment their nuclei if treated with the adequate insult, making the cell death process irreversible.

GPR37 N-TERMINAL DOMAIN PROCESSING DEFINES AUTAPTIC RECEPTOR SIGNALLING.

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Josep Argerich[1,2,3], Victor Fernandez-Dueñas[1,2,3], Francisco Ciruela[1,2,3]
[1]University of Barcelona, Department Of Pathology And Experimental Therapeutics, L'Hospitalet de Llobregat, Spain, [2]Institut d'Investigació Biomèdica de Bellvitge (IDIBELL)), Neuropharmacology And Pain Group, L'Hospitalet de Llobregat, Spain, [3]Universitat de Barcelona, Institut De Neurociències, Barcelona, Spain

GPR37 is an orphan G protein-coupled receptor (GPCR) which has gained attention due to its implication in the pathogenesis of Parkinson's disease (PD). Interestingly, the N-terminus of the receptor (i.e., ecto-GPR37) is subject to metalloproteinase-mediated proteolysis, which leads to several receptor forms at the cell surface. In addition, PD patients have increased amounts of ecto-GPR37 in the cerebrospinal fluid, thus showing an increased expression of GPR37 cleaved isoforms in the brain. Here, we aimed at investigating the impact of ecto-GPR37 on receptor's function and cell viability. To this end, we generated five GPR37 N-terminally truncated constructs ($GPR37^{\Delta 1-54}$, $GPR37^{\Delta 1-171}$, $GPR37^{\Delta 1-199}$, $GPR37^{\Delta 1-219}$, $GPR37^{\Delta 1-247}$) based on the receptor isoforms found in human PD brain samples. Subsequently, we assessed their coupling to different transducers, namely GRK-2, β-Arrestin 2 and G proteins, in HEK293T cells. Thus, GPR37 full length, $GPR37^{\Delta 1-54}$, $GPR37^{\Delta 1-171}$ and $GPR37^{\Delta 1-199}$ showed a robust coupling to GRK-2 and β-Arrestin 2. Also, these truncated forms activate serum response element (SRE)-related signalling pathways which are downstream to β-Arrestin 2. Interestingly, this signalling cascade is attenuated when GPR37 is truncated beyond aminoacid 219. In addition, the impact of GPR37 N-terminally truncated forms expression in SH-SY5Y cells viability was assessed upon 6-hydroxydopamine (6-OHDA) challenge. Thus, the neurotoxic effects of 6-OHDA in SH-SY5Y cells is modulated by the GPR37 N-terminal truncation. Overall, these results provide evidence that ecto-GPR37 may play a key role controlling receptor's constitutive activity and regulating cell viability, which may be relevant to understand its relationship with PD pathogenesis.

GPR37 is processed in the N-terminal ectodomain by ADAM10 and furin.
GPR37 is an orphan G protein-coupled receptor (GPCR) implicated in several neurological diseases and important physiological pathways in the brain. We previously reported that its long N-terminal ectodomain undergoes constitutive metalloprotease-mediated cleavage and shedding, which have been rarely described for class A GPCRs. Here, we demonstrate that the protease that cleaves GPR37 at Glu167↓Gln168 is a disintegrin and metalloprotease 10 (ADAM10). This was achieved by employing selective inhibition, RNAi-mediated downregulation, and genetic depletion of ADAM10 in cultured cells as well as in vitro cleavage of the purified receptor with recombinant ADAM10. In addition, the cleavage was restored in ADAM10 knockout cells by overexpression of the wild type but not the inactive mutant ADAM10. Finally, postnatal conditional depletion of ADAM10 in mouse neuronal cells was found to reduce cleavage of the endogenous receptor in the brain cortex and hippocampus, confirming the physiological relevance of ADAM10 as a GPR37 sheddase. Additionally, we discovered that the receptor is subject to another cleavage step in cultured cells. Using site-directed mutagenesis, the site (Arg54↓Asp55) was localized to a highly conserved region at the distal end of the ectodomain that contains a recognition site for the proprotein convertase furin. The cleavage by furin was confirmed by using furin-deficient human colon carcinoma LoVo cells and proprotein convertase inhibitors. GPR37 is thus the first multispanning membrane protein that has been validated as an ADAM10 substrate and the first GPCR that is processed by both furin and ADAM10. The unconventional N-terminal processing may represent an important regulatory element for GPR37.

Ecto-GPR37: a potential biomarker for Parkinson's disease.
α-Synuclein has been studied as a potential biomarker for Parkinson's disease (PD) with no concluding results. Accordingly, there is an urgent need to find out reliable specific biomarkers for PD. GPR37 is an orphan G protein-coupled receptor that toxically accumulates in autosomal recessive juvenile parkinsonism. Here, we investigated whether GPR37 is upregulated in

sporadic PD, and thus a suitable potential biomarker for PD.

Design, Synthesis and Characterization of a New Series of Fluorescent Metabotropic Glutamate Receptor Type 5 Negative Allosteric Modulators.
In recent years, new drug discovery approaches based on novel pharmacological concepts have emerged. Allosteric modulators, for example, target receptors at sites other than the orthosteric binding sites and can modulate agonist-mediated activation. Interestingly, allosteric regulation may allow a fine-tuned regulation of unbalanced neurotransmitter' systems, thus providing safe and effective treatments for a number of central nervous system diseases. The metabotropic glutamate type 5 receptor (mGluR) has been shown to possess a druggable allosteric binding domain. Accordingly, novel allosteric ligands are being explored in order to finely regulate glutamate neurotransmission, especially in the brain. However, before testing the activity of these new ligands in the clinic or even in animal disease models, it is common to characterize their ability to bind mGluRs in vitro. Here, we have developed a new series of fluorescent ligands that, when used in a new NanoBRET-based binding assay, will facilitate screening for novel mGluR allosteric modulators.

Disease-modifying effects of natural Δ9-tetrahydrocannabinol in endometriosis-associated pain.
Endometriosis is a chronic painful disease highly prevalent in women that is defined by growth of endometrial tissue outside the uterine cavity and lacks adequate treatment. Medical use of cannabis derivatives is a current hot topic and it is unknown whether phytocannabinoids may modify endometriosis symptoms and development. Here we evaluate the effects of repeated exposure to Δ9-tetrahydrocannabinol (THC) in a mouse model of surgically-induced endometriosis. In this model, female mice develop mechanical hypersensitivity in the caudal abdomen, mild anxiety-like behavior and substantial memory deficits associated with the presence of extrauterine endometrial cysts. Interestingly, daily treatments with THC (2 mg/kg) alleviate mechanical hypersensitivity and pain unpleasantness, modify uterine innervation and restore cognitive function without altering the anxiogenic phenotype. Strikingly, THC also inhibits the development of endometrial cysts. These data highlight the interest of scheduled clinical trials designed to investigate possible benefits of THC for women with endometriosis.

IFNAR1C291* EXPRESSION INDUCES NEURODEGENERATION IN VIVO THROUGH IMPAIRMENTS IN PARKIN-MEDIATED MITOPHAGY

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Lluis Riera Ponsati, Clara Mayer, Marina Lukenic, Emilie Tresse, Shohreh Issazadeh-Navikas
Biotech Research and Innovation Centre, Bric, Copenhagen, Denmark

Parkinson's Disease (PD) is the second most common neurodegenerative disease, with the fastest rising incidence in recent years. While its etiology remains elusive, the role of inflammation in PD is constantly strengthened. We have previously reported a mutation in the interferon receptor gene IFNAR1 (IFNAR1^{C291*}) segregating with disease in a family affected by parkinsonian disorders. Here, we develop a mouse model of PD by overexpressing IFNAR1^{C291*} in neurons of the Substantia Nigra and Prefrontal Cortex. We show behavioral deficits as early as 6 weeks post-injection, and the main hallmarks of PD: dopaminergic neuron loss, mitochondrial dysfunction, protein aggregation and neuroinflammation. Additionally, we mechanistically link Type I Interferons with mitophagy through ISG15, an Interferon-inducible Ubiquitin-like protein capable of enhancing Parkin activation and subsequently clearing damaged mitochondria in neurons.

IFN-β rescues neurodegeneration by regulating mitochondrial fission via STAT5, PGAM5, and Drp1.
Mitochondrial homeostasis is essential for providing cellular energy, particularly in resource-demanding neurons, defects in which cause neurodegeneration, but the function of interferons (IFNs) in regulating neuronal mitochondrial homeostasis is unknown. We found that neuronal IFN-β is indispensable for mitochondrial homeostasis and metabolism, sustaining ATP levels and preventing excessive ROS by controlling mitochondrial fission. IFN-β induces events that are required for mitochondrial fission, phosphorylating STAT5 and upregulating PGAM5, which phosphorylates serine 622 of Drp1. IFN-β signaling then recruits Drp1 to mitochondria, oligomerizes it, and engages INF2 to stabilize mitochondria-endoplasmic reticulum (ER) platforms. This process tethers damaged mitochondria to the ER to separate them via fission. Lack of neuronal IFN-β in the Ifnb model of Parkinson disease (PD) disrupts STAT5-PGAM5-Drp1 signaling, impairing fission and causing large multibranched, damaged mitochondria with insufficient ATP production and excessive oxidative stress to accumulate. In other PD models, IFN-β rescues dopaminergic neuronal cell death and pathology, associated with preserved mitochondrial homeostasis. Thus, IFN-β activates mitochondrial fission in neurons through the pSTAT5/PGAM5/ Drp1 pathway to stabilize mitochondria/ER platforms, constituting an essential neuroprotective mechanism.

Aims: Parkinson's disease (PD) affects 1–3% of the population aged over 65. Stress seems to contribute to PD neuropathology, probably by dysregulation of the hypothalamic–pituitary–adrenal axis. Key factors are oxidative stress, mitochondrial dysfunction and neuronal glucocorticoid-induced toxicity. Insulin-like growth factor II (IGF-II) has shown antioxidant and neuroprotective effects in some neurodegenerative disorders. Therefore, our aim was to study IGF-II protective effects against oxidative damage on a cellular combined model of PD and mild to moderate stress, based on corticosterone (CORT) and the dopaminergic neurotoxin 1-methyl-4-phenylpyridinium (MPP+). **Methods:** The dopaminergic neuronal cell line SN4741 (RRID:CVCL_S466) derived from mouse substantia nigra were exposed to 200 µM MPP+, 0.5 µM CORT or both, with or without 25 ng/mL IGF-II, for 2.5 or 6 h. Cell viability, oxidative stress parameters, mitochondrial and dopamine markers and intracellular signaling pathways were evaluated. **Results:** The administration of MPP+ or CORT individually led to cell damage compared to control situations, whereas the combination of both drugs produced very considerable toxic synergistic effect. IGF-II counteracts the mitochondrial-oxidative damage, protecting dopaminergic neurons from death and neurodegeneration. IGF-II promotes PKC activation and nuclear factor (erythroid-derived 2)-like 2 antioxidant response in a glucocorticoid receptor-dependent pathway, preventing oxidative cell damage and maintaining mitochondrial function. **Conclusions:** IGF-II capacity to protect nigral dopamine neurons against mitochondrial-oxidative damage induced by CORT and MPP+ was demonstrated. Thus, IGF-II is a potential therapeutic tool for prevention and treatment of PD patients suffering mild to moderate emotional stress. **Funding:** UMA18-FEDERJA-004. * These authors contributed equally to this work.

EXTRACELLULAR CLUSTERIN PREVENTS ALPHA-SYNUCLEIN DISPERSION

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Merari Ferrari[1], Andressa Sakugawa[1], Mark Wilson[2]
[1]University of Sao Paulo, Institute For Biosciences - Dept Genetics, Sao Paulo, Brazil, [2]University of Wollongong, Molecular Horizons, wollongong, Australia

We hypothesize that clusterin, an extracellular chaperone, reduces propagation of alpha-synuclein (a-syn) from cell to cell, this could result in less protein aggregation inside the cells. Neuron-like SH-SY5Y cells were differentiated during 10 days with DMEM supplemented with 10% foetal calf serum, 10uM retinoic acid and 10ng/ml BDNF. Cells were transfected during 2 days with empty vector (E.V.), a-syn wild-type (WT) or mutants (A30P or A53T) using lipofectamine 3000 and treated with 1ug/ml clusterin diluted in medium. Culture medium, soluble and insoluble protein fractions were collected for Western Blot. Cell viability was evaluated by MTT and Calcein-AM assays. Two-way Anova and $p<0.05$ indicated statistically significant differences. Insoluble a-syn A53T increased threefold compared to E.V., a-syn WT or A30P. Soluble a-syn decreased 30% in cells expressing the mutant A53T, indicating the switch between soluble and insoluble proteins. The increased expression of a-syn promoted an increased release of that protein to culture medium, WT increased 2 fold, A30P increased 2.5 fold and A53T increased 2.8 fold when compared to E.V. Clusterin added to culture medium prevented the increase of insoluble a-synA53T, although no differences were observed in secreted a-syn. Treatment with clusterin mitigated a-syn toxicity demonstrated by MTT where cell metabolism was restored in a-syn A53T-expressing cells. Calcein-AM assay demonstrated decreased number of living cells in all a-syn-expressing cells (5% decrease in a-syn-WT- and in A30P- and 10% in A53T-expressing cells). In conclusion, clusterin traps a-syn in the extracellular medium avoiding its dispersion to surrounding cells and improving cell viability.

INVESTIGATING TRANSPOSABLE ELEMENTS AS CAUSE OF NEUROINFLAMMATION IN PARKINSON'S DISEASE

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Anita Adami[1], Diahann Atacho[1], Oliver Tam[2], Raquel Garza[1], Pia Johansson[1], Vivien Horvath[1], Marie Jönsson[1], Roger Barker[3], Molly Hammel[2], Jenny Johansson[1], Johan Jakobsson[1]

Neuroinflammation is known to be a trait in several neurodegenerative diseases. However, its underlying cause is unknown. We hypothesize that aberrant activation of transposable elements (TEs) triggers neuroinflammation in these neurodegenerative disorders, including Parkinson's disease (PD). By performing RNAseq on post-mortem brain tissue samples from PD patients and control individuals, we were able to identify three TE subfamilies that display a significant change in expression: L1PA2, L1HS, and HERV-K. To mechanistically link TEs aberrant activation with an inflammatory response, we are using a CRISPR activation (CRISPRa) system to induce the overexpression of these PD-activated TEs in human induced pluripotent stem cells (iPSCs) and neuroepithelial-like stem cells (NESCs). The iPSCs will then be differentiated into different cell types to obtain an *in vitro* model for TE-based neuroinflammation. In parallel, a CRISPR inhibition (CRISPRi) system will also be used to find whether any transcriptional consequences occur upon dysregulation of our target TEs in the chosen models, given that some TEs were also shown to be downregulated in PD patients. We also want to culture iPSC-derived cerebral organoids to better observe and assess any possible phenotypical effects of the silencing or overexpression of the target TEs. With this project, we hope to uncover a new pathogenic mechanism of PD, which could lead to innovative and clinically relevant research perspectives for this neurodegenerative disorder.

A cis-acting structural variation at the ZNF558 locus controls a gene regulatory network in human brain development.
The human forebrain has expanded in size and complexity compared to chimpanzees despite limited changes in protein-coding genes, suggesting that gene expression regulation is an important driver of brain evolution. Here, we identify a KRAB-ZFP transcription factor, ZNF558, that is expressed in human but not chimpanzee forebrain neural progenitor cells. ZNF558 evolved as a suppressor of LINE-1 transposons but has been co-opted to regulate a single target, the mitophagy gene SPATA18. ZNF558 plays a role in mitochondrial homeostasis, and loss-of-function experiments in cerebral organoids suggests that ZNF558 influences developmental timing during early human brain development. Expression of ZNF558 is controlled by the size of a variable number tandem repeat that is longer in chimpanzees compared to humans, and variable in the human population. Thus, this work provides mechanistic insight into how a cis-acting structural variation establishes a regulatory network that affects human brain evolution.

THE ROLE OF MICROVASCULAR CHANGES DURING DEVELOPMENT AND PROGRESSION OF PARKINSON'S DISEASE IN A HUMAN ALPHA-SYNUCLEIN OVEREXPRESSION MOUSE MODEL (LINE 61)

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Lisa Porschen[1], Franziska Richter[1,2], Birthe Gericke[1,2]
[1]University of Veterinary Medicine Hannover, Foundation, Department Of Pharmacology, Toxicology And Pharmacy, Hannover, Germany, [2]Hannover Graduate School For Neuroscience, Infection Medicine And Veterinary Science (HGNI), Center For Systems Neurocience (zsn), Hannover, Germany

Microvascular alterations have been increasingly recognized in neurodegenerative diseases including Alzheimer's Disease (AD), Parkinson's Disease (PD) and Multiple Sclerosis (MS). Indeed, key cellular processes associated with PD pathogenesis such as accumulation of alpha-synuclein (αSyn) and concomitant oxidative stress and neuroinflammation have been shown to exert detrimental effects on blood-brain barrier (BBB) integrity. In fact, BBB alterations were detected in PD patients but understanding of the underlying mechanism and information on the nature and extent of vascular pathology remain limited. We aimed to study BBB alterations during disease progression in a αSyn PD mouse model and resolve the underlying molecular and cellular mechanisms. Microvascular changes during PD progression were evaluated in the Thy1-αSyn (Masliah line 61) progressive mouse model using two and six month old transgenic human αSyn overexpressing mice and age-matched wildtype control animals. BBB permeability was analyzed by FITC-albumin dye extrusion assay in different brain regions after transcardial perfusion. Additionally expression levels of tight junctions (TJs) that seal the paracellular cleft between endothelial cells, matrix metalloprotease activation that degrade endothelial TJs and basement proteins, as well as endothelial cell activation were analyzed in isolated brain microvessels. Carrier function of LRP1 and Pgp that are expressed by brain microvascular endothelial cells and may influence the αSyn mediated BBB alterations were also evaluated. A better comprehension of BBB alterations during PD progression would bring new insights into the basic understanding of the pathophysiology of PD and may facilitate identification of novel pharmacological targets.

THE ROLE OF LIPID METABOLISM IN PARKINSON'S DISEASE

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Kirsten Ebanks[1,2], Rina Bandopadhyay[3], Thomas Warner[1]
[1]University College London, Clinical And Movement Neuroscience, London, United Kingdom, [2]UCL Queen Square Institute of Neurology, Reta Lila Weston Institute Of Neurological Studies, London, United Kingdom, [3]UCL Queen Square Institute of Neurology, Reta Lila Weston Institute Of Neurological Studies, LONDON, United Kingdom

Parkinson's disease (PD) is a common age-related neurodegenerative disorder with disabling motor symptoms and no available disease modifying treatment. While commonly believed to be a proteinopathy, specifically a synucleinopathy, recent studies have suggested a prominent role for lipids in pathogenesis. Studies have shown that many PD associated genes play a role in lysosomal function in both neuronal and glial cell types which suggest involvement for not only lysosomal clearance of proteins but also lipids in PD. Previously, cell type specific lipid storage changes have been shown in PD patient brains and lipid droplet binding may play a role in the oligomerization of alpha synuclein, the protein present in the disease's hallmark Lewy bodies. Furthermore, fatty acid binding proteins (FABPs), particularly FABP7 and FABP3, have been shown to play a role in lipid droplet formation. In addition to their roles as lipid chaperones, FABPs have been shown to affect metabolic and inflammatory pathways further pointing to their role in lipid metabolism. Investigating changes in lipid storage may provide powerful insights into disease progression and possible disease modifying treatments. By observing differences and FABP7 and FABP3 expression in PD human tissue relative to controls we can understand the role of lipid dysregulation in PD. Additionally, observing differences in lipid droplet formation in neuronal and glial cell lines during lipotoxicity will further elucidate cell type specific changes in lipid metabolism in PD. Preliminary data shows that FABPs may be upregulated in PD.

Synucleinopathies (e.g. Parkinson's disease and dementia with Lewy bodies) are neurodegenerative conditions characterized by an accumulation of **alpha-synuclein** from the beginning of the prodromal phase. Yet, the pathophysiology is far from being completely understood. We have recently identified the synaptic depletion of eukaryotic elongation factor 1A proteins (EEF1A) at early stages of the disease. We now aim at identifying the **function of EEF1A** at synapses and in the pathophysiological process. First, we analyze the **time course** of each EEF1A variant loss in a PDGF-hSyn mouse model overexpressing alpha-synuclein. Furthermore, we develop a **CRISPR/Cas9-mediated protein tagging** as well as **knock-out strategy** for the endogenous EEF1A variants. With these new tools we will access the **precise neuronal localization** of the protein variants and control EEF1A expression in neurons. We also apply fluorescence activated synaptosome sorting to cortical glutamatergic synapses (VGLUT1-Venus x PDGF-hSyn) and explore the impact of early onset synucleinopathy to the proteomics profile. Finally, we aim at exploring the functions of EEF1A variants at synapse, to that end we test local protein translation, synaptic vesicle cycling and spine morphology. Our work will unravel the function of EEF1A at synapses and provides in depth characterization of its implication in the pathophysiology of synucleinopathy.

The loss of dopaminergic neurons in the substantia nigra (SN) that project to the striatum causes Parkinson´s disease (PD). The abnormal increase of pre-synaptic alpha-synuclein (aSyn) protein levels or aSyn mutations are one of the main drivers of PD and other synucleinopathies. In spite of the extensive research on this topic, the molecular mechanisms whereby quantitative/qualitative aSyn changes trigger neurodegeneration remain largely unclear. In this study, our working hypothesis is that mutations and/or early increases of aSyn protein levels could facilitate pathological protein-protein interactions (PPIs). The identification and modulation of aSyn PPIs could provide new therapeutic approaches to treat PD and other synucleinopathies.Here, we aimed to identify the early aSyn interactome in a mouse model using a methodology that identifies PPIs through proximity biotinylation. By expressing aSyn fused to a promiscuous biotinilase (BioID2 or TurboID) and adding biotin, proximal stable and transient interacting partners become biotinylated. Biotinylated substrates are affinity purified and identified by mass spectrometry (MS). BioID2 and TurboID-tagged aSyn proteins recapitulate aSyn-dependent neurotoxicity. TurboID-tagged proteins however, displayed a more efficient biotinilase activity. Thus, adeno-associated viral (AAV) vectors encoding TurboID, aSynTurboID and pathological mutant E46KSynTurboID were generated and stereotaxically injected into the SN of mice. AAV9-SynTurboID mice showed aSyn increased levels in the SN and in the striatum, loss of dopaminergic striatal terminals and motor deficits with respect to AAV9-TurboID mice. Pull-down experiments from injected and biotin-treated mice as well as MS analysis are ongoing to identify aSyn PPIs from dopaminergic striatal terminals and SN somas.

PARKINSON'S DISEASE LRRK2-G2019S DISRUPTS HDAC6-MEDIATED RECRUITMENT OF MISFOLDED PROTEIN AGGREGATES INTO AGGRESOMES

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Giuseppe Madaro[1], Richard Lucas[1], Claudia Bauer[1], Kavita Chinnaiya[1], Aurélie Schwartzentruber[1], Ruby Mcdonald[1], Mark Collins[2], Jan Aasly[3], Gunnar Brønstad[4], Laura Ferraiuolo[1], Heather Mortiboys[1], Kurt De Vos[1]

Mutations in the *LRRK2* gene are the most frequent cause of dominantly inherited Parkinson's disease (PD). LRRK2 PD exhibits Lewy pathology with accumulations of alpha-synuclein and ubiquitin in intracellular aggregates that are indistinguishable from idiopathic PD. LRRK2 is a multi-domain protein with both GTPase and kinase activities which regulates various cellular processes including protein homeostasis. However, how PD-linked LRRK2 mutations may lead to accumulation of ubiquitinated protein aggregates remains unclear. A main cellular pathway to remove aggregated ubiquitinated proteins is aggrephagy. Here, histone deacetylase 6 (HDAC6) tethers ubiquitinated misfolded proteins to the molecular motor cytoplasmic dynein. This promotes the recruitment of protein aggregates into a perinuclear aggresome and their subsequent clearance by macroautophagy. Here we report that LRRK2 regulates HDAC6-dependent aggresome formation, a crucial step in aggrephagy. We found that the LRRK2 Roc-COR domain directly interacts with the HDAC6 deacetylase domains, and that this interaction is regulated by LRRK2 kinase activity. PD mutant LRRK2-G2019S that has increased kinase activity showed reduced interaction with HDAC6, which could be restored using LRRK2 kinase inhibitors. Loss of LRRK2 interaction with HDAC6 prevented recruitment of ubiquitinated proteins into aggresomes. Accordingly, LRRK2-G2019S impaired aggresome formation and this was recapitulated in LRRK2-G2019S patient-derived iAstrocytes. In conclusion our data reveal HDAC6 as a novel interactor of LRRK2 and suggest that deregulation of HDAC6-mediated aggresome formation and aggrephagy could contribute to the pathology of PD.

Aim Parkinson's disease (PD) presents the selective loss of A9 dopaminergic (DA) neurons of Substantia Nigra *pars compacta* (SNpc) and the presence of intracellular aggregates called Lewy bodies. α-synuclein (α-syn) species truncated at the carboxy-terminal (C-terminal) accumulate in pathological inclusions and promote α-syn aggregation and toxicity. Hemoglobin (Hb) is the major oxygen carrier protein in erythrocytes. In addition, Hb is expressed in A9 DA neurons where it influences mitochondrial activity. Hb overexpression increases cells' vulnerability in a neurochemical model of PD *in vitro* and forms cytoplasmic and nucleolar aggregates upon short-term overexpression in mouse SNpc. The aim of the study was to evaluate the effect of chronic expression of Hb in the SNpc of mice on DA neurons homeostasis. Methods α and β-globin chains were co-expressed in DA cells of SNpc *in vivo* upon stereotaxic injections of an Adeno-Associated Virus isotype 9 (AAV9) and in DA iMN9D cells *in vitro*. Results Long-term Hb over-expression in SNpc induced the loss of about 50% of DA neurons, a mild motor impairment and deficits in recognition and spatial working memory. Hb triggered the formation of endogenous a-synuclein C-terminal truncated species. Similar α-syn fragments were found *in vitro* in DA iMN9D cells over-expressing α and β- globins when treated with pre-formed α-syn fibrils. Conclusion Our study positions Hb as a relevant player in PD pathogenesis for its ability to trigger DA cells' loss *in vivo* and the formation of C-terminal a-synuclein fragments.

SINEUPs: a novel toolbox for RNA therapeutics.
RNA molecules have emerged as a new class of promising therapeutics to expand the range of druggable targets in the genome. In addition to 'canonical' protein-coding mRNAs, the emerging richness of sense and antisense long non-coding RNAs (lncRNAs) provides a new reservoir of molecular tools for RNA-based drugs. LncRNAs are composed of modular structural domains with specific activities involving the recruitment of protein cofactors or directly interacting with nucleic acids. A single therapeutic RNA transcript can then be assembled combining domains with defined secondary structures and functions, and antisense sequences specific for the RNA/DNA target of interest. As the first representative molecules of this new pharmacology, we have identified SINEUPs, a new functional class of natural antisense lncRNAs that increase the translation of partially overlapping mRNAs. Their activity is based on the combination of two domains: an embedded mouse inverted SINEB2 element that enhances mRNA translation (effector domain) and an overlapping antisense region that provides specificity for the target sense transcript (binding domain). By genetic engineering, synthetic SINEUPs can potentially target any mRNA of interest increasing translation and therefore the endogenous level of the encoded protein. In this review, we describe the state-of-the-art knowledge of SINEUPs and discuss recent publications showing their potential application in diseases where a physiological increase of endogenous protein expression can be therapeutic.

SINEUP non-coding RNAs rescue defective frataxin expression and activity in a cellular model of Friedreich's Ataxia.
Friedreich's ataxia (FRDA) is an untreatable disorder with neuro- and cardio-degenerative progression. This monogenic disease is caused by the hyper-expansion of naturally occurring GAA repeats in the first intron of the FXN gene, encoding for frataxin, a protein implicated in the biogenesis of iron-sulfur clusters. As the genetic defect interferes with FXN transcription,

FRDA patients express a normal frataxin protein but at insufficient levels. Thus, current therapeutic strategies are mostly aimed to restore physiological FXN expression. We have previously described SINEUPs, natural and synthetic antisense long non-coding RNAs, which promote translation of partially overlapping mRNAs through the activity of an embedded SINEB2 domain. Here, by in vitro screening, we have identified a number of SINEUPs targeting human FXN mRNA and capable to up-regulate frataxin protein to physiological amounts acting at the post-transcriptional level. Furthermore, FXN-specific SINEUPs promote the recovery of disease-associated mitochondrial aconitase defects in FRDA-derived cells. In summary, we provide evidence that SINEUPs may be the first gene-specific therapeutic approach to activate FXN translation in FRDA and, more broadly, a novel scalable platform to develop new RNA-based therapies for haploinsufficient diseases.

The RNA-binding protein ILF3 binds to transposable element sequences in SINEUP lncRNAs.
Transposable elements (TEs) compose about half of the mammalian genome and, as embedded sequences, up to 40% of long noncoding RNA (lncRNA) transcripts. Embedded TEs may represent functional domains within lncRNAs, providing a structured RNA platform for protein interaction. Here we show the interactome profile of the mouse inverted short interspersed nuclear element (SINE) of subfamily B2 (invSINEB2) alone and embedded in antisense (AS) ubiquitin C-terminal hydrolase L1 (Uchl1), an lncRNA that is AS to Uchl1 gene. AS Uchl1 is the representative member of a functional class of AS lncRNAs, named SINEUPs, in which the invSINEB2 acts as effector domain (ED)-enhancing translation of sense protein-coding mRNAs. By using RNA-interacting domainome technology, we identify the IL enhancer-binding factor 3 (ILF3) as a protein partner of AS Uchl1 RNA. We determine that this interaction is mediated by the RNA-binding motif 2 of ILF3 and the invSINEB2. Furthermore, we show that ILF3 is able to bind a free right (Alu) monomer sequence, the embedded TE acting as ED in human SINEUPs. Bioinformatic analysis of Encyclopedia of DNA Elements-enhanced cross-linking immunoprecipitation data reveals that ILF3 binds transcribed human SINE sequences at transcriptome-wide levels. We then demonstrate that the embedded TEs modulate AS Uchl1 RNA nuclear localization to an extent moderately influenced by ILF3. This work unveils the existence of a specific interaction between embedded TEs and an RNA-binding protein, strengthening the model of TEs as functional modules in lncRNAs.-Fasolo, F., Patrucco, L., Volpe, M., Bon, C., Peano, C., Mignone, F., Carninci, P., Persichetti, F., Santoro, C., Zucchelli, S., Sblattero, D., Sanges, R., Cotella, D., Gustincich, S. The RNA-binding protein ILF3 binds to transposable element sequences in SINEUP lncRNAs.

Structural determinants of the SINE B2 element embedded in the long non-coding RNA activator of translation AS Uchl1.
Pervasive transcription of mammalian genomes leads to a previously underestimated level of complexity in gene regulatory networks. Recently, we have identified a new functional class of natural and synthetic antisense long non-coding RNAs (lncRNA) that increases translation of partially overlapping sense mRNAs. These molecules were named SINEUPs, as they require an embedded inverted SINE B2 element for their UP-regulation of translation. Mouse AS Uchl1 is the representative member of natural SINEUPs. It was originally discovered for its role in increasing translation of Uchl1 mRNA, a gene associated with neurodegenerative diseases. Here we present the secondary structure of the SINE B2 Transposable Element (TE) embedded in AS Uchl1. We find that specific structural regions, containing a short hairpin, are required for the ability of AS Uchl1 RNA to increase translation of its target mRNA. We also provide a high-resolution structure of the relevant hairpin, based on NMR observables. Our results highlight the importance of structural determinants in embedded TEs for their activity as functional domains in lncRNAs.

Aims
To identify genes involved in the degeneration of the dopaminergic neurons (DN) of the *substantia nigra* (SN) by inflammation. **Methods**
We performed functional genomic analysis in a rat model that manifests neurodegeneration provoked by inflammation by chronic expression of TNFα in the SN delivered by an adenovector. We validated these findings by qPCR in two other rat models expressing IL-1β and 6OHDA/LPS. To study the functionality of the genes found, we used Drosophila melanogaster (DM) as a model. Behavioural, histological, and physiological analyses were performed. **Results**
We found that the expression of the plasma membrane calcium ATPase 1 (PMCA1) gene was downregulated in the three rat models. To test the relevance of PMCA1 in DN *in vivo*, we specifically decreased its expression in DN using RNA interference in DM. We found that PMCA downregulation in DN induces an increase in intracellular Ca^{2+}, altered Ca^{2+} dynamics, mitochondrial oxidative stress, increments in synaptic vesicles, active synapses and dopamine levels, without cell death, locomotor alterations and lower survival. **Conclusions**
We found PMCA1 is downregulated in three rat models of Parkinson's disease (PD) by inflammation. The reduction of PMCA in DM DN reproduced features of other DM models of PD. Since DN are subjected to Ca^{2+} dependent-pacemaker, the decrease of PMCA1 could provoke a dysregulation in the Ca^{2+} homeostasis, promoting their vulnerability. These results postulate PMCA1 as a participant in the process of vulnerability and degeneration of DN in PD.

Plasma membrane calcium ATPase downregulation in dopaminergic neurons alters cellular physiology and motor behaviour in Drosophila melanogaster.
The accumulation of Ca and its subsequent increase in oxidative stress is proposed to be involved in selective dysfunctionality of dopaminergic neurons, the main cell type affected in Parkinson's disease. To test the in vivo impact of Ca increment in dopaminergic neurons physiology, we downregulated the plasma membrane Ca ATPase (PMCA), a pump that extrudes cytosolic Ca , by expressing PMCA in Drosophila melanogaster dopaminergic neurons. In these animals, we observed major locomotor alterations paralleled to higher cytosolic Ca and increased levels of oxidative stress in mitochondria. Interestingly, although no overt degeneration of dopaminergic neurons was observed, evidences of neuronal dysfunctionality were detected such as increases in presynaptic vesicles in dopaminergic neurons and in the levels of dopamine in the brain, as well as presence of toxic effects when PMCA was downregulated in the eye. Moreover, reduced PMCA levels were found in a Drosophila model of Parkinson's disease, Parkin knock-out, expanding the functional relevance of PMCA reduction to other Parkinson's disease-related models. In all, we have generated a new model to study motor abnormalities caused by increments in Ca that lead to augmented oxidative stress in a dopaminergic environment, added to a rise in synaptic vesicles and dopamine levels.

Environmental enrichment improves cognitive symptoms and pathological features in a focal model of cortical damage of multiple sclerosis.

FENS Forum 2022
9-13 July 2022 | Paris, France

Multiple Sclerosis (MS) is a neuroinflammatory disease affecting white and grey matter, it is characterized by demyelination, axonal degeneration along with loss of motor, sensitive and cognitive functions. MS is a heterogeneous disease that displays different clinical courses: relapsing/remitting MS (RRMS), and MS progressive forms: primary progressive (PPMS) and secondary progressive (SPMS). Cortical damage in the progressive MS forms has considerable clinical relevance due to its association with cognitive impairment and disability progression in patients. One treatment is available for the progressive forms of the disease, but none are specific for cognitive deficits. We developed an animal model that reflects most of the characteristics of the cortical damage, such as cortical neuroinflammation, demyelination, neurodegeneration and meningeal inflammation, which was associated with cognitive impairment. Cognitive rehabilitation, exercise and social support have begun to be evaluated in patients and animal models of neurodegenerative diseases. Environmental enrichment (EE) provides exercise as well as cognitive and social stimulation. EE has been demonstrated to exert positive effects on cognitive domains, such as learning and memory, and improving anxiety-like symptoms. We proposed to study the effect of EE on peripherally stimulated cortical lesion induced by the long term expression of interleukin IL-1β (IL-1β) in adult rats. Here, we demonstrated that EE: 1) reduces the peripheral inflammatory response to the stimulus, 2) ameliorates cognitive deficits and anxiety-like symptoms, 3) modulates neurodegeneration, demyelination and glial activation, 4) regulates neuroinflammation by reducing the expression of pro-inflammatory cytokines and enhancing the expression of anti-inflammatory ones. Our findings correlate with the fact that EE housing could be considered an effective non- pharmacological therapeutic agent that can synergistically aid in the rehabilitation of the disease.

GLUCOCEREBROSIDASE (GCASE) TRANSLOCATION TO LYSOSOMES AND GCASE LEVEL IN PRIMARY MACROPHAGES DERIVED FROM GBA1 MUTATION CARRIERS WITH AND WITHOUT PARKINSON'S DISEASE

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Alena Kopytova[1], Mikhail Nikolaev[1,2], Artem Izymchenko[1], Darya Bogdanova[1], Irina Miliukhina[2,3], Sofya Pchelina[1,2]

Background Mutations in the *GBA1* gene, encoding the lysosomal enzyme glucocerebrosidase (GCase), are the most common genetic risk factor of Parkinson's disease (PD). However, not all *GBA1*-carriers develop PD during their lifetime. It remains unknown if GCase transport is impaired in *GBA1*-carriers and is it related with PD development. **Aim** To assess GCase translocation to lysosomes and its level in primary macrophages derived from *GBA1* mutation carriers with and without PD. **Methods** Mononuclear fraction was isolated from whole blood of patients with *GBA1* mutation with ($GBA1^+/PD^+$)(N=10) or without PD ($GBA1^+/PD^-$)(N=8) and controls (N=11). Primary macrophages were cultured as described earlier (KopytovaA et al., ParkinsonismRelatDisord.2021). The translocation of GCase to lysosomes (marker LAMP2) was assessed in primary macrophages using confocal microscope (×63magnification). Pearson's coefficient was calculated for the degree of colocalization between GCase and LAMP2. Total protein was separated by SDS-PAGE and transferred to PVDF membranes by electroblotting. Primary anti-GBA and anti-GAPDH antibodies were used. **Results** A decreased translocation of GCase to lysosomes, estimated as colocalization of GCase with the lysosomal marker LAMP2, was observed in $GBA1^+/PD^+$ and $GBA1^+/PD^-$ primary macrophages compared to controls (Table 1). Moreover, the degree of translocation of GCase to lysosomes depends on the severity of *GBA1* mutations (Table 1). A decreased relative GCase protein level was observed in $GBA1^+/PD^-$ 0,49(-0,16–1,18) compared to controls 1,82(0,46–3,74)(p=0.012).

Table 1. Pearson's coefficient for GCase and LAMP2 in primary macrophages derived from *GBA1* mutation carriers with and without PD

Patients	Age, years	Sex, male/ female	*GBA1* mutation	Pearson's coefficient, median (min-max)	p-value	Pearson's coefficient depending on the severity of *GBA1* mutation, median (min-max)	p-value
Controls N=11	55,1 ± 6,2	4/7	NA	0,765 (0,615 – 0,992)	-	-	-
$GBA1^+/PD^-$ N=8	53,8 ± 7,4	3/5	"Mild" (N370S, R120W) N=4	0,682 (0,540 – 0,807)	*p<0.0001	0,712 (0,440-0,807)	*p<0.0001
			"Severe" (L444P) N=4			0,658 (0,534-0,717)	*p<0.0001 a p<0.0001
$GBA1^+/PD^+$ N=9	54,5 ± 8,6	2/6	"Mild" (N370S) N=5	0,695 (0,325 – 0,858)	*p<0.0001	0,740 (0,325-0,858)	*p=0.002
			"Severe" (L444P) N=4			0,660 (0,482-0,757)	*p<0.0001 b p<0.0001

** compared to controls*
a compared to "Mild" GBA1 mutation carriers without PD
b compared to "Mild" GBA1 mutation carriers with PD

Conclusions *GBA1* mutation carriers are characterized by impaired GCase transport to lysosomes that depends on mutation severity but is not affected with the disease status. The study was funded by RSF №19-15-00315.

Comparative Transcriptome Analysis in Monocyte-Derived Macrophages of Asymptomatic Mutation Carriers and Patients with GBA-Associated Parkinson's Disease.
Mutations of the gene, encoding for lysosomal enzyme glucocerebrosidase (GCase), are the greatest genetic risk factor for Parkinson's disease (PD) with frequency between 5% and 20% across the world. N370S and L444P are the two most common mutations in the gene. PD carriers of severe mutation L444P in the gene is characterized by the earlier age at onset compared to N370S. Not every carrier of mutations develop PD during one's lifetime. In the current study we aimed to find common gene expression signatures in PD associated with mutation in the gene (GBA-PD) using RNA-seq. We compared transcriptome of monocyte-derived macrophages of 5 patients with GBA-PD (4 L444P/N, 1 N370S/N) and 4 asymptomatic mutation carriers (GBA-carriers) (3 L444P/N, 1 N370S/N) and 4 controls. We also conducted comparative transcriptome analysis for L444P/N only GBA-PD patients and GBA-carriers. Revealed deregulated genes in GBA-PD independently of mutations (L444P or N370S) were involved in immune response, neuronal function. We found upregulated pathway associated with zinc metabolism in L444P/N GBA-PD patients. The potential important role of in the pathogenesis of GBA-PD was suggested.

Parkinson's Disease Associated with GBA Gene Mutations: Molecular Aspects and Potential Treatment Approaches.
Parkinson's disease (PD) is a multifactorial neurodegenerative disease. To date, genome-wide association studies have identified more than 70 loci associated with the risk of PD. Variants in the gene encoding glucocerebrosidase are quite often found in PD patients in all populations across the world, which justifies intensive investigation of this gene. A number of biochemical features have been identified in patients with -associated Parkinson's disease (GBA-PD). In particular, these include decreased activity of glucocerebrosidase and accumulation of the glucosylceramide substrate. These features were the basis for putting forward a hypothesis about treatment of GBA-PD using new strategies aimed at restoring glucocerebrosidase activity and reducing the substrate concentration. This paper discusses the molecular and genetic mechanisms of GBA-PD pathogenesis and potential approaches to the treatment of this form of the disease.

Ambroxol increases glucocerebrosidase (GCase) activity and restores GCase translocation in primary patient-derived macrophages in Gaucher disease and Parkinsonism.
Mutations in the glucocerebrosidase gene (GBA) encoding the lysosomal enzyme glucocerebrosidase (GCase) cause Gaucher disease (GD) and are the most commonly known genetic risk factor for Parkinson disease (PD). Ambroxol is one of the most effective pharmacological chaperones of GCase. Fourteen GD patients, six PD patients with mutations in the GBA gene (GBA-PD), and thirty controls were enrolled. GCase activity and hexosylsphingosine (HexSph) concentration were measured in dried blood and macrophage spots using liquid chromatography coupled with tandem mass spectrometry. The effect of ambroxol on GCase translocation to lysosomes was assessed using confocal microscopy. The results showed that ambroxol treatment significantly increased GCase activity in cultured macrophages derived from patient blood monocytic cell (PBMC) of GD (by 3.3-fold) and GBA-PD patients (by 3.5-fold) compared to untreated cells ($p < 0.0001$ and $p < 0.0001$, respectively) four days after cultivation. Ambroxol treatment significantly reduced HexSph concentration in GD (by 2.1-fold) and GBA-PD patients (by 1.6-fold) ($p < 0.0001$ and $p < 0.0001$, respectively). GD macrophage treatment resulted in increased GCase level and increased enzyme colocalization with the lysosomal marker LAMP2. The possible binding modes of ambroxol to mutant GCase carrying N370S amino acid substitution at pH 4.7 were examined using molecular docking and molecular dynamics simulations. The ambroxol position characterized by minimal binding free energy was observed in close vicinity to the residue, at position 370. Taken together, these data showed that PBMC-derived macrophages could be used for assessing ambroxol therapy response for GD patients and also for GBA-PD patients.

Genetics variants and expression of the SCARB2 gene in the pathogenesis of Parkinson's disease in Russia.
Lysosomal integral membrane protein-2 (LIMP-2), encoded by the SCARB2 gene, is the specific lysosomal receptor for glucocerebrosidase enzyme. Association between rs6812193 and rs68250047 of SCARB2 with PD has been shown in genetic studies, including large genome-wide association studies. The aim of the current study was to determine whether rs6812193 and rs8475 are associated with PD in Russia. rs6812193 and rs8475 were genotyped in a total of 604 PD patients (65 PD patients with positive (fPD) and 539 PD patients with negative family history (sPD)) and 413 controls and also in 17

patients with PD associated with GBA mutations (PD-GBA) and 18 asymptomatic GBA mutation carriers (GBA-Carriers). SCARB2 expression was measured by real-time PCR in CD45+ blood cells in part of individuals in the studied groups. No linkage disequilibrium was shown between rs6812193 and rs8475 in Russian population. Increased PD risk for TT variant of rs8475 (OR = 2.02; p < 0.001) was found in sPD patients but not in fPD. rs6812193 and rs8475 were not associated with age at onset (AAO) of PD. SCARB2 expression level was decreased in GBA-PD patients and GBA-Carriers compared to PD patients (p = 0.02, p = 0.003, respectively) and GBA-Carriers compared to controls (p = 0.013) with no significant difference in PD patients and controls. SCARB2 expression was not modified with rs6812193 and rs8475. In conclusion, rs8475 was associated with PD status. rs6812193 and rs8475 are not genetic modifier of AAO of PD and do not influence on SCARB2 mRNA level in CD45+ blood cells in studied groups. SCARB2 expression could be modified with GBA mutations and is independent of PD status.

SNCA variants and alpha-synuclein level in CD45+ blood cells in Parkinson's disease.
Parkinson's disease (PD) is the second most frequent neurodegenerative disorder. Impaired metabolism of alpha-synuclein (SNCA) and its aggregation are implicated in PD pathogenesis. SNCA has been identified as a highly significant genetic risk loci associated with the sporadic form of PD in across populations in GWAS and replicative studies. In this study we conducted a genetic analysis of five SNCA single nucleotide polymorphisms (SNPs) (rs356219, rs2619364, rs11931074, rs2583988, rs356168) in 458 PD patients and 353 from North-West region of Russia. We also assessed an association of studied SNPs with alpha-synuclein levels in homogeneous cell fraction of CD45+ blood cells in PD patients and controls. An association with PD was shown for SNPs rs356219, rs11931074, rs356168. After correction for covariates the significant association with the disease only for rs11931074 and rs356168 was shown. Alpha-synuclein level in peripheral blood CD45+ cells was significantly increased in PD patients compared to control subjects (p = 0.02). The effect of SNCA rs356219 and rs356168 on CD45+ alpha-synuclein level in PD patients and control groups was shown. At the same tame the increase of CD45+ alpha-synuclein level in PD patients was revealed only in risk allele carriers as for rs356219 and rs356168 SNPs. Therefore, our study was the first that demonstrated the increased level of alpha-synuclein in CD45+ blood cells in PD patients and showed that it could be influenced by SNCA rs356168 and rs356219. In conclusion we confirmed the significance of the SNCA locus in the PD development.

Blood lysosphingolipids accumulation in patients with parkinson's disease with glucocerebrosidase 1 mutations.
Glucocerebrosidase 1 mutations, the most common genetic contributor to Parkinson's disease (PD), have been associated with decreased glucocerebrosidase enzymatic activity in PD patients with glucocerebrosidase 1 mutations (glucocerebrosidase 1-PD). However, it is unknown whether this decrease in enzymatic activity leads to lysosphingolipid accumulations.

Mutation analysis of Parkinson's disease genes in a Russian data set.
Common variants and risk factors related to familial and sporadic cases of Parkinson's disease (PD) in diverse populations have been identified at numerous genomic loci. In this study, genetic analysis was performed through a screening of LRRK2 G2019S, GBA mutations (L444P, N370S), and common variants (E326K, T369M) in 762 PD patients and in 400 controls. Next-generation sequencing analysis of 22 PD-related genes in 28 early-onset PD cases from North-Western region of Russia was performed. The frequency of LRRK2 G2019S mutation was 5.8% in familial and 0.5% in sporadic PD cases. The frequency of GBA mutations (L444P, N370S) in PD patients was higher compared to controls (odds ratio [OR] = 6.9, 95% confidence interval [CI], 0.9-53.13, p = 0.031), particularly in patients with early-onset compared to late-onset PD (OR = 3.90 [95% CI, 1.2-13.2], p = 0.009). The frequency of E326K and T369M was twice higher among PD patients than in controls (OR = 2.24, 95% CI 1.05-4.79, p = 0.033). However, the screening of 22 PD-related genes using our novel panel of gene resequencing in our series of 28 early-onset PD failed to identify any mutations. LRRK2 and GBA mutations were found to be common risk factors for PD in North-Western region of Russia.

[The clinical features of Parkinson's disease in patients with mutations and polymorphic variants of GBA gene].

Mutations in the glucocerebrosidase gene (GBA) increase the risk of Parkinson's disease (PD) by 6-10 times in all populations and are associated with the early-onset of PD, development of cognitive impairment and presence of psychotic disorders. At the same time, polymorphic variants associated with the twofold increase in the risk of PD were also described in the GBA gene.

ITLN1, PPARg AND TNFa GENE EXPRESSION IN VISCERAL ADIPOSE TISSUE.
The adipose tissue is considered today as an endocrine organ in which tissue-specific regulation of gene expression plays a key role in the processes of development of obesity and comorbidities, such as diabetes and cardiovascular disease. The present study is focused on ITLN1, PPARã and TNFá gene expression in intra-abdominal adipose tissue and its effect on the serum levels of omentin 1 and TNFa in individuals with different body mass. It has been shown that serum TNFa level is significantly higher in the subgroup of patients with overweight and obesity (BMI ≥ 25 kg/m2) as compared to individuals with normal body weight (BMI < 25 kg/m2)($p < 0.03$). We have demonstrated that the expression level of the PPARã gene is positively correlated with the ITLN1 gene expression level in the intra-abdominal adipose tissue ($r = 0.516$, $p = 0.020$). Serum level of omentin 1 positively correlates with PPARã mRNA and protein levels in intra-abdominal adipose tissue ($r = 0.550$, $p < 0.05$ and $r = 0.581$, $p < 0.03$, respectively). For the subgroup of patients with overweight and obesity, we have shown negative correlation of the level of TNFá mRNA with PPARã and ITLN1 mRNA levels was shown ($r = –0.549$, $p < 0.05$ and $r = –0.475$, $p < 0.05$, respectively). This study is the first to show a correlation relationship between PPARã gene expression level in the intra-abdominal adipose tissue and the expression and secretion levels of omentin 1.

Oligomeric α-synuclein and glucocerebrosidase activity levels in GBA-associated Parkinson's disease.
Alpha-synuclein oligomerization plays a key role in the development of Parkinson's disease (PD). Being the most common genetic contributor to PD, glucocerebrosidase 1 (GBA) mutations have been associated with decreased GBA enzymatic activity in PD patients with mutations in the GBA gene (GBA-PD). However, it is unknown whether the activities of other lysosomal hydrolases are being altered in GBA-PD patients and are accompanied by an increase in alpha-synuclein oligomerization. The aim of our study was to estimate GBA enzymatic activity as well as the activities of five other lysosomal hydrolases (galactocerebrosidase, alpha-glucosidase, alpha-galactosidase, sphingomyelinase, alpha-iduronidase) in dried blood spots with assessing plasma oligomeric alpha-synuclein levels in sporadic PD (sPD) patients, in GBA-PD patients and in controls. GBA enzymatic activity and plasma oligomeric alpha-synuclein levels were assessed in sPD patients (N=84), in GBA-PD patients (N=21) and controls (N=62) by LC-MS/MS and ELISA methods accordingly. GBA-PD patients showed lower GBA enzymatic activity compared to controls ($p=0.001$) and to sPD ($p=0.0001$). We also found the reduction of GLA enzymatic activity (but not of other lysosomal hydrolases) in GBA-PD ($p=0.001$). At the same time plasma oligomeric alpha-synuclein levels were increased in GBA-PD group compared to sPD and controls ($p=0.002$ and $p<0.0001$, respectively). Our results suggest that the decrease in enzymatic activity of lysosomal hydrolases in GBA mutation carriers may contribute to PD pathogenesis by increasing the level of neurotoxic oligomeric alpha-synuclein species.

α-Synuclein (α-syn) is a prion-like protein involved in several neurodegenerative diseases such as Parkinson's disease. Recent studies have demonstrated that α-syn could be released in exosomes, thereby contributing to the propagation of α-syn pathology. However, the function of α-syn-containing exosomes on neuronal function is currently unknown. We recently demonstrated that synaptic activity controls the flux of retrograde carriers emanating from the nerve terminal and carrying survival signalling endosomes[1] and autophagosomes[2,3]. To determine the effect of transmitted α-syn on neuronal trafficking, we used conditioned medium from α-syn transfected hippocampal neurons, that was applied on non-transfected neurons cultured in microfluidic chambers. Following the activity-dependent uptake of cholera toxin-B subunit (CTB), time-lapse imaging of retrograde carriers in recipient neurons was then performed. Conditioned medium from α-syn^{WT}-GFP transfected hippocampal neurons downregulated the frequency of retrograde CTB carriers from non-transfected neurons. This effect was abolished using conditioned medium from α-syn^{A30P}-GFP transfected neurons and upon blockade of exosomal release by mutant Hsp90^{MD7} [4]. Transmitted α-syn^{WT}-mEos could be detected in recipient neurons and exhibited lower mobility compared to mutant α-syn^{A30P}-mEos, suggestive of active interactions. Our data demonstrate that the spreading of α-syn via exosomes controls essential neuronal trafficking flux of survival cues in recipient neurons, an effect lost with the Parkinson's disease α-syn^{A30P} mutant. **References** [1]Wang et al., Nat. LOSS OF GBA ACTIVITY EXACERBATE THE TOXICITY OF ALPHA-SYNUCLEIN OLIGOMERS AND PROTOFIBRILS IN AN IN VITRO MODEL OF PARKINSON'S DISEASE.

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Laura Rouvière, Philippe Poindron, Noëlle Callizot, Alexandre Henriques
Neuro-sys, ., Gardanne, France

Aims : Accumulation of misfolded alpha-synuclein (α-Syn), forming Lewy-bodies, causes mitochondrial stress and impairs autophagy-lysosomal pathway in Parkinson's disease. Mutations on GBA is a strong risk factor for Parkinson's disease. Here, we developed and characterized a novel *in vitro* model of Parkinson's disease,based on GBA-linked lysosomal dysfunctions and α-Syn toxicity **Methods** : Primary cultures of mesencephalic neurons were treated with conduritol B epoxide (CBE, 20 µM), a covalent inhibitor of glucocerebrosidase enzyme (GBA), and were injured with an αSyn solution (250 nM) containing oligomers and protofibrils from 24 hours to 96 hours. Survival of dopaminergic neurons, integrity of the neurite network and lysosomal burden was evaluate at several timepoints after injury with αSyn protofibrils with or without application of CBE. These measurements were evaluated by immunocytochemistry. The effect of ambroxol hydrochloride, a molecular chaperone for GBA, was tested in the model. **Results**: Lysosomal accumulation was the first pathological event observed, 72h after application of αSyn oligomers and protofibrils. Neuronal death and neurite network loss were then evidenced 96h after injury. In presence of CBE, neuronal loss was observed earlier, 72h after αSyn application. These results suggest that toxicity of αSyn protofibrils on dopaminergic neurons was exacerbated by the inhibition of GBA with CBE, demonstrating that lysosomal dysfunction increases αSyn toxicity. Moreover, ambroxol hydrochloride was able to reduce neuronal loss and lysosomal accumulation. **Conclusions**: Altogether, we show here that inhibiting GBA activity exacerbates the toxicity of alpha-synuclein protofibrils on dopaminergic neurons, in *in vitro* models of GBA-linked Parkinson's disease.

The accumulation of α-synuclein (α-syn) fibrils in the intraneuronal inclusions called Lewy bodies and Lewy neurites is the main pathological signature of Parkinson's disease (PD). While several aspects linked to α-syn-dependent pathology (i.e. the ones mainly concerning its spreading, aggregation, and activation of inflammatory and neurodegenerative processes) have been under intense investigation, less attention has been devoted to the factual impact of α-syn overexpression on structure, excitability and functional properties of substantia nigra pars compacta (SNpc) dopamine (DA) neurons, despite this has obvious relevance to comprehending the mechanisms related to PD progression. We aimed at determining the consequences of a prolonged α-synuclein overproduction on somatodendritic morphology and functions of SNpc DA neurons. Thus, we performed immunohistochemistry, stereological DA cell counts, analyses of dendritic arborization, *ex vivo* patch-clamp recordings, and *in vivo* DA microdialysis measurements in a bacterial artificial chromosome (BAC) transgenic PD rat model overexpressing the full-length human α-synuclein (*Snca*$^{+/+}$), and in wildtype (WT) rats of 12-13 months of age. Here, we describe compensatory mechanisms that nigral DA neurons adopt during PD progression to functionally counteract a developing neurodegeneration.

URIC ACID REGULATES NEURON-TO NEURON α-SYNUCLEIN TRANSMISSION IN PARKINSONIAN MICROENVIRONMENT

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Yu Jin Shin, Jieun Lee, Yi Seul Kim, Yeon Ju Kim, Jin Young Shin, Phil Hyu Lee

There is ample evidence that α-syn plays a critical role in the pathogenesis of Parkinson's disease (PD) and propagation of α-syn from one brain area to the other areas through neuron-to-neuron transmission could be the primary mechanism for disease progression in parkinsonian patients. The inhibition of α-synuclein transmission throughout brain areas would be the potential disease-modifying strategy to treat PD. UA, a natural antioxidant in the body, has been studied as a potential drug candidate in various neurodegenerative diseases including Parkinson's disease. In the present study, we hypothesized that UA would regulate neuron-to-neuron transmission of α-synuclein in α-synuclein-enriched environment. In a cellular model, high-UA condition reduced the levels of internalized cytosolic α-synuclein not affecting the autophagic pathway and decreased the neuron-to neuron transmission of α-synuclein in α-synuclein-overexpressed BiFC system. In addition, we examined whether elevating serum UA levels in α-synuclein-inoculated parkinsonian model would inhibit extracellular α-synuclein transmission from dorsal striatum to substantia nigra (SN). UA-elevating therapy markedly decreased the neuron-to-neuron transmission of extracellular α-synuclein, which exerted neuroprotective effects on nigral dopaminergic neurons against α-synuclein-enriched conditions. These findings suggest that UA-elevating strategy could be a potential disease-modifying therapy in treatment of parkinson's disease.

PRIMING MESENCHYMAL STEM CELLS WITH α-SYNUCLEIN ENHANCES NEUROPROTECTIVE PROPERTIES THROUGH INDUCTION OF AUTOPHAGY IN PARKINSONIAN MODELS

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Jieun Lee, Yu Jin Shin, Yi Seul Kim, Yeon Ju Kim, Jin Young Shin, Phil Hyu Lee

Mesenchymal stem cells (MSCs) are a potential source of cell-based disease-modifying therapy for parkinsonian disorders. As knowledge regarding the therapeutic properties of MSCs accumulates, some obstacles still remain to be overcome, especially, successful clinical translation requires the development of culture systems that mimic the natural MSC niche, while allowing clinical-scale cell expansion without compromising quality and function of the cells. In recent years, priming approaches using bioactive peptide or complement components have been investigated to enhance the therapeutic potential of MSCs. Here, we investigated an innovative priming strategy by conditioning the MSCs with α-synuclein (α-syn). Treatment of naïve MSCs with α-syn upregulated transcriptional factors responsible for regulation of stemness, which was associated with the elevated expression of genes involved in glycolysis and cell re-programming. Primed MSCs with α-syn enhanced the expression of autophagy-regulating miRNA, and exosomes derived from primed MSCs were packed with autophagy-associated miRNA. In a parkinsonian cellular model, primed MSCs with α-syn enhanced neuronal viability relative to naïve MSCs, through the induction of autophagy and lysosome activity. Moreover, several studies using an α-syn over-expressed parkinsonian animal model showed that the pro-survival effect of MSCs on dopaminergic neurons was more prominent in primed MSC-treated mice compared with that in naïve MSC-treated mice. These findings provide a new insight into the role of autophagy in α-syn-induced MSC priming, suggesting that MSC priming with α-syn can be a useful strategy to advance the application of MSCs for the treatment of parkinsonian disorders.

HIF-1α SIGNALLING AS A THERAPEUTIC STRATEGY IN NEURONAL SURVIVAL

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Laura Leston Pinilla, Aslihan Ugun-Klusek, Sergio Rutella, Luigi De Girolamo

Parkinson's disease (PD) is a progressive neurodegenerative movement disorder characterized by the selective degeneration of a specific subset of dopamine-producing neurons. To date, treatments have focused on compensating dopamine deficiency without addressing the progressive neuronal cell damage. PD related dopaminergic cell death has been associated with environmental factors and genetic predisposition leading to molecular pathway disruption that regulates mitochondrial function, reactive oxygen species and protein degradation. Recent evidence suggests that events causing transient reductions in neuronal oxygen supply (hypoxia) may trigger changes in these key parameters and thereby influence PD development. Indeed, HIF-1α, the master transcriptional regulator of the cellular response to hypoxia, can target these specific disrupted pathways in PD by activating genes involved in mitochondrial fitness, oxidative stress, autophagy and dopamine production, potentially alleviating neuronal damage. Therefore, novel compounds that stabilize HIF-1α may constitute a potential therapeutic strategy for neuronal survival. Our results show how PD-related neuronal stress can block HIF-1α stabilization and influence the molecular processes that lead to neuronal degeneration. Indeed, agents causing mitochondrial damage and increased ROS levels, diminish HIF-1α stabilization in neural cell models. We have subsequently studied a set of novel HIF-1α stabilizing compounds, that reduce PD-related neuronal damage by maintaining mitochondrial integrity, function and dynamics whilst decreasing ROS levels and significantly improving neuronal survival. This constitutes a potential therapeutic strategy to improve neuronal function in PD.

Recent Insights into the Mitochondrial Role in Autophagy and Its Regulation by Oxidative Stress.
Autophagy is a self-digestive process that degrades intracellular components, including damaged organelles, to maintain energy homeostasis and to cope with cellular stress. Autophagy plays a key role during development and adult tissue homeostasis, and growing evidence indicates that this catalytic process also has a direct role in modulating aging. Although autophagy is essentially protective, depending on the cellular context and stimuli, autophagy outcome can lead to either abnormal cell growth or cell death. The autophagic process requires a tight regulation, with cellular events following distinct stages and governed by a wide molecular machinery. Reactive oxygen species (ROS) have been involved in autophagy regulation through multiple signaling pathways, and mitochondria, the main source of endogenous ROS, have emerged as essential signal transducers that mediate autophagy. In the present review, we aim to summarize the regulatory function of mitochondria in the autophagic process, particularly regarding the mitochondrial role as the coordination node in the autophagy signaling pathway, involving mitochondrial oxidative stress, and their participation as membrane donors in the initial steps of autophagosome assembly.

Hypoxia Signaling in Parkinson's Disease: There Is Use in Asking "What HIF?"
Hypoxia is a condition characterized by insufficient tissue oxygenation, which results in impaired oxidative energy production. A reduction in cellular oxygen levels induces the stabilization of hypoxia inducible factor α (HIF-1α), master regulator of the molecular response to hypoxia, involved in maintaining cellular homeostasis and driving hypoxic adaptation through the control of gene expression. Due to its high energy requirement, the brain is particularly vulnerable to oxygen shortage. Thus, hypoxic injury can cause significant metabolic changes in neural cell populations, which are associated with neurodegeneration. Recent evidence suggests that regulating HIF-1α may ameliorate the cellular damage in neurodegenerative diseases. Indeed, the hypoxia/HIF-1α signaling pathway has been associated to several processes linked to Parkinson's disease (PD) including gene mutations, risk factors and molecular pathways such as mitochondrial dysfunction, oxidative stress and protein degradation impairment. This review will explore the impact of hypoxia and HIF-1α signaling on these specific molecular pathways that influence PD development and will evaluate different novel

neuroprotective strategies involving HIF-1α stabilization. Biology (Basel), 2021; 10

Transglutaminase 2 is a ubiquitous enzyme that belongs to transglutaminase family, which consists of nine multifunctional proteins evolved from the papain family and is expressed in various cells and tissues. It acts by catalyzing the Ca^{2+}-dependent covalent crosslinking between γ-carboxamide group of peptide-bound glutamine and primary amine group of lysine residue bound to a polypeptide or protein, producing a proteolytically-resistant isopeptide bond. TG2 has been shown to be upregulated in various types of neurodegenerative diseases, including Parkinson’s disease (PD). This association between TG2 and neurodegeneration has focused on TG2 structure and mechanism of action, highlighting the importance of TG2 activity and post-translational modifications. Aggregates of α-synuclein have been found in tissues of patients with PD, as well as in other neuronal aging-related diseases, such as Alzheimer's and Huntingtin diseases. Consequently, α-synuclein was found to be a target protein of TG2 in cellular models of PD supported specifically by studies of toxin-induced mitochondrial dysfunction. Our aim was to use neuronal cell culture models that simulate various molecular lesions that occur in a parkinsonian nervous system, such as proteasomal inhibition, mitochondrial complex 1 inhibition and lipid peroxidation, all of which eventually result in protein aggregation in those neurons. The transamidating activity of TG2 was quantified under PD-mimetic conditions in vitro using cell viability and biotin-cadaverine incorporation assays to determine whether the role of TG2 is neuro-protective or neurotoxic under different PD-mimetic conditions and determine its potential as a molecular biomarker of disease and/or a target for therapeutic intervention to slow neuronal aging.

The secretome is comprised of small molecules, proteins and lipids, the importance of which has only started to be unraveled both in health and in pathologies, such as cancer and neurodegenerative diseases. Leucine-riche repeat kinase 2 (LRRK2) is associated to Parkinson disease and was suggested to regulate endolysosomal dynamics, a process which relies particularly on membrane fusion mediated by SNAREs. In addition, we previously found that the interaction between the vesicular SNARE VAMP7 and LRRK1, a molecule closely related to LRRK2, regulated lysosomal secretion (Wang et al, iScience 2018). We recently investigated the biochemical links between LRRK2 and vesicular SNAREs and their potential cellular functions. We found that LRRK2 interacted with the post-Golgi v-SNAREs VAMP4, VAMP7 and VAMP8. Parkinson's disease related R1441C mutant of LRRK2 was the most efficient VAMP4 interactor and lead to impaired VAMP4 subcellular localization. Yeast-2-Hybrid assay identified the interaction of VAMP partner Snapin with the COR domain of LRRK2. LRRK2, Snapin and VAMP4 were found in the same protein complex. Secretomics showed that VAMP4- and VAMP7-KO neuronal cells secreted less pro-VGF, a Parkinson's disease potential biomarker. The R1441C mutant of LRRK2 affected the subcellular localization of VGF and LRRK2 expression inhibited the secretion of pro-VGF. Altogether, these results suggest that LRRK2 might regulate secretion via interaction with VAMP4 and VAMP7 (Filippini et al, SSRN 2021). Here we followed up by investigating the effect of overexpressing WT and pathological LRRK2 mutants in neuronal cells expressing or not VAMP7.

Aims: We recently identified 16 novel genes associated with Parkinson's disease (PD). In this study, we focused the attention on the mutations identified in the lysosomal potassium channel TMEM175, necessary for the maintenance of lysosomal acidity. **Methods**: Mutations were identified through the analysis of the our sequence data set (400 cases and 210 controls). The expression profile of *TMEM175* was investigated by qPCR and immunofluorescence (IF). The functional properties of the mutated channel were characterized by patch-clamp technique. The interaction of TMEM175 with AKT regulatory factor was analyzed by co-immunoprecipitation experiments. **Results**: We identified 13 novel deleterious and highly penetrant mutations, affecting important domains of the protein, in 23 PD patients representing the 5.7% of our cohort of patients. None of these variants was identified in healthy subjects, suggesting an important genetic role in PD pathogenesis for this gene. IF experiments in patients-derived fibroblasts showed impaired autophagic flux. Moreover, electrophysiology studies demonstrated the loss of the functional properties of the channel in presence of some mutations identified in patients. Interestingly, these mutations also affected the interaction with the protein kinase AKT, recently identified as a key regulator of TMEM175. Finally, IF analysis on mouse brain showed a higher level of expression of TMEM175 on microglia compared to those observed in neurons, suggesting a possible role of the protein in the inflammatory mechanism underlying neurodegenerative diseases. **Conclusion**: Our data suggest a key role for the mutations identified in *TMEM175* in inflammatory and autophagic processes paving the way for novel therapeutic approaches.

Backgound GBA1 mutations are the most common known genetic cause of Parkinson's disease (PD). Its biological pathway may be important, since activity of the enzyme encoded by glucocerebrosidase (GCase) is reduced even among individuals with GBA mutations (GBA-carriers). Several studies have also suggested that *GBA1* dysfunction may lead to general lysosomal dysfunction and disruption of autophagy *Aim*
To study the effect of *GBA1* mutations on autophagy in primary macrophages from patients with PD and GBA-carriers. *Materials and Methods* Spontaneous autophagy in primary macrophages of GBA1-PD patients (N=9), GBA1-carriers (N=10) and controls (N=12) was assessed by Autophagy Detection kit (Abcam, UK) using a specific dye autophagosomes marker LC3-II. Primary macrophages were cultured as described earlier (Kopytova A et al., 2021.10;84:112-121) *Results* For the first time we detected an increased concentration of autophagosomes, due to an increased concentration of the LC3-II marker in primary macrophages from GBA1-carriers 14.45 (9.60-21.38) CU and GBA1-PD patients 15.60 (6.70-22.62) CU compared to controls 10.33 (6.21- 12.70) CU ($p=0.003$ and $p=0.027$), respectively. An increased number of autophagosomes in macrophages may indicate a defect in macro-autophagy pathway due to autophagosomes inability for proper fusion with the lysosome. The *GBA1* mutations severity effect on autophagy was not detected. *Conclusion* Our results suggest that GBA1 mutations could lead to autophagy disfunction independent of PD status. The study was funded by RSF №19-15-00315.

Ambroxol increases glucocerebrosidase (GCase) activity and restores GCase translocation in primary patient-derived macrophages in Gaucher disease and Parkinsonism.
Mutations in the glucocerebrosidase gene (GBA) encoding the lysosomal enzyme glucocerebrosidase (GCase) cause Gaucher disease (GD) and are the most commonly known genetic risk factor for Parkinson disease (PD). Ambroxol is one of the most effective pharmacological chaperones of GCase. Fourteen GD patients, six PD patients with mutations in the GBA gene (GBA-PD), and thirty controls were enrolled. GCase activity and hexosylsphingosine (HexSph) concentration were measured in dried blood and macrophage spots using liquid chromatography coupled with tandem mass spectrometry. The effect of ambroxol on GCase translocation to lysosomes was assessed using confocal microscopy. The results showed that ambroxol treatment significantly increased GCase activity in cultured macrophages derived from patient blood monocytic cell (PBMC) of GD (by 3.3-fold) and GBA-PD patients (by 3.5-fold) compared to untreated cells ($p < 0.0001$ and $p < 0.0001$, respectively) four days after cultivation. Ambroxol treatment significantly reduced HexSph concentration in GD (by 2.1-fold) and GBA-PD patients (by 1.6-fold) ($p < 0.0001$ and $p < 0.0001$, respectively). GD macrophage treatment resulted in increased GCase level and increased enzyme colocalization with the lysosomal marker LAMP2. The possible binding modes of ambroxol to mutant GCase carrying N370S amino acid substitution at pH 4.7 were examined using molecular docking and molecular dynamics simulations. The ambroxol position characterized by minimal binding free energy was observed in close vicinity to the residue, at position 370. Taken together, these data showed that PBMC-derived macrophages could be used for assessing ambroxol therapy response for GD patients and also for GBA-PD patients.

Plasma cytokine profile in synucleinophaties with dementia.
Immune response may play a pivotal role in the pathogenesis of the common synucleinopathy as Parkinson's disease (PD) and could be mediated with the accumulation of neurotoxic alpha-synuclein. There is limited evidence for immune response in another synucleinopathy as dementia with Lewy bodies (DLB). Recent data suggest that immune response may contribute to cognitive impairment. We aimed to estimate plasma cytokine profile in patients with synucleinopathies with dementia (PD dementia (PDD), DLB). Plasma cytokine levels (interferon-gamma (IFN-gamma), interleukin (IL)-4 (IL-4), IL-6, IL-10, tumor necrosis factor alpha (TNF-alpha), monocyte chemoattractant protein-1 (MCP-1)). were estimated in 16 patients with DLB, 19 patients with PDD, 28 patients with PD without dementia (PD) and 19 individuals without neurological disorders (controls) using Luminex array system. Cognitive status was assessed with the Mini-Mental State Examination (MMSE). TNF-alpha and IL-6 plasma levels were elevated in patients with synucleinopathies with dementia (DLB, PDD) compared to controls and IL-10 plasma level was increased in PDD compared to controls ($p < 0.05$). IFN-gamma levels were decreased in PD and PDD patients compared to controls ($p < 0.001$, $p = 0.026$, respectively) and in PD patients than in DLB patients ($p = 0.032$). Patients with PD, PDD, and DLB were characterized by increased plasma levels of MCP-1 compared to controls ($p < 0.001$). At the same time, no differences in TNF-alpha, IL-10, IL-6 plasma levels in PD patients compared to controls were found. Our study demonstrated more pronounced immune response in synucleinopathies associated with dementia compared to PD without demetia.

Mutation analysis of Parkinson's disease genes in a Russian data set.
Common variants and risk factors related to familial and sporadic cases of Parkinson's disease (PD) in diverse populations have been identified at numerous genomic loci. In this study, genetic analysis was performed through a screening of LRRK2 G2019S, GBA mutations (L444P, N370S), and common variants (E326K, T369M) in 762 PD patients and in 400 controls. Next-generation sequencing analysis of 22 PD-related genes in 28 early-onset PD cases from North-Western region of Russia was performed. The frequency of LRRK2 G2019S mutation was 5.8% in familial and 0.5% in sporadic PD cases. The frequency of GBA mutations (L444P, N370S) in PD patients was higher compared to controls (odds ratio [OR] = 6.9, 95% confidence interval [CI], 0.9-53.13, $p = 0.031$), particularly in patients with early-onset compared to late-onset PD (OR = 3.90 [95% CI, 1.2-13.2], $p = 0.009$). The frequency of E326K and T369M was twice higher among PD patients than in controls (OR = 2.24, 95% CI 1.05-4.79, $p = 0.033$). However, the screening of 22 PD-related genes using our novel panel of gene resequencing in our series of 28 early-onset PD failed to identify any mutations. LRRK2 and GBA mutations were found to be common risk factors for PD in North-Western region of Russia.

[Regulation of ABCA1 and ABCG1 gene expression in the intraabdominal adipose tissue].
Tissue specific expression of genes encoding cholesterol transporters ABCA1 and ABCG1 as well as genes encoding the most important transcriptional regulators of adipogenesis - LXRa, LXRb, PPARg and RORa has been investigated in intraabdominal adipose tissue (IAT) samples.A direct correlation between the content of ABCA1 and ABCG1 proteins with RORa protein level ($r=0.480$, $p<0.05$; $r=0.435$, $p<0.05$, respectively) suggests the role of the transcription factor RORa in the regulation of IAT ABCA1 and ABCG1 protein levels. ABCA1 and ABCG1 gene expression positively correlated with obesity indicators such as body mass index (BMI) ($r=0.522$, $p=0.004$; $r=0.594$, $p=0.001$, respectively) and waist circumference ($r=0.403$, $p=0.033$; $r=0.474$, $p=0.013$, respectively). The development of obesity is associated with decreased IAT levels of RORa and LXRb mRNA ($p=0.016$ and $p=0.002$, respectively). These data suggest that the nuclear factor RORa can play a significant role in the regulation of cholesterol metabolism and control IAT expression of ABCA1 and ABCG1, while the level of IAT LXRb gene expression may be an important factor associated with the development of obesity.

[SNCA rs356219 AND rs356165 VARIANTS ARE ASSOCIATED WITH PARKINSON'S DISEASE AND INCREASED ALPHA-SYNUCLEIN GENE EXPRESSION IN THE CD45(+)-BLOOD CELLS].
Impaired metabolism of alpha-synuclein (SNCA) and its aggregation are now implicated in the pathogenesis of Parkinson's disease (PD). Previous studies have found association between PD and gene locus, containing the SNCA gene. Meta-analysis have shown high significant association of single nucleotide polymorphisms (SNPs) rs356165 (A/G) and rs356219 (A/G) in the SNCA gene with PD. We genotyped these SNPs in 260 PD patients and 262 controls from north-western region

of Russia. Alleles "G" of rs356165 and rs356219 were associated with increased risk of PD development. Linkage disequilibrium was shown between associated marker alleles. We studied the relationship between rs356165 and rs356219 and levels of mRNA SNCA and alpha-synuclein in CD45+ peripheral blood cells in drug-naive PD patients (n = 43) and controls (n = 39). Alleles "G" of rs356165 and rs356219 were associated with increased levels of SNCA expression (p = 0.046) and high alpha-synuclein levels (p = 0.039) in controls. Our data suggest that rs356165 and rs356219 variants might influence on PD development by upregulating SNCA expression.

Increased plasma oligomeric alpha-synuclein in patients with lysosomal storage diseases.
A link between lysosomal storage diseases (LSDs) and neurodegenerative disorders associated with accumulation of presynaptic protein alpha-synuclein has been shown. Particularly, Gaucher disease (GD) patients with a deficiency of the lysosomal enzyme glucocerebrosidase (GBA) and carriers of GBA mutations are at increased risk of Parkinson's disease (PD). It remains unclear whether this link is due to increased alpha-synuclein oligomerization. Here we show that level of oligomeric alpha-synuclein form, associated with PD development, is increased in plasma of GD patients (n=41, median=22.9pg/mL, range1.57-444.58pg/mL; controls (n=40, median=6.02pg/mL, range 1.05-103.14pg/mL, p<0.0001). This difference is absent in GD patients receiving enzyme replacement therapy (ERT) for more than 5 years. Moreover, the levels of alpha-synuclein oligomers in plasma are also higher in patients with other LSDs (Niemann-Pick type C, Krabbe disease, Wolman disease) compared to the median value in controls. Therefore, we suggest that mutations in the GBA gene and at least in several other LSDs genes may be associated with an increase in oligomeric alpha-synuclein in plasma. ERT applied for recovering of GBA functions in GD treatment might decrease formation of plasma oligomeric alpha-synuclein.

Parkinson's disease (PD) is a progressive neurodegenerative disease that affects movement. Its exact etiology is not completely understood. Oxidative stress is considered as one of the factors involved in the pathogenesis of PD. Pyrrole containing compounds are used in a very diverse range of pharmaceuticals products and its derivatives have shown various type of biologic activity such as anti-inflammation and antinociception. we evaluated for the first time, the neuroprotective effect of pyrrole derivative compounds as a potential neuroprotective agent in an *in vitro* model of PD. In the current study we applied three novel synthetic pyrrole derivative compounds 2-(4-chlorophenyl)-5-methyl-1-(4-(trifluoromethoxy)phenyl)-1H-pyrrole, 2-(4-chlorophenyl)-1-(4-methoxyphenyl)-5-methyl-1H-pyrrole and 1-(2-chlorophenyl)-2-(4-chlorophenyl)-5-methyl-1H-pyrrole to investigate their potential neuroprotective effects. PC12 cell line incubated with 6-hydroxydopamine (6-OHDA) to induce cell damage. PC12 cells were pre-treated with pyrrole compounds for 24 hours prior exposed to 6-OHDA. Cell viability assay (MTT), apoptosis (Hoechst staining, Annexin V), oxidative stress (ROS, lipid peroxidation assays), were performed to evaluate their neuroprotective effect. we demonstrated pretreatment with pyrrole derivates compounds for 24 h protected the PC12 cells against 6-OHDA neurotoxicity. This protective role is associated with the increased cell viability. In addition, pyrrole derivates compounds suppressed 6-OHDA mediate cell death by decreasing intracellular ROS and attenuating intracellular lipid peroxidation, which led to apoptosis cell death revealing by Hoechst and Annexin-positive cells.These findings suggest that the synthetic pyrrole derivates exerts neuroprotective effects in this *in vitro* model of PD likely through antioxidation mechanisms. Therefore, they could be considered as the potential neuroprotective strategy to suppress the PD progression.

The involvement of ventral hippocampal microglial cells, but not cannabinoid CB1 receptors, in morphine-induced analgesia in rats.
It is well known that glial cells are involved in pain processing. The purpose of the present study was to investigate the possible involvement of the ventral hippocampal (VH) glial cells in morphine-induced analgesia. A tail-flick apparatus was used to measure pain sensitivity in male Wistar rats that were bilaterally cannulated in the VH by stereotaxic surgery. The results showed that intraperitoneal (i.p.) administration of morphine (2.5-7.5 mg/kg) induced analgesia in a time-dependent manner. The blockade of the VH glial cell activation by bilateral microinjection of a glial inhibitor, minocycline (5-15 µg/rat) into the VH with an ineffective dose of morphine (2.5 mg/kg, i.p) significantly increased morphine analgesia. Considering that the endocannabinoid system via CB1 receptors play a crucial role in pain modulation, we also assessed the possible role of the VH cannabinoid CB1 receptors in the functional interaction between minocycline and morphine in acute pain. Our results indicated that intra-VH injection of the cannabinoid CB1 receptor agonist, arachidonylcyclopropylamide (ACPA; 4-12 ng/rat) had no effect on minocycline-induced potentiation of morphine analgesia. It should be considered that intra-VH microinjection of minocycline or ACPA by itself had no effect on tail-flick latency. Our findings suggest that the activation of the VH microglial cells may be involved in mediating pain sensation, because the inhibition of these cells by intra-VH injection of minocycline could potentiate morphine-induced analgesia. Although endocannabinoids have a regulatory role in glia function, the activation of CB1 receptors could not affect the potentiative effect of minocycline on morphine analgesia.

Doxycycline (DOX), an old tetracycline (TC) antibiotic primarily used for skin problems, recently demonstrated its efficacy in model systems that relate to Parkinson disease (PD) neurodegeneration. The aim of the present work was two-fold: (i) establish a model system to further characterize DOX-mediated neuroprotection and (ii) take advantage of this system to discover novel TCs having better protective effects than DOX and no antibiotic activity. For that, we established cultures of mouse midbrain dopamine (DA) neurons and implemented culture conditions in which these neurons degenerate progressively by iron-mediated ferroptosis. The non-antibiotic derivative of demeclocycline (DMC), DDMC was synthesized by reductions of the dimethylamino function at position 4 and the hydroxyl group at position 12a of ring A of DMC. We found that DOX and DDMC efficiently protect DA neurons from degeneration, DDMC being, however, far more potent than DOX, regardless of cell culture age. Live imaging of reactive oxygen species (ROS) and mitochondrial membrane potential with DHR-123 and TMRM, respectively, revealed that DOX and DDMC curtailed intracellular ROS production and preserved mitochondrial function. The iron chelator desferrioxamine, the inhibitor of lipid peroxidation Trolox and the ferroptosis inhibitor liproxstatin-1 reproduced all the effects of DOX and DDMC, indicating that both TCs inhibited iron-dependent ferroptosis. Noticeably, non-TC antibiotics such as streptomycin, erythromycin and penicillin-G failed to reproduce DOX-mediated neuroprotection. Overall, our data indicate that DOX and its non-antibiotic derivative DDMC have the potential to interfere efficiently with ferroptosis pathways that could intervene in PD neurodegeneration.

SAPOSIN C REDUCES LEVELS OF α-SYNUCLEIN AND DISLODGES IT FROM GLUCOSYLCERAMIDE-ENRICHED LIPID MEMBRANES

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Rika Kojima, Mark Zurbruegg, Tianyi Li, Wojciech Paslawski, Xiaoqun Zhang, Per Svenningsson

Aims: This study aims to investigate the molecular mechanisms of the neuroprotective roles of prosaposin (PSAP) and saposin C in α-synuclein pathology in Parkinson's disease (PD). ***Background:*** PSAP is a secreted protein that serves as a neuroprotective factor. PSAP is uptaken by cells and cleaved in the lysosome, yielding four saposins that work as sphingolipid activators. Among four saposins, saposin C is required for the normal function of glucocerebrosidase (GCase). Mutations in the GBA1 gene, which encodes GCase, is one of the most common risk factors of developing PD. Therefore, PSAP and saposin C has been attracting attention as disease modifier of PD. However, the molecular mechanisms underlying the neuroprotective role of PSAP and saposin C remains unclear. ***Methods:*** By genetically modulating the expression levels of PSAP on SH-SY5Y cells, we investigated the effect of PSAP in α-synuclein pathology. Expression levels of α-synuclein in PSAP stable overexpressed cells and PSAP knockdown cells were assessed by qPCR and Western Blot. The binding of α-synuclein to glucosylceramide-enriched lipid membrane under the existence of saposin C was investigated. ***Results:*** Stable overexpression of PSAP significantly decreased both intracellular and extracellular α-synuclein levels. On the contrary, siRNA knockdown of PSAP increased α-synuclein levels. GCase inhibitor treatment demonstrated that the altered levels of α-synuclein were independent of GCase activity. Under the lysosomal pH, saposin C detached α-synuclein from artificial lipid membranes. ***Conclusions:*** PSAP and saposin C can enhance α-synuclein clearance by detaching it from the lysosomal membrane where α-synuclein forms aggregations.

Clock genes and salt-sensitive hypertension: a new type of aldosterone-synthesizing enzyme controlled by the circadian clock and angiotensin II.
With the current societal norm of shiftwork and long working hours, maintaining a stable daily life is becoming very difficult. An irregular lifestyle disrupts circadian rhythms, resulting in the malfunction of body physiology and ultimately leading to lifestyle-related diseases, including hypertension. By analyzing completely arrhythmic Cry1/Cry2 double-knockout (Cry-null) mice, we found salt-sensitive hypertension accompanied by hyperaldosteronism. On the basis of a DNA microarray analysis of the adrenal gland and subsequent biochemical analyses, we discovered that Hsd3b6/HSD3B1, a subtype of 3β-HSD, is markedly overexpressed in aldosterone-producing cells in the Cry-null adrenal cortex. In addition, we found that Hsd3b6/HSD3B1, which converts pregnenolone to progesterone, is a clock-controlled gene and might also be a key enzyme for the regulation of aldosterone biosynthesis, in addition to the previously established CYP11B2, which synthesizes aldosterone from deoxycorticosterone. Importantly, angiotensin II induces HSD3B1 via the transcription factor NGFIB in human adrenocortical H295R cells, similarly to CYP11B2. As HSD3B1 levels are abnormally high in the adrenal aldosterone-producing cells of idiopathic hyperaldosteronism (IHA), the temporal component of this system in the pathophysiology of IHA is a promising area for future research.

Two transcripts regulated by m6A methylation code for two antagonistic kinases in the control of the circadian clock.
The -methylation of internal adenosines (m6A) in mRNA has been quantified and localized throughout the transcriptome. However, the physiological significance of m6A in most highly methylated mRNAs is unknown. It was demonstrated previously that the circadian clock, based on transcription-translation negative feedback loops, is sensitive to the general inhibition of m6A. Here, we show that the Casein Kinase 1 Delta mRNA (), coding for a critical kinase in the control of circadian rhythms, cellular growth, and survival, is negatively regulated by m6A. Inhibition of mRNA methylation leads to increased translation of two alternatively spliced CK1δ isoforms, CK1δ1 and CK1δ2, uncharacterized until now. The

expression ratio between these isoforms is tissue-specific, CK1δ1 and CK1δ2 have different kinase activities, and they cooperate in the phosphorylation of the circadian clock protein PER2. While CK1δ1 accelerates the circadian clock by promoting the decay of PER2 proteins, CK1δ2 slows it down by stabilizing PER2 via increased phosphorylation at a key residue on PER2 protein. These observations challenge the previously established model of PER2 phosphorylation and, given the multiple functions and targets of CK1δ, the existence of two isoforms calls for a re-evaluation of past research when CK1δ1 and CK1δ2 were simply CK1δ.

Methylation deficiency disrupts biological rhythms from bacteria to humans.
The methyl cycle is a universal metabolic pathway providing methyl groups for the methylation of nuclei acids and proteins, regulating all aspects of cellular physiology. We have previously shown that methyl cycle inhibition in mammals strongly affects circadian rhythms. Since the methyl cycle and circadian clocks have evolved early during evolution and operate in organisms across the tree of life, we sought to determine whether the link between the two is also conserved. Here, we show that methyl cycle inhibition affects biological rhythms in species ranging from unicellular algae to humans, separated by more than 1 billion years of evolution. In contrast, the cyanobacterial clock is resistant to methyl cycle inhibition, although we demonstrate that methylations themselves regulate circadian rhythms in this organism. Mammalian cells with a rewired bacteria-like methyl cycle are protected, like cyanobacteria, from methyl cycle inhibition, providing interesting new possibilities for the treatment of methylation deficiencies.

S-adenosyl-l-homocysteine hydrolase links methionine metabolism to the circadian clock and chromatin remodeling.
Circadian gene expression driven by transcription activators CLOCK and BMAL1 is intimately associated with dynamic chromatin remodeling. However, how cellular metabolism directs circadian chromatin remodeling is virtually unexplored. We report that the S-adenosylhomocysteine (SAH) hydrolyzing enzyme adenosylhomocysteinase (AHCY) cyclically associates to CLOCK-BMAL1 at chromatin sites and promotes circadian transcriptional activity. SAH is a potent feedback inhibitor of S-adenosylmethionine (SAM)-dependent methyltransferases, and timely hydrolysis of SAH by AHCY is critical to sustain methylation reactions. We show that AHCY is essential for cyclic H3K4 trimethylation, genome-wide recruitment of BMAL1 to chromatin, and subsequent circadian transcription. Depletion or targeted pharmacological inhibition of AHCY in mammalian cells markedly decreases the amplitude of circadian gene expression. In mice, pharmacological inhibition of AHCY in the hypothalamus alters circadian locomotor activity and rhythmic transcription within the suprachiasmatic nucleus. These results reveal a previously unappreciated connection between cellular metabolism, chromatin dynamics, and circadian regulation.

As medical advances have led to increased life expectancy, ageing-related neurodegenerative diseases are posing a major challenge to global health and economy. Mitochondrial dysfunction is one of the key hallmarks of ageing and contributes to a wide range of age-related diseases, including neurodegenerative conditions such as Parkinson's disease (PD). Healthy mitochondrial populations are maintained by the processes of proteolysis and mitophagy. Mitophagy is the main process that regulates the turnover of dysfunctional mitochondria and recent evidence has pointed out the involvement of key vesicular trafficking proteins, the Ras analog in brain (Rab) family in this process. Rabs are GTPases that regulate multiple steps in membrane trafficking and fusion. With our research, we aim to clarify links between Rab proteins, impaired mitophagy and PD. Specifically, we aim to understand how Rab proteins are altered in PD and how their alterations (both in quantity and their localizations) impact mitochondrial disposal in PD. Our recent work on mitochondrial proteome alterations of cells derived from *PARK2*-mutated PD patients further highlighted the importance of Rabs. Our current work utilising SH-SY5Y neuroblastoma cells revealed an upregulation of Rab5 and Rab7 in the whole-cell proteome and Rab9 in the mitochondrial proteome in dopamine-treated cells compared to control cells. The possibility to modulate proper mitochondrial clearance is an unexplored therapeutic possibility in PD treatment. Beyond PD, our data may also be relevant to the understanding of the role of Rab GTPases in the biology of mitochondria in normal physiology and possibly in diseases other than PD.

Repeat Expansion Affects the Proteome of Primary Skin Fibroblasts in ALS.
Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease characterized by progressive degeneration of the corticospinal motor neurons, which ultimately leads to death. The repeat expansion in chromosome 9 open reading frame 72 () represents the most common genetic cause of ALS and it is also involved in the pathogenesis of other neurodegenerative disorders. To offer insights into -mediated pathogenesis, we quantitatively analyzed the proteome of patient-derived primary skin fibroblasts from ALS patients carrying the mutation compared with ALS patients who tested negative for it. Differentially expressed proteins were identified, used to generate a protein-protein interaction network and subjected to a functional enrichment analysis to unveil altered molecular pathways. ALS patients were also compared with patients affected by frontotemporal dementia carrying the repeat expansion. As a result, we demonstrated that the molecular pathways mainly altered in fibroblasts (e.g., protein homeostasis) mirror the alterations observed in -mutated neurons. Moreover, we highlighted novel molecular pathways (nuclear and mitochondrial transports, vesicle trafficking, mitochondrial bioenergetics, glucose metabolism, ER-phagosome crosstalk and Slit/Robo signaling pathway) which might be further investigated as -specific pathogenetic mechanisms. Data are available via ProteomeXchange with the identifier PXD023866.

Contextual fear conditioning is enhanced in mice lacking functional sphingosine kinase 2.
The lipid sphingosine 1-phosphate (S1P) is a potent neuroprotective signalling molecule that signals through its own family of five G-protein coupled receptors. S1P signalling enhances presynaptic glutamate release and is essential for neural development. S1P is synthesized by the enzymes sphingosine kinases 1 and 2 (SPHK1 and SPHK2), of which SPHK2 mRNA and activity is more abundant in the brain. In this study we investigated the consequences of global SphK2 knockout (SphK2) on basic motor capabilities, anxiety, learning, and memory in mice, using a range of tests including the elevated plus maze, the cheeseboard, contextual and cued fear conditioning, and fear extinction. Loss of SphK2 resulted in an 85-90% reduction in brain S1P levels, and was associated with a notably higher freezing response in a novel context. SphK2 knockout mice also exhibited increased contextual fear conditioning but the extinction of contextual fear memory was similar

to control mice. SphK2 mice, contrary to their control littermates, did not respond to cue presentation with increased freezing. Anxiety measures in the elevated plus maze were not different between SphK2 mice and control littermates. Also, knockout mice showed no deficits in neurological reflexes or motor functions, and performed as well as their control littermates in the spatial memory test. Our findings demonstrate that SphK2 is responsible for the vast majority of S1P synthesis in the mouse brain, and plays a role in freezing responses as evaluated in the fear conditioning paradigm.

Unraveling the molecular mechanism governing the tissue specific expression of IFNλR1.
The functional receptor for type III interferons (IFNs) is a heterodimer of IFNLR1 and IL10R2. IFNLR1 is expressed in a highly tissue specific manner, with epithelial and liver tissue as the prime expressing tissues in humans. However, knowledge about the molecular pathways responsible for regulating the expression of IFNLR1 is yet unknown. In this study, various bioinformatics tools were used to predict the scores of signal peptides of IFNλR1 and IFNαR1, which was considered as an important difference in the expression of both receptors or participation in regulating the IFNLR1 gene. In silico study revealed that the signal peptide of IFNαR1 had more potential than the signal peptide of IFNλR1 but changing the signal peptide of wild type IFNλR1 with the signal peptide of IFNαR1 in wet lab had barely shown any differences. Selective expression of IFNλR1 was considered to be a plus point towards the targeted anti-viral activity of IFNλs but artificial control on its expression will surely make IFNλs a better drug with enhanced activity. The results of this study may help us in contributing some understanding towards the mechanisms involved in the selective expression of IFNLR1 and exceptionalities involved.

STRUCTURAL 3D MODELING OF VMAT2 MUTANTS TO IMPROVE DIAGNOSTIC AND THERAPEUTIC TREATMENT OF INFANTILE PARKINSONISM

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Reem Alkhater[1,2], Kelly Cardona-Londoñ[1], Hubert Fiumelli[1], Stefan Arold[1], Pierre Magistretti[1]
[1]King Abdullah University of science and technology, Bioscience And Environmental Science, Thuwal, Saudi Arabia, [2]Johns Hopkins Aramco, Pediarics, Dhahran, Saudi Arabia

Genomic medicine provides considerable potential for novel diagnostic targets and therapeutic solutions. We have previously reported the first mutation in type 2 vesicular monoamine transporter (VMAT2) causing an infantile Parkinsonism phenotype. Since then, many more mutations have been identified in VMAT2, giving rise to a spectrum of symptoms with variable responses to treatment. Here, we analyze the molecular impact of the VMAT2 mutations in silico to better understand the pathophysiology and improve treatment approaches. We based our analysis on the high-confidence three-dimensional structure of the VMAT2 protein produced by the AI-based Alphafold2 algorithm. The model was manually inspected, and mutations were evaluated using the Pymol program. Additionally, residue conservation was assessed with Consurf, and pathogenicity was predicted with Polyphen-2, Mutpred2, and Snpeff. We correlated the VMAT2 structural changes due to mutations with phenotypes. We found that some mutations lead to the removal of important portions of the protein, which impairs the transmembrane transporter function, leaving gene therapy the only effective treatment for patients bearing these mutations. Other mutations cause destabilization of VMAT2 affecting interactions with other proteins and regulatory activities. These alterations are compatible with disease phenotypes explained by reduced serotonin transport, and thus can be treated by modifying serotonin transmission in the brain. Collectively, our structure-phenotype analysis advances our understanding of the disease, and may provide insights for creating personalized management protocols in this disease particularly and in Parkinson’s disease.

Parkinson's Disease (PD) is characterized by the degeneration of the *substantia nigra* dopaminergic (DA) neurons, leading to severe motor symptoms. Several lines of evidence emphasize mitochondrial impairment's role in PD; however, the molecular mechanisms underlying DA neurons' specific vulnerability to mitochondrial stress in PD remain poorly understood. **Objectives:** We aim to unbiasedly characterise the mitochondrial stress response of human DA neurons at the transcriptome level. To discover specific molecular mechanisms underlying their vulnerability to mitochondrial stress, we include analysis of highly cell-specific genomic non-coding elements, such as long non-coding RNAs (lncRNAs) and open regions of the chromatin (ORCs). **Methods:** Using RNA-seq and ATAC-seq, we generated datasets from Lund Human MESencephalic cells-derived DA neurons, in control or mitochondrial stress conditions. We confirmed the activation of several pathways upon stress using RT-QPCR, immunofluorescence and Western Blot. **Results:** We demonstrated, for the first time, concomitant activation of several endoplasmic reticulum Unfolded Protein Response (UPR) pathways in human DA neurons upon mitochondrial stress, leading to apoptotic engagement. Our results also suggested altered DA identity following stress, a potential protective mechanism. Importantly, we identified lncRNAs specifically expressed (19%) or inhibited (33%) following stress. Analysis of these lncRNAs and putative gene targets suggested their contribution to specific steps of DA neurons' stress response, such as translation regulation, mediated by the mTOR pathway, which is altered in PD. **Conclusions:** Altogether this study provides invaluable knowledge to 2) identify critical elements of DA neurons' response to mitochondrial stress 2) understand the specific contribution of lncRNAs to this response.

Mitochondrial bioenergetic dysfunction is known to play a key role in Parkinson's pathogenesis and other neurodegenerative diseases. As part of the PD-MitoQUANT project (www.pdmitoquant.eu), we combined a systems model of mitochondrial bioenergetics with biochemical studies to pinpoint and explore bioenergetic molecular dysfunction in Parkinson's disease. We first performed sensitivity analysis and unsupervised clustering to computationally predict the impact of mitochondrial respiratory chain defects on key bioenergetic parameters. We also simulated heterogeneous cell populations to explore the effects of single-cell variability on population-level mitochondrial function. We next applied this systems modelling approach to predict the mitochondrial defects underlying experimental phenotypes observed in an alpha-synuclein cellular model of Parkinson's. Model simulations predicted that, while some experimental findings can be explained by isolated mitochondrial defects such as an impaired proton leak or reduced substrate supply, other findings are likely caused by defects outside the mitochondrial respiratory chain. These predictions will be further validated by integrating additional experimental data such as mitochondrial membrane potential (TMRM), ATP and ROS levels. In summary, we here provide an in-depth computational resource detailing the effects of mitochondrial dysfunction on key bioenergetic parameters. Our systems modelling approach informs and complements experimental design to pinpoint critical defects underlying neurodegenerative phenotypes.

DNA METHYLATION AND EXPRESSION PROFILES OF WHOLE BLOOD IN PARKINSON'S DISEASE

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Erika Driver-Dunckley[1], Travis Dunckley[2], Adrienne Henderson[2]
[1]Mayo Clinic Scottsdale, Neurology, Scottsdale, United States of America, [2]Arizona State University, Neurodegenerative Disease Research Center, Tempe, United States of America

Parkinson's disease (PD) is the second most common age-related neurodegenerative disease. It is presently only accurately diagnosed at an advanced stage by a series of motor deficits, which are predated by non-motor symptoms manifesting over years. Aberrant epigenetic modifications are non-invasively detectable in blood as potential markers of disease. We performed comparative analyses of the methylome and transcriptome in blood from PD patients and matched controls. Our aim was to characterize DNA methylation and gene expression patterns in whole blood from PD patients as an initial step toward the future goal of identifying molecular markers that could predict, accurately diagnose, or track the progression of PD. We found that differentially expressed genes (DEGs) were involved in the processes of transcription and mitochondrial function and that PD methylation profiles were readily distinguishable from healthy controls. Differentially methylated regions (DMRs) were functionally varied, including near transcription factor nuclear transcription factor Y subunit alpha (*NFYA*), receptor tyrosine kinase *DDR1*, RING finger ubiquitin ligase (*RNF5*), acetyltransferase *AGPAT1*, and vault RNA *VTRNA2-1*. Expression quantitative trait methylation (eQTM) sites were found at long non-coding RNA *PAX8-AS1* and transcription regulator *ZFP57* among others. Functional epigenetic modules were highlighted by *IL18R1*, *PTPRC*, and *ITGB2*. We identified patterns of disease-specific DNA methylation and associated gene expression in whole blood. Our combined analyses extended what we learned from the DEG or DMR results alone. These studies provide a foundation to support the characterization of larger sample cohorts, with the goal of building a thorough, accurate, and non-invasive molecular PD biomarker.

Aims Parkinson's disease (PD) is the second most common and the fastest growing neurodegenerative disease. Although some of the underlying cellular and molecular mechanisms of PD have been described we, still lack the insight that allows for the development of efficient therapies beyond dopamine replacement. The goal of our research is to determine the cell type-specific transcriptomic changes and biological pathways that are affected by PD in the human striatum, one of the key brain regions, in order to open new therapeutic approaches. **Methods** We used single-cell RNA sequencing (scRNA-seq) to analyze post-mortem human tissue samples from a broad cohort of PD patients and control subjects. The transcriptomic data was subjected to a computational analysis aimed at discovering the cellular diversity of the striatum and the changes induced by the disease. **Results** Our analysis revealed the cellular composition in the caudate and the putamen, characterizing each cell type by a unique transcriptomic pattern. Among all the cell types, we found that the medium-spiny neurons were the cells most affected by the disease, exhibiting significant changes in the expression of more than 60 genes. Other cell types presented fewer changes that are still under analysis. **Conclusions** PD induces clear cell type-specific alterations in the transcriptome of the human striatum. These alterations span multiple biological pathways, and they include both genes known to be linked to the disease and previously undocumented ones. The dataset generated in this study represents an invaluable source for the identification of disease biomarkers and treatment development.

Membrane Poration Mechanisms at the Cell-Nanostructure Interface.
3D vertical nanostructures have become one of the most significant methods for interfacing cells and the nanoscale and for accessing significant intracellular functionalities such as membrane potential. As this intracellular access can be induced by means of diverse cellular membrane poration mechanisms, it is important to investigate in detail the cell condition after membrane rupture for assessing the real effects of the poration techniques on the biological environment. Indeed, differences of the membrane dynamics and reshaping have not been observed yet when the membrane-nanostructure system is locally perturbed by, for instance, diverse membrane breakage events. In this work, new insights are provided into the membrane dynamics in case of two different poration approaches, optoacoustic- and electro-poration, both mediated by the same 3D nanostructures. The experimental results offer a detailed overview on the different poration processes in terms of electrical recordings and membrane conformation.

Inkjet-printed PEDOT:PSS multi-electrode arrays for low-cost in vitro electrophysiology.
Multi-electrode arrays (MEAs) have become a key element in the study of cellular phenomena in vitro. Common modern MEAs are still based on costly microfabrication techniques, making them expensive tools that researchers are pushed to reuse, compromising the reproducibility and the quality of the acquired data. There is a need to develop novel fabrication strategies, able to produce disposable devices that incorporate advanced technologies beyond the standard metal electrodes on rigid substrates. Here we present an innovative fabrication process for the production of polymer-based flexible MEAs. The device fabrication exploited inkjet printing, as this low-cost manufacturing method allows for an easy and reliable patterning of conducting polymers. Poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) was used as the sole conductive element of the MEAs. The physical structure and the electrical properties of the plastic/printed MEAs

(pMEAs) were characterised, showing a low impedance that is maintained also in the long term. The biocompatibility of the devices was demonstrated, and their capability to successfully establish a tight coupling with cells was proved. Furthermore, the pMEAs were used to monitor the extracellular potentials from cardiac cell cultures and to record high quality electrophysiological signals from them. Our results validate the use of pMEAs as in vitro electrophysiology platforms, pushing for the adoption of innovative fabrication techniques and the use of new materials for the production of MEAs.

Cost-effective and multifunctional acquisition system for in vitro electrophysiological investigations with multi-electrode arrays.
In vitro multi-electrode array (MEA) technology is nowadays involved in a wide range of applications beyond neuroscience, such as cardiac electrophysiology and bio-interface studies. However, the cost of commercially available acquisition systems severely limits its adoption outside specialized laboratories with high budget capabilities. Thus, the availability of low-cost methods to acquire signals from MEAs is important to allow research labs worldwide to exploit this technology for an ever-expanding pool of experiments independently from their economic possibilities. Here, we provide a comprehensive toolset to assemble a multifunctional in vitro MEA acquisition system with a total cost 80% lower than standard commercial solutions. We demonstrate the capabilities of this acquisition system by employing it to i) characterize commercial MEA devices by means of electrical impedance measurements ii) record activity from cultures of HL-1 cells extracellularly, and iii) electroporate HL-1 cells through nanostructured MEAs and record intracellular signals.

Structure-based classification of FAD binding sites: A comparative study of structural alignment tools.
A total of six different structural alignment tools (TM-Align, TriangleMatch, CLICK, ProBis, SiteEngine and GA-SI) were assessed for their ability to perform two particular tasks: (i) discriminating FAD (flavin adenine dinucleotide) from non-FAD binding sites, and (ii) performing an all-to-all comparison on a set of 883 FAD binding sites for the purpose of classifying them. For the first task, the consistency of each alignment method was evaluated, showing that every method is able to distinguish FAD and non-FAD binding sites with a high Matthews correlation coefficient. Additionally, GA-SI was found to provide alignments different from those of the other approaches. The results obtained for the second task revealed more significant differences among alignment methods, as reflected in the poor correlation of their results and highlighted clearly by the independent evaluation of the structural superimpositions generated by each method. The classification itself was performed using the combined results of all methods, using the best result found for each comparison of binding sites. A number of different clustering methods (Single-linkage, UPGMA, Complete-linkage, SPICKER and k-Means clustering) were also used. The groups of similar binding sites (proteins) or clusters generated by the best performing method were further analyzed in terms of local sequence identity, local structural similarity and conservation of analogous contacts with the FAD ligands. Each of the clusters was characterized by a unique set of structural features or patterns, demonstrating that the groups generated truly reflect the structural diversity of FAD binding sites. Wnt5a Deficiency Leads to Anomalies in Ureteric Tree Development, Tubular Epithelial Cell Organization and Basement Membrane Integrity Pointing to a Role in Kidney Collecting Duct Patterning.
The Wnts can be considered as candidates for the Congenital Anomaly of Kidney and Urinary Tract, CAKUT diseases since they take part in the control of kidney organogenesis. Of them Wnt5a is expressed in ureteric bud (UB) and its deficiency leads to duplex collecting system (13/90) uni- or bilateral kidney agenesis (10/90), hypoplasia with altered pattern of ureteric tree organization (42/90) and lobularization defects with partly fused ureter trunks (25/90) unlike in controls. The UB had also notably less tips due to Wnt5a deficiency being at E15.5 306 and at E16.5 765 corresponding to 428 and 1022 in control ($p<0.02$; $p<0.03$) respectively. These changes due to Wnt5a knock out associated with anomalies in the ultrastructure of the UB daughter epithelial cells. The basement membrane (BM) was malformed so that the BM thickness increased from 46.3 nm to 71.2 nm ($p<0.01$) at E16.5 in the Wnt5a knock out when compared to control. Expression of a panel of BM components such as laminin and of type IV collagen was also reduced due to the Wnt5a knock out. The P4ha1 gene that encodes a catalytic subunit of collagen prolyl 4-hydroxylase I (C-P4H-I) in collagen synthesis expression and the overall C-P4H enzyme activity were elevated by around 26% due to impairment in Wnt5a function from control. The compound Wnt5a+/-;P4ha1+/- embryos demonstrated Wnt5a-/- related defects, for example local hyperplasia in the UB tree. A R260H WNT5A variant was identified from renal human disease cohort. Functional studies of the consequence of the corresponding mouse variant in comparison to normal ligand reduced Wnt5a-signalling in vitro. Together Wnt5a has a novel function in kidney organogenesis by contributing to patterning of UB derived collecting duct development contributing putatively to congenital disease.

Comparison of non-sequential sets of protein residues.
A methodology for performing sequence-free comparison of functional sites in protein structures is introduced. The method is based on a new notion of similarity among superimposed groups of amino acid residues that evaluates both geometry and physico-chemical properties. The method is specifically designed to handle disconnected and sparsely distributed sets of residues. A genetic algorithm is employed to find the superimposition of protein segments that maximizes their similarity. The method was evaluated by performing an all-to-all comparison on two separate sets of ligand-binding sites, comprising 47 protein-FAD (Flavin-Adenine Dinucleotide) and 64 protein-NAD (Nicotinamide-Adenine Dinucleotide) complexes, and comparing the results with those of an existing sequence-based structural alignment tool (TM-Align). The quality of the two methodologies is judged by the methods' capacity to, among other, correctly predict the similarities in the protein-ligand contact patterns of each pair of binding sites. The results show that using a sequence-free method significantly improves over the sequence-based one, resulting in 23 significant binding-site homologies being detected by the new method but ignored by the sequence-based one.

How many protein-protein interactions types exist in nature?
"Protein quaternary structure universe" refers to the ensemble of all protein-protein complexes across all organisms in nature. The number of quaternary folds thus corresponds to the number of ways proteins physically interact with other proteins. This study focuses on answering two basic questions: Whether the number of protein-protein interactions is limited and, if yes, how many different quaternary folds exist in nature. By all-to-all sequence and structure comparisons, we grouped the protein complexes in the protein data bank (PDB) into 3,629 families and 1,761 folds. A statistical model was introduced to obtain the quantitative relation between the numbers of quaternary families and quaternary folds in nature. The total number of possible protein-protein interactions was estimated around 4,000, which indicates that the current protein repository contains only 42% of quaternary folds in nature and a full coverage needs approximately a quarter century of experimental effort. The results have important implications to the protein complex structural modeling and the structure genomics of protein-protein interactions.

IDENTIFICATION OF POTENTIAL NEW GENES INVOLVED IN AUTOSOMAL RECESSIVE FORMS OF PARKINSON'S DISEASE

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Christelle Tesson, Aurélie Honoré, Hélène Bertrand, Valérie Drouet, Suzanne Lesage, Alexis Brice
Sorbonne Université, Institut du Cerveau - Paris Brain Institute - ICM, Inserm, CNRS, APHP, Hopital De La Pitie Salpetriere, Paris, France

Parkinson disease (PD) affects 1% of the population above 65 years. It is characterized by the triad of symptoms: tremor, rigidity, and bradykinesia. To date the identified genes associated with early-onset (EO, >40 years) autosomal recessive (AR) PD only explain 45%, other genes remain to be discovered. The aim of the work is to identify new genes involved in AR EO PD, using consanguineous PD families and applying genotyping on DNA microarrays and NGS technologies. Using a series of 99 families with confirmed consanguinity, we looked for homozygous loss of function or missense mutations predicted deleterious in region of loss of homozygosity. Then we firstfocused on variant shared by at least two families. We identified mutations in *PSMF1* an interactor of *FBXO7*. In one families, it remains only this variant moreover both mutations code for amino acid highly conserved upon evolution. Most of the candidate's genes are private genes highlighting genetic heterogeneity of PD. Therefore, in a second time we hypothesized that some candidate's genes can be involved in a common pathway. Using ClusterProfiler we performed GO term enrichment analyses, then we were able to grouped together some genes and were able to see an statistical enrichment in autophagy pathway. We identified a strong candidate gene for AR-PD: *PSMF1*. Further functional data are needed to strengthen the role of this gene in PD, possibly affecting the proteasome activity and α-synucleine aggregation. We will also continue to investigate pathway analyses in order to identify candidates for PD in our families.

Glial cell line-derived neurotrophic factor (GDNF) protects dopaminergic (DA) neurons and reduces motor symptoms, when applied in the striatum, in toxin-induced Parkinson’s disease models. Furthermore, GDNF protects DA neurons against alpha-synuclein propagation in mice model. However, clinical trials based on intraputaminal GDNF delivery have so far failed to demonstrate significant clinical benefits. GDNF interference with dopamine homeostasis via time and dose-dependent neurochemical effects is one of the explanations for poor clinical outcome. Our hypothesis is that these neurochemical effects could be deleterious and mask or reduce GDNF beneficial effect. Methods We have described a doxycycline (dox)-regulated viral vector (AAV-DoxON-GDNF) which allows to finely adjust GDNF dose and period of administration at clinically-acceptable antibiotics doses. We have then injected a high dose of the AAV-DoxON-GDNF vector in order to mimic conditions of GDNF overdosing in a unilateral 6-OHDA rat model. Using Dox regulation, we have administered GDNF at 2 different concentrations: 4-fold (GDNF-LOW) and 20-fold (GDNF-HIGH) higher than the endogenous striatal level. The treatment period was 17 weeks either continuously or transiently for 2 weeks with 2 weeks interruptions. Results At 16 weeks post-injection, the GDNF-LOW group and GDNF-HIGH-intermittent groups showed a significant reduction of the behavioral asymmetry while the GDNF-HIGH-continuous group did not show significant improvements. Immunohistochemistry analysis revealing molecular mechanisms of GDNF pro-survival are supporting the use of low GDNF doses. Conclusions GDNF dose is a parameter to take into account in order to improve the clinical outcome in future trials.

Short Tandem Repeats represent 10% of the human genome. Beyond a threshold specific to each locus, a progressive disease manifest which very often affects the central nervous system. Repeat expansion in the ATXN2 gene is known to be responsible for spinocerebellar ataxia type 2, but when the expansion is interrupted it can cause Parkinson's Disease. Repeat sequence expansions in PD patients have also been found the ATXN3 gene. High-throughput whole exome sequencing (WES) plays an important role in the identification of monogenic forms of PD but detects mostly point mutations or small insertions. In this context, we analyzed WES data from our cohort of PD patients enriched in familial and early-onset forms, previously excluded from major PD genes, using ExpansionHunter software. This software allows to estimate the size of the repeats in the target genes. The putative expansions were then validated by Repeat Primed PCR. Our cohort consisted of 827 exomes performed with Rochev3 (n=213), MedExome (n=171) or Twist (n=443) kits. Our bioinformatics analysis allowed us to identify 1 patient who had a repeat size within the pathological confidence range (>55 CAG repeats) in ATXN3 and 6 patients with repeat sizes within the pathological range (>32 CAG repeats) in ATXN2, 2 of whom belonged to the same family. Sequence analysis of the ATXN2 repeat is in progress in 5 patients and has revealed the presence of 4 CAA interruptions in another. These results demonstrate the usefulness of bioinformatic detection of expansions using ExpansionHunter in exome sequencing data of PD patients.

Aims: Recently, the tetracycline antibiotic Demeclocycline (DMC) was reported to prevent neurodegeneration induced by aggregation of the Parkinson's disease (PD)-associated protein a-Synuclein (aSN) (Braun et al., 2021). However, DMC antibiotic activity precludes its potential use for long-term treatments. Our aim was to synthetize a new DMC derivative with no antibiotic activity and better neuroprotective effects. **Methods**: This compound referred as DDMC was synthetized by removal of the dimethylamino function at position 4 and reduction of the hydroxyl group at position 12a on ring A of DMC. Its antibiotic activity was evaluated using Gram (+) and Gram (-) bacterial strains. Inhibition of αSN aggregation assessed *ex-vitro* by ThT and Congo Red assays was complemented by transmission electron microscopy (TEM) analysis and BIS-ANS fluorescence methods. Seeded aggregation induced by αSN preformed fibrils (PFF) was studied on SH-SY5Y-αSN-RFP cells. The pro-inflammatory potential of αSN fibrillary species was tested by measuring the release of TNF-α and glutamate in microglial cells. **Results and conclusions**: DDMC had no antibiotic activity and was more efficient than DMC in preventing αSN amyloid aggregation in *ex-vitro* assays. Using TEM and BIS-ANS methods, we found that fibrillary species formed in the presence of DDMC were morphologically and structurally different. Interestingly, seeding induced in SH-SY5Y cells was significantly reduced when using fibrils formed in the presence of DDMC. Finally, these fibrils were less inflammogenic in microglial cells. Our results suggest that DDMC may be a novel drug candidate for the treatment of PD and other synucleinopathies.

Elevated Humoral Immune Response to SARS-CoV-2 at High Altitudes Revealed by an Anti-RBD "" ELISA.
The severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) has caused a global pandemic with dramatic health and socioeconomic consequences. The Coronavirus Disease 2019 (COVID-19) challenges health systems to quickly respond by developing new diagnostic strategies that contribute to identify infected individuals, monitor infections, perform contact-tracing, and limit the spread of the virus. In this brief report, we developed a highly sensitive, specific, and precise "" ELISA to correctly discriminate previously SARS-CoV-2-infected and non-infected individuals and study population seroprevalence. Among 758 individuals evaluated for anti-SARS-CoV-2 serology in the province of Tucumán, Argentina, we found a weak correlation between antibodies elicited against the RBD, the receptor-binding domain of the Spike protein, and the nucleocapsid (N) antigens of this virus. Additionally, we detected mild levels of anti-RBD IgG antibodies in 33.6% of individuals diagnosed with COVID-19, while only 19% showed sufficient antibody titers to be considered as plasma donors. No differences in IgG anti-RBD titers were found between women and men, neither in between different age groups ranging from 18 to 60. Surprisingly, individuals from a high altitude village displayed elevated and longer lasting anti-RBD titers compared to those from a lower altitude city. To our knowledge, this is the first report correlating altitude with increased humoral immune response against SARS-CoV-2 infection.

IMPACT OF PD IN CAUDATE & PUTAMEN USING SINGLE-CELL TRANSCRIPTOMICS: SPECIAL FOCUS ON OLIGODENDROCYTES AND OPCS

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Juan Manuel Barba Reyes[1], Leonardo Garma[2], Lisbeth Harder[2], Mónica Diez-Salguero[1], Alberto Serrano-Pozo[3], Patrick Dooley[3], Bradley Hyman[3], Ana Muñoz-Manchado[1]
[1]University of Cadiz, Department Of Biotechnology, Biomedicine And Public Health, Cadiz, Spain, [2]Karolinska Institutet, Laboratory Of Molecular Neurobiology, Department Medical Biochemistry And Biophysics, Stockholm, Sweden, [3]Harvard Medical School, Department Of Neurology, Charlestown, United States of America

Parkinson's Disease (PD) is the second most common neurodegenerative disorder. A core feature of this disease is the loss of dopamine signaling in the striatal region of the brain. PD pathology is not fully understood yet which has prevented efficient development of drug treatments of symptoms beyond dopamine replacement that is still fraught with side effects. Oligodendrocytes are the myelinating cells of the central nervous system (CNS), producing multi-layered myelin sheaths around neuronal axons originated from Oligodendrocytes Precursor Cells (OPCs). Oligodendrocytes play a causal role in neurodegenerative disorders such as Multiple Sclerosis, but if these cell types are also involved in the degeneration process of PD is far from understood. Recent investigations have pointed out a potential role of oligodendrocytes in PD: i) Agarwal et al (Nat Commun, 2020) demonstrated in a single-nucleus RNAseq approach from Substantia Nigra and Cortex tissue that Oligodendrocytes differentially expressed genes associated with variants significantly linked with PD in previous Genome Wide Association Studies (GWAS); ii) Bryois et al (Nat Genet, 2020) studied recent GWAS including PD patients, and showed PD to be genetically associated with Oligodendrocytes. Applying single-cell transcriptomics we profiled postmortem nuclei of Putamen and Caudate from PD and control subjects. We provide insights into subtypes of OPCs and Oligodendrocytes in the Putamen and Caudate nucleus and their potential contribution to PD.

Parkinson's disease (PD) remains an incurable neurodegenerative pathology affecting almost 1% of the population beyond the age of 60. The two main factors that account for this therapeutic failure are the late diagnosis, based on the cardinal motor symptoms of the disease appearing when neurodegenerative process has already past rescue, and an incomplete understanding of PD pathophysiology. In this context, using proton nuclear magnetic resonance, we investigated serum and brain metabolic markers in three different animal models of PD, mimicking different stages of the disease assessed by behavioral and histological evaluation, and in 2 cohorts of de novo PD patients. From our translational study, we first highlighted common metabolic dysregulations in serum of the different animal models and PD patients. We propose a promising composite biomarker exhibiting a high level of predictivity for PD diagnosis in its early phase, before motor symptoms appearance. Moreover, mirrored brain and serum dysregulations strongly suggest dysfunctions in the pyruvate metabolism, a central metabolic node to supply cellular energy, as possible therapeutic target. In order to investigate this hypothesis, we therefore pharmacologically blocked mitochondrial pyruvate carrier (MPC) in PD animals.Indeed, as the sole point of entry for pyruvate into the mitochondrial matrix, the MPC plays a crucial role in coordinating glycolytic and mitochondrial activities. MPC blockage improved motor behavior, decreased dopaminergic denervation and reduced mTOR activity and neuroinflammation. This neuroprotective effect could be based on the reorganization of multiple pathways related to energy metabolism.

LOSS OF 'METABOLIC SPIKES' MAY EXPLAIN DOPAMINE DEPLETION IN PARKINSONS'

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Chaitanya Chintaluri, Tim Vogels
IST Austria, Computational Neuroscience And Neurotheory, Klosterneuburg, Austria

In neurons, spontaneous spiking persists in the absence (and even deprivation) of synaptic input. This is perplexing, especially given that spikes are metabolically expensive. Here, we propose a novel theory on the origin of this baseline activity and present its implications using a computational model of substantia nigra dopaminergic neurons (SNcDA) in the context of Parkinsons' disease (PD). Briefly, we hypothesize that neurons keep their ATP levels at a maximum. During synaptic quiescence, neurons are ATP-surplus and ADP-scarce. With ADP availability as the rate-limiting step, ATP production stalls in the mitochondria when energy consumption is low, leading to the formation of toxic Reactive Oxygen Species (ROS)[1,2] which disrupt many cellular processes. We posit that in order to avoid ROS build-up, neurons actively sense their metabolic state and trigger 'metabolic spikes' to restore ATP production. In a metabolic-state-sensing leaky integrate-and-fire neuron we can reproduce the firing patterns reported for the SNcDA neurons[3] and show that the rate of metabolic spiking is primarily dependent on metabolic costs incurred for i) cellular maintenance (i.e., non-spiking costs) and ii) the metabolic cost-per-spike. When we introduce failures to sense, or produce ROS, or when we increase in per-spike costs or non-spiking costs our model neurons cease metabolic spiking, emulating the cellular symptoms of PD[4]. We conclude that metabolic spikes may be an integrated neuronal mechanism that operates in synergy with synaptic integration and forms a basic principle of neural network dynamics. LRRK2 harbors several phosphorylation sites clustered into 2 major groups, a heterologous cluster (controlled by upstream kinases and phosphatases) and an autophosphorylation cluster. Work from our team and others suggest that phosphorylation of the heterologous cluster of LRRK2 correlates to healthy phenotypes whereas, dephosphorylation correlates to phenotypes associated to pathological processes corresponding to PD. PP1 and PP2 were identified as the upstream regulators of the heterologous LRRK2 phosphorylation cluster *in vitro*. Therefore, the goal of this study was to examine the phosphoregulating partners of LRRK2 *in vivo* and characterize phenotypes of LRRK2 phosphorylation. First, we confirmed co-immunoprecipitation of LRRK2 with its identified phosphatases in rat brain lysate. Next, as LRRK2 dephosphorylation has been reported to prime LRRK2 for ubiquitination and degradation, purified LRRK2 phosphomutant and wildtype constructs were tested for stability, integrity in solution by nano-DSF. LRRK2 is known to influence retrograde and post-Golgi trafficking pathways based on GTP-binding and Rab29 expression activates LRRK2 kinase activity. We recently showed that Rab29 when co-expressed with LRRK2 results in a hyperactivation of kinase activity of phosphodead LRRK2. Studying membrane recruitment of LRRK2 and its pathogenic mutants by Rab29 to the trans-golgi network has shown interesting data and expanding this assay to determine any biological alterations that the dephosphorylated mutants of LRRK2 could have in terms of recruitment would give use further evidence of the effects the dephosphorylation of LRRK2 has on cells.

HIPPOCAMPAL DIFFERENTIAL EXPRESSION UNDERLYING THE NEUROPROTECTIVE EFFECT OF Δ9-TETRAHYDROCANNABINOL (THC) MICRODOSE ON OLD MICE

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Guy Shapira
Faculty of Medicine, Tel Aviv University, Department Of Cell And Developmental Biology, Tel Aviv, Israel

Delta-9 tetrahydrocannabinol (THC) is the primary psychoactive compound of the Cannabis plant and an exogenous ligand of the endocannabinoid system (ECS). In past studies, we demonstrated that a microdose of THC (0.002 mg/kg, 3–4 orders of magnitude lower than the standard dose for rodents) exerts a long-term neuroprotective effect in model mice, alleviating damage from acute neurological insults and late-onset neurodegenerative pathology. Assays measuring the impact of the THC teratment on gene expression, morphology and biochemistry of the brain identified significant neurogenesis, increased abundance of anti-inflammatory proteins and reversal of gene expression alterations linked to neurodegeneration and aging. In our follow-up research, we use high-throughput transcriptome profiling of various brain region to investigate the potential benefits of the treatment for Parkinsons Disease, including promotion of cell-survival in vunrable dopaminergic neurons, inhibition of chronic microglial inflammation and resistance to oxidative stress. We highlight the modulation of the Transforming growth factor beta (TGF-β) pathway and known Parkinsons Disease therapeutic targets, such as Sgk1. We propose the THC microdose as a novel treatment for Parkinsons disease and discuss its potential disease-modifying properties when used at the pre-clinical stage.

IMPORTANCE OF MICROENVIRONMENT IN CEREBRAL IN VITRO MODELS FOR PHENOTYPIC SCREENING

POSTER SESSION 06 - SECTION: EMERGING MECHANISMS IN PARKINSON'S DISEASE

Veronique De Conto[1], Vaihere Cheung[1], Natacha Perrin[1], Gregory Maubon[1], Zied Souguir[1], Elodie Vandenhaute[1], Vincent Berezowski[2], Nathalie Maubon[1]
[1]HCS PHARMA, Pharmacology, LOOS, France, [2]Lille Neuroscience & Cognition, Pharmacologie Médicale, Lille, France

Aim: About 90% of drug-candidates failed in clinical trials, in particular in neurology, due to a lack of efficacy. That highlights a lack of relevance in preclinical models, including *in vitro* models, which do not take into account the microenvironment, composed by glial cells and the Extracellular Matrix (ECM). The objective was to study the influence of the microenvironment in cerebral *in vitro* models, in the frame of Parkinson's Disease (PD). **Methods:** First, we analyzed the influence of astrocytes on Luhmes cell sensitivity, a dopaminergic neuronal cell line, in 2D culture. Then, we developed a hyaluronic acid-based hydroscaffold for 3D cell culture, which mimics the ECM, and study the sensitivity of Luhmes cells in this model. Thirdly, we performed a co-culture of Luhmes cells and astrocytes in this matrix, to form a complex model including both the glial and the matricial microenvironments. **Results:** We observed a protective effect of astrocytes in 2D culture. In the hydroscaffold, Luhmes cells displayed a lower sensitivity compared to 2D culture, that was explained by a partial retention of toxic molecules in the matrix, and differences in neuronal protein expression. In the co-culture, we observed spheroids containing both neurons and astrocytes. **Conclusions:** This work highlighted that the microenvironment of neurons can modify the neuronal response *in vitro*, and should thus be considered carefully in academic research and in drug discovery. This model can be now used to study the microenvironment modifications in pathological conditions, and to develop innovative drugs targeting the microenvironment.

GENETIC ABLATION OF THE RHO GTPASE RND3 TRIGGERS DEVELOPMENTAL DEFECTS IN INTERNAL CAPSULE AND THE GLOBUS PALLIDUS FORMATION

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Bahira Zammou
University of Lleida, Irblleida, Lleida, Spain

The forebrain includes the cerebral cortex, the thalamus, and the striatum and globus pallidus (GP) in the subpallium. The formation of these structures and their interconnections by specific axonal tracts take place in a precise and orchestrated time and spatial-dependent manner during development. However, the knowledge of the molecular and cellular mechanisms that are involved is rather limited. Moreover, while many extracellular cues and specific receptors have been shown to play a role in different aspects of nervous system development, including neuron migration and axon guidance, examples of intracellular signaling effectors involved in these processes are sparse. In the present work, we have shown that the atypical RhoGTPase, Rnd3, is expressed very early during brain development and keeps a dynamic expression in several brain regions including the cortex, the thalamus, and the subpallium. By using a gene-trap allele (Rnd3gt) and immunological techniques, we have shown that Rnd3gt/gt embryos display severe defects in striatal and thalamocortical axonal projections (SAs and TCAs, respectively) and defects in GP formation already at early stages. Surprisingly, the corridor, an important intermediate target for TCAs is still present in these mutants. Mechanistically, a conditional genetic deletion approach revealed that Rnd3 is primarily required for the normal development of Medial Ganglionic Eminence-derived structures, such as the GP, and therefore acts non-cell autonomously in SAs and TCAs. In conclusion, we have demonstrated the important role of Rnd3 as an early regulator of subpallium development in vivo and revealed new insights about SAs and TCAs development.

proNGF Involvement in the Adult Neurogenesis Dysfunction in Alzheimer's Disease.
In recent decades, neurogenesis in the adult brain has been well demonstrated in a number of animal species, including humans. Interestingly, work with rodents has shown that adult neurogenesis in the dentate gyrus (DG) of the hippocampus is vital for some cognitive aspects, as increasing neurogenesis improves memory, while its disruption triggers the opposite effect. Adult neurogenesis declines with age and has been suggested to play a role in impaired progressive learning and memory loss seen in Alzheimer's disease (AD). Therefore, therapeutic strategies designed to boost adult hippocampal

neurogenesis may be beneficial for the treatment of AD. The precursor forms of neurotrophins, such as pro-NGF, display remarkable increase during AD in the hippocampus and entorhinal cortex. In contrast to mature NGF, pro-NGF exerts adverse functions in survival, proliferation, and differentiation. Hence, we hypothesized that pro-NGF and its p75 neurotrophin receptor (p75NTR) contribute to disrupting adult hippocampal neurogenesis during AD. To test this hypothesis, in this study, we took advantage of the availability of mouse models of AD (APP/PS1), which display memory impairment, and AD human samples to address the role of pro-NGF/p75NTR signaling in different aspects of adult neurogenesis. First, we observed that DG doublecortin (DCX) + progenitors express p75NTR both, in healthy humans and control animals, although the percentage of DCX+ cells are significantly reduced in AD. Interestingly, the expression of p75NTR in these progenitors is significantly decreased in AD conditions compared to controls. In order to assess the contribution of the pro-NGF/p75NTR pathway to the memory deficits of APP/PS1 mice, we injected pro-NGF neutralizing antibodies (anti-proNGF) into the DG of control and APP/PS1 mice and animals are subjected to a Morris water maze test. Intriguingly, we observed that anti-pro-NGF significantly restored memory performance of APP/PS1 animals and significantly increase the percentage of DCX+ progenitors in the DG region of these animals. In summary, our results suggest that pro-NGF is involved in disrupting spatial memory in AD, at least in part by blocking adult neurogenesis. Moreover, we propose that adult neurogenesis alteration should be taken into consideration for better understanding of AD pathology. Additionally, we provide a new molecular entry point (pro-NGF/p75NTR signaling) as a promising therapeutic target in AD.

FLRT2 and FLRT3 Cooperate in Maintaining the Tangential Migratory Streams of Cortical Interneurons during Development. Neuron migration is a hallmark of nervous system development that allows gathering of neurons from different origins for assembling of functional neuronal circuits. Cortical inhibitory interneurons arise in the ventral telencephalon and migrate tangentially forming three transient migratory streams in the cortex before reaching the final laminar destination. Although migration defects lead to the disruption of inhibitory circuits and are linked to aspects of psychiatric disorders such as autism and schizophrenia, the molecular mechanisms controlling cortical interneuron development and final layer positioning are incompletely understood. Here, we show that mouse embryos with a double deletion of and genes encoding cell adhesion molecules exhibit an abnormal distribution of interneurons within the streams during development, which in turn, affect the layering of somatostatin+ interneurons postnatally. Mechanistically, FLRT2 and FLRT3 proteins act in a noncell-autonomous manner, possibly through a repulsive mechanism. In support of such a conclusion, double knockouts deficient in the repulsive receptors for FLRTs, Unc5B and Unc5D, also display interneuron defects during development, similar to the / mutants. Moreover, FLRT proteins are chemorepellent ligands for developing interneurons , an effect that is in part dependent on FLRT-Unc5 interaction. Together, we propose that FLRTs act through Unc5 receptors to control cortical interneuron distribution in a mechanism that involves cell repulsion. Disruption of inhibitory cortical circuits is responsible for some aspects of psychiatric disorders such as schizophrenia or autism. These defects include interneuron migration during development. A crucial step during this process is the formation of three transient migratory streams within the developing cortex that determine the timing of interneuron final positioning and the formation of functional cortical circuits in the adult. We report that FLRT proteins are required for the proper distribution of interneurons within the cortical migratory streams and for the final laminar allocation in the postnatal cortex. These results expand the multifunctional role of FLRTs during nervous system development in addition to the role of FLRTs in axon guidance and the migration of excitatory cortical neurons.

BALANCING WNT SIGNALING IN EARLY FOREBRAIN DEVELOPMENT

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Shuang Geng, Annette Hammes-Lewin, Fabian Paul, Sandra Raimundo, Tamrat Mamo
Max Delbrück Center for Molecular Medicine (MDC), Molecular Pathways In Cortical Development, Berlin, Germany

During the initial specification of the forebrain, integration of signals from multiple signaling centers is required to establish regional identity of neural progenitor cells (NPCs). WNT signaling pathway is one of the most important signaling pathways in this process. LRPs (LDL receptor related protein) are crucial for WNT signaling and therefore involved in early embryonic forebrain development. LRP5 and LRP6 are well studied as co-receptors for frizzled, the main WNT receptor. However, little is known about the function of LRP4 as a potential modulator of LRP6 in the central nervous system. To shed light on the common and distinct functions of these receptors and to test for interactions among *Lrp* gene family members linked to the WNT pathway, we chose a genetic approach analyzing *Lrp4*, *Lrp6* null mutant mice as well as *Lrp4*$^{-/-}$;*Lrp6*$^{-/-}$ compound mutant mice. Applying mouse genetics, high resolution immunofluorescence imaging, cell culture models and molecular biology approaches I could show the following results: **1)** Developmental disorders of *Lrp6*$^{-/-}$ mutant mice can be partially rescued by loss of LRP4. **2)** *Lrp4* is a genetic modifier of *Lrp6*. **3)** LRP4 is crucial for balancing the proliferative activity versus differentiation of neuronal progenitors in the developing forebrain **4)** LRP4 modulates LRP5 and LRP6 dependent WNT signaling not only during forebrain development but also in a more general context, i.e. in human cell lines.

ALTERATION OF MOUSE COGNITION AND NEURAL CIRCUITS FORMATION RESULTING FROM MUTATIONS ON THE AUTISM-LINKED GENE NUAK1.

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Géraldine Meyer-Dilhet, Valérie Risson, Manon Riou, Julien Courchet
INMG - PGNM, Rhone-alpes, LYON, France

The development of functional neural circuits relies on tightly regulated cellular processes controlled by complex cascades of signaling pathways, culminating in the proper development of axon terminals and synaptic connections. A disruption of these molecular mechanisms can lead to life-altering neurodevelopmental disorders such as autism spectrum disorders (ASD), mental retardation, schizophrenia or cognitive defects. Our team identified previously that the autism-associated protein kinase NUAK1 plays a central role in controlling axonal development in the mouse cortex (Courchet et al. Cell 2013). In addition, we recently described that *Nuak1* is haploinsufficient for mouse cortical development (Courchet et al. 2018). Knockout of *Nuak1* leads to alterations of cortical connectivity and a wide-array of behavioral alterations including sociability defects, deficits in learning and memory and abnormal sensory gating. Building on this work, we created a mouse line with a mutation of the *Nuak1* gene mimicking a *de novo* mutation identified in autistic patients. The targeted knock-in mutation (Q434*) was achieved using the Crispr-Cas9 strategy. We will present the first data of characterization of this novel, humanized mouse line. Furthermore we turned to a candidate-approach to identify which signaling pathway and transcription factor could explains the roles of NUAK1 in cued- and contextual fear memory. Overall, the comparison of this model with conditional knockout models will allow to better characterize the cognitive defects associated to *Nuak1* and to identify the alterations in the neural circuits underlying these behavioral alterations. Keywords : autism spectrum disorders, NUAK1, mouse model, memory, CREB.

CG7101/DTZAP ENCODES A TRANSCRIPTIONAL REGULATOR OF MITOCHONDRIAL BIOLOGY REQUIRED FOR AXONAL OUTGROWTH, CIRCUIT CONNECTIVITY AND BEHAVIOR

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Iryna Mohylyak[1], Mercedes Bengochea[2], Noemi Asfogo[3], Stein Aerts[4], Olga Corti[3], Bassem Hassan[5]
[1]Paris Brain Institute - ICM, Brain Development Team, Paris, France, [2]Paris Brain Institute, Hassan Lab, Paris, France, [3]Paris Brain Institute (ICM), Inserm U1127, Paris, France, [4]VIB & KU Leuven, Computational Biology, Leuven, Belgium, [5]Paris Brain Institute, Brain Development Team, Paris, France

Molecular processes that lead to robust circuit wiring during development remain to be fully deciphered. We addressed this question using the Dorsal Cluster Neurons, a higher order visual circuit in *Drosophila*. To understand the molecular underpinnings of circuit formation and identify target genes, we performed analysis of DCNs transcriptome with subsequent RNAi-screen of 75-highly expressed genes to study their role in circuit development, synaptic connectivity and behavior. We identified *CG7101*, a gene encoding a transcription factor homologous to mammalian *TZAP*, known for its role as a negative regulator of telomere length, and proposed to regulate the expression of the *mitochondrial fission process 1* gene. *dTzap* knockdown resulted in a DCN-axons decrease in a target area. Previously we've shown that medulla-targeting DCNs regulate object orientation behavior in flies. Knockdown of *dTzap* impaired this behavior, mimicking the complete silencing of M-DCNs, despite the presence of 65% of axons in the correct target space. Transsynaptic tracing showed that *dTzap* downregulation leads to dramatic loss of postsynaptic connectivity, and decrease was not due to loss of the pre-synaptic proteins, suggesting a different mechanism. *CG7101/dTZAP* ChIPseq data revealed binding to a large number of genes involved in mitochondrial biology such as CG7772/*dMtfp1, pink1*, *drp1*, *ewg* and *atg1*, suggesting that TZAP is a conserved transcriptional regulator of mitochondrial homeostasis. We tested this hypothesis in *Drosophila* and mammalian COS7 cells and confirmed impaired mitochondria morphology and downregulation of key mitochondrial genes. Knockdown of *pink1* phenocopied increased mitochondrial size in axons and reduction of postsynaptic labelling, while its overexpression rescued the phenotypes observed upon *dTzap* knockdown.

Aims: RAD51, a protein known for its role in DNA repair, has been linked to congenital mirror movements (CMM). CMM patients perform involuntary movements of one hand that mirror voluntary movements of the other hand. We demonstrated that *RAD51*-mutated CMM patients have abnormal corticospinal tract (CST) midline crossing at the level of the pyramidal decussation. Strikingly, RAD51 is cytoplasmic in the corticospinal neurons in newborn mice, and is present at the pyramidal decussation within the spatio-temporal window corresponding to CST formation. We are investigating the new unexpected role of RAD51 in the development of the CST. **Methods:** We characterized the CST phenotype induced by the deletion or the overexpression of WT or CMM-mutated *Rad51* restricted to the motor cortex using *in utero* electroporation. We analyze the 3D trajectories of corticospinal axons using clearing and an ultramicroscopy method (3DISCO). **Results:** Selective and complete deletion of *Rad51* in the motor cortex does not affect the corticospinal trajectory. In contrast, overexpression of WT *RAD51* or its CMM-mutated variant leads to abnormal tract trajectories in 50% of animals. **Conclusion:** Precise balance of RAD51 levels within corticospinal neurons is mandatory for the correct development of the CST. An altered level of RAD51 could be more detrimental than its absence. This work will help in unraveling the cytoplasmic role of RAD51 in CST development by taking advantage of the CMM paradigm. Our findings will provide new insights into CST development and axon guidance mechanisms.

[1]Sorbonne Université, INSERM, CNRS, Institut De Biologie Paris Seine, Neuroscience Paris Seine, Paris, France, [2]Inserm U 1127, CNRS UMR 7225, Sorbonne Université, UMR S 1127, CIC-1422, Institut Du Cerveau, Icm, Paris, France, [3]AP-HP, Hôpital de la Pitié-Salpêtrière, Département De Neurologie, Paris, France, [4]Sorbonne Université, INSERM, CNRS, Institut De Biologie Paris Seine, Biological Adaptation And Ageing, Paris, France

Aims: Mirror movements are involuntary movements of one side of the body that mirror intentional movements on the opposite side. Congenital Mirror Movements (CMM) is a rare genetic disorder with autosomal dominant inheritance, in which mirror movements are the sole or main neurological symptom. CMM is associated with an abnormal decussation of the corticospinal tract, the major motor projection from the cortex to the spinal cord. Surprisingly, *RAD51*, a gene previously known for its key role in homologous recombination in DNA repair, is one of the CMM causative genes. We are investigating this new unexpected role of RAD51 in the development of the nervous system. Methods: We take advantage of our large cohort to investigate the expression of wild-type and mutant RAD51 in CMM patients' lymphoblasts. RAD51 expression is also characterized in the mouse developing nervous system. We further use biochemical approaches to characterize the functions of RAD51 that may be altered in the mutated proteins. Results: RAD51 is present in the cytoplasm of corticospinal neurons and detected at the decussation at the time of midline crossing by their axons. The CMM mutations of *RAD51* are loss-of-function mutations and the non-truncating mutations impact the dimerization of the protein. Conclusions: Through the CMM paradigm, we demonstrate that *RAD51* is haploinsufficient for the corticospinal tract development. Amazingly, our work uncovers a new cytoplasmic role for RAD51, that may require its oligomerization, a key feature of its well-known nuclear recombinase role.

ROLE OF THE TRANSMEMBRANE TYROSINE KINASE RECEPTOR C-KIT IN THE DEVELOPMENT OF THE OLIVOCEREBELLAR CIRCUIT

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Shayan Moghimyfiroozabad[1,2,3], Fekrije Selimi[4]
[1]Sorbonne Universite, Ed3c, Paris, France, [2]Fondation des Neurosciences de Paris- FNP, Fondation Sorbonne Université, Paris, France, [3]College de France, Center For Interdisciplinary Research In Biology, Paris, France, [4]Collège de France, Cirb, Paris, France

Proper brain development relies on the proliferation, migration, differentiation, recognition and adhesion between different cell populations. Molecular pathways that regulate normal development of other tissues can be involved in brain development as well. One of these pathways is c-KIT/SCF signaling. c-KIT is a transmembrane tyrosine kinase receptor that controls cell survival, proliferation and maintenance of various tissues (e.g. hematopoietic tissue). In the cerebral cortex, c-KIT is involved in the connectivity of callosal fibers to their targets as well as radial migration of neurons. We observed the localization of c-KIT in the cerebellum, whose circuitry and architecture are very well studied. Data from the Allen Brain Atlas show that c-Kit and Scf are expressed in IONs and PCs, respectively, from late embryonic days until adulthood. Using immunolabeling, we showed the localization of c-KIT along the axons of a subset of IONs, and at their glutamatergic synaptic terminals on PCs postnatally, suggesting a potential role of c-KIT/SCF pathway in the establishment of ION-PC connection. To test this hypothesis, we are currently analyzing the consequences of neuron-specific conditional invalidation of c-Kit or Scf in the formation of ION-PC connectivity at the morphological and functional levels. Our results will shed light on the molecular mechanisms regulating the establishment of the olivocerebellar circuit, a network important for motor control and cognition. Furthermore, given that the c-KIT/SCF pathway is an important therapeutic target in cancer, our study will illustrate the potential side effects of those treatments on brain development and function.

ASYMMETRIC METABOLISM CONTROLS THE ACUTE ACQUISITION OF VERTEBRATE AXON COMPLEXITY

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Fumi Suomi[1], Thomas Mcwilliams[2]
[1]University of Helsinki, Faculty Of Medicine, Helsinki, Finland, [2]University of Helsinki, FI, Faculty Of Medicine, Helsinki, Finland

Asymmetric metabolism controls the acute acquisition of vertebrate axon complexity. Fumi Suomi[1], Masgutova G, Rappe A, Rathod R, Courtoy GE, Adolfs Y, Pasterkamp RJ, Nieminen A, Clotman F and McWilliams TG. **Affiliations** [1]Translational Stem Cell Biology and Metabolism Program, Faculty of Medicine, Biomedicum Helsinki, University of Helsinki, Haartmaninkatu 8, Helsinki 00790-FI **Aims**: Mitochondrial metabolism is critical for developing neurons, yet the full repertoire of metabolic signals that shape developing neuronal architecture remain mysterious. We sought to define the metabolic basis of axon growth in developing mouse post-mitotic neurons. **Methods**: We performed high content morphometric profiling of mouse primary neurons in defined metabolic states, and used temporal fluxomics to define the substrate utilization at distinct morphological stages in concert with transcriptomics and *in vivo* analysis of cleared mutant embryos using iDISCO. **Results**: We reveal that glycolysis promotes the branching and complexity of advancing neurites, with unexpected dynamic changes in glucose utilisation. Our transcriptomics analysis reveals that distinct metabolic states control the expression of growth-inhibitory molecules, and converge on a unique transcription factor family. Genetic ablation of these transcription factors disrupts mouse sensory development organisation in vivo. **Conclusions:** Our findings demonstrate the unexpected developmental importance of glycolytic signalling for the development of vertebrate post-mitotic neurons and link metabolism to a novel family of transcription factors.

Developmental Consequences of Defective ATG7-Mediated Autophagy in Humans.
Autophagy is the major intracellular degradation route in mammalian cells. Systemic ablation of core autophagy-related () genes in mice leads to embryonic or perinatal lethality, and conditional models show neurodegeneration. Impaired autophagy has been associated with a range of complex human diseases, yet congenital autophagy disorders are rare.
N Engl J Med, 2021; 384
32269837: Suomi F, McWilliams TG
Autophagy in the mammalian nervous system: a primer for neuroscientists.
Autophagy refers to the lysosomal degradation of damaged or superfluous components and is essential for metabolic plasticity and tissue integrity. This evolutionarily conserved process is particularly vital to mammalian post-mitotic cells such as neurons, which face unique logistical challenges and must sustain homoeostasis over decades. Defective autophagy has pathophysiological importance, especially for human neurodegeneration. The present-day definition of autophagy broadly encompasses two distinct yet related phenomena: non-selective and selective autophagy. In this minireview, we focus on established and emerging concepts in the field, paying particular attention to the physiological significance of macroautophagy and the burgeoning world of selective autophagy pathways in the context of the vertebrate nervous system. By highlighting established basics and recent breakthroughs, we aim to provide a useful conceptual framework for neuroscientists interested in autophagy, in addition to autophagy enthusiasts with an eye on the nervous system.
Neuronal Signal, 2019; 3

Emerging roles of ATG7 in human health and disease.
The cardinal stages of macroautophagy are driven by core autophagy-related (ATG) proteins, whose ablation largely abolishes intracellular turnover. Disrupting ATG genes is paradigmatic of studying autophagy deficiency, yet emerging data suggest that ATG proteins have extensive biological importance beyond autophagic elimination. An important example is

ATG7, an essential autophagy effector enzyme that in concert with other ATG proteins, also regulates immunity, cell death and protein secretion, and independently regulates the cell cycle and apoptosis. Recently, a direct association between ATG7 dysfunction and disease was established in patients with biallelic ATG7 variants and childhood-onset neuropathology. Moreover, a prodigious body of evidence supports a role for ATG7 in protecting against complex disease states in model organisms, although how dysfunctional ATG7 contributes to manifestation of these diseases, including cancer, neurodegeneration and infection, in humans remains unclear. Here, we systematically review the biological functions of ATG7, discussing the impact of its impairment on signalling pathways and human pathology. Future studies illuminating the molecular relationship between ATG7 dysfunction and disease will expedite therapies for disorders involving ATG7 deficiency and/or impaired autophagy.

ECTOPIC POSITION OF CSF-CNS IN THE SPINAL CORD OF C57BL/6N MICE IS ASSOCIATED WITH SNPS IN CRB1 AND CYFIP2.

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Ján Košuth[1], Zuzana Tonelli Gombalová[1], Anna Alexovic Matiasova[1], Jarmila Zrubáková[1], Ivan Žežula[2], Lenka Tomašková[1], Zuzana Daxnerova[1], Juraj Sevc[1]
[1]Faculty of Science, P. J. Šafárik University in Košice, Institute Of Biology And Ecology, Košice, Slovak Republic, [2]Faculty of Science, P. J. Šafárik University in Košice, Institute Of Mathematics, Košice, Slovak Republic

Cerebrospinal fluid-contacting neurons (CSF-cNs) reside the ependymal lining surrounding the central canal of the spinal cord and brain ventricles. In our previous study, we found that majority of CSF-cNs in the spinal cord of C57Bl/6N mice is in ectopic position, unlike those in the other inspected mice strains and mammalian species. The ectopic position of CSF-cN was observed solely in C57Bl/6N mice, which share common similar genetic profile with mouse strain C57Bl/6J. Therefore, we decided to investigate genetic polymorphisms between 6N and 6J substrains to elucidate possible gene candidate(s) responsible for the ectopic presence of CSF-cNs in C57Bl/6N mouse substrain. First, in the *in silico* analysis, we narrowed down the group of 236 homozygous sequence variants differentiating those two substrains to 5 suspected genes bearing the polymorphisms in 6N substrain. We selected 5 genes (*Crb1*, *Cyfip2*, *Adamts12*, *Plk1* and *Herpud2*) which meet all three criteria; i) mutation of the gene in 6N substrain has deleterious effect on the protein function; ii) the gene is expressed in the spinal cord; and iii) the coding sequence of the gene is conserved among other mice strains. Next, employing the segregation analysis of the F2 progeny derived from parental strains C57Bl/6N and Balb/C, we found that concurrent presence of missense mutations in *Crb1* and *Cyfip2* is closely associated with ectopic distribution of CSF-cNs. Our study adds another piece to the growing body of evidence that the employment of C57Bl/6N mice in particular type of experiments should be carefully reasoned.

THE ROLE OF HETEROCHROMATIN IN HUMAN BRAIN DEVELOPMENT

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Ofelia Karlsson, Raquel Garza, Pia Johansson, Vivien Horvath, Ninoslav Pandiloski, Christopher Douse, Jenny Johansson, Johan Jakobsson
Lund University, Department Of Experimental Medical Sciences, Lund, Sweden

Transposable elements (TEs) are particularly active during human brain development. Aberrant expression and epigenetic dysregulation have been linked to several neurological and psychiatric disorders. During embryonic development, most TEs are silenced via epigenetic mechanisms such as the formation of heterochromatin and DNA methylation since they otherwise can pose a threat to the genomic integrity. In this study, we investigate molecular mechanisms that are in control of TEs activity during human brain development, with a focus on epigenetic mechanisms. Using high throughout CRISPRi screen, we targeted key epigenetic regulators associated with disposition of repressive histone marks as well as DNA methylation. Targets such as TRIM28, SETDB1, HUSH-complex subunits and DNMT1 were knocked down in human neuroepithelial stem cells and induced pluripotent stem cell derived forebrain neural precursors cells and cerebral organoids. Looking at transcriptomic changes after differentiation, we examined the effects of the knock down in human brain development. To get a complete profile on how TEs are regulated and expressed is of great importance to better understand healthy human brain development and various mechanisms underlying brain disorders. Our results will provide further insight on how TEs are epigenetically regulated during human brain development.

PIEZO2 LINEAGES IN THE DEVELOPING CENTRAL NERVOUS SYSTEM

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Mireia Pàmpols Pérez, Carina Fürst, Gary R. Lewin, Annette Hammes-Lewin
Max Delbrüuck Center for Molecular Medicine, Department Of Neuroscience, Berlin, Germany

Mechanotransduction is the process by which a mechanical stimulus is converted into electrical activity, which is crucial to various physiological phenomenon such as somatic sensation and vascular homeostasis. The mammalian mechanosensitive ion channel PIEZO2 acts as a highly sensitive mechanosensor in diverse cell types, required for mechanotransduction in the proprioceptive and somatosensory systems. Other functions however remain to be clarified, as clinical studies reported that patients who carry PIEZO2 mutations present diverse symptoms including neurodevelopmental disorders, such as Gordon syndrome and Marden-Walker syndrome. Animal models have the potential to yield insights into these open questions. Studies on Piezo2 so far have only focused on adult mice; a thorough analysis of its expression and function over the course of development has yet to be carried out. We used a mouse reporter line to fate-map Piezo2 cell linages which we combined with RNAscope and ISH expression analyses. The results indicate that 1) Piezo2 is widely expressed in various anatomical structures at different developmental stages and 2) Piezo2^{+} lineages give rise to several tissues that have not been hitherto connected to Piezo2 function. Our studies focus on characterizing the identity of these *Piezo2*$^{+}$ descendent cells in the brain by co-expression studies. We found distinct types of *piezo2* lineage cells in the brain, oligodendrocytes, neurons, which can be found in specific brain regions associated with olfaction like the piriform cortex, and endothelial cells. Moreover, we are currently characterizing phenotypic and physiological parameters of Piezo2 gain- and loss-of-function mouse models.

SPATIOTEMPORAL EXPRESSION OF THE 5-HT6 RECEPTOR IN THE MOUSE BRAIN, FROM EMBRYO TO ADULT

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Séverine Chaumont-Dubel, Vincent Dupuy, Joël Bockaert, Philippe Marin
Institut de Génomique Fonctionnelle , Université de Montpellier, CNRS, INSERM, Département De Neurosciences, Montpellier, France

Pharmacological inhibition of the serotonin 5-HT_6 receptor (5-HT_6R) alleviates the cognitive symptoms observed in neurodevelopmental, neurodegenerative or psychiatric diseases. It is therefore a promising new therapeutic target for these pathologies. However, the molecular mechanisms underlying the beneficial effects of 5-HT_6R blockade remain unknown. This is in part due to the lack of specific antibodies to detect the endogenous receptor and to get a clear picture of where and when it is expressed. In this study, we have used a new mouse model expressing a GFP-tagged 5-HT_6R under the control of its native promoter to characterize the receptor's expression in embryonic and adult brain. We show that the receptor is mainly expressed in projection neurons of the cerebral cortex and the hippocampus as well as in striatal medium size spiny neurons, while it was found in a minor population of interneurons. The receptor was also detected in a large proportion of astrocytes. Finally, we looked at its subcellular distribution in embryonic, post-natal and adult brain. We show that the receptor is located in the primary cilia throughout the life of the mouse, but interestingly, it is relocated to the somato-dendritic compartment at the perinatal stage. This study provides a global view of the 5-HT_6 receptor's expression, which could serve as a basis for further studies aimed at understanding its roles in neurodevelopmental and cognitive processes.

DMRT2 SPLICING REGULATION IN SEX AND DEVELOPMENT OF THE NERVOUS SYSTEM

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Ana Bermejo-Santos, Rodrigo Torrillas-De La Cal, Esther Serrano-Saiz
Centro de Biología Molecular 'Severo Ochoa', Tissue And Organ Homeostasis, Madrid, Spain

Sexual differences in behaviour emerge from sex-specific molecular and connectivity brain conformations. The genetic factors involved in the sexual differentiation of the nervous system are poorly understood, but they could become vulnerability or protective factors in the etiology of mental disorders. The family of *doublesex*/*mab-3* related transcription factors (DMRT) are conserved as sexual regulators of sexually dimorphic traits across distant species. In flies, sex-specific expression of Doublesex isoforms establishes the morphology and behaviour characteristic of each sex. So far, the presence of a similar sex-specific splicing is unknown. Here, we show a novel alternative transcript of the mouse orthologous *Dmrt2*. This splicing potentially generates two DMRT isoforms with a similar structure to Doublesex, sharing the DM domain but differing in the N-terminal. Both variants are expressed in the nervous system and, remarkably, undergo a switch of predominance at embryonic stage and an interesting upward trend in female brains. We found that *Dmrt2* is widely expressed in the cortex, in corticothalamic projection neurons and GABAergic interneurons. This last population is present in hippocampus and subiculum. It also stands out its expression in several areas associated with sex-specific behaviour such as the lateral preoptic area, septal nucleus, amygdala or periaqueductal grey. Moreover, *Dmrt2* is expressed exclusively in post-mitotic neurons from early embryo until adulthood, suggesting a role in late developmental processes and circuit maintenance. Taken together, our results open the possibility of a novel mechanism to generate brain sexually dimorphic layouts through the sex-specific regulation of Dmrt2.

Targeted chromatin conformation analysis identifies novel distal neural enhancers of ZEB2 in pluripotent stem cell differentiation.
The transcription factor zinc finger E-box binding protein 2 (ZEB2) controls embryonic and adult cell fate decisions and cellular maturation in many stem/progenitor cell types. Defects in these processes in specific cell types underlie several aspects of Mowat-Wilson syndrome (MOWS), which is caused by ZEB2 haplo-insufficiency. Human ZEB2, like mouse Zeb2, is located on chromosome 2 downstream of a ±3.5 Mb-long gene-desert, lacking any protein-coding gene. Using temporal targeted chromatin capture (T2C), we show major chromatin structural changes based on mapping in-cis proximities between the ZEB2 promoter and this gene desert during neural differentiation of human-induced pluripotent stem cells, including at early neuroprogenitor cell (NPC)/rosette state, where ZEB2 mRNA levels increase significantly. Combining T2C with histone-3 acetylation mapping, we identified three novel candidate enhancers about 500 kb upstream of the ZEB2 transcription start site. Functional luciferase-based assays in heterologous cells and NPCs reveal co-operation between these three enhancers. This study is the first to document in-cis Regulatory Elements located in ZEB2's gene desert. The results further show the usability of T2C for future studies of ZEB2 REs in differentiation and maturation of multiple cell types and the molecular characterization of newly identified MOWS patients that lack mutations in ZEB2 protein-coding exons.

DMRT5 BEYOND THE CORTEX: EARLY ROLE IN THE SEXUAL DIFFERENTIATION OF THE MOUSE LIMBIC SYSTEM

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Rafael Casado-Navarro, Rodrigo Torrillas-De La Cal, Esther Serrano-Saiz
Centro de Biología Molecular Severo Ochoa (CSIC-UAM), Program Of Tissue And Organ Homeostasis, Madrid, Spain

The mammalian limbic system is sexually dimorphic and regulates sex-specific innate behaviors such as mating, maternal care and aggression. However, the genetic programs involved in the sexual differentiation of the limbic system are poorly understood. Dmrt transcription factors have emerged as conserved regulators of sex-specific traits across phylogeny. They have been studied mostly in invertebrates, where they play an important role in nervous system sexual differentiation, and in vertebrate cortical development. In fact, mutations in *DMRTA2 (Dmrt5)* lead to a recessive human condition characterized by microcephaly and lissencephaly. In this work we use Dmrt5 null mutant mice, RNA-seq and histological techniques to study Dmrt5 function in the mammalian nervous system beyond the cortex and comparing males and females. In this study we showed that Dmrt5 is broadly expressed in the mouse nervous system, including the vomeronasal organ, olfactory tubercle, or ventral tegmental area (all key nodes in the control of innate behaviors). Furthermore, we showed that Dmrt5 is necessary for the correct specification of the main olfactory epithelium, the olfactory bulb, and several hypothalamic nuclei. Additionally, we found a novel function for Dmrt5 as a suppressor of sex differences in gene expression in the posterior hypothalamic area and midbrain. Taken together, Dmrt5 comes out as a crucial transcription factor for accurately generating limbic regions and integrating sex information. Therefore, by studying the genetic factors involved in sexual differentiation we can find potential factors that either afford protection or generate vulnerability in one sex versus the other for sex-biased mental disorders.

Redox-dependent and redox-independent functions of Caenorhabditis elegans thioredoxin 1.
Thioredoxins (TRX) are traditionally considered as enzymes catalyzing redox reactions. However, redox-independent functions of thioredoxins have been described in different organisms, although the underlying molecular mechanisms are yet unknown. We report here the characterization of the first generated endogenous redox-inactive thioredoxin in an animal model, the TRX-1 in the nematode Caenorhabditis elegans. We find that TRX-1 dually regulates the formation of an endurance larval stage (dauer) by interacting with the insulin pathway in a redox-independent manner and the cGMP pathway in a redox-dependent manner. Moreover, the requirement of TRX-1 for the extended longevity of worms with compromised insulin signalling or under calorie restriction relies on TRX-1 redox activity. In contrast, the nuclear translocation of the SKN-1 transcription factor and increased LIPS-6 protein levels in the intestine upon trx-1 deficiency are strictly redox-independent. Finally, we identify a novel function of C. elegans TRX-1 in male food-leaving behaviour that is redox-dependent. Taken together, our results position C. elegans as an ideal model to gain mechanistic insight into the redox-independent functions of metazoan thioredoxins, overcoming the limitations imposed by the embryonic lethal phenotypes of thioredoxin mutants in higher organisms.

THE ROLE OF PI3K/ AKT/ MTOR PATHWAY IN PROGRAMMED CELL DEATH OF CAJAL-RETZIUS CELLS

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Nasim Ramezanidoraki[1], Pierre Billuart[2], Alessandra Pierani[1]
[1]Centre De Psychiatrie et Neurosciences, Neurosciences, Paris, France, [2]Centre De Psychiatrie et Neurosciences, Neurosciences, paris, France

Programmed cell death (PCD) is a critical contributor to nervous system development and its alterations are suggested to participate in the pathophysiology of neurodevelopmental disorders. Cajal-Retzius cells (CRs) play key roles in cortical development and are one of the remarkable examples of PCD in the cerebral cortex. In mice, CRs undergo almost complete PCD in the first two post-natal weeks. The persistence of CRs during postnatal life has been detected in pathological conditions related to epilepsy. It has been shown that the PI3K/ AKT/ mTOR pathway plays an important role in cell survival and its dysregulation is implicated in malformation of cortical development (MCD) and epilepsy. Interestingly we found no evidence of S6 kinase activation in mouse CRs during post-natal stages suggesting that the mTOR pathway is not active after birth. In order to activate it in these cells, we conditionally deleted *Pten* or *Tsc1* genes, which encodes for two inhibitors of the PIK3/AKT/mTOR pathway. Loss of PTEN or TSC1 functions did not affect CRs generation and migration but their morphology at later post-natal stages. In addition, we observed a stronger activation of S6 kinase in the PTEN mutant compared to the TSC1 probably due to parallel activation of PDK1. Finally, activation of the pathway led to CRs persistence after two weeks. Altogether, these results show that the PI3K/ AKT/ mTOR pathway is strongly inhibited in CRs during post-natal stages priming these cells to death.

THE ATYPICAL KINESIN KIF21B CONTROLS NEURONAL MIGRATION THROUGH REGULATION OF ACTIN CONTRACTION

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

José Rivera Alvarez[1,2], Laure Asselin[1,2], Peggy Tilly[1,2], Juliette Godin[1,2]
[1]Université de Strasbourg, Bas-rhin, Strasbourg, France, [2]Institut de Génétique et de Biologie Moléculaire et Cellulaire, Bas-rhin, Illkirch, France

The development of the cerebral cortex progresses through several stages including proliferation, migration and differentiation. Microtubules (MT) and its associated proteins are important regulators of these processes and mutations in genes encoding these components are responsible for cortical malformations, intellectual disabilities and epilepsy. The molecular motors kinesins are key regulators of corticogenesis by regulating cargoes transport and MT cytoskeleton organization. Defective function of kinesins has been related to cortical malformations such as microcephaly, lissencephaly and pachygyria. In this work we studied the physiological roles of Kif21b during corticogenesis, a kinesin that has been shown to be relevant in human cortex development. We showed that Kif21b silencing by *In Utero Electroporation* in mouse embryonic cortices induces morphological changes and locomotion defects in migrating projection neurons. Through rescue experiments with truncated variants of Kif21b we elucidated that its MT motor role is dispensable for migration. Unexpectedly, we identified Kif21b as an actin interacting partner, having a function through which Kif21b regulates actin contraction during the migratory cycle. Altogether, this study unravels unlooked-for physiological functions of Kif21b during neuronal migration.

Šafárik University in Košice, Associated Tissue Bank, Košice, Slovak Republic, [3]Slovak Academy of Sciences, Institute Of Experimental Physics, Košice, Slovak Republic

An important role played by apoptosis and apoptotic-related proteins in many physiological and pathological processes of nervous system makes apoptosis an intriguing study topic for neuroscience. In this work, we focused on the study of apoptosis of cells in the spinal cord of rats in the selected time points during the postnatal life (8, 29, and 90 days) using immunofluorescent detection of active caspase3 (aC3), and protein cleaved PARP-1 (cPARP), which are routinely used as markers of apoptotic cells. Surprisingly, based on the results of stereological quantification, we concluded that the ratio between $aC3^+$ and $cPARP^+$ cells in the spinal cord tissue is 593:1 (P8), 4490:1 (P29), and 487:1 (P90), respectively. To compare the distribution of ac3 and cPARP-1 in the apoptosis, we prepared the primary cell cultures isolated from the spinal cord of 8 days old rats, in which apoptosis was induced using staurosporine treatment and the presence of $aC3^+$ and $cPARP\text{-}1^+$ cells was analyzed in the selected time points afterward. In contrast to the *in vivo* study, the i*n vitro* analysis revealed a similar pattern of distribution of $aC3^+$ and $cPARP^+$ cells in the studied time points after the apoptotic induction. Our data indicate that the aC3 is not an exclusive marker of apoptotic cells in the nervous tissue and may be involved in the non-apoptotic processes during postnatal life. Hence, identification of apoptotic cells by immunodetection of aC3 should be confirmed by other apoptotic markers. PRIMARY CILIUM-ELICITED SIGNALLING PATHWAYS AND CORTICAL INTERNEURON MIGRATION

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Melody Atkins[1], Michèle Darmon[1], Fiona Roche[2], Xavier Nicol[2], Christine Métin[1]
[1]Institut du Fer à Moulin, Umr-s 1270 Inserm/sorbonne Université, Paris, France, [2]Institut de la Vision, Developmental Biology, Paris, France

During development, cortical interneurons undertake a complex migration in order to reach the developing cortex, in which they will form and integrate functional circuits. Our team and others have shown the importance of a small, dynamic structure called the primary cilium (PC) during this process, to initiate the cortical interneuron migration switch from tangential to radial migratory routes. Although known to be a signalling hub concentrating a wide variety of membrane receptors, the nature of the intracellular pathways elicited at the primary cilium downstream of such receptors, and how they could affect cortical interneuron migration, remain unknown. We here aim at elucidating such pathways by focusing on PC-elicited second messengers such as cAMP and cGMP, which are molecules present in many cellular compartments to transduce a variety of signalling pathways. Thanks to a molecular toolbox developed in collaboration with Xavier Nicol (IDV Paris), we target scavengers or photo-activated constructs specifically to the PC – via a 5HT6 targeting sequence – and respectively buffer or activate cAMP or cGMP levels locally and specifically in the PC. By combining ciliary cAMP/cGMP buffering or photo-activation, our results point at distinct and specific roles for ciliary cAMP and cGMP second messengers in the regulation of cortical interneuron migration. Our data provide new insight into the importance of PC-initiated signalling pathways in interneuron migration. Unravelling these cellular and molecular mechanisms is furthermore crucial to shed new light on our understanding of developmental disorders in which PC formation as well as cortical interneuron migration are defective.

THE ROLE OF LYSOSOMAL DYSFUNCTION IN CORTICAL DEVELOPMENT IN THE CONTEXT OF HEREDITARY SPASTIC PARAPLEGIA SPG11

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Dominic Samaroo, Frédéric Darios
Sorbonne Université, Paris Brain Institute, Inserm U1127, PARIS, France

SPG11 is an autosomal recessive neurodegenerative disorder caused by loss-of-function mutations in the gene *Spg11*, which encodes the protein spatacsin. Typically, symptoms include weakness and rigidity in lower limbs, as well as cognitive impairment, which appear before adolescence and progressively worsen throughout the patient's lifetime. The early onset of this disease has led to the hypothesis that spatacsin loss-of-function may cause impaired neurodevelopment. Accordingly, investigations have shown that SPG11 neural progenitor cells (NPCs) demonstrate impaired proliferation, premature neurogenesis, and widespread transcriptional alterations in pathways implicated in cell cycle regulation and cortical development. Loss of spatacsin is known to impair autophagic lysosome reformation, however there remains a substantial gap in our understanding of the subcellular mechanisms underlying the developmental defects of SPG11. To elucidate the relationship between lysosomal dysfunction and impaired neurodevelopment we are using cortical organoids derived from induced pluripotent stem cells (iPSCs) with truncating mutations in Spg11, along with isogenic controls. Within these 3D structures we are focusing on the radial glial progenitor cells (RGPCs) that are found within rosette-like ventricular formations that mimic early corticogenesis. Thus far we have observed that, within these SPG11 RGPCs, there is apical clustering of lysosomes, as well as a disruption in the expression and/or localization of junctional proteins. We are now aiming to elucidate the subcellular mechanisms that underlie the reduced proliferation and increased differentiation of SPG11 neural progenitor cells, as well as identify potential factors and pathways that can be altered to rescue said function.

INVESTIGATION OF NEURONAL PHENOTYPES AND MECHANISMS DURING SUBCORTICAL BAND HETEROTOPIA DEVELOPMENT IN EML1 CKO MOUSE

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Ketakee Ghate[1,2,3], Julien Ferent[1,2,3], Sergi Roig Puiggros[4], Esther Klingler[4], Denis Jabaudon[4,5], Fiona Francis[1,2,3]
[1]Institut du Fer a Moulin, Cortical Development And Pathology, Paris, France, [2]Sorbonne Université, Sciences, Paris, France, [3]UMR-S 1270, Inserm, Paris, France, [4]University of Geneva, Department Of Basic Neurosciences, Geneva, Switzerland, [5]Geneva University Hospital, Department Of Clinical Neurosciences, Geneva, Switzerland

The development of the cerebral cortex is a complex and stereotyped process in which perturbations can lead to malformations associated with severe disorders such as epilepsy and intellectual disability. One such malformation, characterized by mislocalized neurons beneath the cortex, is subcortical band heterotopia. Genetic studies in patients and a mutant mouse model of subcortical band heterotopia revealed mutations in the gene coding for the microtubule-associated protein Eml1/EML1. In addition, phenotypic analyses identified abnormal radial glia (RG) progenitor cells contributing to severe forms of this disorder. However, defects in subsequently generated neurons, their mispositioning, and role in heterotopia abnormal function remains to be understood. Using a tissue clearing method iDisco, followed by 3D lightsheet imaging, we characterized neuronal phenotypes in Eml1 conditional knockout (cKO) mouse embryonic cortices, notably identifying abnormal axon bundles. Moreover, comparing single-cell RNA Seq data from wild-type and Eml1 cKO cortices, we identified candidate pathways that might provide causal mechanism for the abnormal cortical phenotypes of the Eml1 cKO mice.

HYPERACTIVITY OF RAC1 GTPASE AFFECTS THE DIRECTIONAL CONTROL OF MIGRATING INTERNEURONS IN THE EMBRYONIC CORTEX AND RESULTS IN REDUCED INHIBITION AND SUSCEPTIBILITY TO EPILEPSY

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Carla Liaci, Valentina Zamboni, Mattia Camera, Giorgio Merlo
University of Turin, Department Of Molecular Biotechnology And Health Sciences, Turin, Italy

GTPases of the Rho family are components of signaling pathways linking extracellular signals to the control of cytoskeleton dynamics. Among these, RAC1 plays key roles during brain development, ranging from neuronal migration to neuritogenesis, synaptogenesis, and plasticity. RAC1 activity is positively and negatively controlled by guanine nucleotide exchange factors (GEFs), guanosine nucleotide dissociation inhibitors (GDIs), and GTPase-activating proteins (GAPs), but the specific role of each regulator in vivo is poorly known. ARHGAP15 is a RAC1-specific GAP expressed during development in migrating cortical interneurons (CINs) and in a fraction of most subtypes of adult CINs. During development, loss of ARHGAP15 causes reduced morphological complexity and altered directionality of the leading process of tangentially migrating CINs. Likewise, time-lapse imaging of embryonic CINs reveals a poorly coordinated directional control also during radial migration, possibly due to a hyper-exploratory behavior. In the adult Arhgap15$^{LacZ/LacZ}$ cortex, the observed migration defects lead to subtle layering defects of distinct CIN subtypes, spontaneous subclinical seizures, and increased susceptibility to the pro-epileptic drug pilocarpine. These results indicate that ARHGAP15 imposes a fine negative regulation on RAC1 that is required for normal control of directionality during CIN migration, with consequences on their laminar distribution and inhibitory function.

Brain wiring relies on stereotyped axonal connections that are established during the development through growth cone navigation in response to environmental guidance cues. Non-muscle myosin II (NMII), acts downstream of repulsive axonal guidance signals. In association with actin filaments, NMII forms the actomyosin complex that is responsible for growth cone retraction. Since NMII function is ATP dependent, we studied the energetic source for actomyosin activity in axonal guidance and then assessed the consequences of metabolic impairment *in vivo*. We first studied, using rat neuronal cultures, which metabolic pathway supplied energy during growth cone retraction by inhibiting mitochondrial or glycolytic ATP synthesis using drugs or siRNA interference. We showed that glycolysis and not mitochondria fuels growth cone retraction in neuronal cultures. Then, by combining confocal, video and STORM microscopy, we found that glycolytic enzymes were enriched at the growth cone during retraction and associated with actomyosin using proximity ligation assay. Furthermore, we confirmed the direct interaction of glycolytic enzymes and actomyosin by co-immunoprecipitation. Finally, we demonstrated that blocking glycolysis *in vivo*, by ketogenic diet (KD) during pregnancy, impaired corticofugal axons wiring. Collectively, our results highlight a tight energy coupling between ATP production and consumption in axonal guidance. We also show evidence that gestational KD is potentially harmful to offspring.

α-MELANOCYTE STIMULATING HORMONE (α-MSH) AS A TROPHIC FACTOR DURING HYPOTHALAMIC DEVELOPMENT

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Joanne Falck, Selma Yagoub, Jiajie Zhu, Bethany Coull, Lidia Cantacorps, Katrin Ritter, Syeda Zahra, Rachel Lippert
DIfE, Ndf, Nuthetal, Germany

Aims: α-MSH is an endogenous neuropeptide involved in energy homeostasis. α-MSH levels increase during the third trimester (3T) in humans and are attenuated in response to high fat diet (HFD) in rodents. 3T is a critical window for synapse formation within the hypothalamus. This period corresponds to the lactation period (LP) in mice, when neurones from the arcuate nucleus of the hypothalamus (ARH) project axons to areas responsible for eating behaviour from P6-16. Undernutrition, overnutrition and inflammation can impair circuit formation, leading to loss of energy homeostasis and excessive energy intake in offspring. Moreover, α-MSH induces axon elongation and increases synaptic proteins *in vitro*. Therefore, we aim to determine how levels of α-MSH fluctuate throughout the LP in mice in a model of malnutrition, HFD, and test whether α-MSH induces axon outgrowth from the ARH. **Methods:** To investigate the fluctuations in α-MSH, we have taken plasma, hypothalamus and pituitary samples from mothers and offspring fed either a control diet or a HFD during LP; we will quantify α-MSH by ELISA. The trophic action of α-MSH on hypothalamic axons will be assessed in an *in-vitro* model of ARH explants. **Hypothesis:** We predict that α-MSH will increase during P6-16, and could be affected by HFD. We anticipate that α-MSH will induce axon elongation *in vitro*. **Conclusions:** α-MSH drives a number of pleiotropic effects throughout development and in maintaining homeostasis. The findings of this study can inform educational outreach for pregnant people and deepen our understanding of brain development.

FILAMIN A MODULATES DENDRITIC BRANCHING VIA INTEGRIN-AKT AXIS AND ACTIN CYTOSKELETON

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Yunus Emre Demiray[1], Stefanie Kliche[2], Oliver Stork[1,3]
[1]Otto-von-Guericke Universität, Institute Of Biology, Magdeburg, Germany, [2]Otto-von-Guericke Universität, Institut Of Molecular And Clinical Immunology, Magdeburg, Germany, [3]Otto-von-Guericke Universität, Center For Behavioral Brain Sciences, Magdeburg, Germany

Dendritic architecture is essential during brain development as it lays the foundation of neural signaling. Therefore, control of dendritic branching is crucial for the specificity and capacity of the synaptic input. Integrin receptors on dendrites have been shown to be indispensable for branching mechanisms, however, underlying roles of integrin-accessory proteins are still poorly understood. Here, combining in vitro mouse hippocampal cultures with genetic and pharmacological manipulations, we show that Filamin A (FlnA) plays a crucial role in dendritic branching. First, we demonstrated that altering the FlnA expression levels resulted in dendritic hypertrophy in an extracellular matrix (ECM) dependent manner. Further investigation of these phenotypes revealed that shFlnA and FlnA overexpression mediated dendritic branching are differentially regulated by ECM and ß1-integrin signaling. Moreover, silencing of FlnA resulted to a disturbance in the Akt activity, which might be the downstream mediator of the observed growth effects. Finally, we demonstrated that FlnA overexpression mediated dendritic hypertrophy is critically dependent to actin-crosslinking by FlnA. Together, these results suggest that FlnA is an important regulator of dendritic branching by contributing to integrin downstream signaling and actin dynamics. Supported by the German Research Foundation (STO488/4-1 and CRC779 TPB05).

Neural cell adhesion molecule 2 (NCAM2) is involved in the development and plasticity of the olfactory system. Genetic data have implicated the NCAM2 gene in neurodevelopmental disorders including Down syndrome and autism. NCAM2's functions and partners in cortical areas during development and adulthood have remained largely unknown until not long ago. We studied the role of NCAM2 in cortical areas. We used cell biology and molecular approaches, including loss- and gain-of-function experiments in vitro and in vivo models. We showed that overexpression of NCAM2 in hippocampal neuron cultures leads to minor alterations, but its downregulation severely compromises dendritic architecture, leading to shorter dendritic trees and retraction of dendrites. Furthermore, our data revealed alterations in the axonal tree and deficits in neuronal polarization. In vivo studies confirmed the in vitro phenotype observed and revealed an unexpected role for NCAM2 in cortical migration. Proteomic experiments show that NCAM2 interacts with >100 proteins involved in numerous processes. We described a NCAM2-protein complex with the cytoskeletal-associated proteins MAP2 and 14-3-3γ and ζ. We provide evidence that NCAM2 depletion results in destabilization of the cytoskeleton network and reduced MAP2 signal. Thus, our results demonstrate a role for NCAM2 in dendritic formation, in neural polarization and migration, through interaction of NCAM2 with microtubule-associated proteins and its ability to adapt to the external inputs of the cell and to modify the cytoskeleton accordingly. These functions of NCAM2 may offer promising new therapeutic approaches for the treatment of neurodevelopmental diseases in which NCAM2 is implicated.

Neurodevelopmental axonal pathfinding plays a central role in correct brain wiring and subsequent cognitive abilities. Within the growth cone, various intracellular effectors transduce axonal guidance signals by remodeling the cytoskeleton. Semaphorin-3E (Sema3E) is a guidance cue implicated in development of the fornix, a neuronal tract connecting the hippocampus to the hypothalamus. Microtubule-Associated Protein 6 (MAP6) has been shown to be involved in the Sema3E growth-promoting signaling pathway. In this study, we identified the Collapsin Response Mediator Protein 4 (CRMP4) as a MAP6 partner and a crucial effector in Sema3E growth-promoting activity. CRMP4-KO mice displayed abnormal fornix development reminiscent of that observed in Sema3E-KO mice. CRMP4 was shown to interact with the Sema3E tripartite receptor complex within Detergent-*Resistant* Membrane (DRM) domains, and DRM domain integrity was required to transduce Sema3E signaling through the Akt/GSK3 pathway. Finally, we showed that the cytoskeleton-binding domain of CRMP4 is required for Sema3E's growth-promoting activity, suggesting that CRMP4 plays a role at the interface between Sema3E receptors, located in DRM domains, and the cytoskeleton network. As the fornix is affected in many psychiatric diseases, such as schizophrenia, our results provide new insights to better understand the neurodevelopmental components of these diseases.

FUNCTION OF METEORINS IN COMMISSURAL AXON GUIDANCE

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Fanny Eggeler[1], Flavia De Santis[1,2], Yvrick Zagar[1], Manuela Argentini[1], Karine Duroure[1], Alain Chédotal[1], Filippo Del Bene[1]

In the embryonic nervous system, axons are guided to their specific targets by attractive and repulsive cues in the extracellular environment. Many of these cues are provided by axon guidance molecules, a complex network of receptor/ligand pairs which drive the axons of newly generated neurons towards their correct synaptic partners along well-defined paths. We have identified a family of secreted proteins (the Meteorins) whose members might be novel uncharacterized guidance factors. Via the generation of CRISPR-based mutants for each of the three members of the zebrafish Meteorin family (*mtrn*, *mtrnl1*, *mtrnl2*), we are now using a loss-of-function approach to investigate whether Meteorin proteins are involved in axon guidance, and in particular in the proper development of axonal commissures. Supporting this hypothesis, we observed specific axonal development defects in these mutant fish, including defects in several commissural neuron populations, pointing at a new role of Meteorins in the axon guidance process. We are now interested in the molecular dissection of the cellular pathways in which Meteorin proteins are involved, giving a particular focus on the identification of the so far unknown putative Meteorin receptor(s). In parallel, we are currently developing approaches to validate the identified candidates as *bona fide* Meteorin receptor(s).

COMPARATIVE STUDY OF CHROMATIN RESPONSES TO NEURONAL STIMULATION REVEALS BDNF-SPECIFIC GENE REGULATORY MECHANISMS THROUGH THE PIONEERING FUNCTION OF TRANSCRIPTION FACTOR FOS

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Lucia Gordillo-Perez[1], Ignacio Ibarra[2], Vikram Ratnu[1], Judith Zaugg[3], Kyung-Min Noh[1]
[1]EMBL, Genome Biology Unit, Heidelberg, Germany, [2]Helmholtz Center Munich, Institute Of Computational Biology, Oberschleissheim, Germany, [3]EMBL, Structural And Computational Biology Unit, Heidelberg, Germany

Neuronal plasticity, the basic of learning and memory, allows the adaptation of the brain to internal and external triggers. Modulations of the genetic regulatory landscape are key to induce long-term structural and functional changes on the cellular level. Since the regulation of gene transcription relies on rearrangements of chromatin structure -i.e. chromatin accessibility and epigenetic modifications- we hypothesize that understanding the chromatin landscape will help discerning the mechanisms linking neuronal stimulation to gene expression changes. To identify features that define stimulation-specific chromatin-to-gene expression programs, we performed temporal profiling of chromatin accessibility and gene transcription in mouse primary cortical neurons upon either Brain-derived neurotrophic factor (BDNF) stimulation or membrane depolarization using KCl. We discovered that enhancer activation is an early event in the regulatory control of BDNF-treated neurons, where the bZIP motif-binding Fos protein pioneers chromatin opening and cooperates with other transcription factors (EGR, Homeobox, CTCF). Depolarization-dependent transcription occurs faster through direct promoter activation, yet with delayed Fos-dependent enhancer activation. Deleting one of such enhancers resulted in decreased Arc expression, a regulator of synaptic plasticity, in a BDNF-dependent manner. Further, we found that chromatin regions that display BDNF-induced accessibility changes are linked to preferential exon usage of neurodevelopmental disorder-related genes and are enriched in SNPs associated with neuropsychiatric diseases by Genome-Wide Association Studies. Thus, we provide a comprehensive view of BDNF-mediated genome regulatory features using comparative genomic approaches. In future research, we aim to understand whether BDNF-specific chromatin rearrangements could condition the neuronal transcriptional response in subsequent encounters to BDNF.

ALTERED CEREBELLAR BDNF SIGNALING AND SYNAPTIC ANOMALIES IN A MOUSE MODEL OF CHOLESTEROL DYSHOMEOSTASIS

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Serena Camuso[1,2], Jessica Tiberi[1,2], Piergiorgio La Rosa[1,3], Maria Teresa Fiorenza[1,3], Sonia Canterini[1]
[1]University of Rome, la Sapienza, Division Of Neuroscience, Dept. Of Psychology, Roma (Rm), Italy, [2]University of Rome "Sapienza", Phd Program In Behavioral Neuroscience, Roma, Italy, [3]IRCCS Fondazione Santa Lucia, Dept. Of Experimental Neurophysiology, Roma, Italy

Niemann-Pick type C1 disease (NPCD) is a lysosomal lipid storage disease caused by mutations in the *Npc1* gene, leading to cerebellar ataxia, neurodegeneration, and progressive dementia. Our previous studies of *Npc1* mutant mice demonstrated reduced proliferation/migration of cerebellar granule cells (GCs) due to the significant downregulation of Shh and BDNF signaling. Using WB and IF analyses, we observed altered expression/localization of BDNF and its receptor TrkB during the first weeks of postnatal life in the mouse *Npc1^{nmf164}*, showing a slow-progressing form of NPCD. GCs from *wt* mice showed a “polarized accumulation” of receptor in the early-endosomes of leading processes necessary for their migration along with cerebellar layers, while *Npc1^{nmf164}* cerebella exhibited a significantly reduced GCs fraction with BDNF-dependent pTrkB polarization. We demonstrated that BDNF/TrkB alterations translate into abnormal GCs differentiation, as displayed by Golgi-staining, which is concomitant with pre- and postsynaptic functional alterations, in the complex neural networks at the glomerulus level. Given that cerebellar anomalies and BDNF downregulation are hallmarks of many neurodevelopmental disorders, such as autism, we characterized early social-communicative behaviors in our model by performing behavioral tests (Ultrasonic Vocalization, Homing, and the Three-Chamber test), commonly used to investigate the social domain. We propose that impaired BDNF signaling is upstream of complex cerebellar circuit deficits that result in dysfunctional synaptic networks, which are common in many neurodevelopmental disorders. Therefore, a better understanding of the additional physiological roles played by BDNF in a lipid dyshomeostasis mouse model is important to elucidate the link between cholesterol metabolism and brain pathology.

Pleiotropic effects of BDNF on the cerebellum and hippocampus: Implications for neurodevelopmental disorders.
Brain-derived neurotrophic factor (BDNF) is one of the most studied neurotrophins in the mammalian brain, essential not only to the development of the central nervous system but also to synaptic plasticity. BDNF is present in various brain areas, but highest levels of expression are seen in the cerebellum and hippocampus. After birth, BDNF acts in the cerebellum as a mitogenic and chemotactic factor, stimulating the cerebellar granule cell precursors to proliferate, migrate and maturate, while in the hippocampus BDNF plays a fundamental role in synaptic transmission and plasticity, representing a key regulator for the long-term potentiation, learning and memory. Furthermore, the expression of BDNF is highly regulated and changes of its expression are associated with both physiological and pathological conditions. The purpose of this review is to provide an overview of the current state of knowledge on the BDNF biology and its neurotrophic role in the proper development and functioning of neurons and synapses in two important brain areas of postnatal neurogenesis, the cerebellum and hippocampus. Dysregulation of BDNF expression and signaling, resulting in alterations in neuronal maturation and plasticity in both systems, is a common hallmark of several neurodevelopmental diseases, such as autism spectrum disorder, suggesting that neuronal malfunction present in these disorders is the result of excessive or reduced of BDNF support. We believe that the more the relevance of the pathophysiological actions of BDNF, and its downstream signals, in early postnatal development will be highlighted, the more likely it is that new neuroprotective therapeutic strategies will be identified in the treatment of various neurodevelopmental disorders.

New Platinum-Based Prodrug Pt(IV)Ac-POA: Antitumour Effects in Rat C6 Glioblastoma Cells.
Gliomas are the most frequent primary tumours of the nervous system, characterised by high degree of malignancy,

widespread invasion and high-rate proliferation. Cisplatin and analogue are currently employed in clinical trials as active chemotherapeutic agents for the systemic treatment of this type of malignancy. Despite therapy benefits, clinical use of these agents is hampered by severe side effects including neurotoxicity. Therefore, the aim of the present study was to analyse the effect of a new compound of platinum(IV) conjugate, named Pt(IV)Ac-POA, which can generate a synergistic antineoplastic action when released along with cisplatin, after a specific reduction reaction within tumour cells. To assess the effects of the novel compound on rat C6 glioma cells, cell cycle and cell death activation analyses were carried out using flow cytometry. Morphological changes and activation of different cell death pathways were evaluated by both transmission electron microscopy and immunofluorescence microscopy. Protein expression was investigated by western blotting analysis. The novel compound Pt(IV)Ac-POA, bearing as axial ligand (2-propynyl)octanoic acid (POA), which is a histone deacetylase inhibitor (HDACi), acts as a prodrug in tumour cells, inducing cell death through different pathways at a concentration lower than those tested for other platinum analogues. The current results showed that Pt(IV)Ac-POA could represent a promising improvement of Pt-based chemotherapy against gliomas, either inducing a chemosensitisation and reducing chemoresistance.

JNK signaling activation in the Ube3a maternal deficient mouse model: its specific inhibition prevents post-synaptic protein-enriched fraction alterations and cognitive deficits in Angelman Syndrome model.

Deficiency of the E3 ubiquitin ligase UBE3A leads to the neurodevelopmental disorder Angelman syndrome (AS), while higher levels are linked to autism spectrum disorder. The mechanisms underlying the downstream effects of UBE3A loss or gain of function in these disorders are still not well understood, and treatments are still lacking. Here, using the Ube3a maternal loss (Ube3a) mouse model, we report an important JNK signaling activation in the hippocampus, cortex and cerebellum correlating with the onset of behavioral defects and biochemical marker alterations in the post-synaptic element, suggesting important spine pathology. JNK activation occurs at 7 and persists up till 23 weeks in Ube3a mice in two different cellular compartments: the nucleus and the post-synaptic protein-enriched fraction. To study JNK's role in Ube3a pathology we treated mice with the specific JNK inhibitor peptide, D-JNKI1, from 7 to 23 weeks of age. Preventing JNK action in vivo restores the post-synaptic protein-enriched fraction defects and the cognitive impairment in these mice. Our results imply a critical role of UBE3A-JNK signaling in the pathogenesis of UBE3A-related disorders. In particular, it was clear that JNK is a key player in regulating AS synaptic alterations and the correlated cognitive impairments, in fact, its specific inhibition tackles Ube3a pathology. This study sheds new light on the neuronal functions of UBE3A and offers new prospects for understanding the pathogenesis of UBE3A-related disorders.

EXTRACELLULAR VESICLES UNDERLIE CELL-TYPE-SPECIFIC CROSSTALK DURING HUMAN CORTICAL DEVELOPMENT

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Andrea Forero[1], Fabrizia Pipicelli[1], Rossella Di Giaimo[2], Silvia Cappello[2]
[1]Max Plank Institute of Psychiatry, Developmental Neurobiology, Munich, Germany, [2]Max Planck Institute of Psychiatry, Developmental Neurobiology, Munich, Germany

Neuronal differentiation and maturation are guided by both intrinsic and extrinsic factors. Among the extrinsic factors, secreted molecules as well as changes in the extracellular matrix have been shown to regulate these processes (Long & Huttner, 2019, Long et al., 2018). Extracellular vesicles, consisting of secreted vesicles that transfer nucleic acids, lipids, and proteins between cells, have recently been identified as potential modulators in neuronal function (Sharma et al., 2019; Peruzzotti-Jametti et al., 2021). Nevertheless, a comprehensive analysis of the composition and dynamics of EVs in the context of cortical development has not been conducted. Therefore, the aim of this project is to study extracellular vesicle-mediated communication between neural cell types during neurodevelopment. By collecting EVs from both 2D neural cultures and 3D cerebral organoids, we have characterized their protein composition and cell-type specificity in their uptake and release. Our results detected unique protein groups contained in EVs secreted by cerebral organoids at different stages of development and by dorsally or ventrally patterned organoids. Additionally, we observed variances in EV protein content in specific neural cell types (neural progenitors, neurons and astrocytes), and notable differences in the mechanisms of EV uptake. In conclusion, our results highlight the potential role of EVs in cell communication during human cortical development.

Serotonin-specific neurons differentiated from human iPSCs form distinct subtypes with synaptic protein assembly.
Human induced pluripotent stem cells (hiPSCs) have revolutionized the generation of experimental disease models, but the development of protocols for the differentiation of functionally active neuronal subtypes with defined specification is still in its infancy. While dysfunction of the brain serotonin (5-HT) system has been implicated in the etiology of various neuropsychiatric disorders, investigation of functional human 5-HT specific neurons in vitro has been restricted by technical limitations. We describe an efficient generation of functionally active neurons from hiPSCs displaying 5-HT specification by modification of a previously reported protocol. Furthermore, 5-HT specific neurons were characterized using high-end fluorescence imaging including super-resolution microscopy in combination with electrophysiological techniques. Differentiated hiPSCs synthesize 5-HT, express specific markers, such as tryptophan hydroxylase 2 and 5-HT transporter, and exhibit an electrophysiological signature characteristic of serotonergic neurons, with spontaneous rhythmic activities, broad action potentials and large afterhyperpolarization potentials. 5-HT specific neurons form synapses reflected by the expression of pre- and postsynaptic proteins, such as Bassoon and Homer. The distribution pattern of Bassoon, a marker of the active zone along the soma and extensions of neurons, indicates functionality via volume transmission. Among the high percentage of 5-HT specific neurons (~ 42%), a subpopulation of CDH13 + cells presumably designates dorsal raphe neurons. hiPSC-derived 5-HT specific neuronal cell cultures reflect the heterogeneous nature of dorsal and median raphe nuclei and may facilitate examining the association of serotonergic neuron subpopulations with neuropsychiatric disorders.

Serotonin (5-HT) neuron-specific inactivation of Cadherin-13 impacts 5-HT system formation and cognitive function.
Genome-wide screening approaches identified the cell adhesion molecule Cadherin-13 (CDH13) as a risk factor for neurodevelopmental disorders, nevertheless the contribution of CDH13 to the disease mechanism remains obscure. CDH13 is involved in neurite outgrowth and axon guidance during early brain development and we previously provided evidence that constitutive CDH13 deficiency influences the formation of the raphe serotonin (5-HT) system by modifying neuron-radial glia interaction. Here, we dissect the specific impact of CDH13 on 5-HT system development and function using a 5-HT neuron-

specific Cdh13 knockout mouse model (conditional Cdh13 knockout, Cdh13 cKO). Our results show that exclusive inactivation of CDH13 in 5-HT neurons selectively increases 5-HT neuron density in the embryonic dorsal raphe, with persistence into adulthood, and serotonergic innervation of the developing prefrontal cortex. At the behavioral level, adult Cdh13 cKO mice display delayed acquisition of several learning tasks and a subtle impulsive-like phenotype, with decreased latency in a sociability paradigm alongside with deficits in visuospatial memory. Anxiety-related traits were not observed in Cdh13 cKO mice. Our findings further support the critical role of CDH13 in the development of dorsal raphe 5-HT circuitries, a mechanism that may underlie specific clinical features observed in neurodevelopmental disorders.

Generation of a human induced pluripotent stem cell (iPSC) line from a 51-year-old female with attention-deficit/hyperactivity disorder (ADHD) carrying a duplication of SLC2A3.
Fibroblasts were isolated from a skin biopsy of a clinically diagnosed 51-year-old female attention-deficit/hyperactivity disorder (ADHD) patient carrying a duplication of SLC2A3, a gene encoding neuronal glucose transporter-3 (GLUT3). Patient fibroblasts were infected with Sendai virus, a single-stranded RNA virus, to generate transgene-free human induced pluripotent stem cells (iPSCs). SLC2A3-D2-iPSCs showed expression of pluripotency-associated markers, were able to differentiate into cells of the three germ layers in vitro and had a normal female karyotype. This in vitro cellular model can be used to study the role of risk genes in the pathogenesis of ADHD, in a patient-specific manner.

29018333: Forero A, Rivero O, Wäldchen S, Ku HP, Kiser DP, Gärtner Y, Pennington LS, Waider J, Gaspar P, Jansch C, Edenhofer F, Resink TJ, Blum R, Sauer M, Lesch KP
Cadherin-13 Deficiency Increases Dorsal Raphe 5-HT Neuron Density and Prefrontal Cortex Innervation in the Mouse Brain.
During early prenatal stages of brain development, serotonin (5-HT)-specific neurons migrate through somal translocation to form the raphe nuclei and subsequently begin to project to their target regions. The rostral cluster of cells, comprising the median and dorsal raphe (DR), innervates anterior regions of the brain, including the prefrontal cortex. Differential analysis of the mouse 5-HT system transcriptome identified enrichment of cell adhesion molecules in 5-HT neurons of the DR. One of these molecules, cadherin-13 (Cdh13) has been shown to play a role in cell migration, axon pathfinding, and synaptogenesis. This study aimed to investigate the contribution of Cdh13 to the development of the murine brain 5-HT system. For detection of Cdh13 and components of the 5-HT system at different embryonic developmental stages of the mouse brain, we employed immunofluorescence protocols and imaging techniques, including epifluorescence, confocal and structured illumination microscopy. The consequence of loss-of-function mutations on brain 5-HT system development was explored in a mouse model of Cdh13 deficiency. Our data show that in murine embryonic brain Cdh13 is strongly expressed on 5-HT specific neurons of the DR and in radial glial cells (RGCs), which are critically involved in regulation of neuronal migration. We observed that 5-HT neurons are intertwined with these RGCs, suggesting that these neurons undergo RGC-guided migration. Cdh13 is present at points of intersection between these two cell types. Compared to wildtype controls, Cdh13-deficient mice display increased cell densities in the DR at embryonic stages E13.5, E17.5, and adulthood, and higher serotonergic innervation of the prefrontal cortex at E17.5. Our findings provide evidence for a role of CDH13 in the development of the serotonergic system in early embryonic stages. Specifically, we indicate that Cdh13 deficiency affects the cell density of the developing DR and the posterior innervation of the prefrontal cortex (PFC), and therefore might be involved in the migration, axonal outgrowth and terminal target finding of DR 5-HT neurons. Dysregulation of CDH13 expression may thus contribute to alterations in this system of neurotransmission, impacting cognitive function, which is frequently impaired in neurodevelopmental disorders including attention-deficit/hyperactivity and autism spectrum disorders.

Extracellular LGALS3BP regulates neural progenitor position and relates to human cortical complexity.
Basal progenitors (BPs), including intermediate progenitors and basal radial glia, are generated from apical radial glia and are enriched in gyrencephalic species like humans, contributing to neuronal expansion. Shortly after generation, BPs delaminate towards the subventricular zone, where they further proliferate before differentiation. Gene expression alterations involved in BP delamination and function in humans are poorly understood. Here, we study the role of LGALS3BP, so far known as a cancer biomarker, which is a secreted protein enriched in human neural progenitors (NPCs). We show that individuals with LGALS3BP de novo variants exhibit altered local gyrification, sulcal depth, surface area and thickness in their cortex. Additionally, using cerebral organoids, human fetal tissues and mice, we show that LGALS3BP regulates the position of NPCs. Single-cell RNA-sequencing and proteomics reveal that LGALS3BP-mediated mechanisms involve the extracellular

matrix in NPCs' anchoring and migration within the human brain. We propose that its temporal expression influences NPCs' delamination, corticogenesis and gyrification extrinsically.

INSIGHT INTO CAMK2 SIGNALLING; UNCOVERING SUBSTRATES AND FUNCTIONAL PATHWAYS

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Pomme Rigter[1], Jeroen Demmers[2], Ype Elgersma[1,3], Geeske Van Woerden[1,3,4]
[1]Erasmus MC, Clinical Genetics, Rotterdam, Netherlands, [2]Erasmus MC, Proteomics Center, Rotterdam, Netherlands, [3]Erasmus MC, Encore Expertise Center, Rotterdam, Netherlands, [4]Erasmus MC, Neuroscience, Rotterdam, Netherlands

Learning and plasticity depends on functional Ca2+/calmodulin-dependent protein kinase 2 (CAMK2), as established in mutant CAMK2A or CAMK2B mouse models as well as observed in patients suffering from neurodevelopmental disorders with *de novo* mutations in the genes encoding these proteins. Whereas single CAMK2 knockout mice are viable, knockout of both CAMK2A and CAMK2B simultaneously is lethal, suggesting a functional overlap between these two isozymes and critical functions that remain to be uncovered. To gain more understanding of the full function of CAMK2, we generated inducible *Camk2a*$^{f/f}$*;Camk2b*$^{f/f}$*;CAG-Cre*^{ESR} mice and performed mass spectrometry analysis on cortical tissue, focusing on differences in phosphorylation. Our dataset consists of 5622 phosphorylated peptides in 2080 proteins, of which we identify loss of phosphorylation in 130 proteins in our mutant mouse. These proteins are key regulators in the postsynaptic density and glutamatergic signalling. We validate *in vivo* autophosphorylation sites on CAMK2A and CAMK2B and complement the consensus sequence for phosphorylation by CAMK2. In our extensive dataset of potential substrates, we identify novel ones, including proteins that have been implicated in neurodevelopmental disorders. Altogether, our results provide insight into the functional pathways CAMK2 is involved in and could contribute to a more comprehensive understanding of neurodevelopmental disorders.

ELECTRIC AXON GUIDANCE IN EMBRYONIC CHICK RETINA: MOLECULAR MECHANISM AND IN VITRO OPTIC NERVE FORMATION

POSTER SESSION 06 - SECTION: SIGNALING PATHWAYS IN NEURAL DEVELOPMENT

Masayuki Yamashita
International University of Health and Welfare, Center For Basic Medical Research, Ohtawara, Japan

Growing axons are directed not only by chemical signals but also by electric fields (EFs) in a process known as galvanotropism. The axons of developing CNS extend towards the cathode *in vitro* or along the voltage gradient generated by neuroepithelial cells *in vivo* (Yamashita, ***BBRC***, 431:280-283, 2013). However, the axon surface molecule that links EF to axon steering remains elusive. Here I show that integrin triggers axon steering by asymmetrically stabilizing microtubules being regulated by directionally EF-moved Ca^{2+}. Retinal strips from chick embryos were embedded in Matrigel, since Matrigel and the optic fiber layer, where retinal ganglion cell (RGC) axons grow expressing integrin α6β1, contain the extracellular matrix ligand. The cathodal growth of RGC axons was enhanced by monoclonal anti-chicken integrin β1 antibodies dose-dependently. Mn^{2+} abolished these EF effects as Mn^{2+} binds to the Ca^{2+}-dependent negative regulatory site in β1 subunit eliminating the Ca^{2+} inhibition. The EF effect was also abolished by the inhibition of intracellular signals for integrin-microtubule stabilization. Since EF moves Ca^{2+} at the axon surface asymmetrically, the less inhibited integrin on the cathodal side would stabilize the more microtubules to steer the axon towards the cathode. The RGC axons converged on the optic nerve head in organotypic cultures. Mn^{2+} abolished this RGC axon convergence. The stem of an optic nerve was reproduced *in vitro* by focusing the EF to mimic the *in vivo* EF. These results strongly support the idea that RGC axons are electrically directed to the future optic disc.

MUTANT HUNTINGTIN DISRUPTS THE TIMING OF CELLULAR BEHAVIOR OF PROGENITORS IN THE HDHQ7/Q175 HUNTINGTON DISEASE MOUSE MODEL.

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Leslie Ratié[1], Mariacristina Capizzi[1], Julien Le Friec[1], Monia Barnat[1], Sandrine Humbert[2]
[1]Univ. Grenoble Alpes, Inserm, U1216,, Grenoble Institut Neurosciences,, Grenoble, France, [2]Inserm, U1216, Grenoble Institut Neurosciences, Univ. Grenoble Alpes, Grenoble, France

Huntington's disease (HD) is a neurological disease caused by the abnormal expansion of a CAG stretch in the huntingtin gene. Although the HD neuropathology is primarily attributed to cortical and striatal neuronal dysfunction and neurodegeneration in adults, abnormal cortical development occurs in HD gene carriers. In the present study, we used a heterozygous knock-in HD mouse model expressing the full-length mutant HTT ($Hdh^{Q7/Q175}$). This model depicts early onset of characteristic motor defects, abnormal morphology and electrical properties of layer V and II/III cortical neurons. We examined the characteristics of cortical progenitor population in the ventricular zone (VZ) and subventricular zone (SVZ) throughout embryonic corticogenesis and neuronal specification in early post-natal life. Our results revealed that the cell cycle length in HD was increased through the dysregulation of different stage-dependent mechanisms. Early neurogenic divisions gave rise to more transitioning intermediate progenitors that stayed longer in S-phase at the expanse of generating post-mitotic neurons. Proliferation and S-phase rate increased at later stage but not the mitotic index. Finally, we observed defects in radial migration only for late born neurons. These embryonic abnormalities led to the differential post-natal alterations of deep and upper layers. Thus, our study reveals how the HD-causing mutation differentially affects the timing of direct and indirect neurogenesis at different embryonic stages with consequences for post-natal layering.

NWD1 CONTROLS NSPCS PROLIFERATION THROUGH PURINOSOME FORMATION

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Seiya Yamada[1], Ayaka Sato[2], Shin-Ichi Sakakibara[2]
[1]Waseda university, Faculty Of Human Sciences, Saitama, Japan, [2]Waseda University, Faculty Of Human Sciences, Saitama, Japan

Neural stem/progenitor cells (NSPCs) need a spatiotemporally regulated generation of metabolites to engage in the proper proliferation and differentiation. De novo purine synthesis pathway executed by a sequential reaction mediated by 6 enzymes is tightly controlled depending on the demand of purines. Previous studies demonstrated that these enzymes are assembled as a huge multienzyme complex called purinosome. However, there is no evidence showing the formation or the physiological function of purinosome during brain development. In this study, we identified the novel gene NACHT and WD repeat domain containing protein 1 (Nwd1) expressed strongly in NSPCs and immature neurons in the embryonic mice cerebral cortex (Yamada and Sakakibara, 2018). In addition, we revealed that Nwd1 directly interacts with Paics, one of the purine de novo synthetic enzymes, to regulate the purinosome assembly in NSPCs during cortical development. Nwd1 and Paics were co-localized in purinosome in cultured NPSCs, and altered Nwd1 expression affected purinosome formation. To clarify the physiological function of the purinosome in cortical development, we examined the loss-of-function of purinosome components using in utero electroporation. Nwd1 and Paics knockdown inhibited NSPCs proliferations and induced premature differentiation of NSPCs, resulting in the repression of radial migration. These defects by Nwd1 knockdown frequently caused a periventricular heterotopia, associated with epilepsy and intellectual disability, in the postnatal brain due to the formation of ectopic aggregation of neurons. Taken together, these findings indicate the strict regulation of purinosome assembly is important for proper NSPCs proliferation during cortical development.

Drp1 SUMO/deSUMOylation by Senp5 isoforms influences ER tubulation and mitochondrial dynamics to regulate brain development.
Brain development is a highly orchestrated process requiring spatiotemporally regulated mitochondrial dynamics. Drp1, a key molecule in the mitochondrial fission machinery, undergoes various post-translational modifications including conjugation to the small ubiquitin-like modifier (SUMO). However, the functional significance of SUMOylation/deSUMOylation on Drp1 remains controversial. SUMO-specific protease 5 (Senp5L) catalyzes the deSUMOylation of Drp1. We revealed that a splicing variant of Senp5L, Senp5S, which lacks peptidase activity, prevents deSUMOylation of Drp1 by competing against other Senps. The altered SUMOylation level of Drp1 induced by Senp5L/5S affects mitochondrial morphology probably through controlling Drp1 ubiquitination and tubulation of the endoplasmic reticulum. A dynamic SUMOylation/deSUMOylation balance controls neuronal polarization and migration during the development of the cerebral cortex. These findings suggest a novel role of post-translational modification, in which deSUMOylation enzyme isoforms competitively regulate mitochondrial dynamics via Drp1 SUMOylation levels, in a tightly controlled process of neuronal differentiation and corticogenesis.

Nwd1 Regulates Neuronal Differentiation and Migration through Purinosome Formation in the Developing Cerebral Cortex.
Engagement of neural stem/progenitor cells (NSPCs) into proper neuronal differentiation requires the spatiotemporally regulated generation of metabolites. Purines are essential building blocks for many signaling molecules. Enzymes that catalyze de novo purine synthesis are assembled as a huge multienzyme complex called "purinosome." However, there is no evidence of the formation or physiological function of the purinosome in the brain. Here, we showed that a signal transduction ATPases with numerous domains (STAND) protein, NACHT and WD repeat domain-containing 1 (Nwd1), interacted with Paics, a purine-synthesizing enzyme, to regulate purinosome assembly in NSPCs. Altered Nwd1 expression affected purinosome formation and induced the mitotic exit and premature differentiation of NSPCs, repressing neuronal migration and periventricular heterotopia. Overexpression/knockdown of Paics or Fgams, other purinosome enzymes, in the developing brain resulted in a phenocopy of Nwd1 defects. These findings indicate that strict regulation of purinosome

assembly/disassembly is crucial for maintaining NSPCs and corticogenesis.

Control of cell migration by the novel protein phosphatase-2A interacting protein inka2.
Cell migration is essential for many physiological and pathological processes, including embryonic development, wound healing, immune response and cancer metastasis. Inka2 transcripts are observed in migrating cells during embryonic development, suggesting the involvement of inka2 in cell migration. However, its precise role remains unclear. Here, we found that inka2 controlled focal adhesion dynamics and cell migration, likely by regulating protein phosphatase-2A (PP2A) function. A scratch assay revealed that inka2 shRNA-transfected NIH3T3 cells showed rapid wound closure, indicating an inhibitory effect by inka2 on cell migration. Live-cell imaging of NIH3T3 cells expressing EGFP-paxillin using total internal reflection fluorescence microscopy revealed that inka2 knockdown increased the turnover rate of focal adhesions. Given that PP2A, which consists of catalytic (C), regulatory (B) and scaffolding (A) subunits, is known to regulate focal adhesions, we examined the inka2-PP2A interaction. Immunoprecipitation revealed an association between inka2 and the PP2A C subunit. Binding of Inka2 to the C subunit prevented the association between the A and C subunits, suggesting that inka2 can inhibit PP2A function. Furthermore, both inka2 expression and PP2A inhibition decreased focal adhesion kinase-paxillin interaction, resulting in reduced formation of focal adhesions. We assessed the effect of pharmacological PP2A inhibition on the inka2 knockdown-induced increase in cell migration speed and found that treatment with a PP2A inhibitor negated the accelerated migration of inka2 knockdown cells. These results suggest that inka2 knockdown exerts its effects through PP2A-dependent regulation of focal adhesions. Our findings contribute to a better understanding of the molecular mechanisms underlying cell migration.

Expression profile of the STAND protein Nwd1 in the developing and mature mouse central nervous system.
The orchestrated events required during brain development, as well as the maintenance of adult neuronal plasticity, highly depend on the accurate responses of neuronal cells to various cellular stress or environmental stimuli. Recent studies have defined a previously unrecognized, broad class of multidomain proteins, designated as signal transduction ATPases with numerous domains (STAND), which comprises a large number of proteins, including the apoptotic peptidase activating factor 1 (Apaf1) and nucleotide-binding oligomerization domain-like receptors (NLRs), central players in cell death and innate immune responses, respectively. Although the involvement of STANDs in the central nervous system (CNS) has been postulated in terms of neuronal development and function, it remains largely unclear. Here, we identified Nwd1 (NACHT and WD repeat domain-containing protein 1), as a novel STAND protein, expressed in neural stem/progenitor cells (NSPCs). Structurally, Nwd1 was most analogous to the apoptosis regulator Apaf1, also involved in mitosis and axonal outgrowth regulation in the CNS. Using a specific antibody, we show that, during the embryonic and postnatal period, Nwd1 is expressed in nestin-positive NSPCs in vivo and in vitro, while postnatally it is found in terminally differentiated neurons and blood vessels. At the subcellular level, we demonstrate that Nwd1 is preferentially located in the cytosolic compartment of cultured NSPCs, partially overlapping with cytochrome c. These observations imply that Nwd1 might be involved in the neuronal lineage as a new STAND gene, including having a pro-apoptotic or nonapoptotic role, similar to Apaf1.

FATE AND CELL POTENTIAL OF SINGLE PALLIAL PROGENITOR CELLS

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Ana Cristina Ojalvo-Sanz, Rebeca Sánchez-González, Laura López-Mascaraque
Instituto Cajal-CSIC, Molecular, Cellular And Developmental Neurobiology, Madrid, Spain

The assemble of the brain from a pool of Neural Progenitor Cells (NPCs) is a complex process. Increasing evidence supports the heterogeneity of NPCs across distinct brain regions. Some studies suggest that progenitor diversity is more restricted to one specific lineage whereas others show a potential cell diversity depending on the spatio-temporal patterning. A transient progenitor named neuroepithelial cells generates Radial Glial Cells (RGC) that produce, in overlapping waves, neurons, astrocytes, NG2-glia and oligodendrocytes. However, NG2-glia is another remarkable cell type that can also act as a progenitor. In adult mouse brains, NG2-glia can generate OLs, Astrocytes or even Neurons. Moreover, our previous works revealed the existence of NG2-progenitors during development, enabling the production of different neural cell lineages. To elucidate the cell potential of single progenitors, our lab developed the UbC-StarTrack, to tag single progenitors with stable and heritable labelling. This strategy, based on the PiggyBac system, consists of the integration of twelve plasmids, using a hyperactive transposase PiggyBac (HyPBase), that codify up to six different fluorescence proteins aim to cytoplasm or nucleus. To target NG2 or GFAP-progenitor cells, we exchanged the CMV-promoter for NG2 or GFAP-promoter in **UbC-(NG2-PB)-StarTrack** or **UbC-(GFAP-PB)-StarTrack**, respectively. After targeting NPCs at different embryonic stages or P0, we performed clonal analyses of the derived-cell progeny at P30. Data showed that GFAP- and NG2-progenitors produce distinct cell types whose differentiation potential changes with time and space. Our results provide new data of the lineage cell potential of NG2 and GFAP-progenitors that strengthen the heterogeneity of NPCs.

Gliogenic Potential of Single Pallial Radial Glial Cells in Lower Cortical Layers.
During embryonic development, progenitor cells are progressively restricted in their potential to generate different neural cells. A specific progenitor cell type, the radial glial cells, divides symmetrically and then asymmetrically to produce neurons, astrocytes, oligodendrocytes, and NG2-glia in the cerebral cortex. However, the potential of individual progenitors to form glial lineages remains poorly understood. To further investigate the cell progeny of single pallial GFAP-expressing progenitors, we used the in vivo genetic lineage-tracing method, the . After targeting those progenitors in embryonic mice brains, we tracked their adult glial progeny in lower cortical layers. Clonal analyses revealed the presence of clones containing sibling cells of either a glial cell type (uniform clones) or two different glial cell types (mixed clones). Further, the clonal size and rostro-caudal cell dispersion of sibling cells differed depending on the cell type. We concluded that pallial E14 neural progenitors are a heterogeneous cell population with respect to which glial cell type they produce, as well as the clonal size of their cell progeny.

Cell Progeny in the Olfactory Bulb After Targeting Specific Progenitors with Different UbC-StarTrack Approaches.
The large phenotypic variation in the olfactory bulb may be related to heterogeneity in the progenitor cells. Accordingly, the progeny of subventricular zone (SVZ) progenitor cells that are destined for the olfactory bulb is of particular interest, specifically as there are many facets of these progenitors and their molecular profiles remain unknown. Using modified StarTrack genetic tracing strategies, specific SVZ progenitor cells were targeted in E12 mice embryos, and the cell fate of these neural progenitors was determined in the adult olfactory bulb. This study defined the distribution and the phenotypic diversity of olfactory bulb interneurons from specific SVZ-progenitor cells, focusing on their spatial pallial origin, heterogeneity, and genetic profile.

Myeloid-derived suppressor cells support remyelination in a murine model of multiple sclerosis by promoting oligodendrocyte

precursor cell survival, proliferation, and differentiation.
The most frequent variant of multiple sclerosis (MS) is the relapsing-remitting form, characterized by symptomatic phases followed by periods of total/partial recovery. Hence, it is possible that these patients can benefit from endogenous agents that control the inflammatory process and favor spontaneous remyelination. In this context, there is increasing interest in the role of myeloid-derived suppressor cells (MDSCs) during the clinical course of experimental autoimmune encephalomyelitis (EAE). MDSCs speed up infiltrated T-cell anergy and apoptosis. In different animal models of MS, a milder disease course is related to higher presence/density of MDSCs in the periphery, and smaller demyelinated lesions in the central nervous system (CNS). These observations lead us to wonder whether MDSCs might not only exert an anti-inflammatory effect but might also have direct influence on oligodendrocyte precursor cells (OPCs) and remyelination. In the present work, we reveal for the first time the relationship between OPCs and MDSCs in EAE, relationship that is guided by the distance from the inflammatory core. We describe the effects of MDSCs on survival, proliferation, as well as potent promoters of OPC differentiation toward mature phenotypes. We show for the first time that osteopontin is remarkably present in the analyzed secretome of MDSCs. The ablation of this cue from MDSCs-secretome demonstrates that osteopontin is the main MDSC effector on these oligodendroglial cells. These data highlight a crucial pathogenic interaction between innate immunity and the CNS, opening ways to develop MDSC- and/or osteopontin-based therapies to promote effective myelin preservation and repair in MS patients.

Neurostatin and other O-acetylated gangliosides show anti-neuroinflammatory activity involving the NFκB pathway.
In many neuropathologies activated microglia and macrophages cause neurotoxicity and prolong the inflammatory response. We have previously characterized the glycosphingolipid Neurostatin (Nst), which potentially reduces these detrimental mechanisms. Nst, isolated from mammalian brain, is the GD1b ganglioside with O-acetylation of the outer sialic acid residue. Using the enzyme sialate-O-acetyltransferase (SOAT), we obtained several O-acetylated gangliosides and O-propionylated GD1b (PrGD1b). In the present study we investigated the anti-inflammatory effects of these compounds. Nst and other O-acetylated gangliosides reduced nitrite production in microglial cells which were activated with lipopolysaccharide (LPS), but did not affect nitrite production after their stimulation with interferon gamma (IFNγ). Structure-activity relationship analysis showed that Nst was the most active ganglioside as inhibitor of nitrite production. Its ceramide moiety is essential for this, and both, the O-acetylation and the monosaccharide chain are important for the anti-inflammatory activity of the gangliosides. We also found that Nst reduced iNOS, IL-6 and IL-12 transcription in LPS-induced microglia, likely by inhibiting nuclear localization of NFκB. In co-cultures, Nst reduced neuronal cell death caused by LPS-activated microglia. In vivo, Nst diminished microglia activation in a mouse model of acute neuroinflammation. We propose that Nst and other O-acetylated gangliosides are neuroprotective regulators of microglia activity under both physiological and pathological conditions.

The human brain is made of clones that are ultimately traceable to the first postzygotic cell division. Although cell lineage information is fundamental to understanding organismal development, very little direct information is available about humans. We performed high-depth (>250X) whole-genome sequencing (WGS) of multiple tissues from three individuals and identified hundreds of somatic single nucleotide variants (sSNVs). Using variants as “endogenous barcodes” in single cell WGS, we reconstructed early embryonic cell divisions, and estimated their average whole-body mosaic fractions, defined as percentage of cells carrying the sSNV. We revealed asymmetric contributions of early progenitors to extraembryonic tissues and different organs. Identifying first cell generation variants in WGS data from 74 individuals, we found overall asymmetric contributions of the first cell generation clones to the human brain with strong inter-individual variability. Ultra-deep targeted sequencing of clonal sSNVs across 94 biopsies from 17 different organs revealed asymmetries in the clonal contributions to embryonic germ-layers and suggested the onset of gastrulation at ~170 epiblast cells. By analyzing multiple biopsies from several regions of the central nervous system and >1,000 cortical single cells, we estimated ~50-100 founders for the forebrain, and found that early embryonic cell divisions contribute unequally to neuronal and non-neuronal cells. Finally, we performed single nuclei (sn)RNA-seq and snATAC-seq of ~100,000 cortical single cells and identified sSNV lineage markers in a subset of them to couple lineage information with cell type classification. Thus, our study shows that mosaic mutations provide a permanent record of human embryonic development at remarkably high-resolution.

ROLE OF POST-TRANSLATIONAL MODIFICATION OF NEUROG2 IN HUMAN CORTICOGENESIS

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Julien Pigeon, Bassem Hassan
Paris Brain Institute/CNRS UMR 7225/INSERM U 1127/Sorbonne Université, Brain Development, Paris, France

The neocortex has expanded throughout evolution to give rise to higher-order cognitive abilities. Its enlargement relies on the increased diversity and proliferative capacities of cortical progenitors to increase neuronal production. Therefore, in gyrencephalic species where the neurogenic period is protracted, the regulation of the balance between progenitor maintenance and differentiation is of key importance for advanced intellectual capacities. The control of this balance in the dorsal telencephalon is mediated by feedback regulation between Notch signaling and the proneural transcription factor Neurogenin2 (NEUROG2). As the expression of NEUROG2 alone is sufficient to induce neurogenesis in the neocortex, its regulation at the gene level has been extensively studied. However, recent findings highlight that regulation at the protein level profoundly influences its activity by preventing DNA binding. For example, modulation of the conserved Neurog2 T149 phosphorylation in the developing mouse neocortex results in an altered pool of progenitors and number of neurons in the deep and upper layers. We hypothesize that modulation of the activity of NEUROG2 may regulate the pace of the temporal advance of cortical progenitors down the differentiation landscape. To test this hypothesis in humans, where the protracted neurogenic period is essential, we derived 3D cortical spheroids from CRISPR/Cas9 engineered iPSCs lines to either mimic the phosphorylation or prevent it by replacing the NEUROG2 T149, by an aspartate (T149D) or an alanine (T149A) respectively. We will present the initial results of the analysis on the neurogenic potential of human cortical progenitors in control and NEUROG2 phospho-mutant cortical spheroids.

Understanding the spatio-temporal identity and dynamics of germinal zone activity during development is essential to understand brain structure and circuit function. Here, we use several parallel birth dating approaches to systematically determine the date of birth of all cells of the embryonic mouse brain. The results show an increased duration of neurogenesis along the caudo-rostral axis of the neural tube, linked to the cycling properties of ventricular zone progenitors. The results are combined in an online atlas providing a relationship between neuronal localization and date of birth.

LIS1 MUTATION PREVENTS BASAL RADIAL GLIA-LIKE CELL PRODUCTION IN THE MOUSE

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Maxime Penisson[1], Mingyue Jin[2], Shengming Wang[2], Shinji Hirotsune[2], Fiona Francis[3], Richard Belvindrah[1]
[1]INSERM UMRS1270 Sorbonne Université, Institut Du Fer à Moulin, PARIS, France, [2]Osaka City University Graduate School of Medicine, Genetic Disease Research, Osaka, Japan, [3]Inserm UMRS1270 Sorbonne Université, Institut Du Fer à Moulin, Paris, France

Human cerebral cortical development depends on orchestrated events from progenitor proliferation to neuronal migration and maturation. Progenitor cells include apical radial glia, intermediate progenitors, and basal (or outer) radial glia (bRGs or oRGs). bRGs are abundant in gyrencephalic brains, but are fewer in number in lissencephalic species (e.g. the mouse). The *LIS1* gene, which codes for a dynein regulator, is mutated in human lissencephaly – and has also been associated with microcephaly in some cases. LIS1 was shown to be important during cell division and neuronal migration. Here, we studied the role of Lis1 in progenitors. First, we generated bRG-like cells in the mouse embryonic brain, in order to investigate the role of Lis1 in their formation. This was achieved by *in utero* electroporation of a hominoid-specific gene *TBC1D*3 (coding for a RAB-GAP protein) at mouse embryonic day (E) 14.5. We confirmed that *TBC1D3* expression in wild-type (WT) brain generates numerous Pax6^{+} bRG-like cells which are basally localized. Second, with the same methodology, we assessed the production of these cells in heterozygote *Lis*1 mutant brains. We showed that *Lis*1 depletion in the forebrain from E9.5 prevented subsequent *TBC1D*3-induced bRG-like cell amplification. Third, we observed perturbation of the ventricular zone (VZ) in the mutant. *Lis*1 depletion altered adhesion proteins and mitotic spindle orientations at the ventricular surface and increased the proportion of abventricular mitoses. We conclude that disruption of *Lis*1/LIS1 dosage is likely to be detrimental for appropriate progenitor number and position, contributing to lissencephaly pathogenesis.

TRANSCRIPTIONAL AND EPIGENETIC CHARACTERIZATION OF PROGENITOR COMPETENCE DURING NEUROGENESIS.

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Ann Rose Bright
Max Planck Institute of Neurobiology, Mayer Lab, Martinsried, Munich, Germany

Embryonic and adult neuronal development is temporally fine-tuned and resilient against errors. Several studies have shed light on how epigenetic mechanisms (histone modifications, chromatin accessibility, and transcription factors) can precisely shape the regulatory landscape. However, little is known about the epigenetic mechanisms regulating the emergence of inhibitory cell types in the ventral forebrain. To better understand how different types of inhibitory neurons emerge and gets integrated into circuits, it is paramount to gain a better understanding of epigenetic regulatory mechanisms and their cross-talk. We profiled single-cell gene expression and chromatin accessibility in progenitor cells of inhibitory neurons to investigate the influence of chromatin accessibility on the regulation of gene expression and fate decisions. Integration of multi-omic data has uncovered cis-regulatory elements that precisely delineate temporal features during the various stages of embryonic development. These domains showed stage-specific chromatin opening and transcription factor motif composition, as well as enhancer-specific chromatin characteristics. We also identified potential transcriptional regulators and performed in vivo perturbation to understand what role they play in inhibitory neuronal development. A growing body of evidence suggest that perturbations in inhibitory neuron development can result in a variety of complex neuropsychiatric disorders, including autism, bipolar disorder, and schizophrenia. As a result, our research sheds light on the epigenetic mechanisms that control cell fate decisions during forebrain development, which is critical for understanding the brain in health and disease.

Uncovering the mesendoderm gene regulatory network through multi-omic data integration.
Mesendodermal specification is one of the earliest events in embryogenesis, where cells first acquire distinct identities. Cell differentiation is a highly regulated process that involves the function of numerous transcription factors (TFs) and signaling molecules, which can be described with gene regulatory networks (GRNs). Cell differentiation GRNs are difficult to build because existing mechanistic methods are low throughput, and high-throughput methods tend to be non-mechanistic. Additionally, integrating highly dimensional data composed of more than two data types is challenging. Here, we use linked self-organizing maps to combine chromatin immunoprecipitation sequencing (ChIP-seq)/ATAC-seq with temporal, spatial, and perturbation RNA sequencing (RNA-seq) data from Xenopus tropicalis mesendoderm development to build a high-resolution genome scale mechanistic GRN. We recover both known and previously unsuspected TF-DNA/TF-TF interactions validated through reporter assays. Our analysis provides insights into transcriptional regulation of early cell fate decisions and provides a general approach to building GRNs using highly dimensional multi-omic datasets.

Combinatorial transcription factor activities on open chromatin induce embryonic heterogeneity in vertebrates.
During vertebrate gastrulation, mesoderm is induced in pluripotent cells, concomitant with dorsal-ventral patterning and establishing of the dorsal axis. We applied single-cell chromatin accessibility and transcriptome analyses to explore the emergence of cellular heterogeneity during gastrulation in Xenopus tropicalis. Transcriptionally inactive lineage-restricted genes exhibit relatively open chromatin in animal caps, whereas chromatin accessibility in dorsal marginal zone cells more closely reflects transcriptional activity. We characterized single-cell trajectories and identified head and trunk organizer cell clusters in early gastrulae. By integrating chromatin accessibility and transcriptome data, we inferred the activity of transcription factors in single-cell clusters and tested the activity of organizer-expressed transcription factors in animal caps, alone or in combination. The expression profile induced by a combination of Foxb1 and Eomes most closely resembles that observed in the head organizer. Genes induced by Eomes, Otx2, or the Irx3-Otx2 combination are enriched for maternally regulated H3K4me3 modifications, whereas Lhx8-induced genes are marked more frequently by zygotically controlled

H3K4me3. Taken together, our results show that transcription factors cooperate in a combinatorial fashion in generally open chromatin to orchestrate zygotic gene expression.

The interplay of chromatin and transcription factors during cell fate transitions in development and reprogramming.
Reprogramming to induced pluripotency through expression of OCT4, SOX2, KLF4, MYC (OSKM) factors is often considered the dedifferentiation of somatic cells. This would suggest that reprogramming represents the reversal of embryonic differentiation. Indeed, molecular events involving the activity of the pluripotency network occur in opposite directions. However, reprogramming and development substantially differ as OSKM bind to accessible regulatory elements in the genome of somatic cells due to their overexpression, including regulatory elements never bound by these factors during normal differentiation. In addition, rewiring the transcriptional network back to pluripotency involves overcoming molecular barriers that protect or stabilize the somatic identity, whereas extrinsic and intrinsic cues will drive differentiation in an energetically favorable landscape in the embryo. This review focuses on how cell fate transitions in reprogramming and development are differentially governed by interactions between transcription factors and chromatin. We also discuss how these interactions shape chromatin architecture and the transcriptional output. Major technological advances have resulted in a better understanding of both differentiation and reprogramming, which is essential to exploit reprogramming regimes for regenerative medicine.

Assay for Transposase-Accessible Chromatin-Sequencing Using Embryos.
The DNA of eukaryotic genomes is packaged into chromatin by nucleosomes. This not only compacts the DNA but also plays a central role in gene regulation and establishment of cellular identity during development. Because of this packaging, the DNA is relatively inaccessible to nucleoplasmic factors; however, regulatory elements such as promoters, enhancers, and insulators are largely kept nucleosome-free. The assay for transposase-accessible chromatin (ATAC-seq) can be used to identify genomic locations of "open" chromatin, footprints of DNA-binding proteins, and positioned nucleosomes. It therefore is a powerful tool for unraveling the dynamic regulatory landscape of chromatin. The method exploits the action of hyperactive prokaryotic Tn-transposase, which preferentially cuts DNA in accessible chromatin and tags the sites with sequencing adaptors. Here we describe an ATAC-seq protocol for use with embryos.

Molecular identification and characterization of Type I crustin isoforms from the hemocytes of portunid crabs, Scylla tranquebarica and Portunus pelagicus.
Crustins are cationic antimicrobial peptides of ca. 7-14kDa with a characteristic four-disulphide core containing WAP domain, present in the hemocytes of crustaceans. The present study reports the first crustin sequences from two portunid crabs, viz. the mud crab Scylla tranquebarica (St-Crustin, JQ965930) and the blue swimmer crab Portunus pelagicus (Pp-Crustin, JQ753312). St-Crustin and Pp-Crustin represented the complete cDNA sequence of Type I crustin, with an ORF of 336bp encoding 111aa with a predicted molecular weight of 10kDa and a pI of 8. The signal sequence contained 21aa residues, which was followed by a mature peptide with a WAP domain at the C-terminus. Peptide model of St-Crustin and Pp-Crustin indicated a randomly coiled structure enclosing two β-sheets but no helices. St-Crustin and Pp-Crustin shared significant similarities with crustins of portunid crabs (68-95%) and other crabs (60-73%). Phylogenetic analysis showed that St-Crustin and Pp-Crustin possess the same ancestral origin and have a similar evolutionary status like other crustins, which has subsequently diverged at different phases of evolution. St-Crustin and Pp-Crustin were closely related to crab crustins rather than to the crustins of other crustacean groups. The wide distribution of crustins in crustaceans indicates the importance of these AMPs in the innate immunity. Discovery of novel crustins might pave way to the discovery of promising therapeutic/prophylactic agents in health management and disease control in crustacean aquaculture.

Marine yeast Candida aquaetextoris S527 as a potential immunostimulant in black tiger shrimp Penaeus monodon.
A marine yeast Candida aquaetextoris S527 as a source of immunostimulant in Penaeus monodon was studied. Yeast diet was prepared by incorporating 10% C. aquaetextoris S527 biomass into a standard shrimp diet and administered in P. monodon at different frequencies (daily, once in three days, once in seven days and once in ten days) followed by challenge with white spot syndrome virus (WSSV). Immune parameters such as total protein, total hemocyte count, pro-phenoloxidase, nitroblue tetrazolium reduction, alkaline phosphatase activity and acid phosphatase activity were tested. Expression profile of antimicrobial peptide (AMP) genes viz., anti-lipopolysaccharide factor (ALF), crustin-1, crustin-2, crustin-3, penaeidin-3 and penaeidin-5; immune genes viz., alpha-2-macroglobulin (α-2-M), astakine, peroxinectin, prophenol oxidase (proPO) and

transglutaminase, and WSSV genes viz., DNA polymerase, endonuclease, protein kinase, immediate early gene, latency related gene, ribonucleotide reductase, thymidine kinase and VP28 were analyzed. The study demonstrated that marine yeast diet administered once every seven days conferred better protection to P. monodon against WSSV infection, supported by the hematological and immune gene expression profiles analyzed.

CALCIUM/CATION-MECHANOSENSING ION CHANNELS ACTIVITY ARE CRUCIAL MEDIATORS FOR MECHANICAL INDUCTION OF RADIAL GLIA

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

José Pablo Soriano Esqué[1], Carlos Borau[2], Rosalba Sortino[3], Jesús Asín[4], Soledad Alcántara[1]
[1]University of Barcelona, Pathology And Experimental Therapeutics, Hospitalet de Llobregat, Spain, [2]University of Zaragoza, Mechanical Engineering, Zaragoza, Spain, [3]Institute for Bioengineering of Barcelona, Nanoswitches, Barcelona, Spain, [4]University of Zaragoza, Statistical Methods, Zaragoza, Spain

Aims: During brain development, radial glia is the principal embryonic neural stem cell and form a radial palisade spanning the entire neuroepithelia. We have described that poly (methyl methacrylate) with 2µm linear topographies (ln2PMMA) mimic the structure of radial glia-niche. Ln2PMMA physical signals induce the conversion of cultured astrocytes into functional radial glia cells. However, the molecular mechanisms by which radial glia linage cells sense and respond to ln2PMMA mechanical signals remains poorly understood. **Methods:** We used primary cortical astrocyte cultures from newborn mice, grown for 3DIV in control (glass) and ln2PMMA substrates. We used a custom-developed high-throughput-like image analysis algorithm, allowing simultaneous correlation of lineage markers with nuclei morphology, at the single-cell level. We analyzed expression changes in mechanosensing ion channels by WB and RT-PCR. We validate Ca^{2+}/mechanosensing cation channels implication by pharmacological inhibition of CaMKII (KN93) and non-selective cation channels (GsMTx-4). We finally perform Ca^{2+} imaging and microscopy cross-correlation to identify the activity of radial glia cells (Nestin+/Pax6+). **Results:** Ln2PMMA significantly increase the number of Nestin+/Pax6+ radial glia cells. Cells in ln2PMMA significantly decreased TRPA1 and increased TRPC1 proteins. Moreover, ASIC1 mRNA significantly increased, with a protein increase at the limit of significance in Ln2PMMA. Pharmacological inhibition of CaMKII or non-selective cation channels prevents the increase of Nestin+/Pax6+ radial glia in ln2PMMA, although with different effect on nuclear morphology. **Conclusions:** Calcium/cation-mechanosensing ion channels activity are crucial mediators for mechanical induction of astrocyte dedifferentiation into radial glia. We will discuss changes in Ca^{2+} dynamics in radial glia linage cells.

EFFECT OF MICROGLIA IN THE VIABILITY OF DOPAMINE NEURONS DEVELOPED IN MESENCEPHALIC ORGANOIDS

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Juan Santillan-Cigales, Jaime Velasco Velazquez
UNAM, Institute Of Cellular Physiology, Mexico City, Mexico

A role of microgial cells on the development and the degeneration of dopamine neurons has been suggested. In this work, we aim to develop a system to study the soluble and cellular interactions of microglia, differentiated from human pluripotent cells, on the development and viability of dopaminergic neurons, growing on mesencephalic organoids. Pluripotent cells were induced for hematopoietic differentiation and after cell sorting with specific surface antigens, microglial cells were allowed to mature. On a separate culture, midbrain organoids were formed after aggregation of pluripotent cells on neural-inducing conditions. We compared two groups: one consisting of a co-culture of microglia-like cells and mesencephalic organoids and another composed of by mesencephalic organoids and conditioned medium from microglia-like cells. We found that the influence of microglia is of great importance for the development of dopaminergic neurons. These interactions occur through cell-cell communication and secretion of diverse molecules. Thus, microglial cells have effects on the viability of dopaminergic neurons in this 3D model, which results in a new tool for the study of neuroimmune interactions. This represents a novel strategy for the study of diverse pathologies, like Parkinson's disease.

Glycyrrhizin ameliorates oxidative stress and inflammation in hippocampus and olfactory bulb in lithium/pilocarpine-induced status epilepticus in rats.
Glycyrrhizin (GL) is a triterpene present in the roots and rhizomes of Glycyrrhiza glabra that has anti-inflammatory, hepatoprotective and neuroprotective effects. Recently, it was demonstrated that GL produced neuroprotective effects on the postischemic brain as well as on the kainic acid injury model in rats. In addition to this, GL also prevented excitotoxic effects on primary cultures. The aims of the present study were to evaluate GL scavenging properties and to investigate GL's effect on oxidative stress and inflammation in the lithium/pilocarpine-induced seizure model in two cerebral regions, hippocampus and olfactory bulb, at acute time intervals (3 or 24h) after status epilepticus (SE). Fluorometric methods showed that GL scavenged three reactive oxygen species: hydrogen peroxide, peroxyl radicals and superoxide anions. In contrast, GL was unable to scavenge peroxynitrite, hydroxyl radicals, singlet oxygen and 2,2-diphenil-1-picrylhydrazyl (DPPH) radicals suggesting that GL is a weak scavenger. Additionally, administration of GL (50mg/kg, i.p.) 30min before pilocarpine administration significantly suppressed oxidative stress. Moreover, malondialdehyde levels were diminished and glutathione levels were maintained at control values in both cerebral regions at 3 and 24 after SE. At 24h after SE, glutathione S-transferase and superoxide dismutase activity increased in the hippocampus, while both glutathione reductase and glutathione peroxidase activity were unchanged in the olfactory bulb at that time. In addition, GL suppressed the induction of the proinflammatory cytokines interleukin-1 beta (IL-1β) and tumor necrosis factor alpha (TNF-α) in both cerebral regions evaluated. These results suggest that GL confers protection against pilocarpine damage via antioxidant and anti-inflammatory effects.

INVESTIGATING THE EFFECTS OF 16P11.2 DELETION ON CEREBRAL DEVELOPMENT AND INTERNEURON (IN) PRODUCTION USING VENTRAL TELENCEPHALIC ORGANOIDS

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Rana Fetit[1], Mandy Johnstone[2], Stephen Lawrie[3], Thomas Theil[1], Thomas Pratt[1], David Price[1]

Copy number variations of chromosomal region 16p11.2 are genetically linked to 1% of Autism Spectrum Disorder (ASD) cases. The underlying molecular mechanisms linking the deletion to ASD pathophysiology remain largely unknown. **Aims:** Our work investigates whether perturbations in progenitor proliferation and differentiation into interneurons could contribute to the clinical phenotypes of 16p11.2 deletion. **Methods:** We generated ventral organoids from two 16p11.2deletion-CRISPR/Cas9-iPSC lines and three isogenic control lines to mimic ventral telencephalic development. Organoids were analysed using immunohistochemistry and flowcytometry. A combination of flowcytometry and double IdU/BrdU labelling was used to investigate cell cycle kinetics. Linear mixed model analysis was used to assess statistical significance. **Results:** Compared to controls, deletion organoids exhibited a significant increase in the relative neural rosette area, together with a significant increase in COUPTFII expression. No differences were found in the proportions of progenitor and immature neuronal populations. Cell cycle analysis revealed no significant effect of cell line or genotype on the proportion of cells in G1, S or G2M phases, although a trend towards reduced S-phase fractions was noticed in the deletion organoids. Finally, deletion organoids demonstrated a significant increase in total cell cycle duration and durations of G1 and G2M phases. **Conclusions:** Our findings suggest that 16p11.2 deletion impairs the proliferation of ventral progenitors. Prolonged cell cycle and G1 lengths suggest a shift towards asymmetric neurogenic divisions. Whether the interneuron progeny is immature, dysfunctional, or favours a certain interneuron subtype over another is yet to be investigated in detail.

FATE POTENTIAL OF VENTRAL PROGENITOR CELLS DURING THE COURSE OF NEUROGENESIS

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Yana Kotlyarenko
Max Planck Institute of Neurobiology, Mayer, Martinsried, Germany

During neurogenesis, mitotic progenitors located in the ganglionic eminences generate a wide range of inhibitory neurons, that subsequently migrate in distinct telencephalon areas. While the spatial and temporal specification of the individual inhibitory cell types is increasingly understood (Lim et al., 2018; Kelly et al., 2018), little is known about temporal mechanisms driving the generation of the whole pool of inhibitory neurons.
Previous single-cell transcriptomic and epigenomic studies on the excitatory neurons unraveled temporal patterns of genes transmitted from progenitors to their daughter cells and described transcriptional programs and cis-regulatory cascades for corticogenesis (Telley et al., 2019; Di Bella et al., 2021).
We used FlashTag labelling of isochronic cohorts (Govidan et al., 2018), and clonal barcoding methods (Bandler et al. 2021), combined with scRNA-seq, to assess the fate and lineage potential of ganglionic eminence progenitors at different developmental stages of neurogenesis.
Contrarily to their excitatory counterpart, inhibitory neuron progenitors exhibit similar fate potential throughout neurogenesis. However, late-born inhibitory neuron precursors express a transcriptome assortment right after cell-cycle exit, that early-born inhibitory neurons develop only several days after their birthdate. This result indicates a higher degree of transcriptomic maturation of late-born neurons compared to early-born ones, pointing to a possible diversity of lineage potential throughout neurogenesis.

THE ROLE OF NEUROD2 IN THE DEVELOPMENT OF CEREBELLAR GABAERGIC INTERNEURONS

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Bilian Xiong[1], Karen Runge[2], Antoine De Chevigny[2], Ludovic Telley[1]
[1]University of Lausanne, Department Of Fundamental Neurosciences, Lausanne, Switzerland, [2]Aix-Marseille University, National Institute for Health and Medical Research (INSERM), Institut De Neurobiologie De La Méditerranée (inmed), Marseille, France

In the cerebellar cortex, GABAergic interneurons have an important role in regulating Purkinje cell output. They derive from PAX2 progenitors and specify into diverse mature interneurons in different layers of the cerebellar cortex. Previous research has shown that mice lacking Neurod2, a bHLH transcriptional factor, show significant developmental defects and depletion of a subset of GABAergic interneurons, suggesting a potential role of Neurod2 in the specification of cerebellar GABAergic interneurons. However, how it is involved in their specification trajectory remains unclear. To investigate the role of Neurod2 in determining the specification of GABAergic interneurons in the cerebellar cortex, we combine immunofluorescence approaches to assess the development of the interneuron with single nuclei RNA sequencing technology to investigate the molecular differences in interneurons between wild-type and Neurod2$^{-/-}$ mutant mice. We first observe the absence of basket cells and stellate cells (Parvalbumin+) and significantly increased PAX2+ cell population in the molecular layer in mutant mice from adolescence to adulthood. Interestingly, PAX2+ cells in adult mutant mice express markers of Golgi cells that are normally distributed in the granule cell layer in the wild-type, indicating that these PAX2+ cells are no longer immature but develop in a different trajectory and probably contribute to the maintenance of GABAergic synapses in the molecular layer. Single-nuclei RNA-seq from wild-type and mutant conditions from P0 to P35 confirmed our observation. Together, our findings suggest that Neurod2 is necessary for the development of GABAergic interneurons and plays a role in determining their laminar position of in the cerebellum.

Differential spatiotemporal development of Purkinje cell populations and cerebellum-dependent sensorimotor behaviors. Distinct populations of Purkinje cells (PCs) with unique molecular and connectivity features are at the core of the modular organization of the cerebellum. Previously, we showed that firing activity of PCs differs between ZebrinII-positive and ZebrinII-negative cerebellar modules (Zhou et al., 2014; Wu et al., 2019). Here, we investigate the timing and extent of PC differentiation during development in mice. We found that several features of PCs, including activity levels, dendritic arborization, axonal shape and climbing fiber input, develop differentially between nodular and anterior PC populations. Although all PCs show a particularly rapid development in the second postnatal week, anterior PCs typically have a prolonged physiological and dendritic maturation. In line herewith, younger mice exhibit attenuated anterior-dependent eyeblink conditioning, but faster nodular-dependent compensatory eye movement adaptation. Our results indicate that specific cerebellar regions have unique developmental timelines which match with their related, specific forms of cerebellum-dependent behaviors.

NORBIN IS REQUIRED FOR THE TRANSITION BETWEEN DIRECT TO INDIRECT NEUROGENESIS IN THE DEVELOPING MOUSE CORTEX

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Frédéric Moret[1], Sophie Calvet[1], Florie Reynaud[1], Karine Thoinet[1], Marc Flajolet[2], Timothy Capeliez[1], Basile Rambaud[1], Valentine Clerc[1], Valérie Castellani[1]

Background: The cerebral cortex is a highly sophisticated structure organized in neuronal layers dedicated to specific connectivity. Generation of the proper number of neurons in the appropriate layer is essential to cerebral cortex functions. This process depends on a finely regulated balance between the proliferation of neural progenitors-the Radial Glial Cells (RGC)-and their differentiation into neurons through direct or indirect lineages. **Aims:** Many mechanisms involved in this control remain to be discovered. Here we studied the role of Norbin, a cytosolic protein already involved in human epilepsy, schizophrenia and neurodevelopmental delay, in the control of embryonic neurogenesis in the mouse neocortex. **Methods:** Invalidation of Norbin in cortical progenitors was achieved by Nestin Cre-mediated deletion of floxed Norbin alleles at E12.5-E13.5. Analyses of markers of neural progenitors and layer-specific neurons as well as EdU-birthdating experiments were conducted to characterize the effects of Norbin depletion on neurogenesis progression. **Results:** Although initially described as a neuron specific protein, we show that Norbin is also expressed by neural progenitors. The conditional knock-out of Norbin in RGC concomitantly leads to decreased production of intermediate progenitors and alteration of the generation of deep layers neurons, with no effect on RGC number and division rate. **Conclusions:** Our results support the involvement of Norbin in the control of the transition between direct and indirect neurogenesis phases and in the temporal pattern of cortical neuron generation.

Folding of the cerebral cortex is a key phenomenon of mammalian brain evolution and is associated with increases in size and complexity of the brain. The formation of cortex folding relies on the expansion of neuronal progenitors and tangential migration of cortical neurons. In previous work we showed that mice with deletions of FLRT1 and FLRT3 adhesion molecules develop sulci-like cortex folding without alterations of the number of neuronal progenitors, but with changes in radial migration speed. We have used our FLRT 1 and FLR3 double knock out ‘cell migration’ model to ask if the two folding mechanisms synergize and whether the expansion of certain types of progenitors leads to qualitatively different cortical folds. Here, we report that increasing the length of the early cortical stem cell expansion phase by deletion of fibroblast growth factor 10 (FGF10) in the ‘cell migration’ model (*FGF10;Flrt1/3 cTKO*) leads to cortical folding with much increased penetrance and, importantly, with gyrus-like protrusions. Conversely, overproduction of intermediate progenitors by deletion of centrosomal protein 83 (Cep83) in the ‘cell migration’ model (*Cep83;Flrt1/3 cTKO*) leads to cortical folding with much increased sulci-like appearance. These results suggest that expansion of progenitor cells and divergent radial migration of neurons synergize *in vivo* to induce cortical folding. They further indicate that expanding different types of progenitors leads to qualitatively different folding, suggesting that the formation of gyri and sulci requires the timely expansion of distinct progenitors.

The present research stems from an inedited phenomenon that was observed in immature cholinergic neurons isolated from the Nucleus Basalis of Meynert of human foetuses (*hf*NBMs). The Nucleus Basalis of Meynert (NBM) is the main source of cholinergic neurons in the basal forebrain to be crucially involved in cognitive functions and whose degeneration correlates with cognitive decline in major degenerative pathologies as Alzheimer's and Parkinson's diseases. We investigated overall electrophysiological and biochemical properties of *hf*NBM cholinergic neurons by means of whole cell patch clamp recordings or immunofluorescence analysis and we described, for the first time, that these cells display large amplitude, high-frequency, oscillations of membrane voltage when depolarized by a current step injection. This phenomenon, named by us "*voltage waves*", is conceivably due to the activation of BK channels, as confirmed by its sensitivity to iberiotoxin and to low (200 µM) concentration of tetraetylammonium (TEA), considered selective to block BK opening. Immunocytochemical analysis confirmed the expression of BK channels on *hf*NBMs. Of note, a similar phenomenon was also recorded in rat cortical oligodendrocyte progenitor cells (*r*OPCs), which are the only myelinating cells in the brain devoted to the production of myelin either during development or in brain repair/remodelling processes. As for *hf*NBMs, voltage oscillations were blocked by 200 µM TEA. Our data describe "voltage waves" in *hf*NBMs or OPCs by a biophysical point of view and try to dissect the time-window of the BK channel-dependent voltage activity in *hf*NBMs or OPCs at different maturational stages in culture.

The mechanisms underlying human brain evolution constitute one of the most fascinating unresolved questions of biology. We previously identified >30 human-specific gene families highly expressed dynamically during human brain development. Here we focus our study on one such family that contains human-specific paralogs to the ancestral gene WASH1. WASH1 is a well conserved nucleation promoting factor that induces actin polymerization and controls endosome trafficking. We found two human-specific paralogs, WASH1P and WASH3P, to be expressed at high levels during human cortical development. Using in vivo analyses in the mouse and in vitro models, we present evidence that WASH1P can affect cortical neuron migration and fate acquisition, through the inhibition of some of WASH1 ancestral functions. We now investigate the underlying molecular mechanisms and potential relevance to human brain evolution.

Dormant neuronal precursors (DNP) are intriguing cells capable of maintaining a prolonged state of immaturity in the adult brain, before maturing into functional neurons, as we recently reported. In the adult murine olfactory cortex, we compared neighbouring postnatal-developed neurons (PDN) to maturated DNP and revealed several distinctive features of the latter. We now question whether such differences could result from an extremely slow process of DNP maturation. In the DCX-CreRT2::CAG-fl-EGFP mouse, we permanently labelled DNP at 2 months of age to follow their maturation until 9 months (early) or up to 15 months of age (aged). Age-related differences between early and aged DNP emerged when comparing dendrites, soma, and axon initial segment, implying that DNP maturation is remarkably slow. Furthermore, we questioned the extent of functional maturation of aged DNP with single-cell patch clamp experiments on acute brain slices. Strikingly, functional traits of aged DNP were largely comparable to age-matched PDN. Thus, DNP mature gradually, but slowly, in the aged brain until they become comparable to aged DPN. On one hand, the apparent slowness of maturation is puzzling because the completion of the process may approximate or even exceed the lifespan of feral mice. On the other, the scarce olfactory cues available to caged mice may cause the slow DNP maturation, whereas salient olfactory experiences during adulthood of wild mice may be necessary to stimulate a quicker DNP maturation.

POTENTIAL ROLE OF FIBROBLAST GROWTH FACTOR RECEPTOR 1 (FGFR1) IN THE DEVELOPMENT OF THE RETROSPLENIAL CORTEX.

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Ana Pombero[1], Raquel Garcia Lopez[2], Alicia Estirado[2], Salvador Martínez[1]
[1]Miguel Hernandez University, Institute Of Neuroscience, San Juan de Alicante, Spain, [2]University of Miguel Hernandez de Elche, Institute Of Neuroscience, San Juan de Alicante, Spain

The retrosplenial cortex (RSP) is located in a medial and caudal region of the brain between the neocortex and the archicortex. This cortical region is part of the limbic circuit and has been implicated in a range of cognitive functions such as emotion, attention, and spatial memory. The RSP has reciprocal connections with the anterior and dorsomedial thalamic nuclei, the hippocampal formation, the amygdaloid complex, and widespread neocortical areas. The RSP has been implicated in the pathophysiology of schizophrenia in both human studies and animal models with hyperactive behavior. Fibroblast growth factors (FGFs) and their receptors (FGFRs) are expressed in the developing and adult central nervous system and they have important roles in the morphogenesis of the mammalian cerebral cortex. Fgfr1gene is expressed in the dorsal VZ, the primordium of the cerebral cortex, also in upper layers of RSP cortex in postnatal stages (Allen Brain Atlas). Previous studies demonstrated that disruption of the Fgfr1 gene causes a decrease in cortical interneurons, decrease of pyramidal neurons in frontal and temporal cortical areas and locomotor hyperactivity. To understand the role of Fgfr1 in RSP development, we conditionally inactivated Fgfr1 in neuroepithelial cells of the CNS (Fgfr1f/f;NesCre+). Our analyses of volume estimation of cortical layers and the quantification of pyramidal neurons and parvalbumin-positive interneurons in the RSP, suggested that the proper formation of the RSP depends upon the function of Fgfr1.

ALTERATIONS IN THE ANTERIOR CINGULATE AREA AND DENTATE GYRUS IN LIS1 MUTANT MOUSE UNDERLIES A SCHIZOPHRENIA-LIKE PHENOTYPE

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Raquel Garcia Lopez, Ana Pombero, Alicia Estirado, Emilio Geijo-Barrientos, Salvador Martínez
University of Miguel Hernandez de Elche, Institute Of Neuroscience, San Juan de Alicante, Spain

LIS1 is one of the principal genes related to Type I lissencephaly, a severe human brain malformation characterized by an abnormal neuronal migration in the cortex during embryonic development. This is clinically associated with epilepsy and cerebral palsy in severe cases, as well as a predisposition to developing mental disorders, in cases with a mild phenotype. Although genetic variations in the *LIS1* gene have been associated with the development of schizophrenia, little is known about the underlying neurobiological mechanisms. We have studied how the *Lis1* gene might cause deficits associated with the pathophysiology of schizophrenia using the *Lis1/sLis1* murine model, which involves the deletion of the first coding exon of the *Lis1* gene. Homozygous mice are not viable, but heterozygous animals present abnormal neuronal morphology, cortical dysplasia, and enhanced cortical excitability. We have observed reduced number of cells expressing GABA-synthesizing enzyme glutamic acid decarboxylase 67 (GAD67) in the hippocampus and the anterior cingulate area, as well as fewer parvalbumin-expressing cells in the anterior cingulate cortex in *Lis1/sLis1* mutants compared to control mice. The cFOS protein expression (indicative of neuronal activity) in *Lis1/sLis1* mice was higher in the medial prefrontal (mPFC), perirhinal (PERI), entorhinal (ENT), ectorhinal (ECT) cortices, and hippocampus compared to control mice. Our results suggest that deleting the first coding exon of the *Lis1* gene might cause cortical anomalies associated with the pathophysiology of schizophrenia.

AP-2 is a heterotetrameric complex that links clathrin and other endocytic proteins to sites of clathrin-mediated endocytosis. Full body knockout of AP-2(μ) in mice causes embryonic lethality before day 3.5 postcoitus (Mitsunari, T. et al., 2005). In contrast, depletion of AP-2(μ) in neurons results in postnatal neurodegeneration and defective synaptic vesicle recycling (Kononenko et al., 2014, Kononenko et al., 2017). However, it does not block plasma membrane retrieval during neuronal activity, questioning the canonical function of AP-2 in neurons and suggesting that AP-2 might perform different functions (known as moonlight functions) in mitotic versus postmitotic cells.
We show that AP-2 controls neuronal progenitor cells (NPCs) proliferation but is not required for neuronal differentiation. In wildtype NPCs, AP-2 can be found at the centrosomes, where it colocalizes with components of the gamma-tubulin complex. Using mass spectrometry analysis, we identified GCP1, GCP2, GCP3, and GCP4 as novel interaction partners of the AP-2 complex. Deletion of AP-2μ in NPCs leads to defects in primary cilia disassembly and centrosome formation, resulting in cell cycle arrest, altered microtubule dynamics, and delayed cell migration. While, in vivo, we observed a tendency to neurogenic division in the SVZ of AP-2(μ) conditional KO mice and accumulation of Dcx+ cells, causing the disorganization of the cortical cytoarchitecture. This phenotype was not reproduced in NPCs treated with clathrin inhibitor PitStop2, suggesting a novel role of AP-2, independent of its function in clathrin-mediated endocytosis, in centrosome formation, trafficking components of the gamma-tubulin complex between the primary cilia basal body and the centrosome

FENS Forum 2022
9-13 July 2022 | Paris, France

BOARD NUMBER: S06-401

NEUROGENESIS IN GANGLIONIC EMINENCE IN THE LAST TRIMESTER OF GESTATION

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE
